ever, the etiology of this disorder remains elusive [321]. The literature on this topic suggests a genetic heterogeneity, since under the label "atopic dermatitis" variously affected individuals coexist, with or without sIgE and with or without an associated respiratory allergy [321]. There are associations with HLA-DQ antigens in children with AD and CMA (cow's milk allergy) [43] and with FcεRI-β on chromosome *11q13*, as in asthma (Chap. 4), or not [54]. Recently, a major susceptibility *locus* for AD was found to map to chromosome *3q21* (by 2 studies), and an association has been found on chromosome *14q11.2* with genetic variants of mast-cell chymase, promoting AD development. Moreover, the role played by IL_4 gene expression may be critical in AD expression. Additional significant AD linkages have been found on chromosomes *1q21*, *13q12-14*, *17q25*, and *20p*, the latter associated with asthma (Table 4.2). The mode of inheritance may express an autosomal dominant trait in association with a maternal pattern of transmission [54, 216]. Genetic findings suggest that the risk of developing AD in infancy may be influenced by *in utero* exposures, including maternal immunologic profiles (IgE) (OR, 2.28), infections (OR, 0.32), and allergic conditions including both AD (OR, 2.46) and active asthma [138]. AD is less likely a monogenic disorder with essentially weak penetrance, but rather the interaction of multiple genes and multiple exogenous or environmental factors that outline a multifactorial inheritance pattern with a polygenic component, thus better encompassing the variety of biochemical and immune abnormalities involved in the phenotypic expression of the disease. Studies have shown an 80% AD prevalence in offspring of two affected parents [25], a 38% and 61% incidence at age 2 years in cases of single or double family history of atopy (FHA), respectively [282]. As far as family risk is concerned, the early onset of skin lesions is significantly increased if both parents are atopic (OR, 2.5–3.4) and the early onset of asthma or rhinitis is increased to a lower degree (OR, 1.4–1.5) (Tables 4.10, 4.11). A demonstration comes from 77% of children with two atopic parents and early AD who were sensitized against aeroallergens at 5 years [14], this could have been predicted in early infancy by Tables 4.10, 4.11. A strong FHA (≥2 atopic family members) was a significant predictor of poor prognosis, (cumulative OR = COR 2.40) [111]. Genetic factors clearly have a decisive role in AD development: extensive studies have noted that in monozygotic twin (MZ) pairs there is a higher risk (86%) of developing AD than dizygotic twins (DZ) pairs (21%), which was no different than non-twin siblings; the certain existence of discordant MZ twins confirms the influence of exogenous factors (Chap. 4). A promising area of new insights could focus the AD association with different genetic conditions, including autosomal dominant ichthyosis vulgaris and recessively inherited anhidrotic congenital ectodermal dysplasia. An alternative to the correlations of the genetic type between these three disorders lies in the suggestion that an epidermal defect predisposes atopic individuals (who would present a different subclinical pattern of disease) to the action of both allergens and irritants that provoke and aggravate AD [321]. Growing experience in bone marrow transplantation has demonstrated clearing of AD and normalization of elevated IgE levels in patients with Wiskott-Aldrich syndrome (WAS), characterized by generally indistinguishable AD, thrombocytopenic purpura, and immune deficit, following successful engraftment. Conversely, atopic donors transfer both atopy and allergen-specific IgE antibodies to nonatopic recipients [235], thus pointing to an alteration of immunocompetent stem cells. Moreover, considering AD and several T-cell PID (primary immunodeficiencies) characterized by high amounts of IgE antibodies leaves open the debate on whether to include AD in a slight pattern of PID [24, 235]. Apart from the indisputable

Table 7.3. Factors suggesting a role for IgE antibodies in AD pathogenesis

1. Personal or family history positive for atopic disease in 70%–90% of children [146]
2. Serum IgE concentrations are elevated in about 80% of children with statistically significant differences [216]
3. Positive immediate SPTs (skin prick tests) and/or RAST to various dietary and inhalant allergens in about 85% of patients
4. Serum IgE levels are highest in children with coexisting respiratory allergy
5. IgE levels are low during remissions and higher during flaring of AD
6. Most children (50%–80%) have coexisting allergic IgE-mediated manifestations such as allergic rhinitis and/or asthma, and food allergy (FA) [192] (Table 7.10)
7. Positive/negative effects of bone marrow transplantation [179]
8. Presence of immediate and late skin reactions after SPTs with allergens, for example after Der p 1 application on the skin of children with SPT+ for Der p 1 [197]
9. Symptoms and food allergen association in 30%–50% of children; 33% based on studies with double-blind, placebo-controlled food challenge (DBPCFC) [33]
10. Improvement of skin lesions during climatic changes (such as a sea resort) [280]
11. Lesion relapse after exposure to environmental allergens and improvement following allergen elimination [197]
12. Decrease in AD prevalence in at-risk babies when food allergens are eliminated during the 1st year of life

Data from [33, 36, 37, 146, 192, 197, 216, 280].

Table 7.4. Evidence against a role of IgE antibodies in AD

A marked elevation in serum IgE is found in several diseases, not necessarily atopic
About 15%–20% of normal children have high concentrations of serum IgE without any clinical manifestation of atopy
About 15%–20% of children have AD without apparent signs of IgE hyperproduction
The synthesis of IgE could be secondary to a functional imbalance of the immune mechanisms controlling it
IgE antibodies are not a prerequisite for the development of skin lesions, since AD can manifest itself even in notatopic children
The typical skin lesion, the wheal, is not a specific marker of IgE-mediated allergic reaction of AD
AD is present in patients with agammaglobulinemia, normal IgE levels, and PTCs negative for allergens, as well as in Wiskott-Aldrich syndrome

Data from [46, 188].

data that, from a clinical point of view, AD patients do not manifest conditions characteristically associated with systemic immunosuppression [25], in AD there are neither severe defects of CMI, nor an increased susceptibility to generalized infections [261]. The prevalence of viral and mycotic infections localized to skin [25] and decreased responsiveness to contact allergens [59] such as dinitrochlorobenzene (DNCB) [147] can result from SIS abnormalities [24]. AD children have shown:

1. *Several immunological abnormalities* (Table 7.1), which can be regarded as the result of decreased activity of cyclic nucleotides such as reduced T-suppressor activity and exaggerated IgE concentrations
2. *Biochemical abnormalities*, including increase in cyclic-AMP (cAMP) PDE (phosphodiesterase) activity, an abnormal cutaneous permeability barrier, where abnormalities of EFA (essential fatty acids) metabolism may explain the dry skin and the increase in transepidermal water loss characteristic of AD
3. *Additional pathogenic factors* such as food, inhalant and microbial allergens; also pollutants are a significant risk factor (Tables 4.16, 4.24)

Several factors suggest a pathogenic role for IgE-mediated sensitization in AD; Table 7.3 [33, 36, 37, 146, 192, 197, 216, 280] summarizes some important features that speak in favor of the *role of IgE antibodies*, which recently has been further strengthened in view of the following points:

- Understanding the function of CD154, which is known to play an important role in *the induction of the synthesis of IgE also found in peripheral tissues such as the skin* (Chap. 1)
- Identification of LCs in vivo [90]
- Presence of IgE anti-*S. aureus* [151] and anti-*Candida* [180] in patients with skin colonized by such agents

The evidence against a pathogenic role of IgE antibodies in AD is summarized in Table 7.4 [46, 188]: the 15%–20% of AD children with no signs of IgE hyperproduction and IgE hypersensitization may form a subgroup of children with nonatopic AD. Furthermore, several investigations confirm that some immune defects contribute to IgE dysregulation: the observation in patients with PID of high serum IgE concentration and clinical patterns indistinguishable from those seen in AD, as well as bone marrow transplantation data [235], suggest that a genetically inherited bone-marrow-derived defect is central to AD immunopathogenesis. These observations lead us to conclude that the cause is outside of the skin [226].

Immune Dysfunctions

Cell-Mediated Immunity

Several lines of evidence suggest that a variety of qualitative and/or quantitative immune abnormalities demonstrated in vitro and in vivo (Table 7.1) are mostly correlated with decreased PBMC proliferative responses to mitogens and antigens [255]. As a consequence, in AD patients T cells express low amounts of ILs [165] and less IL_1 than healthy subjects [20], whereas high concentrations of IL_2R are frequently observed when the dermatitis is most florid and are correlated with the clinical pattern's extension and severity [299]. IL_2R is significantly associated with CD30: the presence of high amounts of sCD30 in atopic children seems to confirm the role of this molecule as an activation marker useful for in vivo evaluation of a Th2 immune response [75].

Perhaps more substantially, the absolute number of T cells appears to be decreased, especially that of T-cell subsets. The analysis of the Th1 subpopulation shows that 52% of T cells are Th2, 44% Th0, and only 4% Th1 [66]. Studies on skin-derived Der p-specific T cells in AD subjects reveal that 42.2% of T clones express the Th2 phenotype and only 11.5% the Th1 phenotype [220], or 70% the Th2 and 15% the Th0 subpopulations [285]. Th1 dysregulation is mainly associated with that of the CD8 subpopulation, since CD8 levels in the cutaneous infiltrate is much lower than CD4 levels [165]. The CD4/CD8 ratio in T-cell clones may be increased up to 200% compared to controls [290]; however, other researchers were unable to reproduce these findings [181, 261]. Studies using AMLR (autologous mixed lymphocyte reaction), which is thought to represent an inducer circuit for the activation of $CD8^+$ effector cells [146], concluded that in T allergen-specific clones of atopic donors 92% were CD4 and only 8% CD8 (11.5:1). Subsequently, employing more precise methods such as flow cytometry (FC) and a particle counter (PC), the ratio was 4:1, with CD4 cell rates significantly higher in chamber fluids than in peripheral blood, while the reverse

Table 7.5. Immune alterations in children with AD (%)

	Active phase Mean±SD	Quiescent phase Mean±SD	Normal Mean±SD

Cytotoxic activity	20.42±4.41	26.61±4.71	44.74±5.18
	Disease severity (Mean±SD)		
	Mild	Moderate	Severe	Normal
Cytotoxic activity	25.04±1.87	20.39±3.29	16.24±2.77	44.74±5.18

Data from [52].
Affected vs normal, $p<0.0001$.

was true for CD8 lymphocytes [307], even if the CD8 impairment could be attributable to LTB_4 [72].

From a *functional* point of view, the regulation of in vitro IgE synthesis by CD8 cells, and the generation of concanavalin A (Con-A)-activated T lymphocytes in atopic subjects appears to be abnormal [260]. Such a deficit could occur in atopic individuals because of the altered PGE_2 regulation of thymic CD8 subsets, with the consequent reduction of receptors on T cells [48, 165]. FC shows a decrease in CTLs expressing $S6F1^{bright}$ [162], a characteristic that, along with the similar impairment of NK-cell activity and according to the AD active and quiescent clinical stages as seen from Table 7.5 [52], may partially account for the increased susceptibility to viral infections, particularly with *herpes simplex* (HSV) [35]. The selective alterations of NK-cell activity may be the result of the severity of AD more than the dysregulation of IgE antibodies, or of T-cell subsets [255]. In this regard, NK-cell activity can be reduced in vitro by adding PGE_2 and restored by IFN-β and IFN-γ addition [304].

Suggestive findings support the concept that CMI abnormalities are primary, having been observed in neonates with FHA, but without universal results [255]. Recent data suggest that there is no definite data corroborating such a defect: it is true that in healthy infants with AD aged 0–1, the mean level of CD8 cells was 5.5%, but this concentration subsequently increased to 7.5% [303]. In other children aged 0–6, there were no quantitative deficits of CD3, CD4, CD8 and CD19 [160] (Tables 1.34–1.36). On the other hand, it is difficult to demonstrate that AD has an earlier onset when a CD8 T-cell number and function deficiency with a parallel increased ratio of CD4 T cells to CD8 cells is reported at birth or during the first months of life. More crucial are the *qualitative* deficits. Available data suggests an immune imbalance in lymphocyte activation such as the decreased function of CTLs (which again may account for the increased frequency of viral infections), in addition to the increased numbers of non-T non-B cells and the restoration in vitro of both the number and function of lymphocytes [57].

However, AD cannot be simply defined as a clinical manifestation of decreased CMI. More important, immunohistological studies of the cellular infiltrate and studies directed at circulating parameters of CMI indicate a vigorous T-cell activity in AD lesional skin [25]. Increased T-cell reactivity is correlated to the predominant Th2 phenotype, which *down-regulates Th1 cell function and activation.* As Table 1.10 shows, Th2 lymphocytes secrete a wide spectrum of ILs, especially skin-derived IL_4 that affects the switch of immature B lymphocytes to antibody-secreting cells and activates IgE receptors on LCs and monocytes infiltrating lesional skin, automatically antagonizing the expression of Th1 and IL_2R. IgE synthesis is promoted by IL_4 and inhibited by IFN-γ [308]. In addition, there is a *significant relationship between the increased IgE and IL_4 levels.* Consequently several factors are likely to play a role:

- *Increase in Th2 subsets* secreting IL_4 and IL_{10} induced by IL_1, an increase underlying the aberrant IL production profile that promotes the suppression of IFN-γ production [145, 281].
- *Establishment of a Th2-like T-cell IL* production, due to specific clones of allergen-specific $CD4^+$ T lymphocytes with an excess of Th2 [127], which drive an uninterrupted production of both IgE and ILs [155].
- *Skin-infiltrating Th2 cells* after allergen exposure secrete IL_3-IL_6 and GM-CSF, which favor the migration, differentiation, and survival of IgE and eosinophils [25].
- *Increase in PDE activity* by stimulated T cells, which has been suggested to direct differentiation into Th2-type cells, with a high IL_4 production [24].

Interestingly, *the demonstration at the skin level of the concomitant release by PBMCs of atopic donors of reduced quantities of IFN-γ and of substantial amounts of IL_4* [122] was detected only 2 h after the antigenic challenge in house dust mite (HDM) allergen-induced dermatitis in atopic subjects, even before the gene expression [322], and in highly atopic children with a mean age of 5.4 years [267]. Thus in all likelihood, *the relevant expansion of allergen-specific Th2 cells, through the up-regulation of IL_4 levels, has an ongoing impact on the chronic stimulation of IgE synthesis, on the induction of*

Table 7.6. Multiple functions played by IgE in triggering AD lesions

Cells	Mediators/Function	Effects
Mast cell basophils	Histamine, eicosanoids, PAF, etc.	Pruritus, delayed reaction, contact urticaria
Langerhans cells	Antigen presentation, interleukins	Delayed hypersensitivity, regulatory role
Lymphocytes	Interleukins	Mediator release, IgE generation
Eosinophils	MBP, EDN, ECP, etc.	Inflammation

Data from [46].

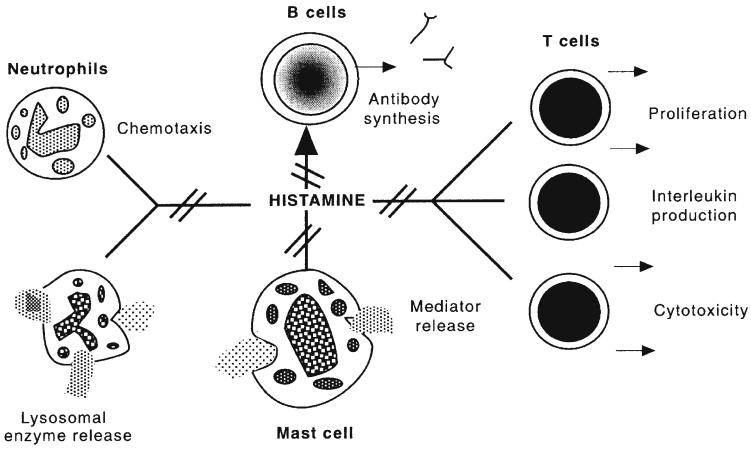

Fig. 7.3. Immunoregulatory effects of histamine. (Modified from [217])

Fcε receptors on B cells and on molecules crucial for antigen presentation, such as monocytes and LCs, as well as on the proliferation of mast cells and perhaps also of eosinophils through IL$_5$. The dominant role of T cells has been confirmed in vivo in children with AD by the spontaneous expression of IL$_4$ mRNA as compared to controls, although in neonates and children <10 years, IL$_4$ secretion was found to be significantly reduced [267]. The proof is that Der p-specific T-cell clones from patients with AD are Th2 cells expressing IL$_4$ and IL$_5$ but not IFN-γ, exactly the opposite of normal individuals [285]. Several studies have found significantly lower IFN-γ concentrations in AD [220, 284] and much higher IL$_4$ levels compared to controls (p<0.0001) [290]. As a consequence, *the Th2 T cells can be viewed as responsible not only for IgE-enhanced synthesis, but also for the high IgE levels in 80% of children*. The significant abnormalities that sanction the exit of Th1 lymphocytes and Th1-like T-cell ILs may be of paramount importance to the pathogenesis either of atopy or AD. A similar immune dysfunction is directly involved in children with WAS or AD [235].

Humoral Immunity: Role of IgE Antibodies

Peripheral B lymphocytes of patients with AD spontaneously produce elevated IgE levels. Since IL$_4$ plays a prominent role in IgE synthesis, its secretion increases in vivo, as shown by anti-IL$_4$ potential inhibition [291]. In addition, B cells of these subjects have an increased expression of the surface antigen CD40 that can be stimulated by anti-CD40 antibodies to generate IgE, also in the absence of IL$_4$, seemingly for a previous exposure in vivo to elevated concentrations of CD40 produced by Th2 T cells along with IL$_{13}$ [155]. Furthermore, IL$_4$ strongly induces the cytoplasmic expression of the ε-chain of FcεRI in DCs and up-regulates the expression of the skin's homing structures E-cadherin and CLA [79]. Thus *the increase in IgE concentrations is a direct result of the manifestations of immediate hypersensitivity and the inflammatory lesions provoked and maintained by mediator release, consequent to mast cell and basophil degranulation and eosinophil action* (Table 7.6) [46]. If IgE levels are so high, clearly the influence of inflammatory mediators released by cells involved in immune reactions will be outstanding. Histamine is elevated in these patients (1.2–5.2 ng/ml, compared to controls (<1 ng/ml) [217] and results (Fig. 1.56) indicate an inhibition of IFN-γ production via IL$_2$ suppression by Th2 T cells. Moreover, monocytes increasing the production of PGE$_2$ reverse the IL$_4$/IFN-γ ratio [48]: consequently, via the almost definitive exclusion of IFN-γ and the deficiency of IL$_{12}$ [145], histamine is able to up-regulate IgE synthesis, thus creating a vicious circle. Histamine has a marked positive effect on NK cells, while it down-regulates the proliferation of B and T lymphocytes and the recruitment of neutrophils and monocytes (Fig. 7.3) [217]. Neutrophil chemotaxis was decreased in 26 out of 34 children (76.5%) and its level was >70% below the control level (Table 7.5).

Several lines of evidence indicate that the intervention of IgE-mediated mechanisms in AD appears to be unpredictable, because AD is not a conventional DTH: the routine histological sections show the characteristics of a type IV reaction, not dominated by IgE antibodies [149]. However, IgE-mediated mechanisms play a role in the pathogenesis of the skin's inflammatory response in AD, as indirectly confirmed by studies which have demonstrated that:

- *An IgE-dependent* LPR can lead to an IgE-mediated cutaneous reaction via a mechanism still triggered by IgE induced by skin allergens that link to mast cell FcεRI.
- *IL_4 release* at the skin level during a DTH could contribute to IgE-dependent cutaneous inflammatory responses being associated with activation of IgE-bearing LCs [20].
- *Children with AD* reacting to DBPCFCs were found to have a rise in plasma histamine compared to children not reacting to DBPCFCs [229] and an increase in skin reactions [230].
- *In areas without lesions,* skin biopsy specimens obtained before DBPCFCs do not reveal eosinophils, which instead infiltrate the erythematous skin several hours later [225].
- *Eosinophils* bind to IgE in AD lesions via both FcεRI and CD23 [263]. The studies so far reported have evidenced that FcεRII is also found on numerous cells ready to respond to IgE, which are very plausibly involved in reactions mediated by cytophilic IgE.

Within minutes of encountering allergens disseminated via the circulation (in ≈50% of cases of alimentary origin), *skin mast cells* found on dermal capillaries become activated by antigen-bridging of IgE molecules, which are bound to the cell membrane by FcεRI and locally release histamine and related mediators [117]. Skin mast cells can also be activated by nonimmunological stimuli such as viral proteins, components of bacterial membrane, anaphylotoxins generated by CICs via complement activation [185] and neuropeptides localized in the dermis, hence confirming more evidently the hypothesis of extended interactions between a peptidergic nervous system and immunocompetent cells: the prospect that mast cells also respond to peptides suggests that they are involved in the neuroimmunological axis [51]. On the one hand, such stimuli further aggravate the inflammation triggered by reagins; on the other hand, they can interfere even in isolation and independently of IgE [51]. Mast cells have an endless activity: it seems that their total number is increased at least in part by an active cell proliferation revealed by mitotic forms at the lesional level [259].

Following the initial, rapid release of plasma histamine and of preformed mediators [225], there is no change in complement activation products, circulating basophil number or total basophil histamine content [229]. Children develop a diffused pruritic, erythematous, macular or morbilliform rash, vasodilation (the initial flare) and increased capillary leakage (formation of an urticarial wheal), characteristic signs of a *type I immune response in the skin* [226]. The reaction peaks within 10–20 min and then the wheal becomes gradually less distinct: by 60–90 min the reaction is diffused, moderately erythematous and edematous, usually no longer pruritic. The initial erythema can occur within 1 h of ingesting an IgE-inducing food [231]. After about 3–4 h, *a mild, diffused pruritus begins and an erythematous or macular eruption heralds the ongoing LPR*. The clinical manifestations are preceded by progressive cellular infiltration, mixed and sequential, in correspondence with the primary lesion. Clinical symptoms are mirrored by the increase in histaminemia: in the first hours it is equal to 13.0±24 [49] to 39±6 [307] ng/ml, coordinately with mediator levels (PGD_2 312 pg/ml in the first 3 h) [49], by 5 h reaches its nadir (<1 ng/ml), by 12 h it rises from 6.72±3.4 [49] to ≈15 ng/ml [20]. LTC_4, LTD_4 and LTE_4 are all very active and potent vasodilators, as are histamine, bradykinin, PGD_2, PGE_2, and PAF (platelet-activating factor), chemotactic for eosinophils [62]. Inflammatory cells are recruited in the first 4 h after initial mast cell degranulation. The expression of adhesion molecules on HEVs is followed by a progressive recruitment first of neutrophils and then of eosinophils in the site of inflammatory reaction [225]. Eosinophils reach the skin 2–6 h after the allergen encounter [29], under the influx of a potent chemoattractant such as MCP-3 [325], as is the case with PAF and IL_8, and reach the greatest concentration with neutrophils within 6–8 h; afterwards activated eosinophils appear to be reduced in number [30] (Fig. 7.4). Eosinophils are thought to contribute to allergic inflammation by the secretion of ILs and mediators that augment allergic inflammation and induce tissue injury in AD through the production of reactive O_2 intermediates and release of their granule proteins [82] (Fig. 7.1b).

Skin biopsy specimens obtained from involved sites after 8 h reveal an infiltration of T lymphocytes (48%), eosinophils (27%), neutrophils (9%) and PBMCs (7%), which increase after 8–12 h essentially around the small vessels; 10%–25% of T cells express CD25 [226]. Numerically, neutrophils are 17×10^5 between 5 and 12 h without hourly differences [307], or up to $11.2\pm6.8\times10^4$ cells at 11–12 h [49]. In patients subjected to challenge, a notable increase in neutrophils is observed in positive compared to negative subjects [227], with ≈74% of the cells at the skin level [307]. Eosinophils and PBMCs total $3–4\times10^5$, significantly increasing from 5–8 h to 9–12 h: they number 9%–10% and 15%–16%, respectively, with significant increases only for PBMCs within the following 24–48 h [307]. At *the LPR peak*, eosinophils constitute >25% of the cells found in the infiltrate (up to $2.5\pm1.7\times10^4$ cells at 11–12 h) [49]. Moreover, $CD4^+$ are found, mostly activated and monocytes able to respond to IL_4 by FcεRII, and, according to some authors, an evident perivascular deposition of fibrin takes place, which persists generally during the following 24–48 h [226].

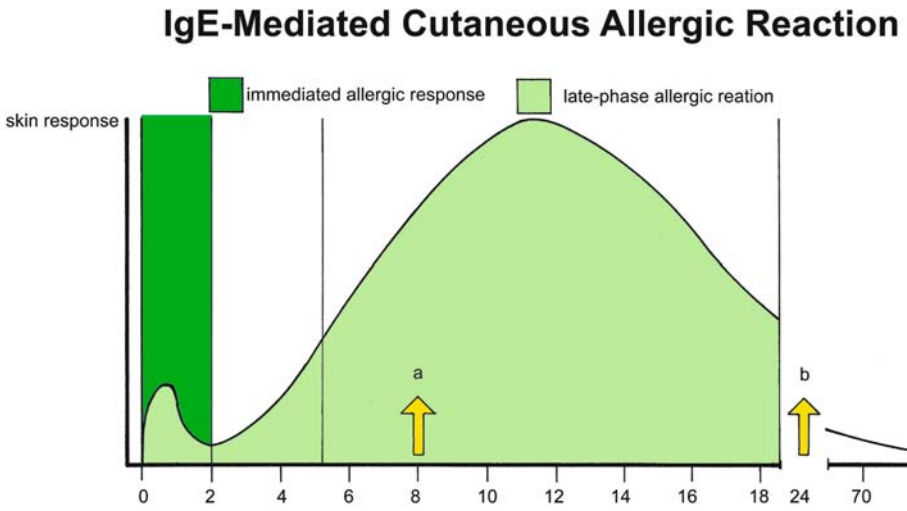

Fig. 7.4. The eosinophils in cutaneous reactions: *a* at 8 h some cells are degranulated without membranes, others have lucent granules together with intact neutrophils; *b* at 24 h the eosinophils appear to be intact, but some nuclei are dissolved

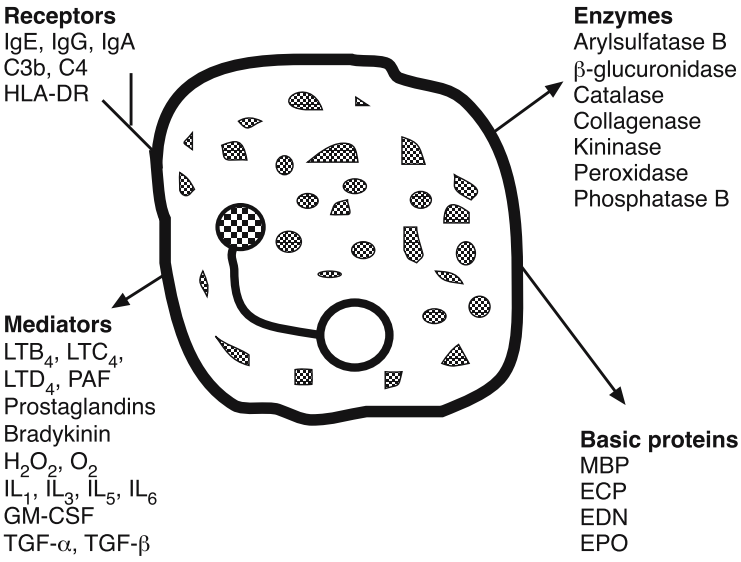
Basic properties of eosinophils. *ECP* eosinophil cationic protein, *EDN* eosinophil-derived neurotoxin, *EPO* eosinophil peroxidase, *GM-CSF* granulocyte macrophage-colony stimulating factor, *MBP* major basic protein, *PAF* platelet-activating factor, *TGF* tumor growth factor. (Modified from [64])



The accumulation of inflammatory cells is promoted by mast cells, endothelial cells and likely by other cell sources that intervene to complete the pathogenic action of mast cells. These cells generate chemotactic factors to attract eosinophils and neutrophils to the serum. *Eosinophils*, sixfold more numerous in skin biopsies obtained from patients with AD vs controls, equal to 709±1,540 vs 115±107/mm^3 [64], present a clear chemotactic response to PAF, LTB_4, C5a, greater if pretractated with GM-CSF, IL_3 and IL_5 [30]. Expression of GM-CSFR β chain and the IL_3R α chain in isolated blood eosinophils was stimulated by IL_4, IL_5, and GM-CSF. Expression of bcl-2 and bcl-xL was also increased after stimulation with IL_4, IL_5, or IFN-γ [204]. In infants and children with AD, *plasma eotaxin levels* are significantly high, probably reflecting the chronic nature of eczematous AD lesions. Eotaxin promotes the selective recruitment of eosinophils [108]. Eosinophils release additional mediators: more PAF, leukotrienes, MBP, EPO, EDN (eosinophil-derived neurotoxin), ECP (eosinophil cationic protein), etc. [142]. MBP and ECP promote mucosal damage; in particular MBP cytotoxic activity is known to damage skin epithelial cells and correlate with disease severity by perpetuating inflammatory reactions [204] (Figs. 7.5 [64], 7.6). The infiltrating PBMCs contribute by producing toxic O_2 radicals [82]. Neither ECP nor MBP serum levels are so abundant in the skin of healthy subjects, contrary to affected patients (MBP 454±90 vs 687±299 ng/ml) [64]. ECP drives eosinophil activation, but not of all cells. Eosinophil analysis in AD has revealed fascinating insights from the recent differentiation of cells with a hypodense phenotype showing signs of activation (Fig. 1.35 c) and correlated with the disease state [157]: in particular eosinophils exhibit a

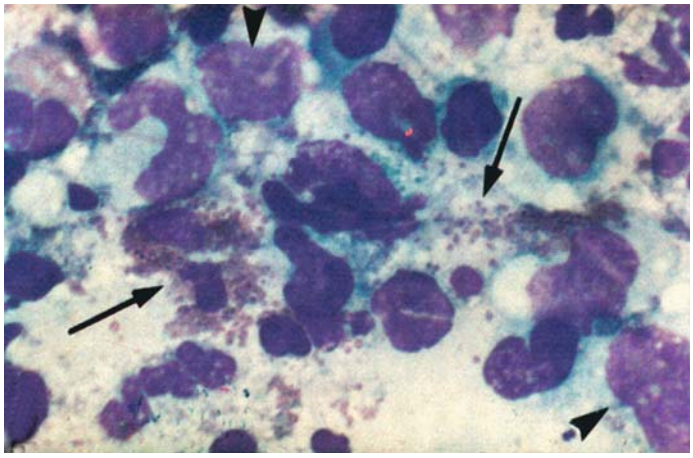


Fig. 7.6. Photomicrograph after a SPT to Der p in an atopic patient 24 h after the intracutaneous injection of PAF. Eight eosinophils are noted (magnification ×400): intensively degranulating (*arrows*), and scattered granules (*arrowhead*)

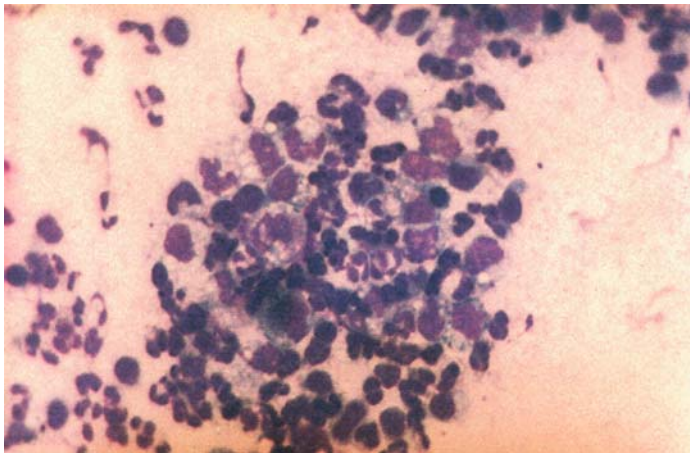

Fig. 7.7. Photomicrograph after the intracutaneous injection of PAF in a control nonatopic patient. The cellular infiltrate is composed of a majority of neutrophils, with a complete absence of eosinophils

normodense profile before challenge and change to hypodense after challenge [225]. *Neutrophils* (Fig. 7.7) are recruited to the site of immune inflammation by NCF (neutrophil chemotactic factor), thus contributing to the maintenance of inflammatory states, developing phagocytic activity and releasing lytic enzymes. No light has been shed on a possible correlation between the entity of their infiltration and DTH extension. However, MBP at this stage can stimulate an increase in expression of CD11b/CD18 and CD11c/CD18 adhesion molecules [172] (Table 1.44); PAF recruits platelets. During the ensuing 24 h, the infiltrating cell population again changes, and later biopsies show a predominance of a parvicellular mononuclear cell infiltrate, namely monocytes and lymphocytes, with *histological appearance virtually indistinguishable from a type IV, cell-mediated hypersensitivity reaction* [73], *type Th2 more than Th1* [148].

An analysis of the AD skin lesions does not allow simple classification into an IgE-mediated LPR vs a T-cell-mediated hypersensitivity reaction. However, in addition to IgE-dependent allergen-induced LPR, there are other mechanisms by which IgE can contribute to cutaneous inflammatory reactions. Previous considerations indicated that allergen-induced mast cell activation could be expressed by a skin LPR, by an extension of the IgE-mediated reaction and that cutaneous LPRs were provoked by mast cells and their chemotactic factors. However, it should be emphasized that there is disagreement as to whether LPR patterns exclusively induced by IgE-mediated mechanisms can be justified, substantiating the controversy on the specificity of the LPR found in involved skin: is this a true LPR? However, there is a clear relationship between the extent of the reaction on the one hand and allergen-specific IgE levels on the other, evidence of the allergen's consistent invasion [64]. Since the levels of PGD_2, the major marker of mast cells, are reduced to basal values, as are those of tryptase [51], it is doubtful that the origin of histamine, following a biphasic course, shows a new peak: the answer is in the further migration of basophils undergoing releasability when stimulated by IL_1. Recent reports have observed mast cell degranulation up to 48 h [185]. Such scientific investigations have re-evaluated the role of LPR, as it seems that it reflects the clinical disease better than the acute phase [142]. However, when LPR reaches its apex several cells are present only to a moderate degree: the neutrophils almost disappear [76]. Neither do they degranulate nor do the amounts of azurophil proteins show differences compared to con-

trols [191]. Eosinophil numbers decrease progressively after 14 h from allergenic stimulation [29]; however, their influx into the epidermis after 24 h is abundant and the infiltration with destructive proteins reaches its apex after 48 h [29, 126]. It was suggested that eosinophils were present but had degranulated during IgE-mediated skin reactions and so were no longer identifiable [125]: routine analysis cannot detect intact cells, although by immunohistochemical analyses their cationic proteins can be identified [329]. It has been hypothesized that eosinophils are associated with a previous mast cell activation [329] or with a preactivation state, making the cells particularly susceptible to the action of IL_5, GM-CSF, IL_3, TNF-α and PAF [125].

By employing immunofluorescent techniques, biopsies of eczematous skin lesions in areas involved in LPR have shown an extensive extracellular MBP deposition in the superficial dermis of atopic skin. MBP was not found in biopsy specimens from uninvolved skin sites in the same patients, a demonstration of local cell degranulation [142]. Similar results were observed testing the skin of pollen-sensitive patients with pollen extract or, alternatively, with buffer [329]. Therefore it is not surprising that in histological sections an elevated MBP content is found, secreted almost exclusively by eosinophils and to a minimal extent by basophils [64]. Cutaneous MBP depositions derive from the activation and degranulation of circulating eosinophils, since MBP is absent in noneczematous skin, indicating that its local accumulation is the result of selective deposition by infiltrating eosinophils and is not caused by nonspecific sequestration in the circulation [225]. Similar findings are not found in healthy patients or those suffering from unrelated skin diseases, such as ACD [127]. MBP releases histamine because of metachromatic cell degranulation, thereby inducing inflammatory reactions, remarkably contributing to the perpetuation of atopic skin inflammation and, in epithelial cell cultures, it provokes *tissue damage similar to that observed in asthma* [64]. ECP titers were significantly elevated in children with AD compared to controls [191, 257], correlated with peripheral eosinophilia, but not with IgE levels [257], nor with granulocyte numbers [126, 191]. In parallel, there is an extended deposition in the dermis of EDN extracellular granules, further stressing the role of EDN in AD [142]. MBP, ECP and EDN levels are closely interrelated, as in tissue deposition, with highly significant differences, above all the correlation between extension of the lesions and MBP levels [190]. Additional severe clinical consequences are elicited by the release of these cytolytic proteins, once deposited locally, since they concur notably to propagate inflammatory responses employing their immunomodulatory ability. ECP, promoting further mast cell histamine release, contributes to destruction of epithelial cells and possibly of keratinocytes [30]. The complete eosinophil degranulation reflects a high degree of activation and conceivably *hyperactivated eosinophils reach the respiratory tree, thus posing the basis of an association between AD and asthma* [238]. Particularly interesting is the hypothesis that eosinophils bind to T lymphocytes via CD54, with consequent, further release of ECP and EPO: their epidermal deposition after 48–72 h may indicate an immunomodulant effect elicited by eosinophils also involving antigen presentation [142] (Fig. 7.4).

Basophils play a key role in both symptoms and DTH pathogenesis: their degranulation is a delayed-type response with the same latency time and clinical evolution as CMI. Recent reports demonstrate that in vitro both IL_3 and GM-CSF, produced by T cells at picomolar doses, favor basophil migration expanding their chemokinetic activity [20]. This stresses that basophil activity should be considered a kind of response consequent to that of T lymphocytes, which form the immunohistological pattern of late reactions [323]. Basophils enrolled by specific ILs [155], chemokines (Tables 1.27, 1.28) and adhesion molecules [20] (Tables 1.20–1.23) accumulate in the seat of cell-mediated reactions, where they influence the inflammatory reactions elicited via chemical mediators with which basophils are equipped, namely histamine and PGD_2, reaching the highest amounts within 11–12 h after a small rise at 8 h, similarly to PBMCs [20]. The findings explain why basophils, histamine and IL_1 are found in the skin windows [20]. In more severe cases, the circulating basophils are primed in vivo, releasing histamine and the potent vasodilator LTC_4, more readily than in children with less severe AD, especially in response to C5a [119].

Here, however, a succinct description of the wide spectrum of eicosanoid contributions to inflammation includes LTD_4 and LTE_4, which cause a skin lesion of the Lewis type: triple response with erythema, vasodilation and wheal persisting for 4 h with a central halo caused by vasoconstriction, accompanied in the case of LTD_4 by dermal edema, evident dilatation of venules and capillaries, and endothelial activation. LTB_4 elicits a transient response followed within 3–4 h by a dermal infiltrate formed in prevalence by neutrophils. PGD_2 produces edema, vasodilation and, like LTD_4, endothelial activation [72].

The *increase in serum IgE antibodies* could elucidate the manifestations of immediate hypersensitivity and the inflammatory lesions provoked and propagated by mediator release; it could be cyclically released by metachromatic cells and also by aspecific mechanisms. However, the elevated serum IgE antibodies cannot account for the eczematous lesions corresponding to a DTH mechanism.

Role of T Lymphocytes

SIS-characteristic T lymphocytes (4×10^{12} in the skin of a normal adult) [25], are the only cells able to directly recognize the presented allergenic peptides of APCs. They have a protracted immune memory, can prolifer-

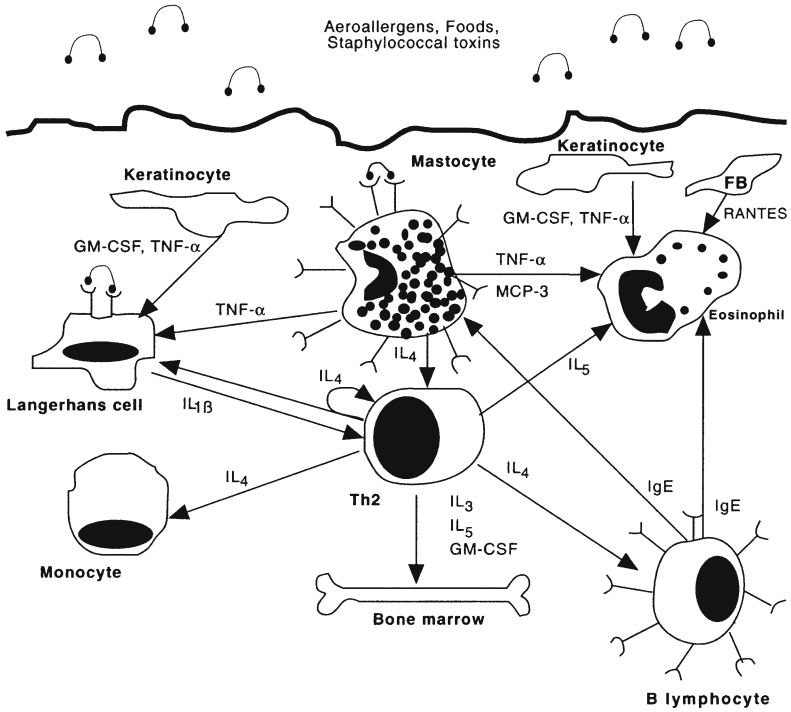

Fig. 7.8. Cell interactions in atopic dermatitis. *FB* fibroblasts. (Modified from [24])

ate very easily, and recirculate to be rapidly recruited to reach target tissues. Their activation is demonstrated by high levels of CD62E and CD49d, expressed by > 90% of skin T cells [307], via the release of different ILs, *relating IgE synthesis, eosinophils, mast cells and basophils.* Th2 cells control IgE synthesis and eosinophil infiltration, exercising a direct effect on immune inflammation, bone marrow production and mast cell maturation and mainly eosinophil maturation, as well as playing a key role in prolonging their local survival by means of IL_{3-5} and GM-CSF [260]. Blood and tissue eosinophils from patients with IgE-mediated allergic responses (thus distinguishing a non-IgE-mediated AD) express CD137, a member of the TNF superfamily. Because CD137 activation blocks GM-CSF–mediated survival in vitro, it can be speculated that the lack of CD137 expression on eosinophils contributes to the excessive tissue eosinophilia [100]. Th2 cells interact with eosinophils and influence their growth, mobility, tissue localization and priming. IL_4 is a growth factor for T lymphocytes in AD; all allergen-specific Th2 clones generate IL_4, IL_5 and GM-CSF, but not IL_2 or IFN-γ. However, IL production becomes significant by adding IL_2 to the culture medium, demonstrating that T cells infiltrate skin lesions after 12 h [30] or after 12–24 h [128]. IL_2 and IFN-γ are primed in normal subjects, but to a trivial extent in patients with AD [292]. A fall in IL_2 levels is also driven by poor PBMC production [126], unlike IL_4 and IL_5 [293]. T-cell infiltrates found in acute and chronic AD skin lesions are in close proximity to the epidermis with subsequent dermal invasion under RANTES (now CCL5) stimulation [325]. T cells consist primarily of $CD3^+/CD4^+CD45RO^+$, which express CD25, CLA and HLA-DR, acquiring specificity in view of the substantial difference in the CD4/CD8 ratio compared to the blood ratio. In children, CD45RO were 87.9%±7.6% of CD4 vs 6%±3.7% of CD45RA [303]; employing CF+CP, the proportion was 9:1 and in blood ≈2:1 [307], a reversed ratio in AD age of onset in infants (Table 2.6). A part of lymphocytes is primed and expresses IL_2R [76], an observation confirmed by an increased expression of $HLA\text{-}DR^+$ from endothelial cells and of CD4 antigen from LCs [126]. Even if there is no clear correlation between extension of clinical lesions and the number of T cells, it is significant that the association between $CD4^+$ and eosinophil number after 24 h is still seen after 48 h [76].

Figure 7.8 summarizes the cell interactions reported in AD, also showing those between keratinocytes and ILs [125]. Although they do not express Fas and Fas ligand, T cells infiltrating the skin of AD patients do not undergo apoptosis, since they are protected from apoptosis by ILs and extracellular matrix (ECM) proteins. Both $CD4^+$ and $CD8^+$ isolated from skin and CLA^+ $CD45RO^+$ T cells isolated from peripheral blood secrete high concentrations of IL_5 and IL_{13}, thus prolonging the lifespan of eosinophil and inducing IgE production [3].

We can speculate that *ILs of cutaneous derivation* may be released during the development of T-cell infiltration in response to allergenic stimuli, *with patterns similar to those of Th2 cells* such as IL_{3-5}, IL_1, and IL_8 endowed with chemotactic activity for lymphocytes. GM-CSF and IL_7 are able to stimulate some T cells as growth factors [155]. Other cutaneous signals to prime T cells are mediated by IL_6, in both the acute and late phase, in close correlation with the eosinophil influx; however, no

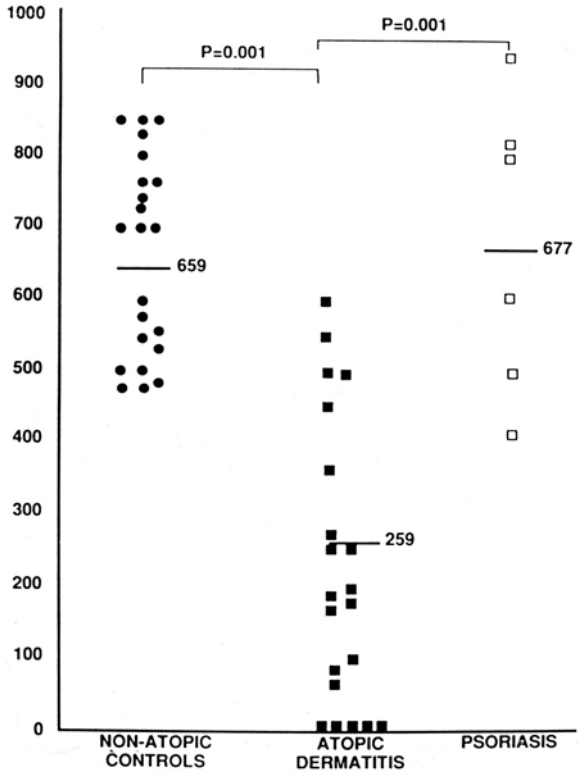

Fig. 7.9. IFN-γ levels in peripheral blood mononuclear cells (PBMCs) of patients with AD. PBMCs from patients with AD produce low IFN-γ levels. PBMCs were stimulated with Con-A (Concanavalin A) for 2 days and then assayed for IFN-γ content; IFN-γ levels of culture supranatants from patients with psoriasis and nonatopic controls are significantly higher than the levels in patients with AD

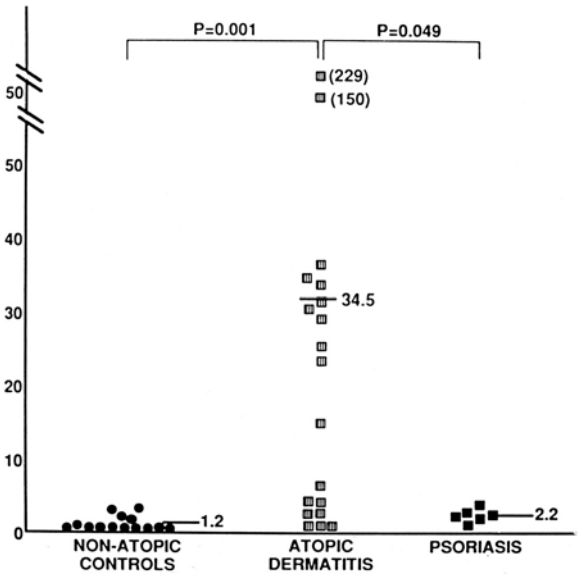

Fig. 7.10. IL_4 levels in PBMCs of patients affected with *AD*. PBMCs of patients affected with AD produce high levels of IL_4. PBMCs were stimulated with Con-A for 2 days and then assayed for IL_4 content; in the supranatants from patients with psoriasis and nonatopic controls, IL_4 levels were significantly lower than the levels in patients with AD

chemotactic activity of IL_6 for these leukocytes has been demonstrated, so we can assume that an association is shared, for example with PAF [155]. Skin biopsies observed after challenge have revealed cells with positive signals only in Th2-like T-cell ILs [128], an unsurprising result since Th2 is the greatest majority of allergen-specific cutaneous CD4 T cells [66, 122, 284, 285]. Indeed PBMCs of patients with AD exhibit negligible IFN-γ levels (Fig. 7.9) and elevated IL_4 levels (Fig. 7.10). Adding an anti-IL_4 to supernatants of patients with AD and controls, IFN-γ concentrations significantly increase only in the controls (Fig. 7.11); instead IgE levels are significantly higher in patients with AD than in controls [122]. Therefore there is a skin LPR mediated by Th2 secreting IL_4 and IL_5, histologically differentiable by the IFN-γ-modulated Th1 LPR [269]. This finding suggests that two histologically indistinguishable cutaneous T-cell-mediated immune reactions exist: the one mediated by IFN-γ-secreting Th1 cells found in conventional DTH reactions, the other mediated by IL_4 and IL_5-secreting Th2 cells and involving allergen-induced CMI [147].

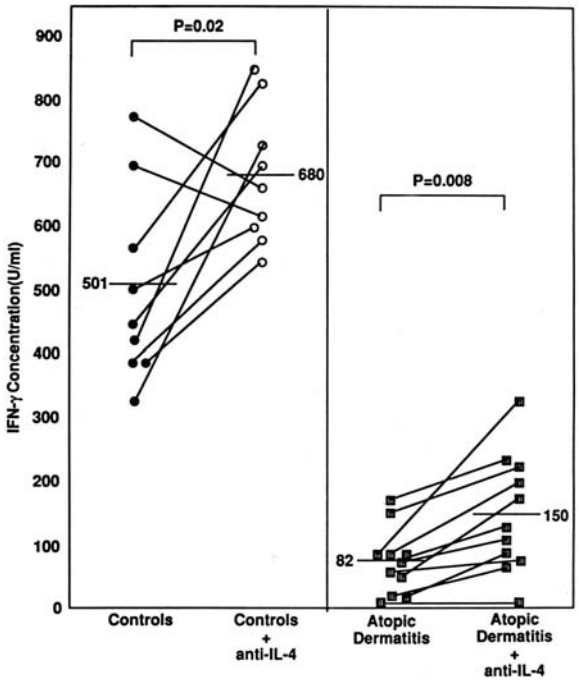

Fig. 7.11. IFN-γ levels in PBMCs of patients with AD. Effect of anti-IL_4 on IFN-γ synthesis PBMCs were stimulated with Con-A for 2 days in the presence and absence of anti-IL_4 and then assayed for IFN-γ content. Anti-IL_4 produced a significant increase in IFN-γ levels in the supranatants from controls and patients with AD. However, in patients with AD, even in the presence of anti-IL_4, Con-A-induced IFN-γ production by PBMSs was significantly lower than the levels in nonatopic controls

How we can distinguish these two phases? Th1 cells found in DTH reactions play the role of effector cells, inducing eczematous lesions [149], and IFN-ɣ is critical for the induction of CD54 by keratinocytes and subsequent accumulation of inflammatory cells in involved skin [86]. The apparent contradiction of LPR with both Th1 and Th2 cells can be unraveled since Th2 cells have been found to be as effective as Th1 cells in inducing skin inflammation [174], recruiting inflammatory cells and inducing IgE via their own ILs [269]. In children with AD and FA, studies on allergen-induced lymphocyte proliferation have demonstrated that in addition to IgE-mediated mechanisms Th1 cells could also be active, producing more IL_2 and IFN-ɣ than in controls [135]. There appears to be a second phase of skin inflammation where Th1 cells predominate in cutaneous lesions [269], and Th1-like ILs such as IL_2 (and sIL_2R) and IFN-ɣ but also IL_4 are found [86, 92, 128]. We can thus elucidate LPR in a biphasic sense, distinguishing a first phase dominated by Th2 followed by a switch to Th1 cells, which worsen the inflammatory state, or show *an effort by the organism to restore homeostasis at the skin level, which fails in subjects with AD* [269]. The existence of both phenotypes can therefore be explained by imagining Th2 cells in an apparent effort to inhibit Th1 cells, to limit tissue damage subsequent to their activation. We have hitherto accentuated the severe IFN-ɣ deficit in at-risk neonates and infants, intensified by PGE_2 and histamine, and record ostensibly contradictory results: on the one hand there is an inhibited IFN-ɣ synthesis parallel to that of IL_{12} by both IL_4 and IL_{10} [145], on the other there is a greater percentage of cells producing IFN-ɣ in children with severe AD compared to normal controls [266]. Data on T cells are still under discussion, active Th2 cells being, in most cases, restricted to allergic reactions, but Th1-like T-cell ILs respond to other allergens, including *Candida* and tetanus toxoid [25], *thus confirming that Th0-cell differentiation into Th1 or Th2 cells is programmed by genetic factors and allergen characteristics* [260], as for Der p 1.

Langerhans Cells

The LC evolutive mechanisms are of indubitable interest. GM-CSF and TNF-α cooperate in LC generation by stimulating undifferentiated hemopoietic precursors to proliferate and differentiate in cells with phenotypic and functional characteristics of human LCs [47]. Evidence has been put forward that, in response to allergens and/or pathogens, the ILs deriving from keratinocytes may prime precursors to transform into effective APCs, establishing an important point of conjunction between immune allergen-specific systems and nonimmune allergen-specific systems [47]. LCs are present in skin reactions 6 h after patch testing (PT) with Der p, exclusively in the epidermis, then in the dermis after 24–48 h [264]. LCs account for some 3 %–8 % of the epidermal cell population; however, based on the increase in number observed using histofluorescence methods, they play a primary role in AD and probably also in the exacerbations, given that they are able to penetrate the skin after epicutaneous contacts, since LCs provoke delayed cutaneous reactions specific to AD patients [272]. In atopic epidermis, $CD1^+$ cells with FcR bind to IgE in patients with elevated serum IgE levels [90]. LCs are HLA class II-positive, bear receptors for the Fc fragment of IgG and C3, and share several properties with lymphocytes localized in lymphoid organs, namely $CD45^+$, $CD25^-$, $CD23^+$, $CD54^+$ [73] (Table 1.28). *IgE of atopic subjects binds to LCs bearing FcεRI on their membrane* [18, 90], this expression is increased by IL_4 and IL_{13}, and *T-cell responses to Der p can only be observed in the case of IgE-positive LCs* [27, 30]. Only FcεRI-bearing LCs [173] in the epidermis carry on the APC function for *T lymphocytes*, as well as the synthesis of various mediators, especially of PGE_2, thus indicating a *correlation between IgE and CMI* [73]. FcεRI on LCs has a higher level in AD than in other skin diseases, since it is proposed along with FcɣRII for the differential diagnosis [315].

LCs are involved in immunological surveillance of the antigens invading the skin, since the $FcεRII^+$ cells, associated with the chemoattracting activity of IL_1, migrate from eczematous epidermal lesions to draining lymph nodes, where antigens undergo processing [253]. However, LCs are equipped with poor phagocytic activity, thus processing may be done by endocytosis, followed by partial degradation and recycling of antigenic peptides [253]. Since the antigen presentation to T cells is the best-known LC function, these peptides are presented to T cells. LCs acquire HLA class II molecules when stimulated by $IL_{1β}$ and sensitize "virgin" T cells when stimulated by GM-CSF [155], presenting antigens directly to Th2 cells [173] and triggering a DTH, as noted above. GM-CSF augments LC activity and functionality and along with IL_1 enhances their differentiation and maturation [272]. Similarly to IgE bound to dermal mast cells, IgE bound to LCs are also specific for aeroallergens, as demonstrated by Der p 1 antigens in close association with LCs after topical antigen application to the skin (see "Role of Aeroallergens"). Evidence has been put forward that LCs play a crucial role in AD pathogenesis. However, an intriguing area is their binding to IgE molecules, since it is unclear whether LCs can produce and activate ILs [272]. It is known that reacting in a specific way with environmental allergens, LCs are involved not only in the induction of skin responses, but also in the regulation of IgE synthesis by B cells, thus delivering *proof of IgE's critical role in the pathogenesis of skin lesions*. It can be hypothesized that via such a mechanism, LCs form a pivotal link between type I and type IV reactions in AD [28]. Furthermore, it is interesting that *$CD4^+$ repeatedly stimulated by LCs may differentiate into Th2 cells* [99]. Interactions of LC IgE^+ (and of macrophage IgE^+) with allergens (and allergen-specific

T cells) may lead to release of IL_1, which stimulates histamine production and promotes proliferation, activation and secretion of other ILs with a pattern similar to that of Th2 cells, as well as of HRF, which primes basophils to release histamine. IL_4 contributes to FcεR increase on macrophages, DCs, LCs and B and T lymphocytes, and is able to induce CD23 on LCs [148]. The activation of IgE-bearing LCs and macrophages by allergens could thereby contribute to the skin inflammation associated with AD. Eosinophils infiltrating cutaneous tissues express CD54 and HLA-DR [142]: the close contact with LCs 24 h after PT [30] thus indicates interactions between these cells. If eosinophils express receptors for both IgE and HLA-DR effectively, they would match APCs as LCs, able to present antigens with a class II-restricted mechanism, and by means of these surface structures, they could be able to drive a lymphoproliferative response.

Interleukins and AD

In summing up the reviewed data on the role of ILs released by epidermal cells in the pathogenesis of AD (Table 7.2), TGF-β and IL_{10} have been identified as inhibitors of several ILs [260], and different patterns have been observed during AD acute and chronic skin lesions. In the first, IL_4/IL_{13} and IL_{16}, and in the second IL_5 and IL_{12} are prevalent compared with uninvolved skin [92, 150], but IL_4 and IL_5 are found after 24 h during the LPR [293]. In neither phase is there IFN-γ expression [148], nor is its production modulated by IL_{18}, unlike that of GM-CSF [26] and even more of IL_{10} [184]. IL_{31} induced by Th2 in monocytes and epithelial cells may be involved in promoting AD development and epithelial responses characteristic of an atopic disease [68]. Furthermore, transgenic mice overexpressing human caspase-1 in keratinocytes – resulting in IL_{18} overrelease – spontaneously develop inflammatory cutaneous changes with high serum levels of IgE and IgG_1 [178], or IL_{18} overexpression may occur independently of IgE or stat6-mediated signaling [136]. IL_{18} causes skin changes in the absence of IgE/STAT6; thus, AD-like inflammation is initiated by overrelease of IL_{18} and accelerated by IL_1 [108]. IL_{15}, a Th1-supportive IL that upregulates IFN-γ, is also down-regulated in individuals with AD and may contribute to elevated IgE [187]. IL_{16}, an IL produced by a variety of immune cells as well as epithelial cells, is a potent chemoattractant for $CD4^+$ T cells in acute skin lesions and may promote a CD4 T-cell infiltration in these lesions, while GM-CSF may enhance eosinophil and macrophage survival in chronic AD lesions [150]. IL_{16} released from LC after allergen-mediated activation through FcεRI may link IgE-driven and cellular inflammatory responses in AD [208]. The significance of ILs in atopic skin is enhanced by the complex network regulating the immune responses in AD: apart from the role, both cardinal and opposed, as discussed earlier, of IL_4 and IFN-γ [308] in the synthesis of IgE and stimulation of effector cells, more ILs are involved in type I IgE-mediated reactions produced by numerous cells including keratinocytes [10]. ILs are important factors that are active in the initiation of immune responses in cutaneous lesions, via modulation of the functions and vitality of LCs as APCs. IL_1 released relatively later in the inflammation sites (10–12 h) may contribute to inviting both adhesion increase and transmigration of neutrophils [20]. IL_3 amplifies mast cell growth and attracts and stimulates basophils; IL_6 enhances the activity of other ILs; IL_8 encourages chemotactic activity on basophils and neutrophils, but inhibits the adhesion to endothelium of both cell types; IL_{10} has a marked effect on the expression of adhesion molecules on endothelium; CD54 and CD62E, and even more TNF-α, prime granulocytes and LCs [155]. TNF-α released by mast cells supports CD62E expression on keratinocytes, facilitating their interactions with $CD11a/CD18^+$ (LFA-1) [300]. IL_4 is an important growth factor for Th2 cells of skin origin: a part of Th2 cells, once activated, leave the atopic skin, reach the bloodstream, produce additional IL_4, and after encountering LCs may stimulate B lymphocytes to generate sIgE in afferent lymph nodes, concurring to elucidate the high IgE levels in children with AD [146]. Moreover, IL_4 regulates IgE synthesis, and is capable of influencing the isotype switching from IgM to IgE/IgG_1 [148]. Table 7.7 outlines the ILs created in AD children by T lymphocytes [308, 309].

Table 7.7. Der p-specific T CD4 lymphocyte clones

IL	Atopic patients	Nonatopic patients
IL_2	+	+++
IL_4	+++	–
IL_5	+++	+
IL_6	+++	++
GM-CSF	+++	+++
IFN-γ	+	+++
TNF-α	+++	+++

Modified from [308, 309].

Interactions Between ILs and Adhesion Molecules

In the first phases of inflammation, keratinocytes releasing IL_1, IL_{10} and TNF-α focus on the regulation of adhesion molecules, chiefly CD54 and CD62E, and are therefore able to influence leukocyte adhesion to epidermal and/or immunocompetent cells and *T-cell localization at the site of lesions*. The prominent role of

CD62E is supported by the evidence that CLA on T-cell membrane is also its ligand, and it is tempting to speculate that CLA with its specific tropism for the skin could materialize the basic clinical expression of AD [149]. As detailed in Chap. 1, CD54 and CD62E mediate the adhesion of all cell types, and CD106 is a source of a selective action for basophils and eosinophils, promoted by IL_4 even in the absence of CD54 and CD62E [20]. Adhesion molecules activate the dermal vascular endothelium, which accentuates the release of CD54, CD62E and CD106, which are found both in the interstitial fluid and in the circulation [24]. Such events allow the adhesion of circulating lymphocytes, $CD4^+CD45RO^+$, and granulocytes to the dermal epithelium; the concomitant secretion by keratinocytes of IL_1 and IL_8/NAP-1 drives a true directional migration of T cells toward dermal sites. CD54 serves as a ligand for CD11a/CD18 and CD11b/CD18, and CD49d/CD29 binds to contrareceptors CD106 and fibronectin [20] (Table 1.44). CD54 binds T cells to epithelial cells, has been shown to serve as a binding site of T-activated lymphocytes to epidermal cells and can promote the transit of inflammatory cells through the endothelium (along with CD62E and CD106) [10]. A similar effect is obtained by stimulating epithelial cells by allergens, demonstrating that the expression of specific adhesion molecules drives the migration and adhesion of various leukocytes and suggesting that endothelial activation in the LPR by ILs plays a cardinal role in the *migration of inflammatory cells at the skin level*. The adhesion molecules allow eosinophils and/or neutrophils to migrate across epithelial layers: only eosinophils express CD49d and are stimulated by RANTES, the most effective chemokine in this site [20], and by MCP-3 [325], released by fibroblasts and basophils (Table 1.55) (Fig. 7.8); thus these mechanisms also drive the eosinophil selective recruitment. Since the treatment of endothelial cells with an anti-CD106 antibody leads to inhibition of eosinophil and basophil adhesion induced by IL_1, but not of neutrophil adhesion [20], it is evident that when CD106 is expressed by epithelium, it represents a further etiopathogenic mechanism, allowing these cells to directly recruit specific cells. Moreover, if the pretreatment with antibodies recognizing CD54, CD62E, CD102 and CD106 inhibit the adhesion of only 60%–70% of basophils, there should be additional ligands on endothelial cell surface with specificity for basophils [20].

IgE and Histamine-Releasing Factors

Different factors are able to drive histamine release: among them is the mediation of increased metachromatic cell releasability secondary to the generation of histamine-releasing factors (HRFs), generated by mononuclear cells or platelets. Some HRFs have been shown to bind to surface-bound IgE molecules and activate and stimulate metachromatic cells to release histamine (releasability). HRFs appear to match CCL chemokines, thus confirming in a hypothetical way that histamine in AD stems from cutaneous mast cells and basophils. It has been demonstrated that a histamine release inhibition factor (HRIF) related to NAP-1/IL_8 at the same time as HRF and HRIF could regulate HRF activity. Peripheral blood basophils of nondieting patients with AD and FA show high spontaneous basophil histamine release (SBHR). In contrast, a SBHR is close to normal in FA patients whose skin lesions have cleared on an appropriate elimination diet for at least 1 year [225]. Subsequently an HRF was reported in children with AD, even those who were FA-free [232]. Consequently, in children with both disorders, circulating food allergens could induce the production of HRF in vivo, which could activate or lower the threshold of metachromatic cell activation. HRF could also account for either the increased basophil releasability seen in some children with AD with a particular severity of clinical manifestations [119] or the increased SBHR production in vitro by basophils in subjects with FA [206]. In these children, HRF could account for the worsening pruritus and cutaneous eruptions [119]. It was postulated that allergic patients have a subset of IgE molecules (IgE^+) [156] that are different from the IgE of normal subjects, to which HRFs could bind in patients with AD associated with FA [225]. The finding that IgE molecules from atopic patients bind HRF but that IgE molecules from nonatopic subjects does not suggests that IgE molecules have a great deal of heterogeneity [156]. These patients could have a hypersensitivity mediated by IgE via HRF, thus presenting sIgE for foods, IgE^+ dependent on the patient's diet, and HRFs produced by PBMCs [225].

Anomalies of IgGs and in particular of IgG subclasses after having found elevated total serum IgG and IgG_4 levels, have been often regarded as a constitutive element of the immune defect of the patients with AD: in about 20% of patients total IgG_4 levels are increased, but the increase is much lower than IgE levels, nor they correspond to 20% of patients with normal IgE levels, therefore the diagnostic value of IgG_4 concentrations in AD patients is very limited. In children the reduction of IgG levels was shown to be related to a higher frequency of relapsing bacterial infections; with children growth serum IgG_4 values normalized, but were not correlated to serum IgE values [1].

The role of *neuropeptides* has received attention that has been recently turned to a feasible neuropeptide involvement on AD pathogenesis, in particular of the ability of SP and CGRP (calcitonin gene-related peptide) ability to up-regulate inflammatory reactions in patients with AD, as well as of PGP9.5 being a marker of noradrenergic innervation, somatostatin, VIP, etc. (Chap. 11), with a significant increase in immunoreactive nerve fibers localized in the epidermis and around dermal vessels. From a pathogenic viewpoint, it is noteworthy that skin mast cells could be activated also by dermal neuropeptides, thus by non-IgE-dependent stimuli [53]. More importantly, a *neuropeptide disequilibrium* enhanced by exposure to road traffic has been suggested that could integrate a neurogenic share of AD pathogenesis [131].

A Concluding Pathogenic Hypothesis

The principal immunological characteristic of AD is the increased production of IgE, a substantial part of which is specific for environmental allergens, including SEs [103]. When IgE synthesis is controlled by CD4-Th2 cells, the preferential expansion of IL_4 and IL_5 producing allergen-specific T cells suggests an abnormal IgE dysregulation in AD. We have stressed that B cells are only rarely seen, if present at all, within the mononuclear cell infiltrates of atopic skin lesions. Therefore, skin-derived IL_4, a potential IgE-inducing function in the dermal lymph nodes, is irrelevant. Subordinately we can postulate that IL_4 induces in B lymphocytes an isotype switching to IgE production, detected in skin-draining lymph nodes and further away as a consequence of spread by the blood or lymphatic circulation, until it reaches AD-involved skin. There is substantial evidence that IL_4 up-regulates CD23 expression on LCs [25] (Fig. 7.8), perhaps an explanation for the presence of IgE on LCs and in infants with AD. Functionally, the expression of FcεRII on skin APCs leads to amplification of the response of Th1 and Th2 cells to minute quantities of allergens. By facilitated antigen processing, only minute quantities of allergens need to be presented to T cells [283]. Thus, serum IgE-complexed allergens in a CD23-dependent system increase processing and subsequent presentation to skin T lymphocytes up to a 1,000-fold, as well as the consequent activation with release of ILs and cytotoxic factors [283]. These results suggest that *cell-bound IgE on LCs* facilitates capture and internalization of allergens into LCs *even before their processing and antigen presentation to T cells.* Moreover, the increased IL_4 production in vivo by T lymphocytes [267, 322] could be responsible for an IgA deficit, coincident with a preferential isotype switching from IgA to IgE.

The activity of Th2 lymphocytes, which infiltrate within the involved skin in response to allergens, is directed to generating a chronic cutaneous inflammation. Of particular relevance is the mechanism based on T response specificity, which in the animal model has been clearly observed in T-cell selective migration from mucous tissues to skin lesions, regulated by interactions between vascular endothelial cells and specific receptors, namely in vivo CLA and CD62L [195, 197] (Table 1.58). CLA^+ T cells are $CD45RO^+$ [194]; in contrast, Der p-sensitive asthmatic patients have CLA^- memory or effector cells [196]. A high number of CD4 cells expressing CLA but not CD62L has been recently demonstrated in children with AD and CMA compared to nonatopic children with different intestinal conditions [2]. That the controls did not express CLA indicates that an elevated concentration of CLA facilitates the leakage of casein-specific T lymphocytes into the skin, thus playing a key role in promoting skin lesions.

Biochemical Dysfunctions

In the last 30 years, consistently sound investigative research that suggests a cAMP dysregulation as a basic characteristic of AD has been put forward. PBMCs stimulated by histamine or isoprenaline produce less cAMP in the skin of patients than in healthy controls. An enhanced intracellular activity of the cAMP-inactivating PDE enzyme activity is mirrored by blunted cAMP levels, which are secondary to histamine release by basophils [60]: thus a correlation between PDE activity, IgE synthesis and histamine release is delineated. Here, however, the conclusions of various researchers are rather conflicting, some stressing that a primary PDE increase is detected in CB (cord blood) PBMCs from offspring of atopic parents, as well as in subjects with remitting AD or AR. Others have put forward the notion that the PDE increase, before and in the absence of obvious allergenic stimulation, is the primary defect, thus the second marker of the atopic constitution, after IFN-γ deficit. However, the enzyme abnormality should be demonstrated to exist *in utero* and in the absence of allergenic stimuli, which in a predisposed fetus could generate IL mediators that in turn would activate PDE [226]. The protein kinase A (PKA) activity was increased and protein kinase C (PKC) activity was decreased in leukocytes of adult patients with AD, an index of increased PDE activity [274]. No significant differences in PDE activity were found between children with AD and normal controls [60], and PDE activity returned to normal in adults with AD following steroid therapy [105]. Another study suggests that an excess of activated Th2 cells promote increased PDE activity via the β receptors, as a consequence of an IgE hyperproduction caused by excessive IL_4 production and histamine release [308]. Additional studies on metabolic anomalies of PDE activity and of cyclic nucleotides may provide further insights on the basic pathogenic mechanism. In Chap. 4, we outlined that the influence of PGE_2 on the immune system can be mediated in part by its capacity to inhibit Th1-like T cell ILs and stimulate cAMP formation, which is reduced in patients with AD.

However, the key role played by *eicosanoids* should not be disregarded: either PGE_2 or LTC_4 directly promote the biochemical abnormalities in addition to cutaneous lesions of AD [72]; the eicosanoid effects on skin are summarized in Fig. 7.12 [217]. A *disturbed EFA metabolism* has been reported in children with AD, putatively secondary to a deficiency in δ-6-desaturase (Fig. 4.30). Such a deficit may depend on exogenous (dietary deficiency, including nucleotides) or endogenous causes (metabolic anomaly or abnormal EFA incorporation into tissues) [236]. EFA deficiency inducing anomalies of epidermal permeability leads to disturbances in some features of AD such as dry and scaling skin, lichenification, and extreme sensitivity to itching to which the skin is predisposed. Since the normal skin

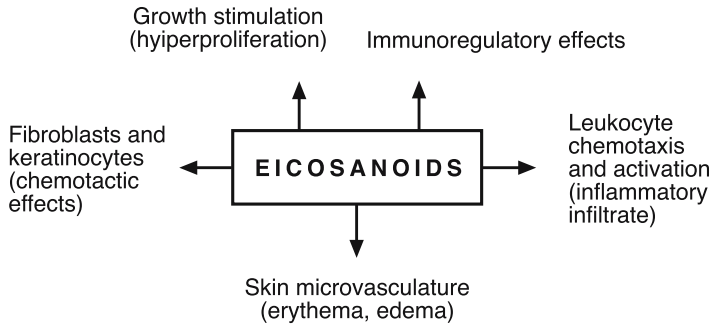

Fig. 7.12. Eicosanoid effects in atopic dermatitis. (Data from [217])

lacks the enzymes necessary to desaturate linoleic acid into AA [236], the epidermal barrier integrity depends entirely on both synthesis and incessant supply by the liver of desaturated metabolites of linoleic acid. This supply is only limited to some extent, the skin is among the tissues that are especially vexed by an EFAD, which may also be considered as a primary defect characteristic of the atopic state. When measuring EFA levels in the cell membranes of red blood cells, neutrophils, monocytes and lymphocytes, it has been demonstrated that AA decrease and linoleic acid increase in monocytes from atopic subjects are at variance with the lymphocytes of the same subjects [211]. These variations in EFA composition in the membranes of immunologically active cells may account for the anomalies found in atopic patients: a reduction in AA levels may be linked to secondary deficiency of PGE_2 reported in AD patients [211].

An increase in linoleic acid has been demonstrated in neonates with high concentrations of CBIgE [256]: such an increase, corresponding to that of IgE antibodies, might indicate a primary, partial inactivation of δ-6-desaturase activity. These findings suggest that EFA composition is genetically determined, therefore representing a basic characteristic and not a consequence of atopy. In our view, measuring EFA serum levels could be a promising approach to a new marker of atopy. In the red-cell membranes of atopic children is found a disequilibrium between high levels of linoleic acid and more reduced levels of polyunsaturated derivatives compared to controls [17], a deficit operative only in erythrocytes, and PBMCs of adults with AD [153]. Elevated concentrations of linoleic acid and of total fatty acids in the atopic skin inflammatory infiltrate can be correlated with an augmented diet supplementation [270]. No differences in γ-linolenic and dihomo-γ-linolenic acid levels be-

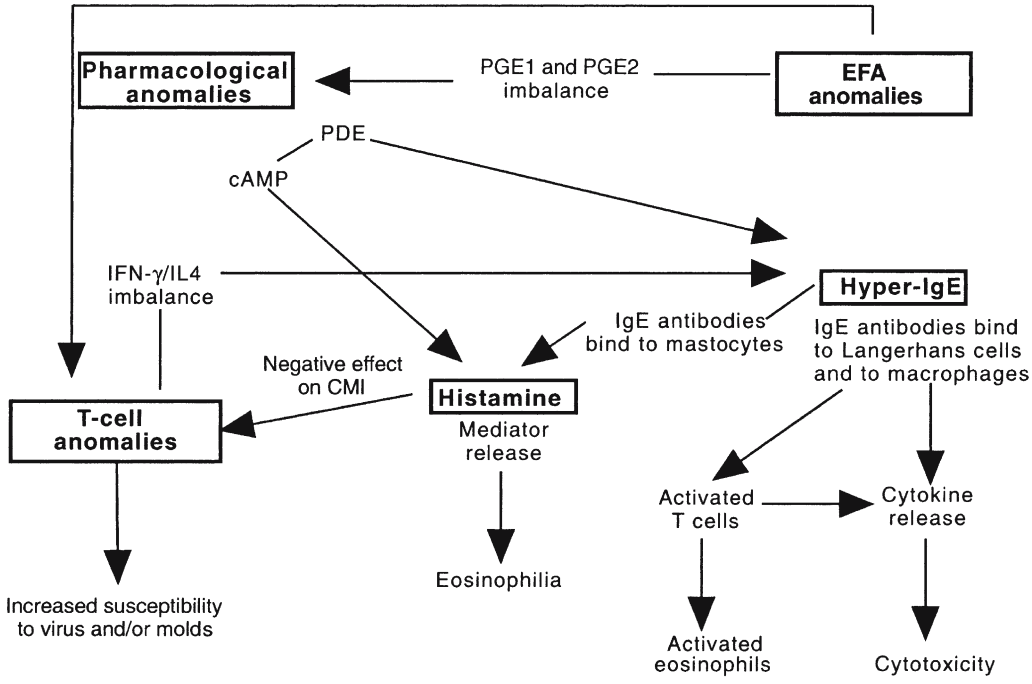

Fig. 7.13. Pathogenetic hypothesis of atopic dermatitis. *CMI* cell-mediated immunity. (Modified from [24])

tween atopic asthmatics and normal controls shows that no inborn deficit of δ-6-desaturase is causative in the atopy pathogenesis [141]. We have suggested (Chap. 4) that these abnormalities may recognize a viral pathogenesis, a further demonstration that this information may have relevance to positive interventions in AD. See Chap. 21 on additional effects of a deficit of EFA and/or nucleotides.

Additional Biochemical or Pharmacophysiological Anomalies

Vasoconstriction. The skin temperature (T) of AD patients is lower than in normal subjects, especially over acral areas: they react rapidly, manifesting a cutaneous vasoconstriction in a cold environment. Such patients show an abnormal response to a cold pressor test (Hines and Brown test), by an excessive elevation of blood pressure when an extremity is immersed in cold water [94].

White dermographism, a nonpathognomonic sign of AD, has been elicited in several dermatoses characterized by erythema; however, it is considered as a useful premonitory sign, since it soon replaces the erythema of triple response and can be elicited on less inflamed skin even in the absence of histamine-induced erythema [94].

Cholinergic responsiveness. A delayed blanch response occurs after intradermal injection of acetylcholine or methacholine, evident only on inflamed skin, similarly to other dermatitis. The mechanism of this paradoxical reaction is controversial: it has been suggested that the subsequent edema develops following a vasoconstriction or a vasodilation. This response can be interpreted as a form of hyperreactivity, assimilable to cholinergic bronchoconstriction recorded in asthmatics [192].

Figure 7.13 [24] summarizes AD pathogenesis.

Additional Pathogenic Factors

Role of Infections

The skin integrity, the most important feature of the cutaneous barrier, means that the skin is resistant to colonization and invasion of microorganisms, unable to pass through juxtaposed epithelial cells, connected by desmosomes. Moreover, pathogen growth is limited by *stratum corneum* relative dryness. However, some bacteria are known to penetrate the skin through the intracellular layers [147]. The reason why atopic patients have an increased proclivity to developing bacterial, viral, and fungal infections, which may run severe courses in AD, is still debated. The potential consequences of defective CMI and the dysfunction of nonspecific immune mechanisms appear to be sufficiently documented by the reductions of chemotactic activity of macrophages and neutrophils, of antibody-dependent cytotoxicity and IL_2 production [35].

There is little doubt that bacteria on the skin surface may also be a key factor and elicit or exacerbate cutaneous lesions, and the pathogenic impact of *S. aureus* is well known, shown at a density of 1×10^6 colony-forming units (CFU)/cm^2 but in greater concentrations when the eczematous lesions are more severe [97]. The unusual tendency of atopic skin to become invaded and colonized by this pathogen has stimulated investigations of the adherence phenomenon. Increased *S. aureus* adherence to corneocytes seems to be both a species-specific and corneocyte-specific phenomenon [55]. Among the receptors responsible for adhesion, fibronectin and laminin are found, whose binding to bacterial wall proteins appears to be irreversible [210]. The reason for *S. aureus* predilection for AD skin lesions seems to depend on the deficiency of defensive mechanisms specific for infection control [210], the dysfunction of skin lipids of endogenous origin [163], and the nutriment offered to germs by both exudate and blood found in inflamed lesions [236]. The specific interactions of *S. aureus* with the immune system is proved by either pro-inflammatory IL production by Th2 lymphocytes or IgA and IgG synthesis reduction in response to *S. aureus* [170]. Reduced sIgA secretion to the skin surface of patients with AD could promote a microorganism colonization [116] and hypogammaglobulinemia G leading to recurring bacterial infections [287].

The following pathogenic observations have been delineated to elucidate the reasons why *S. aureus* is believed to aggravate and/or maintain skin lesions in AD [151, 254]:

- *Induction of an IgE-mediated* response to *S. aureus* or other allergens functioning at the skin surface.
- *Induction of IgE or IgG* directed to the bacterial allergenic material, with a consequent inflammatory skin reaction.
- *Pruritus and scratching* of skin lesions containing *S. aureus* open an epidermal breach, allowing exotoxins and bacterial enzymes to enter the skin of atopic patients.
- *Skin inflammation* caused by SEs A, B, C, D (Table 1.21), which, acting as microbial superantigens, do not require processing for presentation, therefore rapidly stimulating the proliferation of both macrophages and a moderate proportion of T lymphocytes (5%–25%, 1:10,000 for a conventional antigen). This process requires the participation of *HLA class II molecules* restricted only by the specificity of the variable (V) region of the TcR β chain (Vβ) [169] (Fig. 7.14).

Moreover, SE-stimulated basophils of normal subjects do not release histamine. However, basophils of patients with AD react to pertinent SE, but not to other SEs [147]. Recent data show that 80% of children with AD, especially if FA-associated, are sensitized to superantigens colonizing their skin and have sIgE to bacterial toxins, including (Table 1.29): TSST-1 (toxic shock syndrome toxin-1), SEA, SEB, SEC, SED and SEE (staphylococcal enterotoxin A, B, C, D, E, respectively) [169].

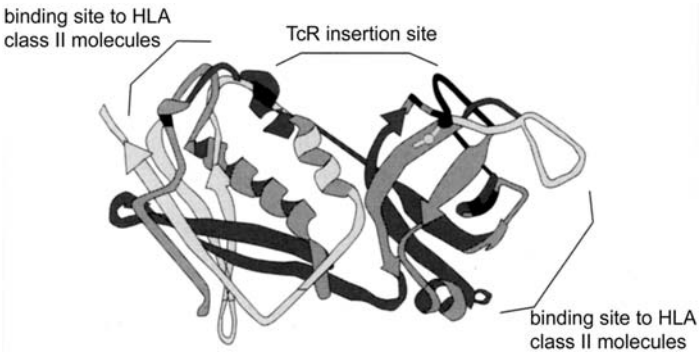

Fig. 7.14. Three-dimensional structure of a staphylococcal enterotoxin B binding site to HLA class II molecules, TcR insertion site and binding site to HLA class II molecules. The figure shows the insertion site for TcR (*top*) and HLA molecules (*side*) allowing the aggregation to related APCs

In particular SEA is capable of activating B cells linked directly to the V_H region Fab, thus acting as a B-cell superantigen [234]. In turn, TSST-1 stimulates IgE synthesis, which is, contrary to SEA, T-dependent, and it is likely that this IgE synthesis develops from a B-lymphocyte polyclonal activation more than from their isotype switching, since even the levels of other isotypes are increased [103]. Characteristically, IgE synthesis is activated by TSST-1 low levels (0.01–1 pg/ml) and inhibited by those elevated (1,000 pg/ml), as well as by IFN-ɣ [103]. In summary, SE ability of binding to HLA class I molecules or stimulating T cells with VβTcR suggests varying mechanisms by which SEs acquire the capacity of exacerbating AD:

- Superficially secreted SEA and SEB penetrate the inflamed skin, where they activate HLA-DR molecules on macrophages or LCs, which produce IL_1 and TNF, both ILs provided with potent pro-inflammatory properties [149].
- SEs putatively prime either a high proportion of Th2 cells (by their VβTcR) to differentiate, thus driving the production of more inflammatory ILs or basophils to release histamine, thus triggering an inflammatory cascade [149] and stimulating IgE production into inflamed skin [151] (Fig. 7.15).
- Roughly 50 % of patients with AD have circulating IgE directed to SEs, namely TSST-1, SEA and SEB, identified at the skin surface, indicating a local immunological sensitization to these staphylococcal SAs [148, 169].
- An analysis of the skin-homing CLA^+ T cells from these patients as well as their skin lesions reveals that they have undergone a TcR V expansion consistent with SA stimulation [32].
- SAs also augment allergen-specific IgE synthesis and induce corticosteroid (CS) resistance, suggesting that several mechanisms exist by which SAs could aggravate the severity of AD [98].
- SEB applied to the skin can induce skin changes of erythema and induration, and the infiltrating T cells are selectively expanded in response to SEB [246].

TSST-1 producers of staphylococci and dermatitis have been found in survivors of toxic shock syndrome, half of whom had IgE levels suggestive of atopy and AD. These findings suggest that exposure to SEs and the consequent immune activation could cause an immunoregulatory imbalance in AD, also because TSST-1 bound to keratinocytes may shift the IL profile, thus emphasizing the role of both IL_4 and IgE [167]. A local inflammation as a result of staphylococcal enzymes and toxic products could activate keratinocytes to express CD54 and secrete a wealth of pro-inflammatory ILs, with further accentuation of the inflammatory state [169]. Recent findings as to the association between staphylococcal adhesion and AD exacerbations point to CD54, leading to increased colonization of epithelial surfaces by *S. aureus*, which propagates to nearby tissues through a variety of enzymes selectively produced. Expressing components capable of modifying the host normal functions, *S. aureus* acts as a highly virulent organism

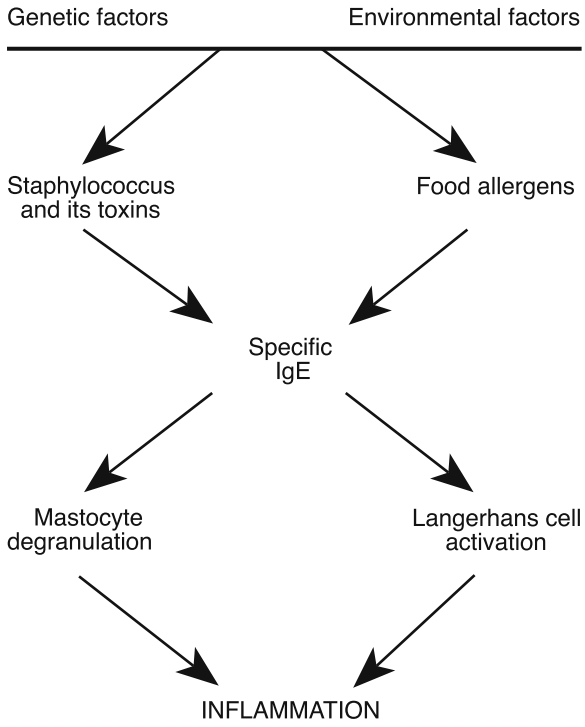

Fig. 7.15. Pathogenic model of atopic dermatitis based on staphylococcal toxins. (Data from [151])

with immunoregulatory properties [169]. Neutrophils, even in a resting state, activate an immune mechanism that produces O_2 metabolites, which are easily stimulated by staphylococcal antigens: reactive metabolites and SEs may cooperate in perpetuating skin lesions [169]. Therefore, as a result of streptococcus-induced sIgE generation, SEs are able to activate either directly by means of sIgE, or indirectly via chemokines, the metachromatic cells and/or other cells equipped with FcεRI, with resulting negative effects on involved skin [144].

Since the original descriptions of a varicelliform cutaneous infection in patients with *eczema vaccinatum* [124], several clinicians have been aware that cutaneous viral infections may run an unusually severe course in subjects with AD, in addition to a raised susceptibility to an atypical incidence of potentially life-threatening disseminated infections [35]. Viral infections may be more frequent in atopic children: EBV (*Epstein-Barr virus*) and *paramyxovirus,* including *varicella-zoster,* CMV (*cytomegalovirus*), RSV (*respiratory syncytial virus*), *mumps virus, measles virus,* etc., may promote a non-specific adjuvant action on IgE synthesis, thus inducing the atopic sensitization, provoking or aggravating skin lesions [254]. In particular, EBV promotes IgE synthesis during the first stages of AD and an increase in antibody titers to EBV has been seen in AD children [254]. EBV activity could be aroused by viral products with IL_{10}-like activity, via IFN-γ inhibition [109]. In adults with present or past AD, Rystedt et al [219] have found greater incidence of multiple recurring respiratory infections (RRI) caused by *Herpes zoster* in subjects suffering from the most severe forms of AD compared to controls. Although antibody titers to EBV are raised in AD [219, 254], there is no statistically significant difference in atopic as compared with nonatopic subjects as regards the outcome of EBV infection; similar results are found relative to HSV, varicella-zoster, CMV, mumps and measles virus antibody titers [254]. During the first 2 years of life, there is a significant association not only between AD and other atopic disease manifestations, but also between AD and RRI manifested in an increased rate of *acute otitis media* (RP 1.13) (ratio of proportion), pneumonia (RP 2.17) and *use of antibiotics* (RP 1.29) [22]. Therefore the infections, in addition to complicating AD, could represent a relevant etiopathogenic factor [35].

Role of Food Factors

Given the importance of the role of food factors, Fig. 7.16 [289] emphasizes that the prevalence of food sensitization is greatest in babies aged 0–2, with SPTs positive for foods in 53% of cases, lower in children aged 3–8 years and 5% in children aged >9 years. DBPCCT studies have found an AD–FA association in 33% of cases [33].

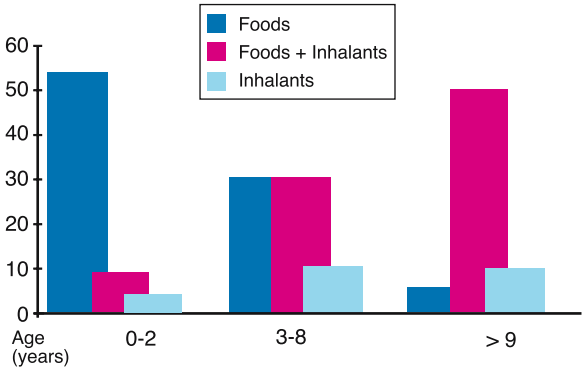

Fig. 7.16. Percentage of positive skin prick tests (SPTs) to food and/or inhalant allergens in children with AD by age group. (Data from [289])

Role of Food Additives

Food additives, mainly HR foods or those containing histamine-like substances, are able to provoke AD exacerbations, even in infants (Chap. 10).

Role of Aeroallergens

Several lines of clinical evidence based on results of different studies have found that the inhalation or contact with aeroallergens can induce pruritus (immediate reaction) and then eczematous lesions (chronic inflammation) [54]. After the first demonstration in 1918 that non-food proteins such as pollen and animal dander were rapidly absorbed through respiratory mucosa and transported to skin mast cells via the circulation [298], other pioneering studies [275, 276] were conducted in the 1950s to ascertain the pathogenic role of inhalants in these patients. Tuft et al demonstrated eczematous lesions in typical sites within 12–24 h of inhaling *Ambrosia* pollens and/or *Alternaria* spores that persisted for several days. An interesting experiment provided conclusive proof that allergens inhaled through the nose may reach the skin by the circulation: a patient who was aware of the rapid onset of pruritus and reddening of the rash on his limbs (within 10 min) after entering a house with a cat was able to remain in the house for more than 1 h without symptoms simply by wearing a mask that filtered the air he was breathing [199]. This data has been confirmed by eczematous lesions that appeared within 1.5–17 h in patients with AD challenged with Der p [279], thus proving that Der p number in mattresses is as high as the rise in relative risk (RR) [7], in close correlation between exposure and subsequent AD onset [11]. Der p finds a rich nurture in skin scales of children with AD, especially in their bedding dust, fallen during sleep [198, 199].

In 1932 Rost reported that AD would improve if patients lived in a climate chamber that was basically dust-free: these children often experience dramatic improvement in their symptoms when living in an allergen-free room such as in hospital wards [214], where inhalant allergens are less common. There the mean Der p 1 level was ≤ 0.2 µg and in the patients' houses > 10 µg in their bedding [233], thus clarifying why pruritus and scratching lesions intensify at night. Figures 7.16 and 7.17 [289] show the uncommon sensitization to inhalants in the first 2 years of life (to Der p a mean of 17%; see Fig. 5.22), although prevailing remarkably from 3–8 years onward and confirming the subsequent high increase for Der p. A significant increase in sensitization and sIgE positive for Der p were found in children born in the autumn, when mites reach their apex [198] (Table 4.12). Later eczematous lesions were demonstrated following aeroallergen application on the skin of patients with AD by an IgE-mediated mechanism. Yet children exhibit PTs positive to aeroallergens in 33%–44% of cases; repeated application of HDM extract on the PT site results in a peak infiltration of skin mast cells, similar to the changes observed in chronic lesions [54]. These observations confirm the action of *Der p as a contact allergen:* thus, a *Der p epicutaneous application elicits a skin reaction,* which more or less resembles a delayed reaction [28]. Der p allergen, once penetrated in the epidermis through skin lesions or epicutaneous application, is capable of binding to IgE bridging mast cells, eliciting an inflammatory reaction strictly distinct from a classic activation. Microscopic investigation of PT lesions revealed an increased proliferation of Der p-specific T cells, able to activate allergen-specific LCs, also without a constant correlation between Der p-specific IgE and test positivity [113]. Delayed reactions to Der p explain both AD onset or worsening in several children: the concordance in these subjects between positivity of immediate and delayed reactions is a further index of the causal link existing between type I and type IV skin reactions [28].

Immunohistopathological investigations have paved the way to new clues, establishing that aeroallergens interfere with AD pathogenesis. Once bound to IgE antibodies, Der p could be presented to activated allergen-specific Th2 cells that generate IL_4, thus stimulating B lymphocytes to produce sIgE in afferent lymph nodes and contributing to the chronic IgE synthesis predominating in atopic children [220]. A parallel, selective accumulation of Der p 1-specific cells (0.4%–2.7% of T cells) is more frequent in involved skin (94% of $CD4^+$ cells) compared to peripheral blood values of the patients [220]; comparable results are obtained by stimulating cutaneous explants with antigen suspensions [181]. These data confirm an inevitable, preferential skin localization of Der p-specific Th2 [284] producers of Th2-specific ILs (Table 7.7). It is not a surprise to find a massive infiltration of eosinophils recruited by IL_5, likely via the T-cell *longa manus* [28]. By topical application of Der p 1, it has been shown that Der p are localized in atopic skin on LC membranes [264] and similarly APCs of peripheral blood LCs present Der p 1 antigens directly to autologous Th0 cells in draining lymph nodes, with resulting Th1 and Th2 clonal expansion [173]. An important and significant pathogenic finding is that mites, via LCs, are believed to select a Th2 response, inducing an inflammatory state able to maintain and exacerbate lesions, also via the demonstrated action promoting cytotoxic effects expressed by IL_4 and IL_5 [284, 285]. T cells of these children respond more intensely to IL_4, on which the proliferation of some T-cell subsets depends [181]. Arguments have been put forward that suggest that repeated exposure to allergens, chronic or seasonal, hasten the development of allergen-specific Th2 cells of skin-derived IL_4 producers, capable of stimulating both growth and local differentiation of additional cloned IL_4 producers [220].

The cardinal role of HDM in worsening AD is emphasized by several reports. Clones of Der p-specific Th2-like T lymphocytes of skin derivation are excellent inducers of IgE synthesis in B cells, which requires the second signal (Chap. 1) provided by several $CD4^+$ of atopic individuals through a T/B, unrestricted HLA interaction [66, 127]. Der p-specific Th2 cells have a greater ability to express CD23 on the APC surface [125]. From a clinical point of view, it is speculated that 40%–50% of patients with high IgE levels specific for aeroallergens have positive PTs to these allergens [198].

The most significant data can be thus summarized:

- Clinical and epidemiological studies demonstrate that *aeroallergen contact may aggravate AD.*
- *Allergen-specific T cells* are isolated in high numbers in SPT sites.
- A part of these T cells are *Th2 cells,* especially if isolated from the bloodstream, with values varying between 11% and 70% and more often *$CD8^+$ cells are very reduced in number* [290].
- These T cells, derived either from the blood or the skin, are able to *trigger IgE switching from B lymphocytes,* probably within regional lymph nodes by virtue of LCs, thus contributing to chronic IgE synthesis.
- Der p-specific cells and Th2-like T cells in skin lesions are not always correlated with serum Der p-specific IgE antibodies or with high total IgE concentrations [66, 290].
- The low correlation is also true for IL levels, for example IL_4 [290].
- However, subjects with Der p-specific IgE antibodies suffer from *more severe lesions* compared to subjects with PT positivity [113].
- It is therefore likely that anti-Der p 1 Th2-like responses are limited to the initial lesions [66]; nonetheless even if further studies are needed to clarify whether such events are specific for AD, it is indisputable that they effectively demonstrate *the role played by mites in AD pathogenesis.*

Aeroallergens other than Der p contribute to skin lesion worsening. In Fig. 7.17, the rate of SPTs to in-

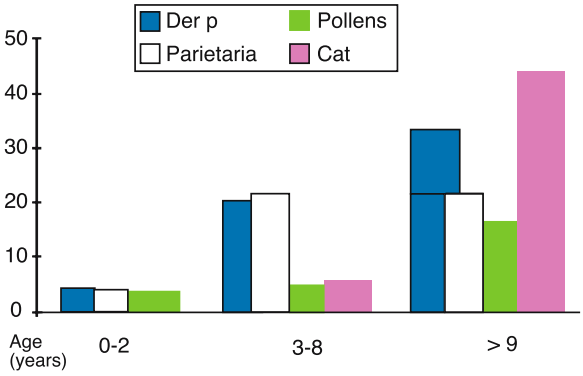

Fig. 7.17. Percentage of positive skin prick tests to inhalant allergens in children with AD by age group. (Data from [289])

halant allergens in children with AD is lowest between the ages of 0 and 2 years, but between 3 and 8 years, pollens increase up to a 20% rate, whereas the low cat sensitization in the first two years (Fig. 5.21) at the age of >9 years acquires an uncommon increase (>40%) [289]. A cat in the home in early childhood increased the risk of persistent AD (COR 2.33) [111]. Aeroallergen sensitization was observed in 66% in moderate AD and 93% in severe AD of children aged 7–15 years [89]. PTs observed in 59 children (mean age, 5.2 years) presenting with AD were, in addition to Der p and Der f (26.8%), positive to garden trees (12.2%), plantain (9.8%), timothy grass, mugwort and damp area trees (4.9% each), and orchard grass (2.44%) [42]. Pollen-sensitized children generally undergo, in spring–summer, a worsening of AD lesions.

Pathophysiology of Itching

Itching is defined as the quintessential feature of AD, and scratching is the major cause of the damaging excoriations, erosions, and lichenification characteristic of AD.

Previously it was thought that itching and pain were transmitted by one type of nonmyelinated fibers [91]. Supporting this view is the observation that itching receptors are correlated with free nerve terminals of nonmyelinated C-fibers, at the dermoepidermal junction. However, studies by intraneuronal microstimulation have shown that two different subsets of receptors and fibers subserve itching and pain. It is feasible that itching mediators are able to act directly on its receptors, indirectly releasing histamine, or directly raising its threshold. As a consequence, the impression of relief, contemporary or subsequent to scratching, would be due to a closure of the so-called gate for pain and itching stimuli arriving in thin C-fibers, via tactile sensations arriving in A-fibers [91, 296].

The mechanisms involved in the pathogenesis of itching remains to be explained, and some observations might help in answering this question [85, 296]:

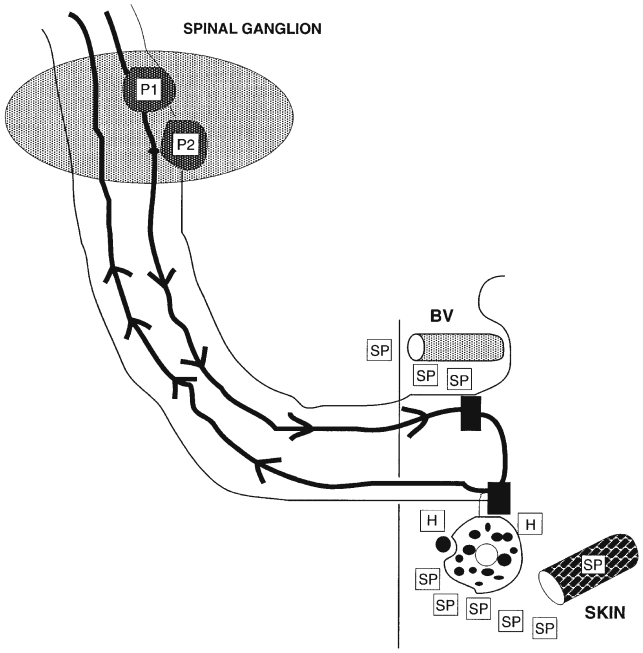

Fig. 7.18. Substance P (*SP*) activates dermal mast cells (*M*), which release histamine (*H*). Histamine stimulates two different populations of nervous cells controlling the pain (*P1*) and itch (*P2*) sensations. By antidromic stimulation of blood vessels (*BV*) vasodilation ensues. (Modified from [91])

- *Histamine* is a classic itching mediator almost exclusively in urticaria, but other pruritogenic factors may be involved as well; likewise serotonin is a weak pruritogenic factor.
- *Neuropeptides* stimulate mast cells to release histamine but little definitive information has arisen about whether neuropeptides are responsible for pruritus.
- *Prostaglandins* stimulate itching by lowering the threshold for histamine in experimental conditions; however, the inhibitors of prostaglandin synthesis such as aspirin have little or no effect in relieving clinical itching.
- In several pruritic skin disorders, T lymphocytes are active. Predictably, *pruritogenic ILs* activated by such activated cells are involved in the AD pathogenesis. This hypothesis is supported by reports showing that cyclosporine A, by inhibiting IL secretion, alleviates itching in some patients with AD.
- *A polymodal nociceptor C* has been shown to play a prominent role in the central itching transmission [296].

However, to identify the central mechanism involved in itching pathogenesis, the more promising advances come from the study of neuropeptides. Several investigators have noted that itching evoked by SP and other neuropeptides is accompanied by wheal and flare reactions, and suggested that itching may be caused by histamine release from dermal mast cells (DM). The pathophysiological mechanism would be based on the following points (Fig. 7.18) [91]: SP activates DMs releasing histamine (H), which stimulates two different populations of nerve cells controlling both pain and itching

sensations (P1 and P2); by antidromic stimulation of blood vessels , the flare response is produced via release of SP and other peptides; SP released from nerve terminals acts directly on vessels and adjacent DMs; the flare reaction reaches its zenith. Thus upstream of neuropeptide-induced pruritus, there is the *SP-mediated mast cell degranulation* which releases H causing vasodilation and activation of sensitive nerves [91]. Therefore, neuropeptides could establish a close point of union between the nervous system and inflamed skin, thus explaining the well-known association between pruritus, skin alterations and emotional stress [85]. Another factor is the frequency of pruritogenic stimuli, accompanied by flare or transpiration, could originate from the finding that C-fibers, because of a threshold lowering, are rapidly activated concomitantly with a skin T increase. However, studies to determine which is the activating mechanism still await basic answers [296].

It seems likely that only the skin is provided with sensory mechanisms that localize the arriving stimuli: this is due to spinal circuits with an inhibiting activity for sensations different from those originating from the central point of the stimulus. Therefore itching is elicited not only by localized stimuli, but especially by stimuli sufficiently expanded and able to provoke a diffused inhibition, different from the moderate response to a punctiform stimulus. Afferent fibers of a small diameter deliver the message to connecting neurones and to synaptic mechanisms, occasioning an hyperexcitability of long duration [85]. As a result of persisting scratching and of consequent mechanical irritation, performed ILs are released by keratinocytes (GM-CSF, TNF-α), which trigger dermal inflammatory responses. Moreover, antigen-specific immune responses in the atopic chronic skin lesions might change into antigen-independent immune responses, which may activate an inflammatory process amplified and automaintained by numerous noxae, not only endogenous but especially exogenous [125]. The fact that itching characteristically worsens at night induces a parallel with nocturnal asthma. As we will see in Chap. 11, the relationship between nocturnal asthma and circadian reductions in plasma adrenaline concentrations can be interpreted as evidence of a permissive mechanism upon release of histamine from mast cells (which could explain the nocturnal fits), and that such a mechanism might help explain the pruritus in AD may be an interesting hypothesis [93].

Irritant Effects

Irritable skin is closely associated with pruritus, even if the pertinent causes are different [277]. The major irritant causes include the following:

- *Defective epidermal permeability* barrier, leading to excessive transepidermal water loss, critical for the penetration of irritants
- *Influence of disease severity*
- *Lowered itching threshold,* unremitting source of irritability, started by minimal environmental changes
- *Excited skin syndrome,* meaning a general increase in atopic skin susceptibility to irritants applied to an unrelated body area [277, 278]

Interestingly, the threshold is not lowered; however, atopic patients perceive as pruritogenic many stimuli that normally are well tolerated by nonsensitive persons: numerous chemical and natural substances may express irritant effects [5]. The chemical products that are the most deleterious are soaps and cleansing agents, which are often very effective in removing lipids and oils from the skin of children with AD, emulsifying them with protective properties, although their moderate use is harmless. Their excessive use makes the skin dry and vulnerable, and the resulting inflammation when improperly used on the skin suggests that they should be employed only by necessity, and thoroughly rinsed [5]. However, lipids are essential in the *brick-and-mortar barrier* of the *stratum corneum;* thus lipid solvents can break down this first line of defense. Natural factors are at first the extreme points and then sudden T changes: undressing of the child, frequent sweating by occlusive clothing, contact with rough fabrics, wool and/or synthetic textiles, inappropriate hygiene and/or bathing with unsuitable detergents, a dry, cold climate or overheated residences, emotional stress, as well as ingestion of sensitizing foods and contact with environmental allergens. Overall, many foods can act as *nonspecific irritants* when coming in direct contact with an impaired skin barrier [83, 247]. UV light abates mast cell responsiveness and eosinophil number during the summer months, but the decreased epidermal water barrier consequent to winter cooling leads to a hyperstimulation of mast cells and nerve terminals [277]. Another cause is humidity: dry skin worsens in a cold environment with reduced humidity compared to a warm environment; therefore dry skin is aggravated in winter [5].

Relapses are inevitable, even if they are attenuated by pertinent treatments; they are generally identified as negative reactions to environmental factors. *Irritant dermatitis* occurs in several atopic children; numerous substances or exogenous factors are implied. Analysis of 300 cases showed that the causes were as follows: winter season 66%, city life 42%, change of residence 29%, foods 19%; 68% improved at seaside and 30% in mountain resorts [236]. There is now extensive evidence that several factors may either precipitate or aggravate AD. These include conditions leading to vasodilation such as hot water, rapid T changes, irritant detergents [36], and preservatives [57].

Clinical Presentation

Clinically AD is a disease characterized by wide individual variations, an erythematous, exuding or papulovesicular eruption, and intensively pruritic lesions; sub-

Table 7.8. Most frequent lesions (%) based on the onset age

Lesions	<1 year	>1 year

Fig. 7.20. Atopic dermatitis of infants: the marked itching can be seen from the child's posture (for details see text)

sequently lichenification and scaling are more prominent. Scratching often leads to excoriations, blood can leak out of the injured capillaries in the excoriated dermal papilla, which mixes with serum and results in serosanguineous crusts, impetiginization, and secondary infections. The aspect of the lesions during the acute phase is very different from that seen in the chronic phase. For unknown reasons, the distribution of the clinical manifestations differs according to the period of patient's life in which onset occurs; therefore it can be subdivided into three phases [36]:

- Early infantile phase (up to 2 years)
- Late infantile phase (up to 12 years)
- Childhood and adolescent phase (up to 18 years)

Table 7.8 shows the most frequent sites of lesions in children aged <1 or >1 year [236].

In the *early infantile phase* (acute phase), although seborrheic dermatitis may precede and coexist with AD, infants are typically involved at about 3 months of age (47.5%–100% of cases) (Table 5.5), with erythematous-exudative eruption with poorly defined contours and confluent, whose topography is almost pathognomonic (Figures 6.4 to 6.18). The predilection site is especially the face (about 80% of cases), including the cheeks, zygomas, auricles and retroauricular sulcus, with a characteristic sparing of the skin triangle including the nasal, perioral and mental regions (Fig. 7.19). Moreover, lesions may extend progressively to involve the forehead, neck folds, scalp, trunk and extensor surfaces of the limbs, so that at age 18 months the lesions may involve all body areas. The increased drooling occurring with teething can be of further irritation to the inflamed skin [137]. Itching is unremitting and stressful, especially for parents, who undergo long sleepless nights trying to prevent the baby from worsening the disease by scratching the skin furiously. Scratching lesions may also be apparent in young infants who are restless, sleepless, tearful and, to get relief from pruritus, discover how to rub their skin against crib linen or bedclothes by continuous movements, or on their leg surface using the contralateral limb (Fig. 7.20) [320]. The lesions thus provoked expose the skin to bacterial infections, usually by *S. aureus*. The sometime marked oozing causes *hypoalbuminemia* [273].

In the *late infantile phase* (subacute phase) the disease often appears as a continuation and extension of the previous phase and its major feature is lesion chronicity. In 3%–5% of cases, AD arises between the ages of 4 and 6 years. The lesions are more localized, less oozing and more often scaling, and impetiginization occurs on an erythematous basis, but is less exudative than in the previous phase, and eczema of *dorsal folds of the limbs* typically develops (Fig. 7.21), with involve-

Fig. 7.21. AD of infants: the lesions of the limbs are on the extensor aspects

ment of the antecubital and popliteal spaces as well as of the wrists. Additional predilection sites are the face, neck, legs, ankles, wrists, and hands [94]. When the face is involved, the lesions extend to palpebral and perioral regions, the cheeks (Fig. 7.22a) and the retroauricular areas (Fig. 7.22b), appearing persistently fissured with moderate serous oozing. Pruritus is again unremitting, especially in the acute phases, and children are easily irritable and restless; scratching lesions are frequent, provoked even through clothing. In older children, either the back or the sole of the foot may be involved (assuming the aspect of an ACD), often diagnosed as athlete's foot, while in fact it is a rhagadiform dermatitis [319]. Since the lesions are long-lasting, undergo thickening, dryness and lichenification, skin dryness worsens in cool and dry winter months, and improves in summer. The course is relapsing or chronically persistent and continues into the subsequent phase. A *reversed pattern* primarily affecting the elbows, knees, dorsal hands, and wrists has a less favorable prognosis [288].

In the *childhood and adolescent phase* (chronic phase), AD is the prolongation of infantile phases. The predilection sites are virtually the same: localization to the perioral region, mostly cheilitis with radial fissures, to the periorbital region and neck, and *flexural aspects of the limbs* now being the predominating type of lesion. Lichenification, with skin thickening, greater evidence of fine scaling and xeroderma, is more frequent than the inflammatory component persisting at the periphery of lesions. Dry skin is scarcely elastic. Emotional and environmental stresses (exposure to a cold, desiccating climate) may add a further negative effect. Itching remains unaltered in everyday life, even if scratching lesions are less frequent, but somatic factors are accentuated by significant psychological problems, frequently caused by insomnia or cosmetic disfigurement. On the other hand, psychological factors may also deteriorate the clinical conditions, most likely establishing a vicious circle.

Both the symptoms and the division into phases so far outlined can facilitate the diagnosis, but frequently the typical aspects are not reproduced, especially in subacute and chronic phases, and a persisting progression with wide *interindividual variations* prevails [236], corresponding to the effects of irritant factors. Despite these difficulties and shortcomings, the clinical symptoms will hint at the basic characteristics of AD and have a major impact on therapeutic decisions.

Fig. 7.22. **a** After the first 2 years of life, AD of the face involves the palpebral and perioral regions, the cheeks and **b** the retroauricular sulcus

Additional Clinical Features

Besides full-blown AD, whose features are universally accepted, there are the diagnostic findings shown by Table 7.9 [94, 96, 166, 177, 224, 311]. These findings may help to recognize the constitutional stigmata or minimal forms that should be observable with no technical devices without distinctive symptoms or clues to atopy.

Table 7.9. Diagnosis of atopic dermatitis

Major criteria[a]
Pruritus
Typical morphology and distribution of age-related lesions
Facial and extensor involvement in infants and young children
Flexural lichenification and linearity in older children and adolescent
Chronic or chronically recurrent dermatitis
Personal or family history of atopic disease (asthma, allergic rhinitis, AD)

Minor criteria[a]	
1. Xerosis[b]	15. Anterior subcapsular cataracts
2. Ichthyosis	16. Periorbital darkening[b]
3. Palmar hyperlinearity[b]	17. Facial pallor or erythema[b]
4. Keratosis pilaris[b]	18. Pityriasis alba[c]
5. Immediate, type I skin prick response	19. Worsening of itch when sweating[b]
6. Elevated total serum IgE	20. Intolerance to wool and lipid solvents[b]
7. Early age at onset	21. Perifollicular accentuation
8. Susceptibility to cutaneous infections (*Staphylococcus aureus*, *Herpes simplex*)[b]	22. Food allergy or intolerance
9. Hand and foot dermatitis[b]	23. Course influenced by environmental or emotional factors
10. Nipple eczema[c]	24. Delayed blanch reaction[b]
11. Cheilitis	25. White dermographism[b]
12. Chronic recurrent conjunctivitis[b]	26. Infra-auricular fissuring[b, c]
13. Dennie-Morgan folds	27. Scalp dermatitis
14. Keratoconus	

Three major criteria[d]
1. Family or personal history of atopic disease, asthma, allergic rhinitis, AD
2. Pruritus
3 Typical facial or extensor eczematous or lichenified dermatitis

Three minor criteria[d]
1. Xerosis, ichthyosis, or hyperlinear palms
2. Periauricular fissures
3. Perifollicular accentuation
4. Chronic scalp scaling
History of involvement of the skin creases[e]
Personal history of asthma or allergic rhinitis[e]
History of skin dryness in past 12 months[e]
Flexural dermatitis[e, f]
Onset before age 2[e, g]

[a] Hanifin and Rajka criteria [96] modified by Hanifin [94] (the diagnosis is made according to the presence of *at least 3 major features and 3 minor features*). Hanifin has proposed a list of minor features restricted to numbers 1–6, 8, 9, 11, 27.
[b] Statistical associations suggested in [166].
[c] Statistical associations suggested in [177].
[d] Sampson criteria [224] for infants and young children.
[e] In a refined version [311], child *must* have itchy skin condition for at least 12 months *plus* three or more other features.
[f] In children aged <4 years with history of atopic disease in first-degree relative.
[g] Not influential in children aged <4 years.

Constitutional Stigmata

The following minor criteria are included with the incidence indicated in parentheses [202]:

Dry skin or *xerosis* (48%–98%) may be localized or generalized; the skin is rough to the touch, not inflamed, sometimes slightly scaly, also ichthyosiform; the pathogenesis is uncertain; the association ichthyosis vulgaris is uncommon (2%–6%) [165] (see "Complications").

Hyperlinearity of the palms (and soles) or an increase in palmar creases is frequently referred to (28%–

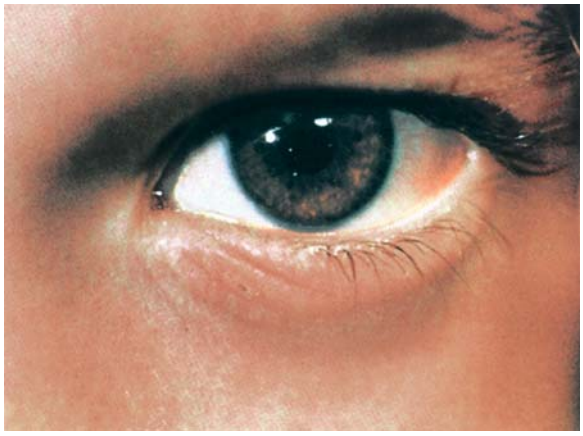

Fig. 7.23. Dennie-Morgan infraorbital folds with AD of the lower lid in a 6-year-old child

Fig. 7.24. Orbital darkening (for details see text)

Fig. 7.25. Typical Hertoghe's sign (for details see text)

Fig. 7.26. Low hairline (for details see text)

88%). We do not dispose of conclusive data on their interpretation.

Dennie-Morgan infraorbital folds (12%–85%) (Fig. 7.23) [318] are symmetrical creases below the margin of the lower eyelids, usually of both eyes (not to be mistaken for the physiological *sulcus palpebralis inferior*). Considering the folds as closely related to eyelid dermatitis has been proposed; however, they are found more frequently in younger than in older subjects with AD.

White dermographism (38%–100%) is observed more frequently in atopic lesions compared to other types of dermatitis, but also in healthy controls, and in lesions of other chronic inflammatory dermatoses.

Facial pallor (22%–85%) is a diffuse paleness frequent in young patients. Just as white dermatographism is attributable to an abnormal vascular reactivity with a tendency toward vasoconstriction of small blood vessels, facial pallor may occur in patients with white dermatographism following skin rubbing.

Orbital darkening (41%–85%) or allergic shiners: a blue-grey discoloration of the orbital skin with accentuation of the lower orbit (Fig. 7.24) [202]; sometimes there is slight edema. Even if different pathogenic mechanisms have been proposed for AD (a combination of irritation and inflammation) and for perennial rhinitis (edema and/or spasm of the *musculus tarsalis* which impede venous blood flow from the orbital region), orbital darkening is frequently observed in atopic patients with neither of the two diseases.

Hertoghe's sign (Fig. 7.25) [202]: thinning or complete absence of the eyebrows in their lateral aspects.

Low hairline (Fig. 7.26) [202]: distance of ≤3–≤1.5 cm from eyebrows, direct transition from scalp to eyebrows [202].

Minimal Forms

Minimal forms include the following [319, 320]:

Follicular or Patchy Pityriasiform Lichenoid Dermatitis. This is more properly a *keratosis pilaris,* a hyperkeratosis obstructing the follicular orifices appearing in infancy and persisting until it peaks in adolescence. The lesions are common on the extensor surfaces of upper

arms, face, forearms and buttocks with partly confluent areas, where papules that are mildly bran-like, flesh-colored, scaly and nonhyperkeratotic have been noted, with a characteristic aspect of gooseflesh; mild itching is also present. Lesion progression is observed in winter, whereas the summer can lead to improvement or healing of the rash, especially during a seaside holiday. The differential diagnosis involves supracollicular keratosis, follicular hyperkeratosis in the context of an autosomal dominant ichthyosis vulgaris, *lichen nitidus* and *planopilaris* and Gianotti-Crosti syndrome (see "Differential Diagnosis").

Papular Variant. Papules are found on the extensor aspects of the knees, occasionally at the elbows and back of the hands, at variance with the follicular form, more evident in the spring and summer, and are often associated with pollinosis, thus suggestive, from a pathogenic point of view, of an inhaled precipitant such as an AR equivalent or a mechanical component such as friction or rubbing. The differential diagnosis includes the lesions seen in juvenile papular dermatitis, lichenoid eruption by rubbing, and toboggan dermatitis. However, in these conditions both family and/or personal history and sIgE to inhalant or food allergens are positive.

Nummular Variant. The chronically occurring eruption of strictly demarcated, papulovesicular, coin-shaped, excoriated, occasionally exuding lesions covered by scaly crusts leaves the adjacent skin uninvolved; there is itching-scratch succession; it is differentiated from herpetiform and vesicobullous dermatitis.

Localized Minimal Variants. These include:

- *Exfoliative cheilitis* with perlèche: irritant effect provoked by acid foods more than by an allergic reaction [188]; frequent licking to ease the dryness and rubbing of the adherent scales exacerbate the lesion (Fig. 7.27) [318].
- *Retroauricular intertrigo* or earlobe rhagades.
- *Lower lid dermatitis* (Fig. 7.28) [318]: habitually occurring in spring as a pollinosis equivalent, often associated with Dennie-Morgan infraorbital folds and Hertoghe's sign.
- *Nipple dermatitis:* pathognomonic when present (22%–42% or 12%–23% of cases) [215, 217].
- *Tylotic, rhagadiform finger pad* dermatitis (Fig. 7.29) [318]: more frequent in girls and right-handed subjects, characterized by pale erythema, minimal edema, keratosis, scaling, fissuring, accompanying pain may lead to functional impairment in the involved hand.
- *Vulvar dermatitis* is characterized by circumscribed, scaly, erythematous lichenification of the labia, secondary to the severe pruritus of this very sensitive skin, and has a chronically relapsing course [94].

Fig. 7.27. Exfoliative cheilitis with perlèche in a 6-year-old child

Fig. 7.28. Eczema of the upper lid in a 14-year-old boy (for details see text)

Fig. 7.29. Tylotic, rhagadiform, finger pad eczema

Fig. 7.30. Atopic toes, plantar aspect often misdiagnosed as a foot mycosis

Juvenile Plantar Dermatosis. This is also known as atopic foot dermatitis (Fig. 7.30) [318], more commonly reported in males aged between 3 and 6 years, and more marked in summer and winter months. Characterized by enhanced scaling, and intertriginous and wet areas, it is often misdiagnosed as a foot mycosis and thus treated with antimycotics. Association with AD ranges from 50 % to 74 % of cases. The seat is the great toe, less commonly the forefoot, with erythema, scaling, fissuring, etc., the back of the foot if the shoes are involved. The pathogenesis is also related to repeated microtraumata (frictional ACD), a clammy microclimate due to the wearing of synthetic socks and/or high shoes, and/or contact allergy to parts of shoes. The disease has a mean course of 7–8 years; a complete remission should by expected with adolescence in the majority of cases [319, 320].

As regards the diagnostic importance of both stigmata or variants in AD, in addition to the figures cited so far, only the association of some forms yield highly significant statistics [166, 177] (Table 7.9).

Complications

- *Hypoalbuminemia* in young infants can be the result of extended and markedly exuding lesions [273].
- *Bacterial infections,* whose role has been re-evaluated, especially that of staphylococci and streptococci, which can influence both the severity and tendency for AD relapses. In particular, *S. aureus* colonizes the skin of atopic subjects in 90 %–100 % of cases, and bringing it into close contact with normal skin for 24 h produces eczematous lesions that persist for several days. The lesions are superficial, exuding, with extensive serous weeping, erythematous, with honey-colored crusting, often accompanied by lymphadenopathy and intense itching. Usually AD lesions worsen in the presence of an infection, since *S. aureus* antigens and type I immune reactions are involved in the maintenance of chronic skin inflammations [146] (Fig. 7.31, 7.32). Streptococci also colonize the skin of atopic subjects and provoke infections that often resist therapy. As previously mentioned, significantly higher incidence of *herpes*

Fig. 7.31. Severe infection due to *Staphylococcus aureus* in a baby with AD as a result of food allergy

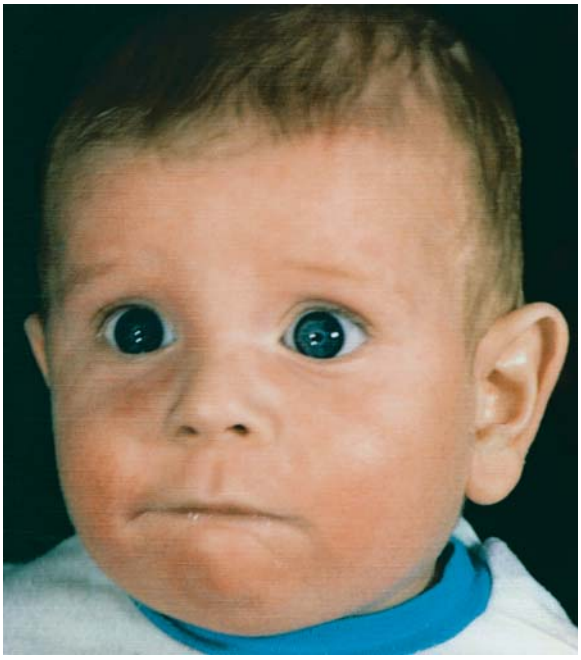

Fig. 7.32. Dramatic improvement in the same baby after 7 days of treatment with erythromycin

zoster and respiratory infections are seen in adults who suffered from a more severe AD during infancy.

- *Mycotic infections* are a more frequent isolation from hands, feet and the nail bed and involve *Trichophyton rubrum* and *Pityrosporum* species in dermatitis of the head (70% of cases in infants), neck, shoulders and mid-thorax, both involved in exacerbations of the lesions [120]. *Pityrosporum* is distinct in the *orbicularis* and *ovalis;* however, the A serotype is from *Malassezia furfur* and B and C are provided with two IgE-binding proteins of 67 and 37 kD [63]. It induces IgE-mediated immune reactions from the age of 4, as confirmed in children with elevated IgE levels by IgE anti-*Pityrosporum*, which correlates well with the course of skin lesions and a poor prognosis [152]. *Candida albicans* is implicated in AD exacerbations, as demonstrated by antibodies anti-*Candida* IgE [237] cross-reacting with anti-*Pityrosporum* IgE via mannans with high PM [69, 180]. *Pityrosporum* infection is diagnosed with RAST, ELISA and monoclonal antibodies [326]. These studies confirm a significant association (p=0.0001) with yeast sensitization [152].
- *Viral infections* [35, 36]:

– *EBV* as discussed in "Role of Infections."

– *HSV* (*Herpes simplex* 1 and 2) usually induces superinfections of eczematous lesions extended to normal skin, sporadically assuming a very severe course. The lesions are characterized by clusters of superficial blisters and intensely itching vesiculopustules probably lasting roughly 2 weeks with subsequent outputs. Ocular complications (herpetic keratitis progressing to blindness) are possible [94].

– *Herpes labialis* is usually rarely considered, but can cause a hemifacial involvement and may be confused with *Herpes zoster.* Characteristic of this infection are its recurrences in different parts of the body, some patients suffer from exacerbations of the lesions concomitant with this virus [94]. Children should not have direct contacts with persons affected with *Herpes labialis* [35].

- *Eczema herpeticum,* whose form of cutaneous type 1 or 2 HSV infection, commonly by heteroinoculation, is not evident <5 years. The localized form is characterized by itching and by papular, vesicular, bullous, erythematous or eczematous lesions. In children, the cluster lesions have a predilection for the face and hypogastric, gluteal and perineal regions; herpetic gingivostomatitis may occur in young male children with active, severe and persistent AD, often after prolonged topical or systemic CS therapy. Disseminated, life-threatening disease may have a poorer prognosis in young children and immunocompromised subjects.

– *Eczema vaccinatum* is a severe eruption by poxvirus, mostly by autoinoculation or heteroinoculation, with vesicles and pustules without seat predilection and high fever. Defervescence occurs within 10 days in uncomplicated cases. Virus dissemination with organ involvement is life-threatening. *Eczema vaccinatum* may by clinically indistinguishable from *eczema herpeticum.*

– *Molluscum contagiosum:* children with AD are susceptible to this infection, which is extensive, recalcitrant, and characterized by roundish, shining, often umbilicated papules, having a diameter of 1–2 mm, with a central body, or *molluscum* body, containing epidermal viral cells with cytoplasmic inclusions. The infection is extenuated by autoinoculation. The risk of developing dissemination of the organism is favored by long-lasting use of CSs; otherwise the infection has a chronic course (1–2 years).

– Virus of human papilloma causes warts, often multiple with a chronic course, which can increase in number by autoinoculation [236].

Additional Complications

- Cold abscesses involving subcutaneous tissue should be differentiated from hyper-IgE syndrome.
- Subcapsular cataract, anterior and/or posterior, for which various types of treatment have been implicated, especially with CSs and PUVA (psoralen ultraviolet A), or herpetic infections [36]. Onset is in early childhood with an incidence of 16% [94].

Association with Other Atopic Diseases

- *Respiratory allergy* (mean, 46.8%), asthma (RP 1.45) [22]. In children with AD, a latent predisposition for asthma has been reported [238] and is significantly higher in children with a smoking mother [175] or in those who have experienced an early age of AD onset [48, 218]. The age of onset is statistically lower in children who are asthmatic compared to nonasthmatic children (p=0.011) [58]. AD can also start within the 1st year and asthma in the following years [192]. Moreover, AD worsens in the spring in pollen-allergic children. As much as 35% of 500 6-year-old children were asthmatics, 50% of those with severe AD and 15% with mild AD [206], showing that asthma begins earlier and more frequently in severe cases of AD [206, 218]. In 14 studies meta-analyzed in Table 7.10 [9, 23, 39, 58, 88, 154, 205, 206, 215, 221, 228, 286, 294], the mean incidence of asthma is 46.8%; in highly selected pediatric populations, it is between 66% [221] and 79% [88]. In up to 95% of these children, bronchial hyperreactivity has been described, PD_{20} (provocation dose 20) is of 0.22 µmol in children with AD and asthma and 2.10 µmol in those with no association [222]. Early AD is associated with asthma at school age, and children with AD and wheeze have a marked loss in lung function. The prevalence of early wheeze was significantly higher in children with early AD compared with children with no early AD (46.3% vs 32.1%, p=0.001) [111].
- *Urticaria* (21%–34.8%) [215] (RP 2.04) [22] is found in up to 43% of children [9]. Urticarial lesions of the immediate type to mite allergens have been reported

Table 7.10. Asthma prevalence in children with atopic dermatitis

Authors (reference)	No. of children	Median age (years)	Asthma (%)	Follow-up (years)

in children; acute and contact reactions are associated with FA or pseudo FA.

- *FA* (30%–50%) has an RP of 3.20 [22]. Children with CMA show cutaneous symptoms in 34%–64% of cases (see "Relationships Between AD and FA" and Chap. 9).
- *Atopic keratoconjunctivitis,* whose incidence is unknown, has an RP of 2.25 [22]. The associated ocular disease involves about 3% of the general population and especially adolescents.
- *ACD* (8.6%–32.2%) (Table 5.9) shows an increased incidence up to 44% of children aged 6 months to 12 years [57], up to 43% of children aged >8 years [168], in atopic children >10 years [61], or a progressive increase: 11% of children <2 years and 58% of those >15 years [108].

Association with Nonatopic Diseases

- *Gastrointestinal disorders:* in children with celiac disease, scaly skin lesions resembling AD have been reported, which may improve on a gluten-free diet. Some patients with eosinophilic gastroenteritis also have AD.
- *Ichthyosis vulgaris:* skin signs are commonly shown in children >2 years of age, rarely involving the extensor limbs and with hyperlinearity of the palms. The disease occurs in 2%–6%. AD changes are seen in >50% of ichthyosic patients.
- *Dermatitis herpetiformis* Duhring: pruritic erythematous or papular lesions are frequently or infrequently associated with AD, but especially with celiac disease.
- *Cystic fibrosis:* an association with AD is observed in 8%–13% of cases.
- *Metabolic abnormalities:* a dermatitis indistinguishable from AD was described in 19%–50% of children with phenylketonuria, principally during the 1st year of life.

Diagnosis

The diagnostic approach to AD includes a medical history, physical examination, and laboratory studies. For the diagnosis of AD associated with FA see below and Chap. 9. The main points are discussed as follows (Table 7.9):

- *FHA* is positive in 60%–70% of cases (Tables 4.9–4.11).
- *Personal history* includes important elements such as the course of AD onset, the foods administered, and environmental and/or emotional changes.
- *Medical examination* is based on the child's symptoms or on the clinical criteria laid down by Hanifin and Rajka [96] (Table 7.9), who recommend taking into account three major criteria and at least three minor criteria. There is a simplified version, with a sensitivity of 80%, specificity of 97% and a positive predictive

value (PPV) of 80% [310]. More adequate for infants and toddlers is the 3+3 criteria [224], because there has been much controversy [166, 177] surrounding the minor criteria [96], which are based on symptoms that are not standardized and do not occur commonly [37]. To assess AD lesions we refer the reader to the diagrams of Figs. 6.1 and 6.2 and, to evaluate the severity of the lesions, to Appendix 7.1 and the SCORAD scoring index shown in Fig. 6.19, which takes into account the morphology as well as the extension (20%), intensity (60%), objective symptoms, pruritus and sleep disturbances (20%) [311]. Figures 6.4–6.18 show a wide photographic documentation useful for the objective diagnosis.

- *Laboratory studies* include several methods, as follows:

– *SPT* or *P+P*, SPTs for food and inhalant allergens, P+P only for fresh foods. When positive (in 75%–85% of cases there is high sensitivity), SPTs may have no absolute correlation with clinical symptoms and the course of AD [147], since a positive SPT to a food is only suggestive of the actual existence of clinical FA. Applying the criteria of analytical reliability (Table 6.16) to SPTs for foods is credited with a high negative predictive value (NPV) with the foods often responsible for immediate symptoms, namely cod, peanuts, etc. As regards SPT use in planning a diagnostic elimination diet, see below.

– In addition to food allergens, it is always appropriate to test, including in infants, *aeroallergens* (major trigger, Der p), adding the PT in children with negative SPTs when an IgE-dependent sensitization is suspected [89].

– *Total serum IgE levels* are elevated in about 80% of children, especially if respiratory allergy coexists, although there is no close correlation between IgE values and AD. In case of need, serum IgE can be determined together with RAST [37], or very elevated values are employed for prognostic screening.

– *RAST* is useful in children with such widespread lesions that it can be impossible to carry out SPTs, and in the case of antihistamine administration. However, a routine use should be avoided [37]. RAST is used to identify food-specific IgE but patients with high total serum IgE levels can have false-positive RAST because of a nonspecific allergen binding [147]. RAST is no more specific than SPTs in detecting clinical sensitivity. We have not always found correlations between sIgE and responses to the diet [37]. A modified RAST has been developed for determination of IgE antibodies to *Candida albicans* [180].

– Clinical–biological studies have investigated the determination of *ECP levels* (normal values, <16 µg/l) as a diagnostic tool [173]. As discussed previously in "Humoral Immunity", there is a correspondence between AD state and ECP activity, but the lack of correlation between ECP levels and those of circulating eosinophils [157], serum IgE [258] and AD severity [157] makes this test unsuitable for everyday diagnostic purposes. ECP may be useful in monitoring the AD course and evaluating the ongoing pathological process [125, 191, 258], as well as for asthmatic children.

– In children with AD and asthma, *LCT_4 is a more sensitive variable* than ECP and/or peripheral eosinophilia to evaluate eosinophil activation state [238].

– Finally, measuring *CD54 levels* has been suggested, as they show a good correspondence with AD severity [123].

Differential Diagnosis

Figure 7.33 [242] shows how to differentiate types of AD according to stage. Moreover, depending on the child's age the following disorders should be taken into account [36, 94]:

Early Infantile Phase

- *Seborrheic dermatitis,* the most frequent, is easily differentiated from AD and often coexists with AD. However, a number of babies with AD develop typical seborrheic dermatitis [94] (Table 7.11) [318, 324].
- *Diaper dermatitis* with secondary eruption, with early age of onset (1–2 months) and localization to the diaper area, with possible extension, even if rare, to the face and/or to deep-seated folds. Itching is absent or mild. The lesions are often superinfected with *Candida albicans*.
- *Acrodermatitis enteropathica,* best-known clinical expression of Zn deficiency and consequent ID, is a disease with an autosomal recessive mode of inheritance. The skin lesions, characteristic and pathognomonic, are initially vesiculopustular and subsequently crusting and psoriasiform, because of insufficient Zn absorption, are preferentially periorificial, and localized to the hands, feet and head. The appearance of lesions when the baby is weaned from breast milk to cow's milk (CM), accompanied by diarrhea and steatorrhea and the regression of both conditions after Zn therapy are differentiating [36] (Chap. 21).
- Rare disorders include

– *Leiner's disease* (scaling erythroderma).

– *Staphylococcal scalded skin syndrome* (SSSS) due to the absence of epidermolytic toxin-producing strains.

– *PID:* hyper-IgE syndrome, ataxia-telangiectasia, WAS, IgA selective deficit, X-linked agammaglobulinemia, severe combined immunodeficiency (SCID), and X-recessive hyper-IgM syndrome. In SCID-Omenn syndrome, infants show a diffuse, exudative erythroderma, often defined as AD, like LC histiocytosis. Nezelof syndrome is characterized by AD-like lesions and very elevated IgE concentrations (Chap. 22). In secondary ID, AIDS and AD may be associated.

– *Metabolic disorders,* including phenylketonuria, Hartnup disease, mucopolysaccharidosis I H, histidine-

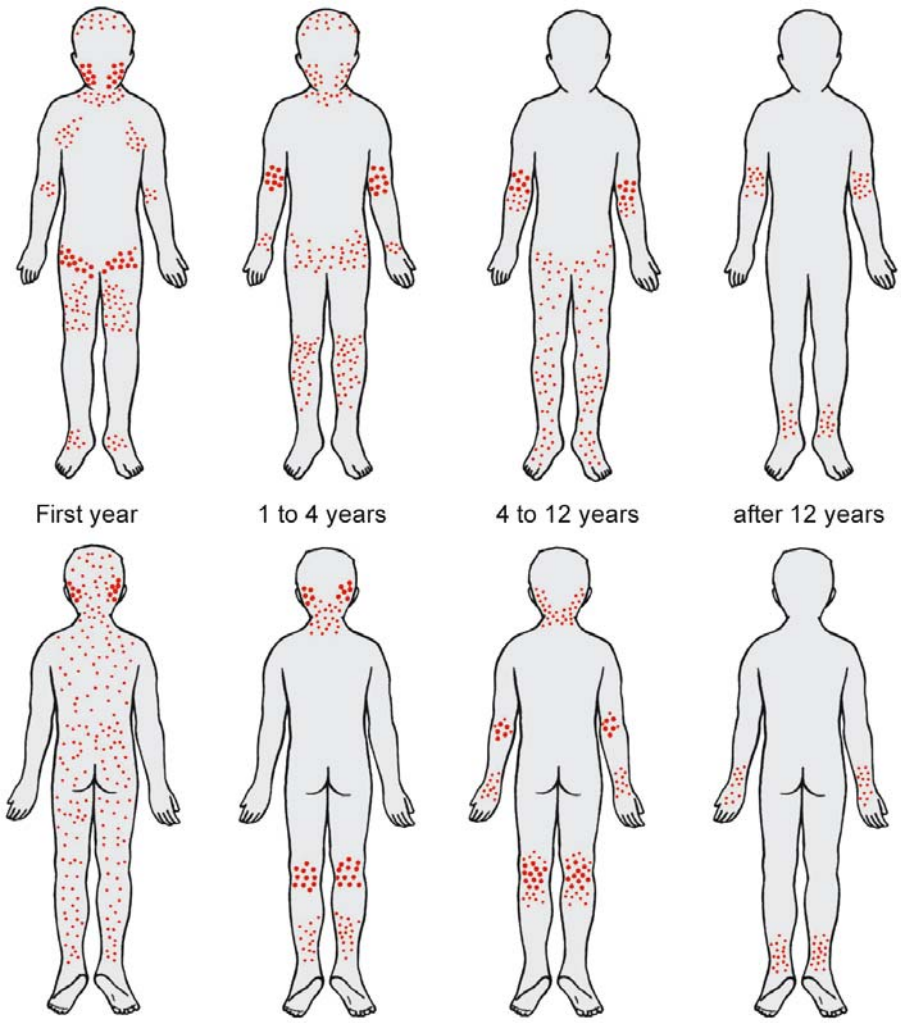

Fig. 7.33. The clinical manifestations are different depending on age. (From [242])

Table 7.11. Differential diagnosis between seborrheic dermatitis and atopic dermatitis

Clinical and laboratory data	Seborrheic dermatitis	Atopic dermatitis
Family history of atopy	Usually lacking	Positive for atopic disorders
Age of onset	Usually <2 months	Usually >2 months
Distribution	Scalp, forehead, nasal folds, neck, axillae, diaper area; in older babies eyelids and eyebrows	Cheeks, forehead, extensor surfaces of limbs; flexural surfaces in older children with limb involvement clearly diagnostic
Lesions	Erythema with yellow-reddish greasy scales	Erythema, papules, vesicles, crusts; no greasy scales
Pruritus	Absent or minimal	Severe, a hallmark of the disease
Skin tests	Negative	Usually positive
Serum IgE	Normal	Usually increased
Specific IgE	Negative	Often positive for foods, later for inhalants
Prognosis	Clears in 3–8 weeks; no recurrences	Chronic, relapsing
Associated allergies	Uncommon	High incidence of associated allergic disease (asthma, rhinitis, food allergy)

Data from [318, 324].

mia, biotin-responsive multiple carboxylase deficiency, and prolidase deficiency occur: some cases have eczematous lesions, mostly insufficiently studied. In trisomy 21, 21 %–56 % of cases may have atopic symptoms, along with those of an ID of the cellular type as well as of a congenital ichthyosis.
– Cutaneous lymphomas (mycosis fungoides, Sézary's syndrome and Hodgkin's disease, T-cell lymphomas) may initially present with eczematous lesions.
– Histiocytosis X.
– Congenital amyloidosis.
– Congenital perceptive hearing loss.
– SIDS (sudden infant death syndrome).
– Netherton's syndrome is an autosomal recessive disorder characterized by hyper-IgE, dermatitis indistinguishable from AD, *ichthyosis linearis circumflexa, trichorrhexis invaginata* and bamboo hairs.
– In cystic fibrosis, there may be an increased prevalence of atopy and of FHA.

Late Infantile Phase

- *ACD,* often confused with back of the foot dermatitis, similarly presenting with erythematous and pruritic lesions. Atopic stigmata are often absent. If a doubt exists, the PT is diagnostic (Chap. 8).
- *Mycosis* of the sole of the foot or *tinea pedis,* where so-called athlete's foot is often diagnosed. A culture of locally collected material may be helpful.
- *Pityriasis rosea* has shown an increased incidence in schoolchildren, of typical oval, pale, erythematous, papular or scaling, isolate lesions, especially of the trunk. The absence of itching and the self-limiting aspect of lesions are diagnostic.
- *Gianotti-Crosti syndrome* in preschool children may manifest with monomorphic, erythematous or papular lesions, nonpruritic, of red to purpuric color and symmetric aspect, affecting the face (especially the cheeks), forearms and hands, occasionally with involvement of the lower limbs, but absent from the trunk, palms of the hands and soles of the feet. The characteristic aspect of the lesions, absence of pruritus and outcome within 2–3 weeks are distinctive.
- *Scabies* can be easily confused with infantile AD because severe pruritus, blisters, and granulomas occur in both conditions, but small papules or pustules are electively localized to the cutaneous axillary and genital folds, extensor surface of the elbows, and interdigital spaces of both hands and feet, and have a distribution that does not predispose to misdiagnosis. The detection of the parasite *Sarcoptes scabiei* or the scabies in other family members is diagnostic.
- *Eczema herpeticum* (see "Complications") culture of isolates allows the differential diagnosis between HSV and varicella zoster.
- *Cutaneous lymphomas* and congenital amyloidosis (extremely uncommon).

Childhood and Adolescent Phase

- *Psoriasis* presents with reddened lesions covered by whitish scales and with very distinct limits, involving extensor surfaces, elbows, knees, etc., and with more or less frequent pruritus. Common linkages have been found with AD and psoriasis in three chromosomes (Table 4.2).
- *Pyoderma* has a characteristic course, with itching less frequent than in AD.
- *Dyshidrotic eczema* manifests with pruritic vesicles of the palm of the hands and soles of the feet, worsened by dyshidrosis and hyperhidrosis.
- *ACD.*
- *Microbial eczema,* characterized by disseminated lesions, nummular, clearly demarcated, measuring a few cm [36, 94].

Other Dysfunctions

- *Mycotic infections* in addition to those by *Candida* and *Pityrosporum* previously described, for example, *tinea corporis* characterized by usually roundish, erythematous or scaling patches, with clear-cut and polycyclic limits and resolution from center to periphery; *tinea capitis,* characterized by roundish patches of atrichia amid normal hairs; and *tinea manuum* occurring with hyperkeratosis on a slightly erythematous basis and also with skin dryness, but the clinical picture is not always diagnostic and should be completed by history and mycological examinations.
- *Molluscum contagiosum* (see "Complications").
- *Impetigo,* a bacterial infection marked by blebs and pustules with erosions and brownish-yellow crusts on exposed skin and on the face around the nose and mouth.
- *Miliary,* a benign and transient skin alteration resulting from immaturity of sudoriparous glands that do not succeed in coping adequately with an external or internal T-cell increase. Reducing the child's excessive clothing eliminates the problem.
- *Insect venoms* produce wheals and/or localized papules.

Table 7.12 summarizes the most common causes of pruritic skin rashes [305].

Table 7.12. Most common causes of pruritic skin rashes

Contact dermatitis
Drug-induced erythema
Exanthematous disorders
Herpetiform dermatitis
Infestations
Lichen simplex chronicus
Mastocytosis
Parasitosis

Systemic disorders (rare) seen in pediatric age Endocrine disorders Hepatitis Myeloproliferative disorders Obstructive disease of biliary tract
Urticaria

Modified from [305].

Management

The treatment of a multifactorial condition is complex, including dietetic manipulations and environmental measures (Table 7.13). Indications to be followed are different depending on the acute or chronic stage of AD [37]. If FA complicates AD, see Chap. 9.

Avoidance of causal agents and of aspecific irritants is without doubt the first step to be taken. Adopting measures aimed at preventing, reducing, or even minimizing trigger factors is adequate and in certain cases necessary for maintaining control of the disease. To guarantee children a good quality of life and make the condition tolerable, it is vital to control the itch for which children with AD have a lower threshold [36]. In addition, topical treatment should be individualized to control both inflammation and skin infections. The secret of successful treatment in children with AD is to avoid prescribing only symptomatic therapies, but rather to *try to find first the casual factors,* specific to each child. Therefore every form of treatment should be tailored to the individual child [97]. The following points can be used for managing most children:

1. General and local hygienic and preventive measures:
– Itching control
– Child's hygiene
2. Local aspecific cutaneous treatment
3. Medical treatment
4. Specific antiallergic measures
5. Other measures
6. Antiasthmatic measures

Table 7.13. Suggestions for the management of children with AD

Dietary management (Chap. 24)
Favor prolonged breast feeding Favor delayed weaning and solid food introduction Avoid allergenic foods
Hygienic norms
Ensure pruritus control and prevention Ensure skin hydration and protection Minimize too frequent bathing and hot water Avoid detergent or fragrance-filled soaps Reduce skin contact with coarse fabrics in clothing and bedding Minimize excessive sweating Reduce causes of inflammation
Avoidance of irritants
Reduce environmental allergens, including mites and furry pets Eliminate parental cigarette smoke Minimize extreme fluctuations of temperature and humidity
Medical management
Local therapy by topical corticosteroids to combat inflammation and exudation Antihistamine medications to reduce pruritus Secondary infection control by topical or systemic antibiotics
Additional control
Ensure day and night rest Minimize of emotional stress Distract children with games and manual activities

Management should be individualized.

General and Local Hygienic and Preventive Measures: Acute Phase

Common sources of skin irritants to be avoided can be summarized into eight main points [94]:

- Woolen or coarse clothing
- Nylon or occlusive clothing
- Plastic mattresses, pillow covers and bedding (Chap. 24)
- Excessive contact with hot water
- Bathing without proper medication
- Exposure to chemicals, above all detergents and solvents
- Vigorous scrubbing in a hot shower
- Contact with dust, dirt, and newsprint

These measures should be individualized, eliminating every factor that aggravates the lesions [5].

Itching Control

- *Reduce the lesions provoked by scratching,* which can be accomplished by trimming and cleansing fingernails, using 100% pure cotton mittens or gloves and stockings to prevent scratching during the night. For this purpose, we also suggest using pure cotton pyjamas [36] and protecting the skin by covering the affected areas with a heavy wrapping or other restraints for infants with AD. Alternatively, the lesions are best bandaged with well-fitting sterile cotton dressings and kept in place with an elastic bandage, after having sparingly applied a low-potency CS ointment and emollients to nonaffected areas [5], also as an effective barrier against the persistent scratching that often undermines therapy. When the lesions are extensive, bandage the child using the above procedure (total-body involvement) (Fig. 7.34 a): for this purpose the common gauze for dressing or tubular bandages may be employed. This wet-wrap dressing can also be achieved by using damp but not soaking wet cotton pyjamas covered by dry cotton pyjamas [5]; severe lesions on hands and feet may be dressed with gauze and bandage wraps. *Occlusive dressings* usually soothe the inflamed skin of children with AD, dry up the weeping exudative lesions, and prevent nocturnal scratching (Fig. 7.34 b).
- *Avoid contact with coarse* bedclothes, wool blankets and pillows, feather and kapok mattresses and pillows, sheets and pillow-cases that are not of pure cotton or linen and unwashable blankets as well as bedding with wool, nylon or synthetic textiles or adherent, heavy, rough clothing. Even in winter, the inherent softness of 100% cotton, free of dye and starch, used next to the skin and for bedding is preferable.
- *Children should only wear* underwear of white cotton (removing every colored label) and pure (not interwoven with wool or with synthetic textiles), or of smooth linen, always with long sleeves. Underwear should not adhere too closely to the skin. Moreover, infants should not be given plastic diapers, instead only those of linen or white cotton, as previously suggested, and these are to be changed regularly. *Avoid sweaters* and pullovers touching both wrists or neck; avoid wool hats, caps, and scarves. Keep children from playing on rugs or on wall-to-wall carpeting.
- *Avoid contact of underwear* and bedding with irritating chemical substances, including fabric softeners and harsh enzymatic disinfectants and bleach during washing. Clothes should be rinsed carefully to eliminate irritating residual laundry detergents, and should be preferably washed with Marseille soap. The irritating and drying effects of many soaps and detergents should be emphasized. Even new clothing and sheets should be washed thoroughly prior to use to remove sizing and other chemicals with which they may have been treated.
- *Avoid physical activities* which require an excessive effort and occlusive clothing (Table 7.13), which with sweating aggravates pruritus. Excessive clothing in AD

a

b

Fig. 7.34. **a** The child is bandaged (for details see text) either to avoid uncontrolled scratching or to apply topical medications. **b** The particular bandaging is done to avoid paroxysmal nocturnal scratching: 2 min of uncontrolled scratching can offset 10 days of successful therapy

children may be a hindrance to normal heat dispersion, which automatically is converted into overheating. In healthy children, the cool-warm equilibrium is re-established via both transpiration and evaporation, with a consequent rapid cooling. The alteration of this homeostasis in children with AD results in high amounts of perspiration seeping into inflamed skin, with a notable accentuation of pruritus, via the above-discussed irritating mechanisms [5]. Therefore, we repeat the suggestion of using 100% cotton next to the skin, by far the best choice, because even increased perspiration fails to cool the skin, and evaporates rapidly from the skin surface [44].

- Experience suggests that when the child is undressed, for example during the doctor's visit, both pruritus and scratching increase, thus indicating that the child should remain dressed, as far as this is feasible, also because clothing protects the skin from the excoriations provoked by scratching [5].
- *Avoid indoor overheating* during the winter season, especially in poorly ventilated houses. The indoor T should be kept at 18–20 °C and relative air humidity at 45%–55% to prevent additional skin drying (Chap. 24).

Child's Hygiene

As a cause of persistent skin inflammation, the irritating and drying effects of normal or perfumed soaps, bubble baths and surface-active detergents should not be overlooked (Chap. 8). Although water alone is best [137], mild cleansers (Marseille soaps for washing) may be used, as well as oleate or hypoallergenic soaps, or non-soap cleansers, provided that they are fragrance-free and designed for sensitive skin, and carefully rinsed away. If alternative products are available check their composition carefully, since they may contain CM proteins or other sensitizing proteins [97]. Moreover:

- *Daily bathing* (not showers!) in a soaking lukewarm water (mean T of 36 °C [36], limited to 10–15 min is recommended to optimize hydration of the *stratum corneum;* then rinse the baby carefully with tepid water. Within 3 min of leaving the water, apply hydrating ointments or totally unfragranced creams soon after having dried the baby: waiting longer dehydrates the skin through evaporation of the water absorbed by the *stratum corneum* [94]. The frequency of bathing should be evaluated according to the individual tolerance to water. If the water is rich in limestone, a depurator of reasonable cost can be suggested.
- *The face or neck* can be hydrated by applying a wet cotton towel or facecloth to the involved areas for 10–15 min; hands and feet can be hydrated by soaking the limbs in a basin.

– In AD active phases, it may be useful to have the assistance of another person to occupy the baby's hands.
– We suggest that the skin of the child is dried very delicately: patting not rubbing with a soft absorbent towel of pure cotton, white, smooth and washed as pointed out above.
– If, despite all precautions and efforts, especially during the acute phases of AD, bathing provokes irritations, we suggest reducing bathing to the simplest terms, or employ only tub water, cleansing the body with a dry towel, thus restricting bathing to what maintains the child socially tidy, assuring the mother that frequent washings have more esthetic than sanitary justifications [5]. Other authors suggest using a minimal amount of antiseptic liquid with an insignificant risk of systemic effects, leaving the mother with the impression of washing her child [236].
– Avoid the child soaking in the tub at length and avoid overly frequent bathing since both dehydrate the skin, thus lowering the itching threshold.
– In conclusion, from a practical standpoint the dry skin of children with AD suffers from frequent, prolonged and vigorous washings.

- *Hydrating lotions* or creams should not contain additives, fragrances or other potentially irritating substances. If this is not the case, a commercial preparation that is sure to be tolerated by children can be suggested [236]. Such products are to be employed in particular at the first signs of cold weather to protect the exposed parts of the body.
- *Swimming* is usually well tolerated. However, swimming pools are frequently treated with chlorine or bromine: therefore it is suggested that children shower and use a mild soap immediately after to remove these potentially irritating substances and lubricate their skin [5].
- For *scalp hygiene,* even if the dermatitis is commonly mild, the above measures should be adopted. A mild or baby shampoo in young children and a hypoallergenic shampoo in older children can also be used, paying attention that the shampoo does not come in contact with the skin of the face. For children with an extremely sensitive scalp or more severe or extended lesions, and keeping in mind the scalp's high capacity of absorption, especially in the first 2 years of life because of the scalp's small dimensions, especially formulated shampoos and conditioners are recommended [97].
- Thoughtful attention should guide the selection of reliable *shoes for children* with juvenile plantar dermatosis (atopic feet dermatitis), avoiding excessive heat or humidity to prevent plantar dyshidrosis or other occlusive effects. Therefore, boots, high heeled and rubber shoes should be avoided. The most suitable are those made of natural fibers, replaceable in winter with shoes of pure leather with the following characteristics: the vamp should not treated or finished with chemical substances; the likely glued cover should permit foot transpiration; the internal insole should be of leather or of cork; children should always wear heavy white stockings, avoiding synthetic socks [5].

Local Aspecific Cutaneous Treatment

The principles are different depending on the acute or chronic stages [35, 94, 95, 107, 164]. During the phases of skin dryness and lichenification, an emollient cream or lotion is necessary, taking care that they are free of substances to which the child is sensitive. Their use combined with hydration helps re-establish and preserve the *stratum corneum* barrier. Moisturizers have also been shown to decrease the need for topical CSs [95]. Taking into account an EFA deficit, using creams containing EFA of the ω-6 series is recommended when needed. Next, skin cleansing and hydration is necessary: based on the type of lesions prominent in the three clinical stages, the treatment is adequately adapted to the pertinent phase, with special attention to the itching-scratch cycle. In a chronic condition such as AD, where scratching is the worst evil, skin protection turns into a basic prerequisite [35]. The therapeutic option most favored by dermatologists is topical therapy [5, 107], whose goals we summarize. Their prerequisites are, on the one hand, to lessen the clinical manifestations promptly, and on the other, to painstakingly treat the inflamed skin, thus bringing the skin back to normality again as much as possible. The inherent peculiarities at the *stratum corneum* suggest that there is the inclusion of hydrophilic and/or lipophilic ointments, apt to penetrate more rapidly into this stratum, where hydrophilic and hydrophobic-lipophilic strata alternate. This performs an important reservoir function and allows a sound but constant diffusion of the medications toward the deepest strata of the epidermis. Topical treatment has therefore an elective indication at the level of epidermis, which, being avascularized, is barely reachable by systemic medications [107]. Furthermore, the suggested galenic preparations, or nonsteroid topicals, have the advantage of being practical, free of unwanted side effects, as effective as possible, esthetic and low-cost, and they contain a lesser amount of chemical ingredients added as preservatives, or solubilizers, which can be eliminated by contacting the local dealer. However, it is hoped that we will soon obtain that on the packages of cosmetics and emollient topicals, etc., there will be a clear indication of their composition [107]. As regards preparations in general, since every child has a different tolerance, it is advisable to make a one-sided trial in both cases. The best results are obtained when therapy is instituted promptly, beginning with an accurate cleansing of the inflamed skin: a careful removal of crusts and remnants without rubbing is best applied with the aid of wet compresses, while greasy substances are removed more readily by using suitable solvents. Consequently, different vehicles and excipients are used depending on the AD phase (Table 7.14) and the exposed skin (Table 7.15) [107].

Table 7.14. Stages of AD and rules of topical therapy

Stages of eczema	Management
Acute and exudative	Indifferent bases (oil, water emulsions)
Acute and not exudative	Wet on wet (creams, soft pastes)
Subacute	Mild exsiccating (creams, soft pastes)
Chronic	Hydrophilic to lipophilic (ointments)

Modified from [107].

Table 7.15. Rules of local therapy

Exposed skin	Lotions, ointments and creams during the day; ointments during the night; if necessary (scaling or hyperkeratosic lesions) also ointments during the night
Scalp and hairy skin	Lotions and creams; avoid pastes and ointments, difficult to remove
Creases, folds (intertriginous and diaper areas)	Lotions, powders, creams and soft pastes; avoid fatty excipients which have macerating effect; in the diaper area the use of greasy pastes may be helpful when a highly protective effect is required

Moisturizers are available as lotions, creams, and ointments. Modified from [107].

Acute stage with vesicles, oozing, crusting and erosions: wet on wet hydrophilic packs are suggested, by which an antiseptic and decongestant action is accomplished as follows:

- *Layers of sterile gauze* may be imbued with chlorhexidine hydrochloride 0.01%–0.05% or Burow's solution with Al at 5% (at 1:10–1:40 dilution), squeezing away the excess fluid from the gauze and changing it several times to avoid skin exsiccation. The medications are maintained in place for no more than 20 min and in total should not exceed 2 h/day, but should be used only for a few days because of their drying effect.
- *Oatmeal may be added* to medicated, refreshing baths, it may feel soothing to certain children but increases water absorption. K permanganate ($KMnO_4$) 1/10.000–20.000=0.1%–0.05% is very effective, but $KMnO_4$ can be used only in hospitalized children because it colors the skin brown, especially the nails.
- Packs, creams and soft pastes should be employed in acute but not exudative stages (Table 7.14).

Subacute stage with lesions dominated by erythema, edema, serum papules, oozing scales:

- An exsiccating, lenitive and refreshing action is accomplished using *creams and soft pastes* with a mild exsiccating and anti-inflammatory effect. Mild ingredients should be used. Hydrophilic soft pastes, for example mixtures of water and powders, can be used: water paste with ZnO (zinc oxide) act by virtue of their ointment component in an absorbing, draining and refreshing manner since they favor the transpiration and avoid the local accumulation of warmth, always a negative factor.
- *Moderately emollient action* using oil-in-water or water-in-oil emollients, which when used as vehicles for active ingredients show a high release rate and good penetration into the skin of incorporated ingredients such as basis cream. Moreover, they are useful in removing scales and cleansing the lesions from grease and water remnants. They have a limited occlusive, but not drying effect, thus allowing a sufficient evaporation and transpiration of skin lesions, with an added refreshing effect.

Chronic stage with scaling, lichenification, infiltrated lesions:

- *Vehicling action of active components* by means of *hydrophilic to lipophilic ointments* (water-oil type), for example a simple emollient. Ointments in particular ensure an emollient and deep action, because of an occlusive effect of the lipid phase that creates a state of permanent humidity by preventing the surface evaporation of fluids, thus favoring skin hydration.
- *Refreshing and moderately greasing action* preferably using lipophilic ointments (oil and powders) such as the *Lassar's paste,* based on ZnO, talc, vaseline, lanolin ana. g 25 for lichenified lesions. In lanolin-intolerant children, it can be substituted with an equal quantity of vaseline; Lassar's paste is mild enough to be well tolerated and ZnO helps dry and soothe weeping lesions; both have a greater penetrability and a higher accentuated covering effect than the emulsions. Lotions composed primarily of water and alcohol are not indicated in lichenified lesions [107].
- In both cases, *avoid overly occlusive medications,* which may not be tolerated well by many children: cotton drapes, smooth and less abrasive, are very helpful for bandages (Fig. 7.34), alone for topical medications, or for passive skin protection from contaminants and traumas (scratching, rubbing, etc.) [5].

Pay attention to lipophilic or overly greasy preparations, a possible cause of irritation if applied for several days, not only on the lesions, but also on healthy skin, especially in warm seasons and/or on sensitive skin such as that of the face or intertriginous areas. In treating juvenile plantar dermatosis, avoid antibiotics and CSs; instead keep feet and hands dry and warm, applying vaseline as necessary [164].

Usually, regional differences in the degree of xerosis and grease compatibility are found in atopic skin: the skin on the trunk and limbs tolerates and needs greasier ointments than that on neck and trunk. Moreover, children react to discomforting topicals less by crying than by increased scratching [107].

Medical Treatment

Medical treatment is first aimed at eliminating itching and reducing infections, thus providing symptomatic relief. Pediatricians often prescribe hydroxyzine as the first drug (2 mg/kg/day, divided into two doses), a histamine H1-blocker. Because its antipruritic action with mild side effects of drowsiness persists beyond the normal drug half-life, it is often sufficient and advisable to administer one night dose of 1 mg/kg. Its use is preferentially restricted to limited periods of time, to avoid a possible outbreak of tachyphylaxis (reduced effectiveness of a drug after repeated applications).

Topical CSs are nowadays the mainstay of AD treatment, a very effective pharmacodynamic therapy that also suppresses local inflammation (Table 7.16) [84, 97] and are much more effective when associated with a wetwarp occlusive dressing (Fig. 7.34). Once the remission is obtained, dry skin can be treated with hydrating and emollient creams or lotions as above. Topical CSs are available in several bases, including creams, ointments, lotions such as fluorocortin butylester, which imparts anti-inflammatory and antipruritic effects, similarly to 0.1% methylprednisolone cream [207]. Fluticasone propionate (FP) ointment and mometasone furoate cream (Table 7.16) can be used once as opposed to twice daily [95]. The main points to remember with CS therapy are as follows: use of low-potency products and the minimal quantity necessary to obtain symptom control. Using these drugs without moderation, and/or for continuous long periods may lead to well-known side effects, such as atrophy changes, secondary infections, rebound effects, tachyphylaxis and ACD [170]. Tables 7.17 [107] and 7.18 [84, 97] summarize both advantages and side-effects of topical CSs. *Employing high-potency CSs and on extended cutaneous areas* (Table 7.18) *should be avoided* due to a concrete risk of systemic side effects [84]. CS use may result in a rapid improvement, but they do not solve the problem: following a negligible application of the above-mentioned measures, there is a quick recrudescence of AD as soon as they are withdrawn. Moreover, prolonged or systemic CS treatment may enhance skin susceptibility to specific viral or bacterial infections because of its immunosuppressive effects [35].

Proper use of CSs in AD requires following a number of rules, even before any prescription is given. It is advisable to:

1. Inform the parents and/or the child about the problems related to the disease and those that are foreseeable with the use of CSs.

Table 7.16. Potency of topical corticosteroids employed in children with atopic dermatitis

Indications and preparations	
Group I	
Betamethasone dipropionate 0.05% (cream and ointment)	Diflorasone diacetate 0.05% (ointment)
Clobestasol propionate 0.05% (cream and ointment)	Halobetasol propionate 0.05% (cream and ointment)
Group II	
Amcinonide 0.1% (ointment)	Diflorasone diacetate 0.05% (ointment)
Betamethasone dipropionate 0.05% (cream and ointment)	Fluocinonide 0.05% (cream, gel, ointment, and solution)
Desoximetasone 0.25% (cream)	Halcinonide 0.1% (cream)
Desoximetasone 0.05% (gel)	Mometasone furoate 0.1% (ointment)
Group III	
Amcinonide 0.1% (cream and lotion)	Fluocinonide 0.05% (cream)
Betamethasone dipropionate 0.05% (cream)	Fluticasone propionate 0.005% (ointment)
Betamethasone valerate 0.1% (ointment)	Halcinonide 0.1% (ointment and solution)
Desoximetasone 0.05% (cream)	Triamcinolone acetonide 0.1% (ointment)
Diflorasone diacetate 0.05% (cream)	
Group IV	
Hydrocortisone valerate 0.2% (ointment)	Mometasone furoate 0.1% (cream)
Flurandrenolide 0.05% (ointment)	Triamcinolone acetonide 0.1% (cream)
Fluocinolone acetonide 0.025% (ointment)	
Group V	
Betamethasone dipropionate 0.05% (lotion)	Flurandrenolide 0.05% (cream)
Betamethasone valerate 0.1% (cream)	Hydrocortisone valerate 0.2% (cream)
Fluticasone acetonide 0.025% (cream)	Prednicarbate 0.1 % (cream)
Fluticasone propionate 0.05% (cream)	
Group VI	
Alclometasone dipropionate 0.05% (cream and ointment)	Flucinolone acetonide 0.01% (cream and solution)
Betamethasone valerate 0.05% (lotion)	Triamcinolone acetonide 0.1% (cream)
Desonide 0.05% (cream)	
Group VII	
Hydrocortisone hydrochloride 1% (cream and ointment)	Pramoxine hydrochloride 1.0%
Hydrocortisone hydrochloride 2.5%	(cream, lotion, and ointment)
(cream, lotion, and ointment)	Pramoxine hydrochloride 2.5%
Hydrocortisone acetate 1% (cream and ointment)	(cream, lotion, and ointment)
Hydrocortisone acetate 2.5% (cream, lotion,	
and ointment)	All medications: 1–2 applications/day

Data from the US Pharmacopeia.
The 7 classes are as follows: class 1 is most potent; class 7 least potent; classes 1–3, potent steroids; classes 4, 5, mid-strength steroids; classes 6, 7, mild steroids

2. Avoid overly potent steroids and scheduling long-term local therapies.
3. Never use the agents on thin-skinned areas of the face, neck, diaper and groin area, or axillae, which have a high absorption.
4. Restrict the application to eczematous lesions, using a hydrophil carrier base in the acute phase and an ointment base in the chronic phase.
5. Give parents practical indications on the quantity of ointment to be used, for example applying the agent in strata as thin as possible, to be massaged delicately to favor the penetration into the skin [84, 107].

Additional rules for sparing topical CSs are as follows:
1. Step-down therapy, changing from high- to low-potency CSs.
2. Preference in general for low- or moderate-potency CSs.
3. Daily rotating treatment of different skin regions (no more than 20%/day).
4. Tandem therapy (1–2 applications every morning or night, then alternating with a CS-free basic ointment), or every 1 or 2 days (interval therapy).
5. Limit systemic CSs to short-term treatments, associating topical preparations to prevent a generalized extension of AD (involving >20% of the skin).

When the child improves, use a sandwich therapy, in other words, an antiseptic solution covered by a CS and alternatively by its vehicle, or the vehicle in the morning and the drug in the evening, and then limit the applications to only one in the morning, or an alternate-day regimen [84, 107]. In children with very elevated total

Table 7.17. Therapeutic effects of topical corticosteroids

Anti-inflammatory effect
Via inhibition of:
Eicosanoid synthesis
Cell infiltrate
Via inhibition of receptor expression on:
Lymphocytes
Dendritic cells
Mast cells
Monocytes
Macrophages
Antiproliferative effect
Via inhibition of DNA synthesis on:
Lymphocytes

Stimulation of sebaceous gland secretion
(by enzyme inhibition)

Data from [84, 107].

IgE after an IV methylprednisolone bolus (20 mg/kg/day for 3 days), a prolonged improvement of skin lesions and itching was observed, along with a significant and transient reduction of CD4 compared to CD8 T cells [78]. A *short burst* of a potent topical CS, FP cream, was just as effective as prolonged use of a milder preparation for controlling mild or moderate AD in children. No differences were found between two groups of children for all outcomes. Both groups showed clinically important improvements in disease severity and quality of life compared with baseline [271]. Children aged 3 months to 6 years with moderate to severe AD (mean body surface area treated, 64%) were treated with FP cream, 0.05% bid for 3 to 4 weeks. No significant adverse cutaneous effects were noted. Thus FP appears to be safe and effective for the treatment of severe AD for up to 4 weeks *in children as young as 3 months* [77].

The new nonsedating antihistamines (doses in Table 7.19) [13] may be effective in children, some inhibiting immediate reactions, others not completely reducing IgE-mediated inflammatory lesion size [161]; however, not all interrupt the itching-scratch cycle [296]. In a DBPC study in children aged 6–12 years with positive FHA, cetirizine at a dose of 5 or 10 mg/day for 8 weeks according to their weight has been shown to be effective in controlling symptoms without apparent negative effects [140]. Cetirizine can be employed with success, as in the ETAC study in babies at risk of developing asthma by the age of 5 years as well as levocetirizine aged >6. Loratadine has provided significant daytime relief.

Cromolyn has been shown to be very active, especially in AD associated with FA; however, not all studies share our results [38]. From a scientific point of view, cromolyn has a stabilizing action on mast cell membrane, inhibiting cells in the first line in inflamed AD, namely mast cells, neutrophils, eosinophils and monocytes. In addition to this long-standing base, significant contributions show that cromolyn prevents the in vitro IL_4-induced IgE synthesis and raises the IgG production by B cells [38, 106]. Cromolyn has a neuropeptide antag-

Table 7.19. Pediatric doses of antihistamines and preventive medications

Medication	Dosage
Antihistamines	
Cetirizine	0.2 mg/kg daily[a]
Levocetirizine	1 tablet/day for children >6 years
Loratadine	0.2 mg/kg daily
Preventive medications	
Cromolyn	20–30 mg/kg/3–4 doses 20 min before meals
Ketotifen	Children aged 6 months–3 years 1/2 scoop (2.5 ml = 0.5 mg) × 2 >3 years one scoop × 2[b]

[a] For children 2–5 years old, a cetirizine formulation in drops is available, 5 mg/daily (10 drops) in a single evening administration; if the weight is not much under 20 kg, 2.5 mg/daily (5 drops) may be sufficient.

[b] Reducing after about 10 days to the single evening administration. Children aged over 3 years may also take the tablet formulation: one tablet daily (2 mg), preferably in the evening [13]. Children older than 6 years can take the levocetirizine orally.

Table 7.20. Percent fatty acids in oils from vegetable plants

Fatty acids	EPO	F	B	BC	GS
Oleic 18:1 ω9	0.6	40.4	15.8	10	16
Linoleic 18:2 ω6	72.7	10.4	39.1	48	71
γ-Linolenic 18:3 ω6	8.7	18.9	18.7	17	–
α-Linolenic 18:3 ω3	–	–	4.7	13	<1
Stearidonic 18:4 ω3	–	–	–	3	–

onist activity, determining a dose-dependent inhibition of SP- and neurokinin B-induced cutaneous edema, as well as the SP in vitro binding to various tissues in concentrations similar to those inhibiting the edema formation [62]. Cromolyn inhibits CD4, CD19 (B cells) and PBMCs expressing soluble CD23 (sCD23) in patients with AD compared to healthy controls [106]. In a cromolyn multicenter study [168], after 8 weeks, positive effects were reported in 59% of cromolyn-treated and in 36% of placebo-treated children. The association of a diet regimen with cromolyn greatly relieved symptoms in children with AD and asthma. Moreover, topical cromolyn (cream or 4% solution) reduces SPT responses and pruritus [193]. Table 7.19 reports cromolyn doses. This is a crucial issue because in a review of 18 pediatric studies that have evaluated cromolyn effectiveness in several atopic diseases, 3 out of 12 AD-related trials, too low doses were used [38]. In a double-blind, randomized, PC trial, children aged 2–12 with AD were treated with a new aqueous skin lotion of cromolyn with a significant decrease in SCORAD scores, improvement of the overall skin condition and reduced use of topical CSs after 12 weeks compared with placebo. Local mild to moderate irritation, redness and burning at the site of application occurred in 11/154 (7.1%) children and were transient. None was reported as severe or very severe. The results of this trial show that this new aqueous-based formulation of cromolyn provides useful clinical benefits in children with AD [252].

Ketotifen has been demonstrated to be active in preventing the clinical manifestations of both AD and respiratory allergy, with the added advantage of simple administration. It shares with cromolyn the mast cell-stabilizing property and has an antihistamine action. In children affected with AD, it reduces the lesion breakthrough and significantly improves the clinical picture after 2–3 months of treatment [13]. In a randomized DBPC study of babies aged 1–36 months, in placebo-treated babies asthma was reported >3-fold as high compared to the active group, thus showing it to be effective in preventing respiratory symptoms [111]. The syrup doses are indicated in Table 7.19.

The evidence that *bacterial infections of the skin* are typically caused by coagulase-positive *Staphylococcus aureus*, which prefers wet and exudative lesions (the serum is a very good culture medium) (Fig. 7.31). Avoiding their extension and worsening requires a vigorous treatment with systemic antibiotics such as both macrolides erythromycin, generally effective for most children (Fig. 7.32) and clarithromycin (15 mg/kg/day in divided doses, from 6 months on), or cephalosporins. The local treatment includes crust removal and application of wet medications on the exudative lesions. However, it is reasonable to bear in mind that broad-spectrum oral antibiotics may affect gut microflora. *Candida* and *Pityrosporum* infection may be treated with antimycotic clotrimazole for topical use and if necessary by systemic route. Severe infections by *Herpesvirus* should be treated with IV acyclovir and less severe cases with topical acyclovir. Topical treatment is with wet compresses and/or lotions with disinfectants.

Based on several *reports on EFA deficit,* the oral administration of evening primrose oil (EPO), containing 72% linoleic acid and 9% γ-linolenic acid (ω6 series), showed conflicting results, especially in children (Table 7.20) [121]. The significant clinical improvement and the concomitant normalization of EFA serum levels observed in adults with AD and serum deficit of both EFA treated with EPO were not associated with both in vitro and in vivo results [316]. A meta-analysis has revisited nine PC studies [171], claiming a particularly consistent response for pruritus, but a paper showing no improvement at all was rejected [8]. However, an essential prerequisite was not established, that is the baseline compa-

rability of treatment groups in terms of disease severity. Some researchers studying breast milk lipid composition in atopic mothers of African [317] and European children [41] with recent onset of AD have shown a reduction of long-chain EFA levels. Other studies revealed that breast milk of atopic mothers provides their infants with normal amounts of ω-6-fatty acids [241]. In Appendix 7.2, the EFA values of 676 European and African mothers are meta-analyzed [41, 134, 317]. Given the normal human milk content of EFAs, valid means and limits have been extrapolated to control the values of affected and healthy subjects. In view of this, on one hand the first could result as normal, and on the other statistical analyses in small samples could reflect physiological variations [134]. No clinical benefit of EPO has been found [15] in children with AD and asthma and in psoriasis [250], because no difference was found in the proportion of γ-linolenic and dihomo-γ-linolenic acids between atopic children and controls [141]. While larger, controlled studies are necessary to determine whether EPO therapy is truly effective, it appears more promising to underline the scientific supremacy of both colostrum and breast milk, which contain elevated levels of EFA (Table 2.14) and nucleotides (Tables 2.16, 2.17). Table 7.20 shows the percent EFA levels also in fungal, borage, black currant and grapeseed oils. The use of EPO has received unanimous opinion [95]. Even if γ-linolenic acid levels were normal in atopic subjects [141], any treatment with this acid should be in prospective plethoric, since no study has provided evidence that AA levels can be restored [141]. Appendix 7.3 shows the recommended dietary allowances of ω6 and ω3 FFA. Concern has been aroused by dietary trans-fatty acids (Chap. 21); however, in no product for children may their level be >6% of total lipid concentration.

Therapeutic advances include two calcineurin inhibitors such as tacrolimus and pimecrolimus [95]. *Tacrolimus,* a macrolide antibiotic, currently marketed as immunosuppressant for transplant rejection, which appears to be safe and effective in children with AD aged >2 years as a topical ointment. It dramatically improved the clinical appearance and degree of itching [137] in more than 10,000 patients worldwide and exhibits potent immunomodulatory properties (Table 7.21) [240]. Tacrolimus 0.03% strength is indicated for children aged >2 years and should be applied twice daily until lesions clear and then twice daily for an additional 7 days [240]. The ointment was more efficacious then 1% hydrocortisone in 624 children aged 2–15 in a randomized DB trial [209]. *Pimecrolimus* cream 1% has similar therapeutic actions. Pimecrolimus benefits were consistently seen at 6 months and sustained for 12 months, providing evidence that long-term treatment leads to better control of AD, reducing or eliminating the need for topical CSs [137].

However, following recommendations made by the FDA's Pediatric Advisory Committee during its Feb. 15, 2005 meeting, the FDA Talk Paper T05-06 March 10, 2005 declared that pimecrolimus and tacrolimus are approved for short-term and intermittent treatment of AD in patients unresponsive to, or intolerant of other treatments and are not approved for use in children <2 years. Although the long-term effect of pimecrolimus and tacrolimus on the developing immune system in infants and children is not known, the Calcineurin Inhibitor Task Force of the ACAAI and the AAAAI concludes that based on current data, the risk-benefit ratio of topical pimecrolimus and tacrolimus are equivalent or superior to most conventional therapies for the treatment of chronic relapsing AD.

Table 7.21. Immune functions elicited by oral or in vitro tacrolimus

Inhibits degranulation
Inhibits synthesis of mast cell mediators and ILs
Decreases the expression of activatory molecules such as CD25, CD40, CD80 and HLA class I and II
Inhibits LC stimulatory function
Decreases FcεRI on LCs
Decreases inflammatory dendritic epidermal cells
Inhibits SEB proliferation on PBMCs

Data from [240].

"Probiotics" is a general term for nutrition supplements containing one or more cultures of living microorganisms, which upon ingestion in certain numbers (typically lactic acid bacteria and *Bifidobacterium*), have a beneficial effect on the host by improving the endogenous microflora. Prebiotics, undigestible oligosaccharides that beneficially affect the host by selectively stimulating the growth or activity of one or a limited number of probiotic-like bacteria, normally present in the gut. Infants who experienced AD while being exclusively breast fed and receiving probiotic supplementation had significant to complete resolution of AD lesions. Intestinal colonization with bacteria is important in promoting Th1 responses and IgA production [137]. Adequate probiotic intervention after antibiotic treatment is likely to improve the intestinal ecosystem, thus preventing the emergence of Th2-shifted immunity after antibiotic treatment. *Lactobacillus* GG is used to manage AD and CMA: in 31 infants aged 2–16 months, it provided a significant improvement in their clinical score and reduced α-1 antitrypsin concentration and TNF fecal excretion [158] and in 35 infants aged a mean of 5.5 months, the SCORAD scores decreased from 19 to 5 units in the study group and from 13 to 8 units in the placebo group [132].

The improvement in AD severity with probiotic treatment in children aged 6–18 months was associated with significant increases in the capacity for Th1 IFN-γ re-

sponses and altered responses to skin and enteric flora and showed a *significant increase in IFN-γ responses* to mitogens and *Staphylococcal* SEB toxin. This effect was still evident 2 months after the supplementation was ceased. Although IL_{13} responses were significantly reduced in children receiving probiotics after 8 weeks, this effect was not sustained after ceasing supplementation [201].

Phototherapy with UVA1 rays has been shown to be very effective if applied in large doses without provoking relevant undesired effects similar to PUVA therapy administered twice weekly [243].

For recalcitrant cases of AD that seem to be unresponsive to any treatment, for desperation therapy of severe forms [65], there are toxic drugs (thymic hormones, IFN-γ, IFN-α and rIL_2), employed in adults, but side effects require their withdrawal. The rationale for using recombinant IFN-γ is the impaired capacity of patients with AD to produce IFN-γ in response to various stimuli. It can correct the immunological disorders of AD, antagonize IL_4 action, and improve NK-cell function, CD8 T cell proliferation, etc. (Chap. 1). In two subjects aged 2–22 months with severe forms, IFN-γ and IFN-α administered in sequence have led to dramatic improvement, without untoward effects other than transient myalgia, headache, or malaise [203]. In other trials with IFN-γ, the clinical benefit was not associated with a fall in serum IgE levels [93, 176, 246], nor with a reduction of IL_4 levels, although in 6 out of 8 patients with elevated IgE there was a significant down-regulation of antibody production [246]. The improvement of symptoms is associated with a reduction in CD25, and it might therefore inhibit an excessive activation of T cells [176]. Five children aged 8–13 during treatment with IFN-α showed an improvement of lesions, and a significant reduction of serum IgE, IgG_4 and eosinophils [130]. Cyclosporine A acts on an early stage of the T-cell activation process, inhibiting NFAT transcriptional activity to block TcR-mediated signal transduction. No therapeutic assay has been done in children to inhibit the isotype switching acting on CD40. Cyclosporine suspension (dose: 5 mg/kg bid) for 8 weeks was given to 3 children with severe AD, refractory to all traditional therapies. The marked clinical improvement reduced their excruciating symptoms without clinical or hematological side effects. The sIL_2R concentration decreased even after 8 weeks of treatment, regardless of IgE levels [143]. Treatment with IVIg (intravenous immunoglobulins) at high doses in children with Kawasaki disease and yearlong severe AD, at a dose of 4–6 g/daily for 5 days, induced the remission of AD lesions within 4–7 days, with a dramatic reduction in serum IgE and in vitro spontaneous IgE production [129].

A DBPC pediatric trial showed that SIT (specific immunotherapy) is effective when protracted [83]; however, the small series studied does not allow the SIT role to be fixed definitively. The potential candidates should have been tested not only in vitro but especially with SPTs positive to Der p. A DBPC trial has experimented SIT with allergen-antibody complexes in adults with AD and Der p hypersensitivity: after 1 year, 82% of patients showed an 83% mean improvement in their symptoms associated with the decrease of Der p-specific IgG antibodies [144]. Chinese herbal therapy [6] is a kind of alternative therapy discussed later (Chap. 16). *Infliximab* monotherapy may be an additional therapeutic option for the management of refractory, severe AD [95].

Specific Antiallergic Measures

Specific antiallergic measures consist in the following actions:

- Avoid food allergens, prescribe a correct diet, and avoid perioral contact with potentially irritant foods.
- Avoid environmental allergens, in particular by admission to allergen-free rooms: Der p, in addition to directly participating in AD etiology, is responsible for the exacerbation and perpetuation of skin lesions induced by different inhalant allergens. The lesional skin is thus devoid of the normal defense barriers easily colonized by Der p, always found in houses and in higher numbers between seasons [199]. From a practical standpoint it is important to see that an inevitable vicious cycle is entered since itching is aggravated by mite-sensitizing substances, with further appearance of scratching lesions and consequent infestation by other mites. Pharmacological treatment usually offers no improvement, whereas an anti-mite strategy pursued aggressively is highly effective in reducing both severity and extension of skin lesions [262]. Infants with very early signs of AD and a positive FHA are candidates for early intervention measures against respiratory allergies [14]. Therefore, if necessary, appropriate removal of mite allergens (as detailed in Chap. 24), centered on thorough cleansing of the potentially Der p-rich bedroom [67, 262] is carried out, also as a preventive measure for the high number of children affected from AD in the first few years of life (44.2%–53.2%) (Table 5.8), who experience thereafter the onset of respiratory allergy caused in 65% of cases by sensitization to Der p [198].

Additional Measures to Be Suggested to Parents

An indirect demonstration is the observation of impressive skin improvements noted when children are admitted to hospital where Der p has an unfavorable habitat and so a lesser survival expectation, reducing its concentration to dust levels lower than 2 μg/g [67].

- In children with widespread cutaneous manifestations and recalcitrant to therapy, the so-called mini-hospitalization [181], or organizing a dust-free climate chamber [233] to calm the skin, should be considered.

Both can be helpful to remove children from an irritant-rich environment and to re-establish control of severe AD [36].

- In summer, let children spend long holidays at the seaside; a cautious exposure to UV rays can be resolvent in children recalcitrant to common treatment [182]. It is known that following exposure to sunlight and to UV rays, flare responses are reduced in July compared with November [278], thus allowing a long period of relief to both children and their parents. In particular, Turner et al [280] have demonstrated that *the more southern the holiday destination the more the child's condition improves. Why then are sunny beaches not actively advertised for this benefit?* In confirmation of this hypothesis, in children who significantly improved on an elimination diet, but still retained skin lesions despite the strict avoidance regimen and the topical treatment, we have evaluated every 3 months in the 1st week of the month the severity score of AD and peripheral blood eosinophils. We have seen that the AD severity score, pruritus and eosinophils per cubic millimeter were significantly decreased in the month of September compared to the start in January (p=0.0001–0.0005). Heliotherapy is known to selectively deplete epidermal LCs in AD lesions [182], an effect attributable to IL_{10} [155], combined with a CD4 T-cell numerical decrease and a CD8 T-cell quantitative and functional increase [278]. Basically, most of the UV radiation is reflected by dry, light drift sand, more than three-fold higher than the reflection from the seawater. Sunscreens should be used to avoid sunburn [252]. However, sunscreens can be irritants, and care should be used to identifiy an nonirritating sunscreen (Chap. 8).
- Avoid excessive sweating, favoring soft, cotton clothing, eliminating coarse, thick fabrics, also taking into account the season, climate and weather. Moreover, avoid sports leading to excessive transpiration.
- Avoid extreme T changes, such as prolonged exposure to the sun's rays, then extreme cold, then heat, etc.; moving rapidly from one environment to another should also be avoided, as large changes in ambient T, above all from cold to hot, and changes in humidity, are associated with deterioration of the skin condition. In addition, skin dryness reduces the barrier function to toxic agents, with a notable risk of lesions after exposure to water and irritant substances.
- According to experts, and taking into account the concurrent role of emotional factors, the causes of stress that create a closed circle should be removed. Owing to their particular and transient psychological structure, children are inclined to be more susceptible to common stress-related problems and their effects. This causes skin exacerbations, often linked to upsets in the mother-child relationship [80]. Parents full of love and understanding should find a routine to be near their child in those frequent critical moments. Parental attempts to stop scratching by physical restraints will surely make scratching longer and more concealed.
- Parents should be advised to distract their children with manual tasks if possible, varying age-related toys such as building blocks, meccano toys, drawing and painting with pencils, pastels (not felt pens), wooden, rubber, and metallic toys, computer games, etc., or with a structured, concrete task. During a structured task, children concerned with task involvement scratch significantly less. During unstructured tasks, children left to their own resources are engaged in significantly more scratching [80]. If the child likes to play with modeling clay and the like and has or had hand lesions, it is imperative that potentially sensitizing substances are not touched; pure cotton gloves can be worn, but only for the shortest time, paying attention to the development of rubber or latex allergy. Reinforcing the child's involvement in appropriate activities means that scratching will be less and of lower duration;
- In children who have severe symptoms and uncontrollable scratching, despite repeated interventions and advice by pediatricians, referral for psychological counseling may be welcomed.
- Growth-related problems are in proportion to asthma development. Height should be more or less normal, depending on the extension of lesion involvement [94]; however, growth retardation is unlikely to be found in allergic children with AD.

Antiasthmatic Measures

Because children with AD often develop asthma, we refer to the measures explored in Chap. 24, stressing the necessity of unquestionably keeping both pets and cigarette smoke outdoors, especially since maternal smoke heralds asthma [175], and reducing HDMs in the environment [11], as suggested in Figs. 4.15, 4.23 and 7.17.

Relationships Between AD and FA

Ninety years ago, it was observed that the elimination of suspect foods from the diet resulted in AD improvement [239]. Subsequently it was demonstrated that various food antigens cross the gastrointestinal barrier and come across skin mast cells within minutes and up to 2 h after ingestion [31]. More recent evidence indicates that IgE-mediated sensitization to food antigens plays a significant role in the pathogenesis of AD and that sIgE to foods are active in 43%–72% of subjects [36, 40, 224, 227]. Data supporting of the relationships between FA and AD are as follows:

- SPT and sIgE positivity to foods.
- Some foods are able to trigger immediate symptoms, including skin reactions, FA expression, generalized urticaria, contact urticaria, gastrointestinal symptoms such as vomiting, diarrhea, colitis, etc.
- Improvement of symptoms after appropriate restriction diets [40].

As regards SPT and sIgE positivity, it is certainly illustrative and relevant that children with AD have a very high prevalence of in vivo and in vitro test positivity compared to children with asthma and/or AR. This clearly favors a specific role of food allergens in AD. However, although food allergens are an expression of FA according to von Pirquet, they cannot yield a definitive proof of FA responsibility in such a disease.

Epidemiology

In children aged <2, the implicated foods are, in order, egg, CM and legumes; in those aged 2–10, they are egg, nuts, CM, legumes, cereals and fruits [200]. In the ETAC study, 32% of children are sensitized to CM (Fig. 5.16) and 45% to egg (Fig. 5.17).
In a group of 89 allergic children aged 7–13, seen by us, 21 (24.7%) had FA.

Pathophysiology

It is widely known that the younger the child, the more enhanced is intestinal permeability in those with AD and FA: as an immediate consequence of food allergen ingestion these proteins are allowed to transfer easily into the blood. The liver is considered a physiological filter and eliminates exogenous allergens; however, it is possible that this role is reduced in infants whose hepatic system, reticuloendothelial system and hepatocytes are immature. Exposure to food allergens, while the immune system and the gastrointestinal tract are still immature, may deleteriously influence the liver. In AD infants aged <6–18 months, when breath tests were used with methacetin – more sensitive than conventional liver function tests – significant hepatic alterations were found. The result was an improvement in both liver function and clinical symptoms, but not in skin lesions [110].

Pathogenesis

Experimental Studies

Several studies have investigated the correlations between AD and FA. As early as 1928, it was demonstrated that ingested antigen, although in small amounts, quickly cross the intestinal mucosa and are disseminated to skin mast cells through blood circulation [31]. Three years later is was shown that crossing the mucosa induced mast cell degranulation at the skin level [301]. Subsequently, convincing evidence for a pathogenic role of FA in AD was shown in infants and children [71], who, 24 h after having been passively sensitized to either fish or egg, ingested both foods and developed a skin reaction at the sensitized site [313]. A child with AD and wheat allergy was hospitalized and subjected to a restriction diet until his skin symptoms cleared and prior to instituting a food challenge test (FCT) with wheat, also to a half-body occlusive dressing: the child showed intense pruritus, but eczematous lesions flared only on the part of his body that was exposed and highly traumatized by scratching [71]. The association between AD and FA was thus proved after having been disputed for nearly a century [239], but the introduction of solid foods anticipates this combined association (Table 4.30), whose predictive value at 12 months is known to foster asthma development [139]. The RR of an infant with AD having IgE-mediated FA is 5.9 for the most severely affected group. As AD severity increased so did the prevalence of IgE-mediated FA, and the frequency of reported adverse FA reactions.

As originally demonstrated by Engman et al [71], the severe pruritus, secondary scratching, and subsequent development of eczematous skin lesions was speculated to be the result of food antigen reacting with IgE-bearing cutaneous mast cell and leading to mediator release, including histamine. This reasoning agrees with results of a classic study on histamine release after FCTs [229]. Only children with AD and hypersensitivity to various foods experiencing positive DBPCCT developed a significant rise in plasma histamine level compared to children having a negative challenge (Fig. 7.35) [229]. Although histamine was the only mediator they tested, it is possible that additional mediators released by mast cells are involved. However, since histamine is rapidly cleared in the portal and renal circulation, only a fraction of histamine released by gut-associated mast-cells will reach peripheral sites. It is therefore likely that the histamine thus released in a sensitized patient may facilitate the entry of larger amounts of antigen by inducing local anaphylaxis. These antigens reach cutaneous mast cells very rapidly, thus inducing a further peripheral mediator release and perpetuating the peripheral cascade of mediators. It has also been postulated that mediators released by intestinal mast cells may induce cutaneous and respiratory symptoms; however, histamine was assayed in plasma draining cutaneous areas [229]. A study on the role played by T lymphocytes, sIgE and the results of elimination diets has elucidated some pathogenic aspects [135].

A 1936 report documented that FA was a contributing factor in AD. It was shown that CM feeding predisposed to the development of AD, but exclusively breast-fed babies had seven-fold more chances of escaping eczema compared to CM-fed babies [87]. In 1953 [81], it was clearly shown that children with FHA had a 75% less likelihood of developing AD and asthma than CM-fed children if in the first 6 months of life they had been fed soy and also excluded beef and egg from their diet. A subsequent DB crossover study demonstrated a marked improvement of AD in 21 2- to 8-year-old children receiving a CM- and egg-free diet. It was noted that 14 of 20 patients responded more favorably to the antigen-

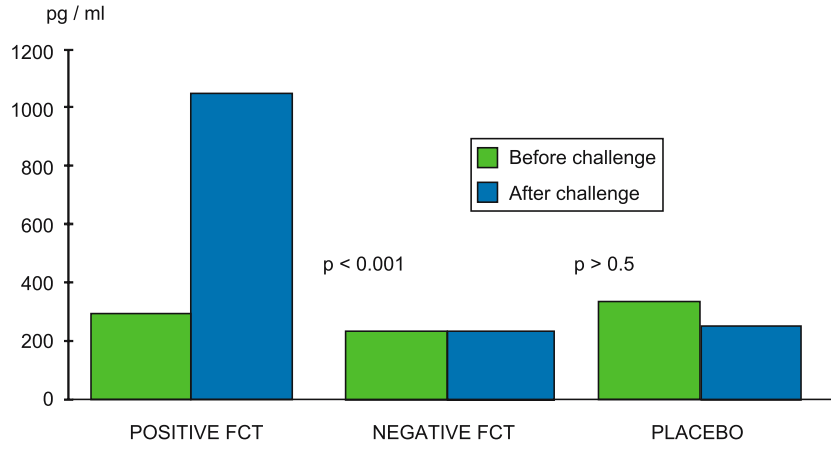

Fig. 7.35. Histamine plasma levels before and after food challenge tests (*FTCs*) in 33 children with atopic dermatitis, with a mean increase from 296±80 to 1,055±356 pg/ml (p<0.001) in children with immediate reaction to FCTs, but not in those with negative FCTs. (Data from [232])

avoidance diet employing a soy formula as a CM substitute, whereas only one had a more favorable response to a non-CM and egg-free diet [7], thus demonstrating with a rigorous method the involvement of CM and egg in the AD pathogenesis.

Clinical Studies

Sampson and his collaborators have dedicated a great deal of scientific commitment to clarifying the role of FA in AD [223–232], and trials by our division have demonstrated a clear correlation between eating certain foods and developing and worsening skin symptoms, thus concluding that the foods more frequently implicated in severe AD are, in order of frequency, CM, egg, wheat and fish [40, 48]. The younger the child, the greater the role played by FA [200]. Characteristically, in two children with eczematous reactions following a positive DBPCCT, the MBP deposition in skin lesions was ascertained [224], thus confirming the role of foods in AD.

Analyzing the data discussed in Chap. 5, we evaluate the most significant results in this area of atopy:

- Sampson reported that over several years 400 children were evaluated by 1,303 DBPCCTs, 447 of which (34%) were positive, 62% for at least one food [223]. Cutaneous reactions developed in 75% of positive challenges, with a clear correlation between food ingestion and development of symptoms in 56% of cases [230]: foods were implicated in 90% of positive reactions in children with AD [227].
- About 40% of 40 children given appropriate elimination diets and re-evaluated after 1–2 years showed food tolerance and improvement of their clinical course [230]; CM was responsible for 81% and egg for 76% of positive DBPCCTs (similar to our values), and fish was included among the 33% of other foods. The 80% of positivity for peanuts and an uncommon 67% for wheat should be noted. The total of DBPCCT negative results was 30.57% [231], in our cases (single blind), the rate was 36.2%;
- Burks et al reported that 75% of 46 children (mean age, 5.7 years) had positive DBPCCT for three foods: CM, egg and peanuts. Moreover, fish and wheat were positive in 8.3% of cases, chicken and soy in 4.2%; the DBPCCT was negative for beef, pork, cereals and chocolate [33]. In conclusion, FA is an important trigger factor in the AD development in one-fourth of children. In a later study in 71 children (mean age, 4.1 years), the incidence related to three foods increased to 81%, with overlapping results as regards wheat (8%), fish (5%) and chicken and soy (3%) [34].
- The role played by foods in the flare-ups of AD associated with FA was studied in 91 children (median age, 4.5 years) in whom after a food elimination diet and a randomized DBPCCT, both AD and associated symptoms became significantly worse on CM and tomato challenge compared to controls, but not on egg challenge. The appropriate diagnosis and exclusion of CM, egg and other foods elicits a positive reaction by DBPCCT, which results in a statistically significant reduction in the symptom score to ≤3 in 74% of children and clinically, a reduction in erythema, lichenification and extension of involved skin [248].
- Only 54 of 96 children (41/54 with FA) completed the diagnostic protocol (elimination diet and FCT): CM and egg were the most offending foods (Fig. 7.36) [12]. The pathogenic significance of these foods has been confirmed by FCT results in 88 children with AD and followed by us for 8 years: only 25 children (28%) tolerated the offending food(s) (p=0.003). Moreover, *24/27 children (89%) showed an association of CMA and AD* (p=0.0000) [47], corresponding to the 93% reported in children aged <2 years with severe AD [88].

Polysensitizations in children with AD associated with FA were found to be SPT- and RAST-positive to different foods that only rarely were clinically prominent [12, 39]. Instead by FCT the rate was of 26.8% [12] or 29% (CM, egg and wheat) [39]; by DBPCCT, 89% of 113 children reacted to one or two foods, 9.5% to three and one child to four [230]. Children given restricted diets often eliminating three foods (CM, egg, wheat) may experience significant improvement in their clinical

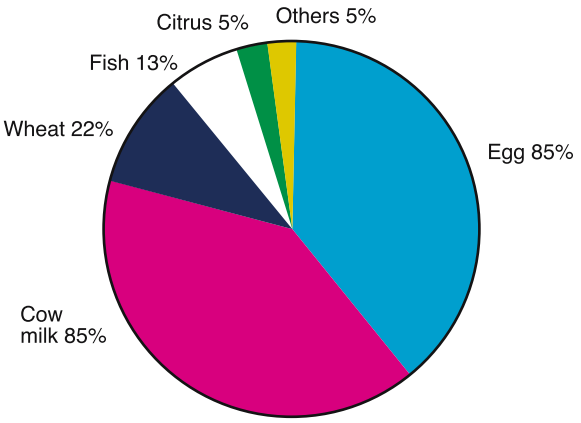

Fig. 7.36. Foods that provoked positivity of FCTs in 41 of 54 children with atopic dermatitis. (Data from [12])

course, and an appropriate environmental control contributes to the avoidance of future flare-ups.

Clinical Presentation

A frequent challenge in these children are the IgE-mediated immediate lesions: symptoms prevalent on the face, such as urticaria-angioedema and above all contact urticaria, characterized by the development of erythema and/or wheals within a few minutes, where the direct contact with food is materialized. The appearance of typically eczematous lesions, usually perioral lesions, of short duration (a few minutes), evident immediately after eating, makes us nearly certain that contact urticaria is the primary diagnosis and CM, egg, fish, fruits, vegetables, and nuts are responsible [88], aggravating AD in 85% of cases [189]. An additional characteristic symptom is acute urticaria originating in seats distant from those where the contact with antigens ensued [230], although the most frequent distant skin reactions occurring within 2 h of ingesting the offending food is an extensive erythematous or morbilliform rash and pruritus [33, 230]. The immune mechanism underlying such reactions, as discussed in "Pathogenesis," is the classic IgE-mediated reaction type I (the type IV triggered by T cells promotes worsening of lesions and/or gastrointestinal symptoms); otherwise the mechanism is pseudoallergic. The probable underestimating of contact urticaria is generally one of the main causes of the poor credit accorded by pediatricians to food-induced reactions in AD [88]. As recently reported, it is significant that some children complain of LPRs (8–12 h) heralded by pruritus and worsening of their lesions; in certain cases there is a continuous progression from one phase to the other, thus allowing a parallel with the biphasic reaction seen in asthma [49]. We propose the data shown in Table 7.22 [45, 263], which demonstrates the triggering of clinical forms in different ways, also by

Table 7.22. Small quantities of offending allergens may be heedlessly or inadvertently ingested by, or may reach food-allergic children by different routes

Negligible quantities of offending food(s) may contaminate other foods:
Because of inadequate cleaning of kitchen utensils, pots, etc.
Because of clumsy attempts to separate or eliminate an offending food from the others
Because of direct or indirect contact between two foods, such as when one uses the same pots or trays to serve different courses that may inadvertently reach the sensitive child:
Touching or licking kitchen utensils, bottles, tableware, glasses, cups, etc. with residues of the offending food
Inhaling the fumes during cooking or baking of offending food
Being unknowingly in the vicinity of or during servings of offending foods in restaurants, at parties, etc.
Being in the vicinity of a person eating the incriminated food
Inhaling food allergens from carpeted and smooth floors
Opening wrappings or cans containing the food or inadvertently touching it
Kissing, or being kissed/caressed by persons who have consumed/touched the food
Failure to eliminate specific components of the offending food:
Lactose can be contaminated with CM proteins
Lecithin can be contaminated with egg or soy proteins
Starch can be contaminated with wheat, corn, tapioca proteins
Gluten-free products may contain other wheat proteins
Unlabeled inclusion of the offending food as ingredient:
Errors in processing and preparations
Unlabeled and/or unspecified restaurant foods
Unknown source of food ingredients: lecithin (egg or soy-bean) starch (wheat, corn, tapioca, potatoes, etc.)
Deliberate/accidental feeding
Hidden bottle at maternity ward
"Grandmother effect" such as egg feeding in dieting babies
Cross-reactivity among closely related foods:
Cow, sheep and goat milk
Chicken, turkey, duck and goose eggs
Protein hydrolysates and CM proteins

Data from [45, 263].

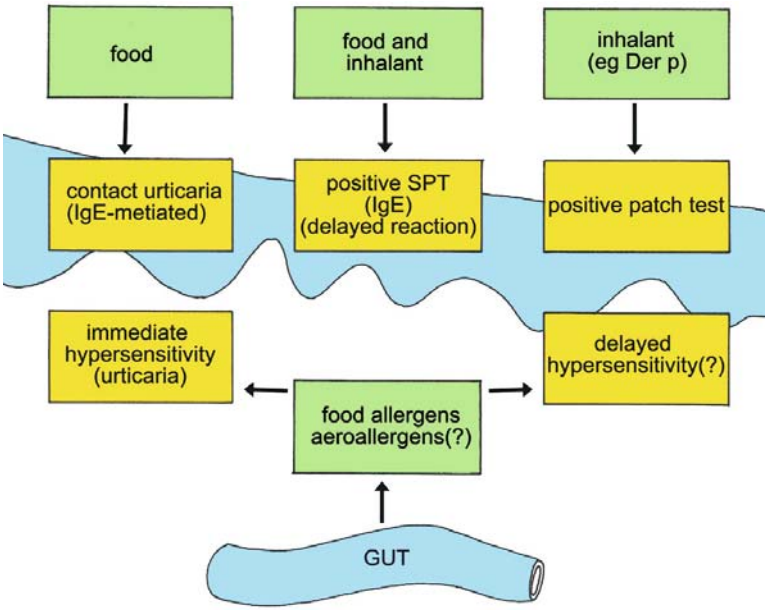

Fig. 7.37. Possible correlation between skin and immediate and delayed hypersensitivity for inhalant and food allergens

skin contact, especially of peanuts [45, 263] and by CM inhalation (Chap. 20).

Possible correlations between immediate and delayed hypersensitivity to inhalants and foods expressed on the skin are outlined in Fig.7.37.

Diagnosis

Diagnosis is based on a careful personal and/or family history. DBPCFCs are the rule, but open FCTs (OFCs) are necessary in small children. As regards SPT and RAST reliability in AD associated with FA, the conclusion is:

- Compared to SPTs, RAST sensitivity is lower and specificity is greater, therefore neither method can be utilized separately at the clinical level. In addition, the RAST NPV lower than that of SPTs is less useful for the diagnostic process [40] (Table 6.21).
- Comparing SPTs and PTs in children aged 2–36 months, 67% positivity was found in immediate reactions to FCTs, 89% was found in late reactions. RAST was positive in 55% of positive FCTs and in 25% of negative FCTs [118]; in children, there may be a dissociation between the SPTs and PTs for inhalant allergens; thus combined SPTs and PTs enhances identification of FA, since the PT is less invasive in infants, even if it contradicts other results [118].
- Because of SPT and/or RAST NPV, they may be used to exclude a priori the onset of immediate reactions to the FCT. Sampson [224] maintained that SPT negativity has a NPV >95; however, his group has acknowledged that in patients with SPT negative to foods it is necessary to reinforce the diagnosis with positive results [212], as we have demonstrated (Chap. 6).
- In 91 children, the clinical outcome of the restricted diet could not be predicted by personal and/or family

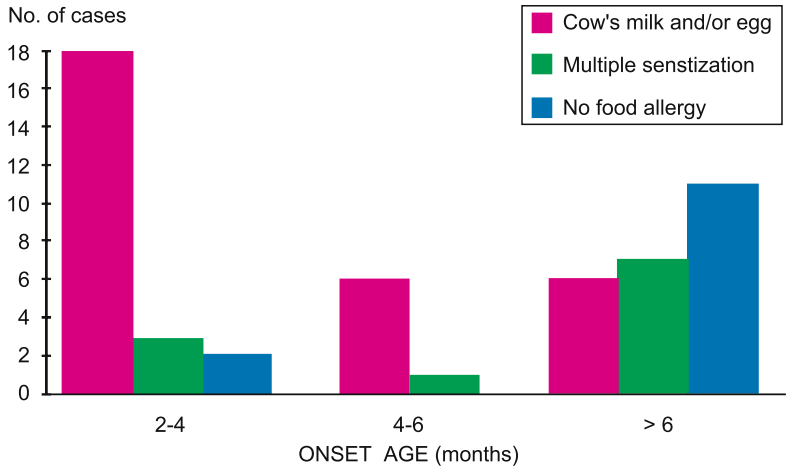

Fig. 7.38. Onset age of atopic dermatitis in 54 children according to the sensitizing food. (Data from [12])

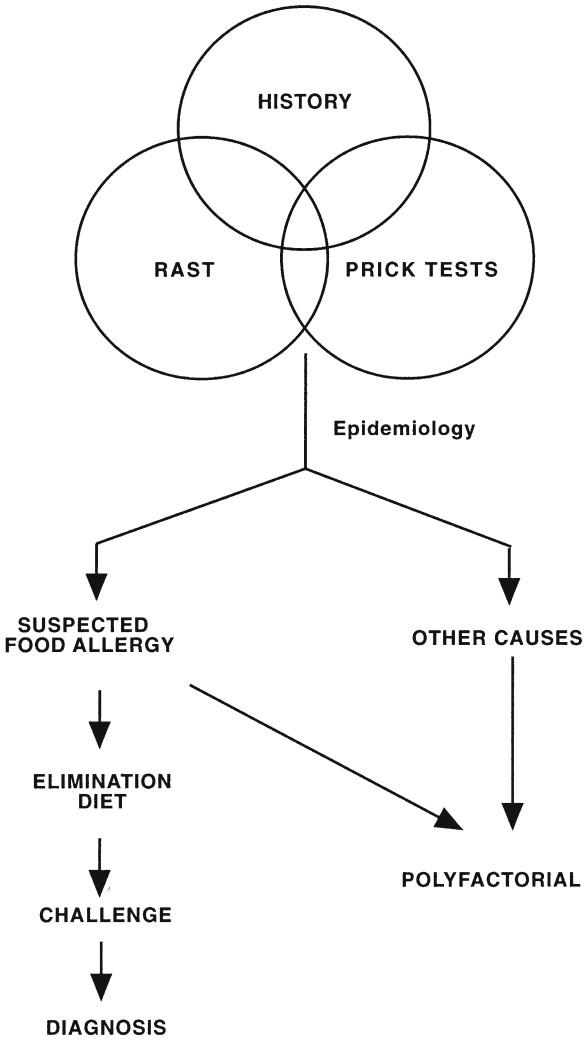

Fig. 7.39. Algorithm for a diagnostic titer to be followed in AD with suspected FA

history, initial SPT results, or total and food-specific IgE. Results of FCTs could not be predicted by initial serum immunoglobulin levels, and no initial level was helpful in planning food diets in those children [249].

To select the food allergens to be tested, it is practical that they be based on history, epidemiological criteria, child age and the diet followed [12, 230], avoiding the foods eliciting positive reactions in 90% of these children [36, 40, 224, 230]. Figure 7.38 [12] shows that if AD onset occurs in the 1st month following birth, CM and egg are usually responsible. If, however, AD onset occurs after this time, it is probable that additional foods were introduced into the infant's diet (wheat, cereals, legumes, fruits, etc.). According to our studies [12, 37], it is easier to identify the offending food when it is consumed sporadically, such as fish, whereas identification proves problematic when the food is a diet cornerstone. Chocolate has been acquitted [33]. Figure 7.39 exemplifies the diagnostic titer to be followed.

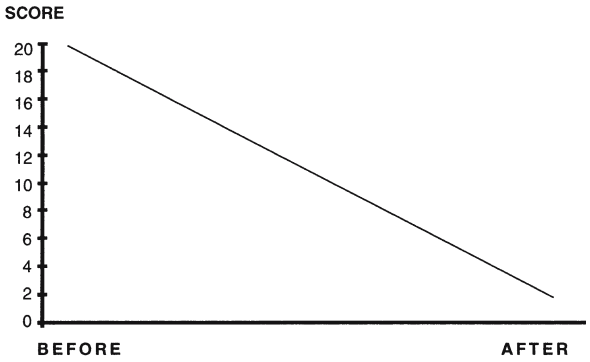

Fig. 7.40. The impact of a 4-week elimination diet on the clinical scores of children with AD. p=0.0001

With older children and adolescents additional foods enter the diet [51]; beyond the infant age, history is often unreliable, especially in predicting immediate reaction, hence the recourse to FCT is frequent. Since the typical reaction of AD is delayed (type IV), the worsening of lesions occurs even after 72 h (often later), thus complicating the individuation of the cause-effect ratio (Chap. 9). A diagnostic elimination diet should be tried if FA is suspected after obtaining a reliable history, medical examination, and SPTs.

Treatment

A standard therapeutic elimination diet eliminating tomato, citrus fruit, and coloring and preserving additives is effective in 80% of children with the assistance of a dietitian [248]. This type of diet should be prescribed to all children with AD to a moderate or severe degree, because of its positive effects [37] (see Chap. 9, including drug therapy). Table 7.22 shows that tiny shares of offending allergens may be negligibly or inadvertently ingested by or may reach FA children by different routes. However, arguments put forward that criticize diet treatment should be reappraised in light of the results of HRF studies [225, 232]. Patients placed on appropriate diets for at least 6–9 months experienced a fall in HRF spontaneous generation, leading to normal SBHR levels and eosinophil density and good clearing of their AD. There is a correlation with the results demonstrated by Fig.7.40 with a very significant statistical reduction in the clinical score in children with AD after 4 weeks of a diet eliminating both CM and egg.

Course and Prognosis

The course of AD is capricious and marked by exacerbations and remissions, which are often unexplained. Figures in the literature for the persistence of AD

Table 7.23. Outcome of atopic dermatitis (AD) associated with food allergy (FA) in 56 children (follow-up 5 years)

Outcome of AD	No. of cases	%	Median age at the last follow-up
Remission	32	57	6 years + 7 months (4–14 years)
Median age 4 years (2–13 years)			
Persistence	24	43	6 years + 9 months (4.7–13 years)
Development of respiratory allergy	27	54	4 years (1–10 years)

Remission vs persistence, p=0.02.

Table 7.24. Outcome of FA associated with AD in 56 children (follow-up 5 years)

Tolerance to the offending foods	No. of cases	%	Median age
To all foods	25	60	
To one or more	6	14	
To none	11	26	
To cow's milk			3.5 years
To egg			4 years
To wheat			4.5 years

Data from [39].
Tolerance vs persistence, p=0.0001.

vary widely. Several babies improve between 18 and 24 months of age, but when AD onset is after 24 months, the overall clearance rate is 50% at ≈10 years; several investigators have shown that children followed up from infancy for 10–22 years have associated respiratory allergy. In the 115 children, 62 (53.9%) developed respiratory allergy [48]. Table 5.8 shows a mean remission rate in one-third of cases, with development of asthma in 48.7% and of AR in 53% of cases: this is the substantial motive by which the ETAC program has been started for the early treatment of atopic children to prevent the onset of respiratory allergy. We complete the data outlined in the Table 5.8:

- Sampson and Scanlon followed up 75 children with AD and FA aged 3–18 years, and 25% of them acquired food tolerance after 1 year of elimination diet and 9% after 2 years. After 3 years of elimination diet, *no other child* was food-tolerant [231].
- In Tables 7.23 and 7.24, we detail the unlucky outcome of 56 children [39]. Subsequently we found that (Table 7.25) [48] 43% of 115 children had not lost their food hypersensitivity at the age of 14, and 37.4% suffered from multiple sensitizations developed in 98% of them within the 4th year; 55% of intolerant children had CMA, 31% egg allergy and 12% wheat allergy [48].
- Guillet et Guillet reported [88] an association persisting in 73% of children aged 2–7 and in 67% of those aged 7–16 also suffering from respiratory allergy in 27% and 33% of cases, respectively.
- Only in 11% of 82 children with early-onset AD was a clearance rate found at 5 years from onset. In the same time span the children developed sensitization to inhalant allergens with a peak increase at age 3 years, and asthma onset in 27% of cases within the 1st year was reported [9].
- In the 88 children, 30 were also tolerant and developed asthma, 10/15 children with CMA and 4/15 children with egg allergy (Fisher = 0.032).
- In the 1,314 children of the MAS study [111] the severity of the clinical manifestations (OR 5.86) and atopic sensitization (OR 2.76) were major determinant of prognosis.

In conclusion, we can affirm that FA could be considered as an unfavorable prognostic factor of AD, being the marker of an atopic predisposition. The data hitherto examined highlight the priority of recommending to the parents of neonates at risk of atopy that breast-feeding be continued up to the 6th month, with a gradual weaning and no early introduction of cereals, to prevent

Table 7.25. Atopic dermatitis and outcome in 115 children (follow-up 14 years)

Outcome	Atopic dermatitis		
	Yes	No	(%)
Cured	38 (68.3%)	52 (96.3%)	78.3
Improved	18 (30%)	2 (3.7%)	17.4
Unchanged	4 (6.7%)	–	3.5

Data from [48].
p=0.0001.

and/or delay the development of atopic disease [40]. In France, the management in schools of children with FA is clearly inadequate and we do not know in how many other nations.

New avenues. Omalizumab (anti-IgE) treatment induces the decrease of FceRI expression in skin mast cells which is slow and associated with decreased actue allergen wheal size.

Pediatricians and AD

Pediatricians should pay special attention to the confidence and cooperation of parents and the information given to them, especially on AD causes and natural history, and the target and limits of treatment. They should explain that since AD is a hereditary condition, no perfect treatment exists, and that the goal is to achieve the best possible control of the clinical manifestations, while awaiting spontaneous remission. Parents concerned with the future of an atopic child are helped to reflect above all on positive events: consequently pediatricians should balance negative statements clearly stating that the prognosis is favorable, stressing the good general health, the psychophysical and intellectual development of their child, analogous to that of friends, the absence of permanent disfigurements, etc. Pediatricians will discern the prerequisites for therapeutic success. Parents need help, understanding, encouragement, and safety, and one should listen carefully to their complaints and enable them to put questions or express concerns without hesitation, especially when the disease appears to be severe: the number and duration of the meetings will depend on the disease condition, response to treatment, degree of anxiety, reliance on planned therapy and serenity stemming from the pediatrician's advice. The establishment of compliance and proper communication between the pediatrician and parents or older children may be the steps that move the field further, the crucial point for achieving lasting success in the treatment of children suffering from AD. Older children and adolescents with AD experience frustration, sadness, and anxiety, which very often exacerbate their disease and increase itching. These children may be ostracized and ridiculed, which can be addressed by a supportive home environment from parents and siblings [137]. Finally, better understanding of the immunological and inflammatory aspects of AD should also provide new targets for therapeutic, dietary and pharmacological treatment.

Other Allergic Skin Disorders

A Skin Panorama

In this chapter we discuss allergic skin disorders other than atopic dermatitis (AD): the urticaria-angioedema syndrome, allergic contact dermatitis (ACD), protein contact dermatitis (PCD), phytodermatitis, allergic photodermatitis and allergic vasculitis.

Urticaria-Angioedema Syndrome

Urticaria and angioedema comprise a unique syndrome, with the two frequently associated. Angioedema may be isolated: when associated with urticaria it is commonly underdiagnosed. Such disorders are well known to pediatricians and allergists and often are a manifestation of type I IgE-mediated reaction.

Fig. 8.1. Urticaria (for details see text)

Definitions

Urticaria (Fig. 8.1) is a cutaneous vascular reaction characterized by transient localized areas of edema (lasting from 2–3 min to <24 h) on hairless or hairy skin. Wheals, lesions that affect the superficial dermis, are circumscribed and slightly prominent, surrounded by a variable rings of erythema (flare) with a flat surface or a raised border. Hives have a variable form and size and are accompanied by more or less intense itching. *Angioedema* (Figs. 5.12 and 8.2) is a "urticaria involving the deep dermis and subcutaneous tissues," with deeper and less localized edematous swelling, which affects both skin and mucosal sites, preferring areas of loose connective tissue such as the face, eyelids, tongue, lips, extremities and genitalia, but may occur anywhere. These lesions are typically painful, rather than pruritic. Superficial mast cell degranulation induces wheal manifestations, whereas that of deeper mast cells induces extended vascular edema [117].

Urticaria can be divided into four main types based on a chronological outcome of clinical manifestations:

Acute urticaria (recurring <6 weeks), certainly the more frequent urticaria in pediatric populations

Chronic urticaria (recurring more times for a total of 6 weeks)

Fig. 8.2. Angioedema in a child sensitive to Fel d 1 after having stroked a cat during a visit to the house of a cat-loving friend

Recurrent chronic urticaria with sporadic manifestations recurring 2–3 times/year

Idiopathic urticaria, usually chronic: most cases are thus considered since no precipitating cause can be identified after having excluded all potential causes of urticaria (70%–80% of cases) [18, 37]

Prevalence

Pediatric urticaria is credited with a 2%–5% prevalence [60], with a total value of 3.9% (Figs. 5.5, 5.9) or at 0.5–1 year (Table 5.5). Isolated angioedema is present in up to 9.6% of allergic children [60]. Higher incidences are found in cohort studies. Urticaria was seen in 28 (49%) and angioedema in 34 children aged 1–3 years (60%) [144]. Urticaria was associated with angioedema in 38.6% of children [29]. Urticaria manifested mostly in male children (59.8%), mainly of preschool and school age rather than the under-1-year age group [13]. Acute urticaria may have an even higher prevalence (91.7%) [13] than that seen in AD: probably its frequency is underestimated since often, above all when caused by foods, a specialist is not consulted, the parents or the patients having recognized the evident cause-effect correlation (Chap. 7).

Classification

Table 8.1 [37, 42, 45, 117] shows the division into hereditary and acquired types, further subdivided into types that are apparently primary and secondary to other disorders.

Etiopathogenesis

Genetic Factors

A genetic influence was demonstrated in 56 children with urticaria-angioedema subjected to challenge with additives: the 25 children with positive challenge showed a positivity, with statistically significant differences, of family (64.2%) and personal history (80%) and elevated IgE levels (40%) [59]. A 67% rate of food urticaria occurred in atopic children [67, 90]. Children are more likely than controls to have a personal or family history (FH) of atopy (FHA) [169]. As a consequence, children affected by IgE-mediated atopic disease are more at risk of urticarial manifestations compared to the general population; likewise dermographism and aquagenic urticaria are significantly more frequent in atopic children than in nonatopic children [60]. Recently, Muckle-Wells syndrome and familial cold urticaria, two rare autosomal dominant disorders, both localized on chromosomal region *1q44* [50] have been found to be associated with mutations, all located in exon 3 of the *CIAS1* gene [62].

Pathogenic Mechanisms

Several pathogenic mechanisms are operative in urticaria, either immunological or nonimmunological (Table 8.1), which may be involved in acquired types of this syndrome.

The urticaria-angioedema caused by an immunological pathogenesis include [44]:

- IgE-mediated urticaria:
  - Foods, inhalants, insect bites, etc.
- Exercise-induced anaphylaxis (EIA)
- Physical urticaria (by external stimuli: cold, sun rays, pressure, vibrations, etc.)
- Non-IgE-mediated urticaria
- Complement and circulating immune complexes (CIC)-mediated urticaria
  - Cutaneous vasculitis
- Serum sickness
- Infections

Urticaria caused by a nonimmunological pathogenesis includes:

- Non-IgE-mediated mast cell activation
- Anaphylactoid reactions
- Chronic/idiopathic urticaria

Immunological Mechanisms

Several pathogenetic mechanisms may involve types I–III immune reactions [45, 175].

Type I mechanism is fulfilled once specific IgE is bound to basophils or skin mast cells. Contact with allergens leads to consequent degranulation, mediator release and development of typical skin and mucosal lesions. This IgE-mediated mechanism is operative on reactions to foods such as cow's milk (CM), egg, fish, wheat, parasites (helminths), some protozoa, insect venom, pollens, pet dander [53, 103], β-lactamine metabolites, insulin, enzymes, sera [227] and latex [112]. T-cell expression of cutaneous lymphocyte antigen (CLA), a unique skin-homing receptor, was selectively up-regulated in patients with CM-induced urticaria and may play an important role in the pathogenesis of this disease [28].

Type II mechanism involves complement-fixing IgG or IgM antibodies, complement activates C3a, C4a, and C5a components capable of directly activating mast cell degranulation. Known examples are the hemolytic reactions after blood transfusions (due to incompatible groups) and immunoglobulins (mainly IgA) and sulfamide administration [227]. This mechanism has been found in physical urticaria such as cold-induced, cholinergic and dermographic types [53].

Table 8.1. Urticaria-angioedema syndrome: pathogenic classification and classification of acquired forms

A. Pathogenic classification

1. Immune-mediated urticaria
   - FcεRI cross-linkage
     - Allergens
     - Autoantibodies
     - Anti-IgE
     - Anti-FcεRI
     - Polyvalent lectins
   - Anaphylotoxins

Most common etiological agents causing IgE-mediated reactions
- Foods
  - Beans
  - Celery
  - Cow's milk and dairy products
  - Fish (cod)
  - Nuts
  - Parsley
  - Seafood
  - Spices
  - Tomato
- Inhalant allergens
  - Animal danders
  - Molds
  - Pollens
- Physical stimuli
  - Cold
  - Exercise
  - Heat
  - Pressure
  - Sunlight, etc.
- Insect venom

More common etiological agents causing immune complex-mediated reactions
- Virus
  - Coxsackie virus
  - Cytomegalovirus
  - Hepatitis virus
  - Infectious mononucleosis
  - Psittacosis virus
- Bacteria
  - *Mycobacterium*
  - *Staphylococcus*
  - *Streptococcus*
- Molds
  - *Candida albicans*
  - *Trichophyton*
- Antigens deriving from neoplastic cells
- Cryoglobulins
- Nuclear antigens
  - LES or other autoimmune diseases

2. Nonimmunological mediated urticaria

Substances with histamine-releasing activity
- Drugs
  - ASA
  - NSAIDs
  - Penicillin
  - Pyrazolone
  - Radiocontrast materials
  - Sulfonamides, etc.
- Proteolytic enzymes
  - Trypsin
  - Papain, etc.
- Substances on the cell surface
  - Biliary salts
  - Dehydrocholic acid
  - Tween 20
- Compounds with high MW
  - Dextran
  - Egg-white
  - Polyvinylpyrrolidone
- Agents causing mast cell histamine release (see Chap. 10)
- Chemically defined substances contained in foods
  - Tyramine, etc.
- Chemically undefined substances contained in foods
  - *Complement activation* (nonimmunological pathway)
  - *Complement activation* (classic pathway)
  - Bacterial endotoxins
  - Immunoglobulin aggregates (myeloma, dermatomyositis)
  - Proteolytic enzymes
  - Staphylococcal A protein
  - Uric acid crystals
  - *Complement activation* (alternative pathway)
  - Lipopolysaccharide complexes (dextran, zymosan, agar)
  - Na dehydrocholate
  - Polysaccharides of cell wall of Gram-positive organisms
  - Polyvinylpyrrolidone
  - Snake venom

B. Classification of acquired forms

1. Apparently primitive acquired forms
   - Drugs
     - ACE inhibitors
     - Amphetamine
     - Antibiotics
     - ASA and NSAIDs
     - Codeine and morphine
     - Curare and derivatives
     - Hemoderivatives, plasma expanders, gammaglobulins
     - Heterogenic proteins (organ extracts, specific antiserum, etc.)
     - High-molecular-weight substances (dextran, polyvinylpyrrolidone, Na dehydrocholate, etc.)
     - Hormones
     - Iodinated radiocontrast materials
     - Local anesthetics
     - Opiates
     - Oral antidiabetics
     - Proteolytic enzymes (trypsin, chymotrypsin, streptokinase, etc.)
     - Radiocontrast dyes
     - Sulfonamides
     - Vitamins (thiamine, polymyxin b)

Table 8.1. (Continued)

- Foods
  - Cocoa and chocolate
  - Cow's milk and dairy products
  - Egg
  - Fermented cheese
  - Fish (cod)
  - Fruits (strawberry, banana, etc.)
  - Peanuts, nuts, hazelnuts, etc.
  - Shellfish, shrimp
  - Tomato
- Food additives
  - Na benzoate
  - Na metabisulfite
  - Na salicylate
  - Tartrazine yellow
- Venoms
  - Insect
  - Snake
- Contactants
  - Cosmetics
  - Topical medications
- Idiopathic urticaria
- Psychogenic urticaria

2. Urticaria associated with other affections
   - Autoimmune disease
   - Cryoglobulinemia
   - Endocrinopathies (diabetes mellitus, hyper- and hypothyroidism, hyperparathyroidism)
   - Infections (bacterial, viral, mycotic, etc.)
   - Neoplastic disease
   - Parasitosis
   - Serum sickness
3. Physical urticaria
   - Aquagenic urticaria
   - Cholinergic cold urticaria
   - Cholinergic urticaria
   - Cold urticaria
   - Contact urticaria
   - Delayed pressure urticaria
   - Dermographism, urticaria factitia
   - Exercise-induced urticaria (anaphylaxis)
   - Localized heat urticaria
   - Pressure urticaria
   - Solar urticaria
   - Vibratory angioedema

Data from [37, 42, 45, 117].
ASA acetylsalicylic acid, *ACE* angiotensin converting enzyme, *LES* lupus erythematosus, systemic, *NSAIDs* nonsteroidal anti-inflammatory drugs.

Type III mechanism is manifest via an interplay between CIC, activated complement and kinins and the anaphylotoxin system, which is seen with serum sickness. This mechanism is observed in childhood infections [7], urticarial vasculitis, Schönlein-Henoch syndrome (SHS), panarteritis nodosa, cryoglobulinemia, hereditary complement deficiencies, autoimmunity etc. [53]. Such a pathogenic mechanism has been considered in food-induced reactions, since elimination of CM from the diet of a patient with angioedema and bronchospasm resulted in CIC disappearance, and reintroduction of CM caused a return to previous CIC levels within 24 h[119]. These II and III types are objectively rare in children.

Several investigators consider that a *type IV mechanism* may be operative via IL_3 and IL_5 generation, which are capable of acting on both mast cell degranulation and eosinophil recruitment, thus explaining some types of chronic urticaria [37], especially eotaxin-driven allergic acute urticaria [95].

The skin is particularly rich in *mast cells*. In Chap. 7 we described their origin in bone marrow and subsequent migration into the skin aided by chemoattractants and adhesion molecules [37]. In immediate-type hypersensitivity, mast cell activation is triggered by allergen cross-linkage of high-affinity IgE receptors (FcεRI) borne on their cytoplasmic membrane and on peripheral blood basophils. Mast cells may be activated by specific allergens or by HRFs (histamine release factors) [46] or chemokines, produced by peripheral blood mononuclear cells (PBMCs) that are part of the cell infiltrate causing skin inflammatory lesions. Cutaneous mast cells are tryptase and chymase-containing mast cells (TC) (Table 1.27) and contain in the granules both types of proteases, tryptase and kinase [194], which are able to induce further degranulation [53]. Tryptase in particular can be viewed as a marker of mast cell activation, since its concentration in lesional skin increases proportionately to histamine concentration [103]. Leukocyte emigration is regulated by vasoactive and chemotactic mediators released from mast cells, inducing a sequential up-regulation of endothelial adhesion molecules (CD62P, CD62E, CD54 = ICAM-1, and CD106 = VCAM), β2-integrins on leukocytes, and ILs on endothelial, epithelial, and infiltrating cells [91]. In chronic/idiopathic forms, T lymphocytes (50%) are characteristically found with perivascular distribution, monocytes (20%), mast cells (10%) and no B lymphocytes [103]. CD4 prevails over CD8 [19]. One hypothesis postulates that there is a predominance of activated CD4, as seen in delayed pressure urticaria (DPU) [103]. However, a more likely hypothesis shows no evidence of CD4 activation, although it confirms the unbalanced CD4/CD8 ratio [19]. CD62E has been found in both groups of patients, but CD54 only in DPU patients [19]. Both CD62E and CD54 act as T-lymphocyte adhesion receptors and their increase found in DPU patients may reflect the inflammatory nature of this disorder [19].

In chronic urticaria, IgG Aabs (autoantibodies) directed against IgE in function of anti-IgE and/or anti-

FcεRI have been detected. These Aabs selectively directed against the receptor α subunit are of the IgG_1 or IgG_3 subclass and effectively fix complement and in the absence of IgE induce basophil and mast cell histamine release in both instances [92]. The number of mast cells is not significantly different compared to controls, so the histamine increase may be due to circulating *basophils* recruited into skin lesions [194]. Moreover, the serum of ≤60% of patients reacting with basophils of healthy donors stimulated in vitro basophil releasability [88, 89, 92]. Consequently, cross-linkage of Aab IgG to FcεRI is a pathogenic mechanism peculiar to chronic urticaria, which operates by stimulating or facilitating metachromatic cell degranulation [88] with consequent histamine release [67]. Such Aabs could correspond to HRFs with molecular weight (MW) >100 kD, equally provided with IgG anti-IgE Aabs able to interact with IgE [252]. These data explain why some patients suffer from severe and ongoing symptoms [89]. Basophil histamine release plays a significantly pathogenic role because basophils, when stimulated with anti-IgE that interact with IgE present on basophils, release less histamine [249], even if the levels are variable between subjects [88, 252]. The easy basophil degranulability acts as an opening key to the gaps between endothelial cells, which allows allergen and CIC to break into the perivascular tissue [225]. The skin histamine content and its releasability are increased in vivo during active disease and in remission. Mast cell release following an allergen challenge is not different between patients with chronic urticaria and normal controls [67]. Therefore, the histamine level increment could depend on a transient functional imbalance more than on an intrinsic mast cell defect [194]. To reconcile apparently conflicting data, we should admit that histamine may derive from mast cell nonimmunological stimulation.

Although *eosinophils* are not the most prominent cell type found in urticarial lesions, several eosinophil-derived mediators, including EDN (eosinophil-derived neurotoxin) and MBP (major basic protein) have been detected in late-phase reactions (LPR) in chronic urticaria between 2 and 5 h after allergen challenge [251]. These cationic proteins have been shown to elicit wheal and flare when directly injected into the skin. Eosinophils may also comprise a part of the inflammatory cell infiltrate, along with neutrophils, in DPU and solar urticaria [121]. Moreover, eosinophils are major LTC_4 producers in allergic inflammation [103].

Histamine plays a central role in urticarial lesions by increasing vascular permeability and intensely itching wheals on clinical grounds [231]. The classic *Lewis triple responses* (Fig. 8.3), produced by subcutaneous histamine injection or by gentle stroking with a smooth object, are paradigmatic of what occurs in urticaria linear erythema; flare and wheal are due, respectively, to vasodilatory (H_1 and H_2 action) and vasopermeability (H_1 action) histamine action, to which is added (for the vasodilatory phase) a local axon reflex with dilation of small perilesional arteries, a neurogenic response of the short-circuit type, sending a stimulus back to the cutaneous nerve endings of the involved area. The increased vascular permeability leads to activation of the plasma kinin-forming system and production of bradykinin, which is especially important in hereditary angioedema. Likely the histamine-mediated stimulation of neural sensorial fibers provokes the release of substance P (SP) and of tachykinins with histamine-release action, with consequent amplification of symptoms [103]. Additional mediators important in the pathogenesis are both PG (prostaglandins) and LT (leukotrienes), deriving from arachidonic acid metabolism, PGD_2 is active in mastocytosis, LTB_4 and LTC_4 in pressure urticaria, LTB_4 and PAF in cold, heat, and cholinergic urticaria [103]. With the advent of LT-receptor antagonists, the LTC_4 contribution to chronic urticaria symptoms is more evident [103].

Fig. 8.3. Triple Lewis response: the inner circle is the wheal, the outer one the flare

In other urticarial types, the immunological mechanism is not always identified: allergens may be produced in solar urticaria, both in serum and epidermis, triggered by solar ray exposure, which in aquagenic urticaria in contact with water become soluble in the corneum layer, and diffuse to dermal mast cells. Cryoglobulins, cold hemolysins and cryofibrinogen are observed in some cases of cold urticaria [60].

Serotonin chemotactic factors, kinins, derivatives of tissue and plasma kininogen with an inflammatory action, tenfold more pronounced than that of histamine and MIF (monocyte-macrophage migration inhibiting factor), and 15-HETE (15-hydroxyeicosatetraenoic acid) in LPRs may also participate in the wheal formation process [37].

Immunohistopathology

Urticaria is histologically characterized by dilation of venules and capillaries, tissular edema and a predominant perivascular infiltrate, of variable composition and intensity. The histological peculiarity of urticarial wheals is common to all types, independently of etiology; mast cells and related mediators are the cornerstone of the lesions [166]. The more evident alteration is the dermal edema with vascular turgor, secondary to an increased size of endothelial cells: edema and infiltrate preferentially involve the dermal deeper strata, extending in certain cases to subcutaneous tissues, where flushing and itching stimuli are lacking because of the scarcity of capillary bed and nerve endings. The perivascular cell infiltrate is represented, especially in chronic forms, by T-activated lymphocytes, monocytes, eosinophils and mast cells; the clear-cut prevalence of *neutrophils* is characteristic. Activated T cells are predominant compared to all other cells, followed by mast cells and both B lymphocytes; NK cells are absent [117]. Since this pathology involves the vascular compartment, the etiological agents more frequently responsible are internally transported. In immune processes persistent for >30 min, numerous leukocytes are active, among which neutrophils are disposed between the walls of capillary and post-capillary venules which, if their number increases, may lead to urticarial vasculitis more frequently associated with chronic forms [89]. Eosinophils are seen more rarely, and perivascular infiltrations by lymphocytes expressing the CD4 phenotype are frequently detected [19]. Histopathological evidence in chronic lesions is similar to what is seen in AD and ACD LPRs: vasoactive mediators and chemotactic factors recruit PBMCs, neutrophils, and eosinophils into the cutaneous microenvironment; inflammatory cells in turn stimulate mast cells to dismiss HRFs [46]. It is tempting to speculate whether the initial stimulus comes from activated T cells or from mast cells [19, 103].

Nonimmunological Mechanisms

Several naturally occurring and exogenous nonimmunological compounds have histamine-releasing action via nonspecific mast cell activation. These compounds include (Table 8.1) ASA (acetylsalicylic acid), which, in common with NSAIDs (nonsteroidal anti-inflammatory drugs), generally inhibits the cyclooxygenase pathway, resulting in derailment of the arachidonic acid pathway towards LT production (Fig. 1.57). These drugs have a short half-life; thus possible plasma increments are sporadically detected, unlike in patients with mastocytosis or urticaria pigmentosa, who are primarily susceptible because of an increased skin mast cell population [61]. Nonimmunological activation has been demonstrated in several types of idiopathic, heat- and cold-induced, cholinergic, etc. urticaria [60], which respond to H_1 anti-histamines in the absence of allergens [44]. Urticaria may be caused by a host of agents, including detergents, foods, and endogenous peptides such as endorphins, neuropeptides or tachykinins [131]; but compound 48/80 and codeine cause histamine release only in the skin mast cell [45]. Likewise, physical stimuli may act on peripheral skin nociceptors, thus inducing neuropeptide release. Experimental evidence demonstrates that SP has a vaso-permeabilizing effect on epithelial cells. Tachykinin release into the skin may explain the functional aspects of several types of physical urticaria and the lack of response to anti-histamines and corticosteroids (CSs) [225].

Nonimmunological mechanisms activating mast cells should be re-examined in light of the new acquisitions on neuropeptides, and interactions between the peptidergic nervous system and immunocompetent leukocytes, thus suggesting that mast cells fall in the neuroimmunological axis. SP, NKA (neurokinin A) and CGRP (calcitonin gene-related peptide), via a retrograde axon reflex stimulating mast cells to release histamine (Chap. 10), act moreover on blood vessels. Alternatively the reflex may originate from mast cells, by leading to a tachykinin antidromic stimulation [115]. Abnormalities of skin mast cell responses to neuropeptides may underlie pathological manifestations in several types of cutaneous urticaria, for example in patients affected with cold or heat urticaria, in areas devoid of tachykinins following application of capsaicin (stimulating SP release from sensorial termination and provoking an equal increase in vascular permeability), vascular responses to thermal challenge are reduced. Similarly, patients with chronic urticaria show an increase in cutaneous symptoms in response to codeine. As a consequence, such mechanisms activating mast cells nonimmunologically may have great weight from a physiopathological point of view [166], probably in several cases of chronic urticaria.

Pathogenesis of Hereditary Angioedema

Hereditary angioedema includes [155]:

- Genetic deficiency of C1 inhibitor (C1-INH)
  - Hereditary angioedema type I and type II
  - Five other genetic syndromes
- Acquired forms

The gene for human C1-INH is localized to chromosome *11q11–q13.1* [204].

Hereditary angioedema is inherited as an autosomal dominant trait with incomplete penetrance and is relatively uncommon (0.1%). *Type I* (85% of patients) results from a complement esterase inhibitor deficiency (C1-INH), with MW of 104 kD, produced in liver, monocytes, megakaryoblasts, fibroblasts and placental cells, acting as a regulator of coagulative, fibrinolytic, inflammatory processes, etc. Owing to C1-INH deficiency,

complement is also activated after minimal stimuli, often of a traumatic nature, with formation of C3a and C5a, activation of kinin-like C2 factor, and secretion of more chemical mediators, associated with angioedema onset. In *Type II* (10%–15% of patients), C1-INH levels are normal, since the deficiency is functional. More precisely, in Type I patients, C1-INH-deficient production results from one chromosome 11 gene, which is defined as unproductive; in Type II patients, a gene mutation leads to a functionally inactive C1-INH (MW = 96 kD): therefore the product of a solely normal gene is insufficient to ensure a C1-INH adequate concentration [155]. Consequently, in both cases C2 and C4 are reduced, the C4d/C4 ratio is elevated, and Clq and C3 levels are normal [250]. A *type III* has been recently described in women with normal C1-inhibitor protein, C1-inhibitor function, and C4 levels [35].

Twenty-one children with hereditary angioedema had Type I and five suffered from Type II [70]. In either type, the onset age is between 6 and 20 years in subjects with positive FH [250], or within 2.5–12 years of age [70], but acquired forms develop in adults aged >50 [250]. In 11 members of a family, the mean age at onset of symptoms was 11 years [247]. In children <10, intestinal colic and edema of the extremities are the most frequent manifestations [69]. Edema formation primarily afflicted subcutaneous tissues. Mechanical trauma was identified as a precipitating factor in 80% of children [70]. A 10-year-old child died from laryngeal asphyxia, and an 8-year-old had membrano-proliferative glomerulonephritis [69]. C1-INH deficiency is evident when C1-INH concentrations fall under 15%–20% of normal and occurs frequently in patients with reduced inhibitor activity, in whom the lacking control of complement C1-esterase enzyme activity, and of activated Hageman factor, plasmin and kallikrein, lead to release of vascular permeability factors [60].

The additional five genetic syndromes are as follows [166]:

- *Familial deficiency of C3b inactivator,* autosomal recessive; the alternative pathway is activated with production of anaphylotoxins.
- *Familial deficiency of carboxypeptidase-N,* inactivator enzyme of anaphylotoxins and kinins.
- *Muckle-Wells syndrome,* autosomal dominant, with painful urticarial dermatitis, deafness of the perceptive type and renal amyloidosis.
- *Melkersson-Rosenthal syndrome,* with chronic orofacial noninflammatory tumefaction (tapiroid face), usually limited to lips, characteristic fissured tongue and relapsing facial palsies. Several patients reported with this autosomal dominant syndrome have no FH of the disease [142, 202]. Additives might be implicated in the pathogenesis [202].
- *Episodic angioedema* (from 1 week to 1 month) associated with eosinophilia, periodic attacks of fever, myalgia and oliguria; 8 out of 12 patients were aged between 2.5 and 18 [168]. Eosinophilia is usually associated with an increase in IgE and/or IgM levels; the pathogenesis is based on T-lymphocyte activation with production of interleukins (IL_1 and IL_2R) [168]. An adolescent had similar symptoms and an IL_5 elevation [8]. An increased IL_6 production could be related to blood monocytes and endothelial cells stimulated by an eosinophil mediator [208].

Vibratory angioedema described within the physical urticaria is also hereditary.

Acquired C1-INH Deficiency

Type I acquired C1-INH deficiency (35 cases) has been shown in patients with lymphoproliferative disease, especially B cell-mediated, such as chronic lymphocytic leukemia, macroglobulinemia, essential cryoglobulinemia, or lymphocytic lymphoma. These patients may have a nonfunctioning C1-INH, and extremely low C3 levels, or by C1-INH consumption at a higher level than that of re-synthesis. This is caused by an excessive C1 activation, with consequent C1 reduced serum levels, either via particular CIC (idiotype-anti-idiotope), which appear to fix C1q, or via anti-C1-INH Aabs, which block the normal activity of C1 inhibitor. The clinical manifestations are shared with those of hereditary forms [155].

Type II acquired C1-INH deficiency with C1-INH deficiency and IgA/IgG_1 Aabs directed at C1-INH: the resulting C1-INH functional block could lead to an uncontrolled activation.

Rare cases not belonging to either type may be recorded [155]. Briefly, these deficiencies depend on anti-C1-INH Aabs interfering with normal interactions between C1-INH and proteases, thus increasing C1-INH catabolism. Moreover, there is the risk that some patients may be associated with autoimmune disease, including LES, autoimmune hemolytic anemia, diabetes mellitus, rheumatoid arthritis, etc. [250].

Pathogenesis of Urticaria

Possible types of urticaria [60, 156] include:

1. Prevalently IgE-mediated
2. Complement-mediated
3. Drug- and/or additive-induced
4. Pseudoallergic (by agents directly releasing histamine)
5. Infection-induced

Prevalently IgE- or Non-IgE-Mediated Urticaria

Apparently Primitive Urticaria

Foods are common causes of urticaria in children, the mechanisms are immunological of type I [90], or non-IgE-mediated, or aspecific. There is insufficient proof to confirm a CIC role in urticaria syndrome. Glycoproteins with MW of 10–50 kD are often responsible, since they resist enzyme digestion and heat denaturation. The

foods most frequently implicated are fish (mostly cod), seafood >CM and dairy products >peanuts and nuts >egg >fruits, etc., in some cases with IgE-mediated (55%) or aspecific mechanisms (75%) [90], and acute urticaria provoked by caresses after peanut contact (Table 7.22). In pediatric cohorts, urticaria was secondary to foods from 11% [144] to 57% [90] of cases. In young infants, CM and egg play a role [184], with cases of urticaria and shock by CM, peach and wheat at 4–6 months of life [90]. A wheat allergic boy experienced systemic urticaria and angioedema within 40 min after the ingestion of 9 g of packed rice crackers contaminated by 1.50 µg/g of wheat [137]. Two children seen by us showed severe urticaria while touching or eating a peach. The mother of one boy had urticaria by maize, pollens, and fruit in general. A drop of CM fell on the foot of a 10-month-old child and a generalized urticaria was spread to the whole leg. In two pediatric cohorts, urticaria was caused by CM in 18%–26% [40, 60], peanuts in 63.6%, tomato in 37.3% and egg white in 26.2% of cases [60]. In 67% of 100 children, the foods were implicated in this frequency order: eggs and nuts, fruit, CM, vegetables, fish and shellfish [67]. Fish often induces IgE-mediated urticaria-angioedema in children (60%–92% of cases) [41, 49, 164]; urticaria on the face and arms in one boy following hand immersion in water used to wash codfish and in another after handling a raw peach, complicated the latter by glottis edema [184], have also been noted. As in our cases [41], if a fish-allergic child with AD eats a few milligrams of fish, he does not show worsening AD but persisting angioedema despite an elimination diet (Fig. 8.4). Fish provoked urticaria in 23.8% and urticaria-angioedema in 33.3% of 21 children by *inhalation of airborne particles* [49]. An uncommon case was elicited by a hemostatic sponge of bovine fibrin used in tooth extraction [242]. Immediate reactions have been reported after contact with apple, endive, lettuce, flour, garlic, honey, lamb, pear, potato, turkey, and wheat [184] (Table 8.1).

Inhalant allergens may occasion urticaria since they cross-react with food allergens (Table 1.73), or by direct skin contact: above all, exposure to inhalant allergens in children with AD may cause lesion flare-ups, preceded by urticarial lesions (Chap. 7). There might be a reduction at the threshold by which release of mast cell products can be induced (priming effect) during hay fever season. Grass pollens cross-react with peanut and tomato: in a pediatric study [60]: skin prick tests (SPTs) were positive to grasses more frequently than to Der p. A case similar to peanuts was angioedema, which occurred after stroking a cat (Fig. 8.2).

Urticaria associated with other conditions such as urticaria associated with AD may reach an elevated prevalence in children (Chaps. 5 and 7).

Insect bites and stings cause acute urticaria. Urticarial reactions can be part of a systemic reaction to Hymenoptera stings heralding potentially fatal anaphylactic reactions on subsequent stings.

Fig. 8.4. Angioedema provoked by the ingestion of a few milligrams of fish in a fish-allergic child (for details see text)

Complement-Mediated Urticaria

Complement may be activated in different ways in urticaria [45, 157] (Table 8.1).

Classic pathway activation via aggregated immunoglobulins such as IgG and IgM in CICs, and the same mechanism may be active to a varying degree in other forms of urticaria, as well as in cases of myeloma or dermomyositis, etc.

Alternative pathway activation might result from venoms, antigens, radiological contrast media, complex carbohydrates (agar, dextran, polyvinylpyrrolidone, zymosan), polysaccharides and lipopolysaccharides (LPS) of the cell wall of Gram+ and Gram– organisms. Moreover, activated complement C3a, C4a, and C5a anaphylotoxins are capable of triggering mast cell histamine release, thus playing the pivotal role of possible mediators of urticaria [45].

Urticaria Induced by Drugs and/or Presumed Arachidonic Acid Metabolism Abnormalities and/or Additives

The whole spectrum of drugs are the most common causes of urticaria by pseudoallergic mechanisms in 29.8% [13] and in 22% of children [90]. ASA is the most usual and best studied drug that acts directly and even provokes relapses in subjects with chronic urticaria secondary to different causes. ASA was the most frequently used antipyretic [53.8%) [13]. ASA also cross-reacts with NSAIDs in ASA-sensitive patients suffering from clinical manifestations following NSAID treatment, in addition to colorings and preservatives [59]. Other causative drugs were antibiotics (60.9%) [13] or 47.7% [29], antipyretics (35.1%), or a combination of antibiotics and antipyretics (16.2%) [13]. Contaminant penicillin derivatives in CM or poultry meat routinely penicillin-treated may cause immediate allergic reactions or chronic urticaria [156], prevalently in highly sensitized subjects [157]; gastrointestinal symptoms are frequently elicited, but the food challenge test (FCT) is rarely positive [156].

The *additives* (Chap. 10) most often incriminated are as follows [59]: E102 (70%), E110 (64.2%), E127 (35.7%), E160b (60.7%), E211 (57.1%), aspartame (48.2%) and ASA (12.6%). A cause–effect ratio is more evident in chronic urticaria, that is 30%–50% [60]. The pertinent role in children is unknown, since the related FCTs have rarely been done.

Pseudoallergic Urticaria

Several histamine-releaser foods, if ingested in sufficient amount, have the ability to act on mast cells by an aspecific mechanism, thus inducing urticarial reactions also in nonsensitized subjects. In both cases (immunological and nonimmunological mechanisms), the symptoms are practically overlapping, but a nonimmunological response is best defined as a *pseudoallergic* reaction [18, 60]. Urticaria provoked by additives contained in prepared foods is a frequent finding among children consulting in our department.

Infection-Induced Urticaria

Urticaria may occur during parasite and infectious disorders, especially in chronic urticaria [159]. Among infections with helminths, oxyuriasis, and ascariasis are most diffused in infancy [175]. The underlying mechanisms are uncertain, such as urticaria in the prodromes of hepatitis B and infectious mononucleosis (IMN), either spontaneously or following ampicillin treatment [227]. Urticaria has been associated with enterovirus, cytomegalovirus (CMV), and other infections, but clinically these infections are not unlike those of different etiology. Among 44 children aged 1–12 [22 aged 1–2), 90.9% had symptoms of respiratory tract infection, suggestive of viral infection in 79.5% [29]. Infection, either associated or not with drug intake, was the cause in 46 children (81%). The organisms were enterovirus (50%), parvovirus B19 (20%), Epstein-Barr (15%), and mycoplasma (15%) [29].

In conclusion, a cause was suspected in 28 out of 52 children (54%) such as a viral illness (19%), antibiotics (15%), or a combination (35%) [169]. Even if the pathogenic mechanisms appear to be numerous, conflicting with clinical monomorphism, they may actually be related to a few vasoactive factors that play a role of potential mediators [175].

Clinical Presentation

Urticaria (Fig. 8.1) is a skin eruption characterized by raised, erythematous wheals, with defined or serpiginous borders, irregular form (usually oval), color varying from pink or reddish to whitish, surrounded by normal skin or by a bright-red flare, and with variable form, seat extension and duration. These lesions, accompanied by intense itching, are fleeting and resolve completely within 24 h of onset, especially after Hymenoptera stings, without leaving any trace, even if new elements may follow while the old ones clear. Lesions lasting longer should raise suspicion for the diagnosis of vasculitis presenting as urticarial lesions Wheals vary in size (from 1–2 mm to 1–2 cm) and number and in some cases undergo a coalescence involving very large areas (*giant urticaria*) up to 10 cm in diameter and assuming the aspect of a geographical map. Urticaria may be generalized or localized and in the latter case the lesions affect preferentially the trunk and limbs, but also the palms and soles, the face and scalp. An important characteristic is that the color typically blanches with pressure; this simple test is helpful *to differentiate an erythema from a skin hemorrhage* [117].

Acute allergic urticaria is an IgE-mediated allergic reaction associated with systemic anaphylaxis. It is extremely common, possibly affecting about 10%–20% of the general population. Most frequently, this a self-limited disorder [103]. However, excluding drug reactions and insect stings, acute allergic urticaria comprises 2%–6% of the total number of urticaria cases seen in a dermatology clinic [117]. This is an eosinophil-driven disease, as demonstrated by a study on 19 infants and children aged from 9 months to 8 years and recruited from the emergency room while presenting with acute attacks of wheals and itching, accompanied by angioedema in seven subjects. Total serum IgE levels were above the highest normal for their age. The eotaxin values were significantly higher than the controls' corresponding values. As a potent eosinophil selective chemoattractant, eotaxin is a chemokine that promotes the selective recruitment of eosinophils, the major effec-

tor cells in allergic inflammation. Eotaxin is thus implied in the causation of the tissue eosinophilia that characterizes allergic acute urticaria and may also be a biomarker of lesional activity [95].

Angioedema (Figs. 8.2, 8.4) is sometimes referred to as angioneurotic edema, coined by Osler who did not refer to neurosis at this time [158]. Isolated angioedema is rather rare at the pediatric age, is more often a symptom of a generalized anaphylactic manifestation, as when it is caused by an insect sting [175]. In 26 children, pedigree analysis revealed 19 patients with afflicted relatives, and clinical manifestations of the disease first occurred at 2.5–12 years of age [69]. Angioedema was caused by food in 40% (Fig. 5.12), insect bites in 30%, infection in 20%, and an antibiotic in 10% of children [187]. The swelling involves deeper skin layers with fewer mast cells and nerve endings, and is thus painless and nonpruritic. It is characterized by gradual onset of circumscribed bouts of edema, localized in subcutaneous tissue, skin and mucosa, more evident in the face, lids, lips, tongue, upper airways, gastrointestinal mucosa and less in the limbs, involving the mucosa to varying degrees and discomfort, accompanied by extreme weakness. Incidence of angioedema of the head or neck, most often facial was 80%, tenderness or pain 40%, dyspnea 30%, dysphagia (including drooling and spitting) 30%, and hoarseness 10% [187]. The clinical manifestations, self-limited and present in two-thirds of cases in patients up to 13 years of age, are usually preceded by local trauma, also mild, such as local inflammation, minor surgery, dental extraction, fatigue, and emotional stress, sometimes without an apparent cause [60]. It is characterized by recurrent attacks of self-limiting angioedema affecting the face, limbs, gastrointestinal system and upper airways [247]. Additional symptoms are erythematous rashes, pleuritic pains, urinary retention and seizures or hemiparesis, sometimes simulating a cerebral edema. The swelling progresses over hours, commonly increasing over 12–72 h and then subsiding over 1–3 days, leaving a normal-appearing skin [155]. The frequency may vary from a single episode over the entire life to weekly recurrences.

Gastrointestinal exacerbations may cause vomiting, watery diarrhea, colicky abdominal pain and guarding, but in the absence of fever and leukocytosis there is instead enteritis [103]. When the intestinal mucosa is involved, an occlusive syndrome may occur with subintrant colic and other symptoms mimicking an acute surgical emergency, sometimes resulting in unnecessary exploratory laparotomies and even appendicectomy [237], regardless of signs of peritoneal irritation. Extravascular fluid leakage to gut edema can lead to hypotension and hemoconcentration [155]. The most severe complication is laryngeal edema, which, when not treated quickly and aggressively, can be lethal; the laryngeal involvement provokes death by asphyxia [169]. Usually an asphyxial crisis is not suddenly precipitated, because in certain cases the attack, before the real appearance of swelling, is preceded by dysphagia, dysphonia and other prodromic signs such as subjective sensation of pharyngeal prickling, pruritus or burning. Subsequently a sensation of painful tension precedes the edema. These are warning symptoms allowing the timely institution of medical therapy, thus eluding tracheostomy [103]. In these patients, oral surgery represents a particular danger since edema can easily progress to upper airway obstruction. Trauma precipitates facial and airway edema via dental manipulation or adenotonsillectomy. Normal activity such as writing and/or computer typing are causes precipitating hand edema. In rare cases, symptoms can be triggered by infections [237].

Physical Urticaria

Physical urticaria can be subdivided into thermal, mechanical and cholinergic urticaria, with an 8% incidence in children [90]. In some patients more than one type of physical urticaria may be present (Table 8.1, Fig. 8.5) [42].

EIA syndrome with a family tendency, is rather rare and differs from other physical urticaria due to its sporadic occurrence. Four clinical phases have been proposed: (1) the prodromal manifestations are cutaneous (pruritus, warmth, flushing and fatigue), (2) early symptoms include urticaria and angioedema, (3) the full-phase symptoms are respiratory and gastrointestinal and (4) as in phase 1, and less often shock [183]. Occasionally the symptoms occur without a break. Triggering factors are cold and certain foods and drugs [42]. Three clinical forms have been described: one is EIA occurring after jogging started within 2 h of any meal (postprandial EIA), another form occurs only following a specific food ingestion, and the third when no food is identified [190]. High histamine concentrations and mast cell degranulation were detected in skin biopsies [190] (see Chap. 20).

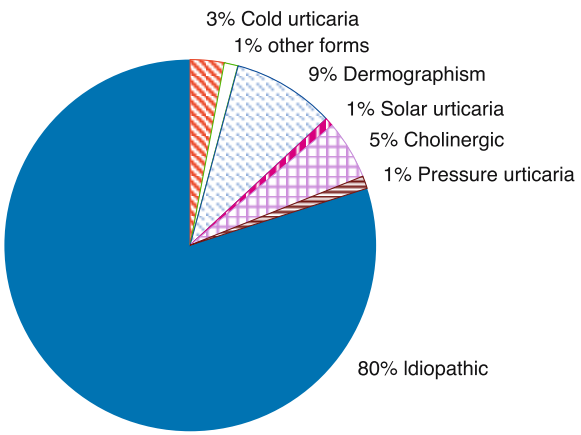

Fig. 8.5. Forms of physical urticaria

Dermographism or dermographic urticaria, meaning literally writing on the skin, is the commonest physical urticaria, which is seen in about 5%–10% of normal subjects without a sex predilection [103]. In 238 children aged 2–14 years, the prevalence was 24%, with a significant predominance of females (33%) over males (16%) [136]. Following the application of a linear pressure or a gentle friction, there is characteristically the production of a wheal (diameter >2 mm) and flare reaction. If the skin is stroked with a wooden tongue-depressor, a fingernail, an instrument with blunted point (a key), or a retracted ball point pen [156], within 2–3 min the usual white line secondary to reflex vasoconstriction is followed by pruritus, flushing and a linear edema, which occur exactly in the distribution of the stimulus [111, 175]. A positive response occurring at a stroke pressure of 3.6 g/mm^2 of skin surface or less confirms the diagnosis. Less obvious triggers are pressure from clothes or leaning against a chair [117]. Three types of dermographism have been reported according to the chronology of the wheal and flare reaction, following a stimulus application:

Type	Onset	Duration
1. Immediate (common)	2–5 min	30 min
2. Intermediate	30 min – 2 h	3–9 h
3. Late onset, delayed (rare)	4–6 h	24–48 h [111]

Symptoms are more common on the trunk and limbs and are differentiated by the classic triple response because minimal stimuli lead to extreme responses. Many subjects are carriers of a mild dermographism, while a wheal response to the mechanical skin stimulus is less frequent. An association between skin and bronchial hyperreactivity (BHR) has been suggested in children with dermographism [136]. In about 70% of patients, a passive antibody-mediated transfer (Prausnitz-Küstner reaction) has been documented, which underlies an IgE-mediated reaction, along with findings of mast cell degranulation histamine release [183] or mechanisms involving IgM antibodies [117].

Variant types of dermographism have been described [67, 183, 233]:

constitutional, its onset is often in infancy and duration may be lifelong.

acquired primitive, with a sudden onset and a duration of 1–2 years.

acquired secondary, associated with cutaneous mastocytosis, upon challenge with penicillin or insect sting, or in patients with hyperthyroidism, scabies, etc.

cold-dependent, the classic wheal is produced only during skin cooling, but not if the skin is stroked when skin temperature (T) is normal.

delayed form, causes burning and pain instead of pruritic symptoms.

Pressure urticaria, initially classified as a rare familial variant of dermographism. DPU appears commonly after 6–24 h or more after pressure has been applied for a period as short as 2–3 min. Pressure areas are diffused and result from prolonged sitting on a nonupholstered seat; wearing tight clothing and straps, watches, belts; wearing tight shoes; or walking, jogging, and climbing ladders. Swelling of the soles of the feet may limit ambulation and become progressively disabling. The typical lesion is painful as it is deep-seated and edematous [183]. The trunk, buttocks, feet and hands are the regions affected in 95%–98% of cases [64]. Reactions persist for 36 h on average and for 86 h at most [64], so that the more delayed types are practically indistinguishable from delayed dermographism [42]. *Immediate forms* are full-blown within 30 s to 4 min. Skin biopsies reveal signs of vasculitis with neutrophils in the lower dermis and subcutaneous tissue 4–5 h after peak swelling, then lymphocyte infiltrate after 24–48 h, thus denoting a cell-mediated immunity (CMI), with tissue eosinophilia but not in the bloodstream [225]. A mechanism elicited by histamine probably coexists, with participation of axonal reflexes and neuropeptide involvement as SP [156]. The increased IL_1 levels may contribute to leukocyte recruitment and systemic symptoms such as fever and malaise [117]. Up-regulation of adhesion molecules CD62E and CD106 has led to the hypothesis that vascular endothelial activation plays an early role in the lesion upsurge [19].

Cold urticaria refers to a group of urticarial manifestations induced by exposure to the cold such as typical (primary, secondary) and atypical, familial immediate or delayed, and acquired systemic or localized:

Primary typical cold urticaria (idiopathic) is characterized by a rapid onset (2–5 min) after a local cooling induced by a blunt decrease, even of 1 °C, of body T, with itching, burning, flushing and edema *limited to cold-exposed skin* (face, limbs) occurring on skin rewarming even after 1 h [42]. An act of short duration is sufficient, such as holding cold objects or drinking cold beverages may produce hand or lip swelling, respectively. Eating cold foods may also cause a glottis edema. Total body exposure to cold such as showering or bathing in cold water, especially in open places with further cooling, may produce such widespread vasodilation that severe hypotension and collapse ensue, and in extreme cases even death by drowning for persons diving into cold waters, often labeled "faintness" [111, 233]. Histological findings often overlap with those of other physical forms. In children aged 12.6 years, atopy was present in 67% of cases, and girls more frequently had cold urticaria, other types of physical urticaria were present in 25% with no familial inheritance; 83% of children had localized and generalized symptoms [181]. Among 30 children <18 years old, the age of onset was at ≈7 years, with a strikingly high rate of asthma (46.7%) and AR (50%), and a FHA of 89.3%; 33% had anaphylactic reactions [4].

Secondary typical cold urticaria is associated with cryoglobulinemia, cryofibrinogenemia, cold hemagglu-

tinins and hemolysins; complement deficiencies; urticarial vasculitis; viral infections (IMN); insect stings or drugs (griseofulvin, penicillin) [175].

Atypical cold urticaria has varying manifestations and syndromes:

1. *Systemic or generalized* cold urticaria has systemic symptoms characterized by giant urticaria and negative ice cube test [110] (ICT).
2. *Two rare familial types* of cold urticaria (20 cases) plus four large North American families [93], both with autosomal dominant trait: in the immediate type mapped to chromosome *1q44*, burning papules or macules appear after 30 min to 4 h associated with chills, fever, arthralgias and neutrophil leukocytosis. In the delayed type, they occur in the skin area of cold exposure after 9–18 h, accompanied by burning with absence of pruritus. In several cases, histological features include mast cell degranulation and an increase in blood histamine levels following cold exposure. In other cases, the IgE-mediated reaction is passively transferred [100, 233]. This syndrome is associated with the *CIAS1* gene [62, 93].

Acquired cold urticaria manifestations and syndromes:

1. *Cold-induced cholinergic urticaria* and cold-dependent dermographism, appearing after cold exposure. These forms are linked to both delayed cold urticaria and systemic types by ICT negativity [233].
2. *Localized cold urticaria* affects certain areas of the body after cold contact under specific predisposing conditions mostly related to cold injuries or insect stings [111].

In most of these syndromes, the most closely studied pathogenic aspect is the participation of histamine; TNF-α-induced mast cell release is relevant, which could be implicated in shock-like clinical manifestations [209].

Solar urticaria (1%–4% of urticaria cases), rare in children [240] and familial cases, affects both sexes, usually when they are <30 [141]. Within 30 s to 3 min after skin exposure to sun or UV (ultraviolet) spectrum light, patients note erythema preceded by, or immediately followed by, pruritus and then wheals (5–10 mm, persisting for 15 min to 3 h, less if patients take shelter in a shaded place [42]. Patients complain of itchy, pricking, tingling, or burning lesions. If a sufficiently large area of skin is exposed, *systemic symptoms up to anaphylaxis* may occur [183]. In about 25% of cases, it is associated with dermographic urticaria or with a history of AD [141]. A rare delayed form is characterized by a 17- to 72-h time-lag for lesion onset [111]. An axon-induced flare encircles the area with changing borders beyond the involved sites [111]. This disorder has been classified into six different types depending on the wavelengths of light to which patients react: only types I and IV can be passively transferred and may be antibody-mediated. In type VI, or erythropoietic protoporphyria, protoporphyrin IX acts as a photosensitizer activated by sun rays with a wavelength of 400 nm [197]. Skin biopsies show neutrophils and eosinophils within a time-lag of 5 min to 2 h, replaced by PBMCs after 24 h [151] and eosinophils degranulate in skin lesions with MBP deposition [121].

Contact urticaria with erythematous and wheal-like eruptions is aroused 30–60 min after normal skin exposure to the offending substance, most often induced by nettles and certain vegetables (see "Phytodermatitis"), some coelenterates such as jellyfish, as well as drugs, foods, cosmetics, fragrances (cinnamic aldehyde), chemical substances (disinfectants and bleaching), cat, dog, horse hair (in order of frequency), etc. [103]. Contact can be achieved via airborne agents, including grass pollen, as in sensitized children walking outdoors during days or in places with notable pollination, or playing in the grass, etc., or indirectly via toy contamination with pollens. Food allergens include egg, CM, tomato, chicken, honey, peanut butter, sunflower seeds, and cooked chick-peas [1, 115], also during their manipulation by children affected with oral allergy syndrome (OAS). Symptoms are usually elicited within 30–60 min; cases with onset delayed up to 6 h have been reported.

There are four clinical forms [117]:

- Contact urticaria, localized, the most frequent, usually caused by foods and pet danders.
- Contact urticaria with angioedema, also with systemic manifestations, often formaldehyde-induced.
- Contact urticaria with asthma, sometimes associated with gastrointestinal and oculorhinitic disorders. the onset is triggered by cephalosporins, various vegetables and processionary caterpillars, whose urticating hairs caused toxic-irritative effects on both skin and mucosa by direct contact as in 60/653 children (9.18%) with 4 IgE-mediated cases (6.7%) [222], and on the airways by aerodispersion (allergen Tha p 1, Table 1.74).
- Contact urticaria with anaphylactic shock, a severe reaction often associated with penicillin, neomycin, bacitracin, etc.

A delayed type of contact urticaria is limited to some families.

Contact urticaria can be categorized into three groups from the pathogenetic point of view [115]:

- *Immunological contact urticaria,* almost always IgE-mediated: Table 8.2 [115].
- *Nonimmunological contact urticaria,* mostly triggered by preservatives or additives employed the world over (Table 8.2).
- *Urticaria characterized by an undefined mechanism* including OAS and protein contact dermatitis; see, respectively, Chap. 9 and the second part of this chapter.
- *Vibratory angioedema,* a hereditary disorder more commonly transmitted as an autosomal dominant condition, arising in children and persisting into adult age, decreasing progressively in severity [42]. Patients complain of pruritus, erythema, edema and wheals of 5–10 mm, within minutes in response to the application to the skin of an even gentle vibratory stimulus and lasting up to 24 h, depending on the stimulus and body sur-

Table 8.2. Substances producing immune contact urticaria and nonimmunological urticaria

A. Substances producing immune contact urticaria

Animals and related products
Amnion fluid, bovine blood, cat and dog dander, cockroaches, pig gut, rat liver, placenta, saliva, serum

Cosmetics
Hair sprays, nail polish, perfumes

Foods
Apple, apricot, banana, beans, cabbage, carrot, celery, cheese, cherry, chicken, chives, cow's milk and dairy products, cucumber, egg, endive, fennel, fish, flour, garlic, kiwi, lamb, lettuce, liver, maize, malt, mango, mustard, onion, orange, parsley, peach, peanut butter, plum, potato, sesame seed, spices, strawberry, sunflower seed, tomato, turkey

Medications
Antibiotics (ampicillin[a], bacitracin[a], cephalosporins, chloramphenicol[a], gentamicin, neomycin[a], penicillin[a], rifamycin, streptomycin[a]), ASA, benzocaine, benzoyl peroxide, chlorpromazine, dinitrochlorobenzene, mechlorethamine[a], promethazine, pyrazolones (aminophenazone[a], methimazole, propylphenazone), tocopherol

Metals
Copper, nickel, platinum, rhodium

Plants and related products
Birch, camomile, castor bean, china, chrysanthemum, corn starch, emetine, hawthorn, latex, lichens, lime, mahogany, marine flora, papain, rose, rouge, seaweed, tobacco, teak, tulip

Preservatives and miscellaneous chemicals
Aliphatic polyamide, aminothiazole, benzoic acid, benzyl alcohol, *p*-hydroxybenzoic acid, chloramine, chlorocresol, diethyltoluamide[a], formaldehyde, gentian violet, lanolin, lindane, nickel salts, parabens, phenylmercuric propionate, polysorbates, sodium hypochlorite, tropicamide

Textiles
Silk, wool

Miscellaneous
Acetone, acrylic monomer, aliphatic polyamide, aminothiazole, ammonia, ammonium persulfate, benzophenone, butylated hydroxytoluene, carbonless copy paper, epoxy polymer resin[a], formaldehyde resin, human sperm, lanolin alcohols, lindane, methylethylketone, monoamylamine, naphtha, naphthylacetic acid, nylon, paraphenylenediamine, Perlon, phosphorus, sesquisulfide, plastic, polyethylenglycol, polypropylene, potassium ferricyanide, sodium silicate, sodium sulfide, sulfur dioxide, terpinyl acetate, vinylpyridine

B. Substances producing nonimmunologic contact urticaria

Animals
Arthropods, caterpillars, coelenterates, corals, jellyfish, moths, sea anemones

Foods
Cayenne pepper, fish, mustard, thyme

Medicaments and chemical substances
Acetic acid, butyric acid, cinnamic acid, cinnamic aldehyde, cinnamon oil, balsam of Peru[a], benzocaine, camphor, cantharides, capsaicin. chloroform, dimethylsulfoxide, iodine, methyl salicylate, methylene blue, myrrh, nicotinic acid esters, nicotinic acid tetrahydrofurfurylesther, resorcinol oil, tar extracts, tincture of benzoin, witch-hazel

Plants
Nettle, seaweed

Preservatives and miscellaneous chemicals
Benzoic acid, formaldehyde, sodium benzoate, sorbic acid

Miscellaneous
Butyric acid, diethylfumarate, histamine, pine oil, turpentine

Modified from [115].
[a] Substances that have caused local reactions and anaphylactic symptoms in skin tests.

face area involved. If the stimulus is appropriately intense a systemic reaction may occur, inciting stimuli are motorcycling, toweling, massaging, and the like. A form with delayed onset (4–8 h) and one acquired idiopathic form have been reported [42, 103, 111].

- *Aquagenic urticaria* is another rare form: 15 pediatric cases have been recorded [129, 146, 163, 236]. Age ranges from 2–15 months [146] to 7 years [163]; eight children had associated symptomatic dermographism [146, 163]. A familial tendency has been observed in 11 families [146, 183], in one family over three generations in association with familial lactose intolerance [213]. Affected individuals develop pinpoint wheals after skin contact with water, snow, or more or less intense perspiration, regardless of the T [183]. The lesions (pruritic wheals of 1–3 mm) predominate on the trunk and, less often on forelimbs, occur from 2–3 min to 30 min after exposure to water [156]. On immersion, seven babies became pale, hypotonic, still and unreactive [146]. The lesions may subside after 30 min [156]; however, recovery took a few seconds after withdrawal from the bath and stimulation [146]. These features may even go unnoticed [156]. Biopsy specimens of the lesions reveal mast cell degranulation and hyperhistaminemia; also a cholinergic mechanism seems to play a role [183]. The sex ratio is unfavorable to females (2:1) at puberty or pre-puberty age [238].
- *Cholinergic or thermolytic urticaria*, also known as generalized heat urticaria, along with dermographism is the most common physical urticaria (5%–7% of all urticaria forms), prevalently affecting adolescents and young adults. Prodromic signs may

Table 8.3. Ascertained causes of chronic urticaria in children (%)

No. of children	Age (years)	Ascertained causes	Physical forms	Infections	Foods	Inhalant allergens	Additives	Drugs	Reference

97	4.5	78.5	5.1	2	14.4	8.2	18		[18]

arise within 2–30 min of the triggering event, consisting of pruritus, tingling, warmth, or burning of the skin [183]. The ensuing cutaneous manifestations are erythematous and wheal-like, 1–3 mm in diameter, with surrounding bright red flares. These may become confluent to form intensely itching papular wheals, which appear abruptly after variations in ambient T or changes in body T following fever, intense sweating after vigorous exercise, hot showers or sauna, intense transient emotional stimuli, often accompanied by symptoms of cholinergic stimulation, such as lacrimation, salivation and diarrhea, with the involved area returning to normal after about 1 h [117, 175, 183]. In severely ill patients, systemic symptoms such as angioedema and cardiovascular, respiratory or gastrointestinal signs may be associated with anaphylaxis [156]. A similar picture can be produced in affected individuals by acetylcholine: it is postulated that *pathogenic mechanisms* are based on body T increase and the following skin exposure to a warm stimulus can affect the higher nerve centers [197]. Thus, acetylcholine release may be evoked along peripheral nerve endings, also inducing histamine release, probably by a direct action of cholinergic receptors on mast cells [197].

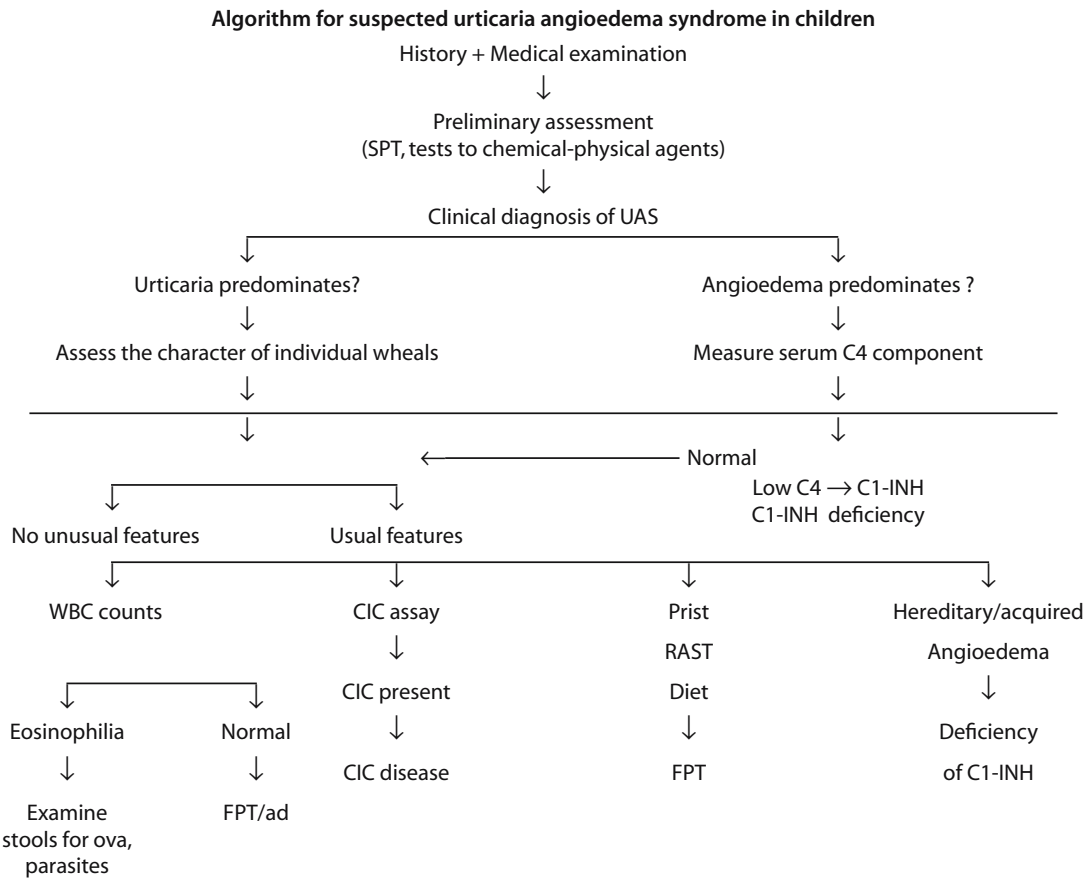
- *Cholinergic cold urticaria* occurs when systemic cold contact produces a form similar to cold urticaria [4, 181].
- *Localized heat urticaria,* also rare (18 cases) is apparent with immediate urticarial reactions within 5 min after heat application, for example warm water [54] at a T of 43 °C and lasting about 1 h, with increased plasma histamine levels [42]. A 5-year-old girl developed sudden-onset episodes of pruritus (after 3 min of heat exposure), redness, and local skin swelling, which resolved within 90 min. Histamine increased at 3 min after heat challenge and then declined [134]. A delayed familial localized heat urticaria is very rare; lesions appear 6–18 h after exposure to localized thermal stimuli and last 12–24 h [111].

The mother of a child seen by us experiences urticaria to both cold and warm objects or even the weather.

Chronic Urticaria

Chronic urticaria is defined as persisting or recurrent urticaria lasting >6 weeks, which may be presently considered the most frequent cause of urticaria [18]. In follow-ups, several cases may progress from acute to chronic urticaria, for example 12 (30%) of 40 children in one study [144]. In three studies on 366 children aged 1–14 [18, 201, 229], several causes were ascertained, summarized in Table 8.3 [18, 229], including physical forms (cholinergic, dermographic, cold and pressure urticaria), infections (parasites and/or streptococci), foods (CM, egg, fish, nuts), food additives (tartrazine, salicylates), aeroallergens (pollens, cat dander) and drugs (penicillin, phenobarbital). In 75% of children, urticaria was attributed to pseudoallergens such as coloring agents, preservatives, saccharin/cyclamate and monosodium glutamate [65]. In 43 children with additive sensitivity (32 also with angioedema), both SPTs and FCTs were positive in 2%–28% of cases [201]. We stress the cases provoked by yeast extract (Chap. 10) and penicillin [157]. In 132 children, in most cases the cause remained unknown (63.6%) [13]. *Chronic idiopathic urticaria syndrome* applies to many patients without an easily identifiable cause; however, frequently these patients suffer from a chronic disease [89]. Recently, two youngsters were reported, one with positive autoimmune markers, the other with juvenile rheumatoid arthritis (JRA), thus opening the door to *autoimmunity in the pathogenesis* of chronic urticaria [54].

Histopathological features show that the preponderant cell types are $CD4^+$ T cells predominant over $CD8^+$ T cells, and that mast cells degranulate [19], thus being considered the primary effector cells in chronic urticaria with a significant increase in number [19]. Significantly increased are intradermal $CD3^+$, $CD4^+$, $CD8^+$, and $CD25^+$ T cells, as well as eosinophils, neutrophils, basophils, and macrophages. T cells from these patients are characterized by a Th0 cytokine profile, with significant increases of IL_4 and IL_5 mRNA and cells positive for IFN-ɣ. A pattern distinct from that seen in the allergen-induced LPR, where IFN-ɣ is absent [248]. An increased histamine release may be induced by nonspecific mast cell activation. It is unlikely that the histamine release is secondary to peripheral blood basophils [45]. Actually, basophils of these patients have a decreased releasability; thus mast cells as the source of spontaneously released histamine in these patients is further substantiated by increased tryptase levels in blister fluid [45]. On skin biopsies, there is evidence of neutrophils within capillary and post-capillary venular walls, but not of structural damage [89]. Spontaneous wheals show expression of CD62E and CD50 on vascular endothelial cells and of CD106 on perivascular cells [89].



Algorithm for diagnostic approach of patients with suspected hereditary angioedema

Fig. 8.6. Algorithm for diagnostic approach of children with suspected urticaria angioedema syndrome (*UAS; top*) and suspected hereditary angioedema (*bottom*). *Top*: *CIC* circulating immune complexes, *FPT* food provocation test, *FPT/ad* with additives, *WBC* white blood cells. (Modified from [89]). *Bottom: 1* inhibitor, *ACE* angiotensin-converting enzyme, *Funct* functional, *D* decreased, *N* normal, *I* increased. (Modified from [155])

Psychogenic Urticaria

Psychogenic factors may exacerbate symptoms of urticaria-angioedema due to diverse causes; however, it is insufficiently understood whether they are primary or associated with other unidentified factors.

Diagnosis

A complete etiological diagnosis (Fig. 8.6) [89, 155], with particular attention paid to the patient's history (Table 8.4) [53] and a thorough physical examination [89, 103, 155, 156, 233] are necessary tools for the evaluation of children with urticaria.

Table 8.4. Flowchart for the diagnosis of urticaria and related forms of angioedema

Features	Manifestations	Diagnosis of urticaria (angioedema)
Genetic factors		Hereditary angioedema, some physical urticaria
Duration of clinical symptoms	<6 weeks	Acute
	>6 weeks	Chronic
Onset related to the time of stimulus application	Rapid	All types
	Delayed	Pressure, cold, cholinergic, contact urticaria
Width of lesions	Few wheals	Cholinergic, aquagenic, solar urticaria
	Arciform	Drug-induced urticaria
	Giant, involving subcutaneous tissue	Angioedema, pressure urticaria
Color	Yellow	Associated with hepatitis B
Localization	Contact and stroking	Dermographic urticaria
	Contact with foreign substances	Contact urticaria
	Photo-exposed sites	Solar, heat urticaria
	Pigmented sites	Urticaria pigmentosa
	Points of pressure	Dermographic, pressure urticaria
Duration of lesions	Short	All types
	Long-term	Vasculitis, familial cold urticaria
Causative factors	Aeroallergens	Acute and chronic urticaria
	Chronic disease	Chronic urticaria
	Cold	Cold contact, familial cold urticaria
	Exercise, foods	Exercise-induced anaphylaxis
	Exercise, stress	Cholinergic urticaria
	Foods, additives	Acute and chronic urticaria
	Heat	Heat contact urticaria
	Insects	Papular urticaria
	Medications	Acute and chronic urticaria
	Natural water	Aquagenic urticaria
	Rx-examinations	Acute and chronic urticaria
	Sunlight	Solar urticaria
	Vibrations	Vibratory angioedema

Modified from [53].

When *hereditary angioedema* is suspected, the history should be complete (FH may be negative in 20% of cases), especially investigating previous recurrent episodes of edema. Diagnosis is made by studying the complement components (C4, C3 and C2) and C1-INH levels (algorithm):

- In asymptomatic periods, the C4 level is decreased and the C2 level is normal; during the attacks the C4 level usually cannot be measured, C2 levels are reduced, C3 turnover is enhanced, and CH50 (50% hemolytic complement) may be reduced.
- C1-INH immunochemical assay: the levels are reduced in 85% of cases; in the remaining 15% the levels are normal or increased, so that functional studies with enzymatic and immunochemical tests should be done [155].
- If C4 and C1-INH are very low, then C1-INH antigenic protein assay should be done to distinguish type I (low levels) from type II (normal) antigen, despite low functional protein [35].

In one family, C1-INH levels were undetectable or low in some patients and CH50 was undetectable in all of the patients. The C4 level was low, and in a 10-year-old boy diagnosis was based on low C1-INH, CH50 and C4, in addition to his FH [247].

Diagnosis has been *successfully made at birth* using cord blood and by examining C1-INH functionality [230].

Diagnosis of *urticaria* (Table 8.4) first requires a distinction between acute and chronic urticaria [44]:

- Genetic factors, atopy
- Aspect of the lesions
- Triggering causes
- Clinical manifestations
- Duration of clinical manifestations
- Associated symptoms

The child's lifestyle should be investigated, particularly food preferences and potential, continuous or occasional drug intake, as well as information on additives, inhalants, recent infections, stress, work, and hobbies [175]. The ability to establish a cause and effect recurrent relationship becomes particularly significant. It should be ascertained whether or not [44]:

- It is a clear-cut type of urticaria
- There is a pathogenic mechanism correlated with what has been ingested, inhaled, or injected

Table 8.5. Foods that contain ASA, benzoates or colorings to be excluded from the diet

Almonds, toasted	Fruit juices
Apple	Grape
Banana	Green peas
Beans	Margarine
Cabbage	Mayonnaise
Carrot	Nuts of all types
Cherry	Onion
Citrus fruit	Parsley
CM, powdered	Peanut
Coca-Cola	Potato
Cranberry	Red, green peppers
Cucumber	Rhubarb
Eggplant	Spinach
Eggs, powdered	Strawberry
Fizzy drinks	Vinegar
In addition	
Processed foods of all kinds, bottled, canned, cased, dry packaged, frozen	
Gelatins, marmalade, soft drinks, ice-creams and sherbets, yogurt	
Caramels of all kinds, chocolate and chocolate puddings (not plain chocolate)	
Bakery foods, candies, cake mixes, chips, puddings and pie fillers, pancakes, wafers	
Cheese, processed cream-cheese, macaroni and cheese of all kinds	
Salad dressings, ketchup, mustard and other prepared sauces (bearnaise, curry, hollandaise, tomato, fish)	
Smoked and frozen fish (anchovy, kipper, sardine)	
Colored toothpaste, chewing-gum	

Diet in use in the Division of Pediatric Allergy and Immunology of Rome, University La Sapienza.

- There is a contact reaction (difficult to discern if AD coexists)
- There is an association with a systemic disease
- There are infectious episodes, past or present

For *food-induced urticaria,* a possible approach involves:

- When the reactions occur <2–3 times/week, it is useful and economic to record the ingested foods in a diary, a practice which focuses the attention of both the family and the child on food factors.
- When the manifestations recur with greater frequency or daily, a diagnostic elimination diet is prescribed, also to detect occult, clinically relevant allergens present in many different foodstuffs. A positive result indicates the opportunity to continue with SPTs or RAST, but FPTs ensure conclusive evidence to be looked for only in children who have a history of previous food-induced anaphylactic shock. A possible therapeutic elimination diet is discussed in Chap. 9.

In *additive-induced urticaria,* countless food dyes and preservatives are suspected [59]. An elimination diet such as the one we prescribe should exclude ASA, benzoic acid and dyes (Table 8.5), frequently prescribed to the children seen in our department: a positive result validates the search for causative additives. (See Chap. 10 for a complete list.) A diet free of ASA and other pertinent additives is similarly helpful in children with drug-induced urticaria [227]. In our department we have noted that almost all children improve by eliminating all prepared foods, with no exception.

In the case of pseudoallergic urticaria, the above-mentioned causes should be chosen among nonimmunological mechanisms. When aeroallergens are suspected, interventions for allergen avoidance should be scheduled. Total serum IgE levels could increase, with a possible peripheral eosinophilia [117].

Physical Urticaria

- *EIA:* it is important to assemble a circumstantial history. Then the patient is invited to run in place or on a treadmill for at least 5–10 min. Positive responses follow the four phases, sometimes a differential diagnosis with cholinergic urticaria may be necessary [190].
- *Dermographism:* by gentle stroking of the skin, in normal responses an immediate blanching followed by a red flare for 10 min is detected, in simple forms a linear wheal and flare appear lasting 10–15 min and in symptomatic forms there are pruritus with linear wheal and flare lasting 30 min to 3 h. In the delayed variant, the wheal decreases within 20–30 min, recurs in the same site by 3–8 h and persists for 24–48 h. The diagnosis is confirmed by using the dermographometer (Fig. 8.7), which is pressed on the skin and a typical response occurs at the pressure of 3.6 g/mm^2 = 3.5×10^5 Pa [117].

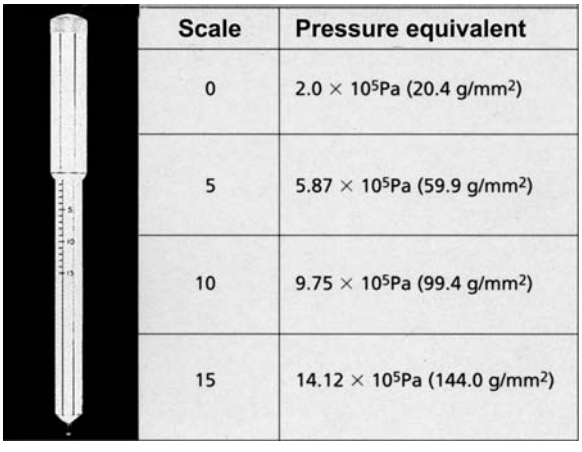

Fig. 8.7. Dermographometer

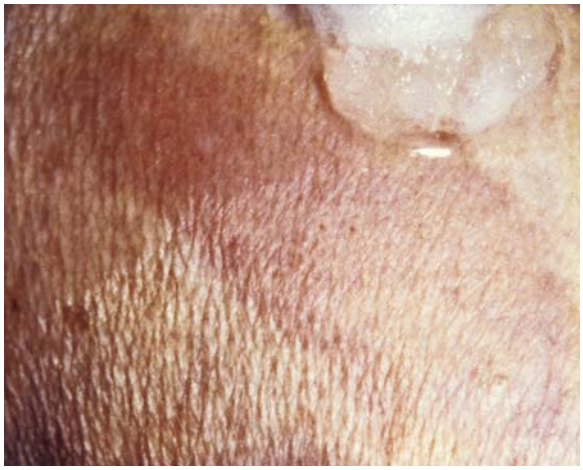

Fig. 8.8. Positivity of ice cube test in cold urticaria

Fig. 8.9. Vibratory angioedema edema and erythema of the palm and forearm after the test

• *Pressure urticaria:* hanging a 6–10 kg weight across the shoulder or thigh for 10–15 min will produce painful swelling at the pressure site after 4–8 h. In younger children the pressure is adjusted according to age. In delayed pressure urticaria, the dermographometer is set at 9.75×10^5 Pa (99.4 g/mm^2) and held firmly against the skin of the back for varying numbers of seconds [117].

• *Cold urticaria:*

• In the localized form, diagnosis is confirmed by placing *an ice cube at 1 °C* on forearm skin for 10–20 min, then rewarming the skin until it returns to a normal T: within 5–20 min an edema appears matching the cube basis (Fig. 8.8). A negative test (and for systemic cold urticaria) is repeated by having the patient stand for 10–20 min in a cooled room at a T of 4 °C [110]. By the end of the test, characteristic wheals and flares develop, especially on the trunk and proximal aspects of the limbs, or giant urticaria [110] in 92% of cases [181]. Children with negative ICT at 10 min had similar symptoms and response to antihistamines as patients with positive ICT. All children with cold urticaria and their parents should be cautioned regarding the risk of anaphylaxis [4]. In selected cases it is necessary to test both cryoglobulins and cryofibrinogen [156].

• In systemic cold urticaria, the ICT is negative and the cooled room test positive. Levels of both histamine and PGD_2 are increased [140, 156]. Measuring blood histamine levels after a negative ICT appears to be a sensitive way to diagnose patients without risk of anaphylaxis during generalized cold exposure [140].

• The prevalence of secondary cold urticaria is 1%; however, we recommend the related screening.

• *Solar urticaria:* a small skin area of 1×1 cm for 1–2 min is exposed to a source of monochromatic light of various wavelengths for 10 min at a distance of 10 cm. If the result is negative the exposure time-lag is increased. Fluorescent tubes, carbon arc, etc., in combination with emission of a broad wavelength spectrum, employing different filters to ascertain which one provokes urticaria [111, 183], are used. A differential diagnosis from erythropoietic protoporphyria requires measuring protoporphyrin and coproporphyrin levels [240].

• *Contact urticaria:* an accurate history and SPTs may disclose some offending agents such as topical drugs, diverse chemical substances, cosmetics, vegetable substances, pet danders, etc. The rub test may confirm the diagnosis, that is the suspected item is rubbed gently on normal skin, and inspected for signs of a reaction at 60 min [117].

• *Vibratory angioedema:* symptoms may be reproduced by gently stimulating the medial aspect of the forearm with a laboratory vortex for 4–5 min or laying a finger-pad on a common tube mixer for 10 min. Positive responders should develop a pruritic circumferential edema, which distinguishes the condition from delayed dermographism and delayed pressure urticaria [42, 111] (Fig. 8.9).

• *Aquagenic urticaria:* challenge tests are performed using tap water compresses at 35 °C or any other T applied to the upper body for 5–30 min. Wheeling is usually evoked at the site of contact with water [129, 238] after 20 min [129]. The condition responded to treatment with UV-B and oral antihistamines [163].

• *Cholinergic urticaria:* to reproduce the eruption, exercise such as jogging on the spot, running on a treadmill in a plastic occlusive suit, running up and down stairs with warm clothes or with an exercise bicycle should be continued until it provokes an increase in perspiration, or by half-body immersion in a hot bath (42 °C) to raise body T. In case of a negative response, an intradermal test is done using 0.05 ml of methacholine chloride at 0.02% or carbachol at 0.002%, which in positive tests induce a localized wheeling surrounded by flushing within 20 min. The test is positive in 33%–50% of patients. However, it is rarely a reproducible test [44, 183].

• *Localized heat urticaria:* a heated cylinder with water heated to 50–55 °C is applied to the skin for 5 min [42].

Chronic Urticaria. Patients are investigated according to the above-mentioned epidemiological data. Following this evaluation, the diagnosis is by exclusion, apart

from cases clearly connected with foods [99]. Neither laboratory data nor SPTs to foods are of value in adults in whom up to 90% of cases remain unassessed [159], whereas the contrary is true in children, both for foods [18, 229] and additives [18, 201, 229]. In a 6-year-old boy with a 3-month history of recurrent, severe angioedema episodes a diagnosis of autoreactive chronic urticaria (ACU) was made after an autologous serum skin test (ASST) [10].

Differential Diagnosis

The differential diagnosis [45] includes the following disorders:

- *Exanthematous infections* in children and EBV, CMV, coxsackie, rotavirus infections, certain infestations by parasites and microbial infections.
- *Papular urticaria,* provoked by insect bites in exposed areas, is characterized by pruritic papules and wheals, with immediate or delayed onset, expressing immunological mechanisms of type I or IV, respectively. The lesions are often located on the lower limbs and tend to persist longer than urticarial lesions, most frequently seen in young children [103].
- *Erythema multiforme,* a self-limited disorder, typically characterized by pruritic urticarial lesions, wholly similar to urticaria in the earlier stages, which last longer and may have a targetoid aspect evolving into bullous lesions. It is more often located on the dorsal surfaces of both hands and feet, frequently misdiagnosed as urticaria.
- *Dermatitis herpetiformis* is seen in children aged 3–7 years. The early lesions have an evident urticarial component. Sites of predilection are the shoulders, elbows, knees and buttocks, often confused with cholinergic urticaria.
- *Urticaria pigmentosa* is a localized mastocytosis occurring in infants and children before the age of 10, with most cases developing in the 1st year of life [12]. Individual macules or papules, and nodular, lichenoid or plaque-like lesions range in color from pink to salmon, and in size from a few mm to several cm, which, when stroked, form a linear pruritic wheal, Darier's sign, the hallmark for clinical diagnosis. The condition usually fades at puberty; a skin biopsy may confirm the diagnosis [45, 61].
- *Juvenile urticaria pigmentosa* occurs at birth or in the 1st months of life and takes the form of a solitary nodule 1–5 cm in diameter (mastocytoma), most often on the back of the hand, wrist, neck, or the lesions may present as disseminated macule, plaques, or bullae, ranging in color from red-brown to yellow-tan. It most commonly fades at puberty.
- *Systemic mastocytosis* is similar to urticaria pigmentosa, but uncommon and more severe. It is characterized by onset in the first few months of life and mast cell accumulation in the dermis, bone marrow and gastrointestinal tract and clinically, by congestion, migraine and hypotension secondary to histamine release [166].

Urticaria as a sign of systemic disease: urticaria may be the only sign of infections caused by bacteria, viruses, yeasts, and molds. Several parasitic infections are causative agents in urticaria and eosinophilia, such as infestations by *Ancylostoma, Ascaris, Echinococcus, Fasciola, Filaria, Schistosoma, Strongyloides, Toxocara, Trichinella,* etc. Urticaria may be associated with malignancy, endocrine disorders (hyperthyroidism, hypothyroidism), and autoimmune disease.

Treatment

Specific management consists in the removal of all offending agents, stimuli, or allergens, and the drug management of possible predisposing or concurrent factors (infections, infestations, etc.), or ongoing problems. A truly specific management is not as yet available, since the etiopathogenetic mechanisms underlying urticaria are largely unknown. A stimulating prospective involves the histamine releasing IgG Aab neutralization by means of soluble FcεRI-α [92].

An *aspecific* or second-line *management* includes the following:

- New-generation nonsedating H_1 *antihistamines,* alone or combined with H_2, are the mainstay of symptomatic management, such as chronic urticaria [192], efficaciously controlled in particular by cetirizine [10], levocetirizine and cimetidine associated with hydroxyzine [192]. Cetirizine and levocetirizine dosage schedules are shown in Table 7.19.
- In a double-blind (DB) study, 31 children aged 2–6 years (mean 3.85) with idiopathic chronic urticaria were treated with cetirizine at a dosage of 5 mg daily, which showed a significantly more rapid resolution of symptoms and itching compared with 31 children treated for the same length of time with oxatomide, at a dosage of 25 mg daily [113].
- Membrane stabilizers such as ketotifen (Chap. 7), which has been found useful in cold-induced and cholinergic urticaria and dermographism after the demonstration that the drug inhibits histamine release at a specific challenge [103]. Similarly, ketotifen was effective in urticaria refractory to antihistamines and in chronic urticaria [101].
- In more severe cases and/or those resistant to other therapies, systemic CSs are required for transient relief [103].
- For pediatric cases of extreme severity, a resort to *Epi-pen* may be suggested [4].

A child aged 10 was treated with ε aminocaproic acid plus montelukast plus ranitidine. This regimen induced a full remission of urticaria in about 48 h. The treatment was gradually tapered in the subsequent months, and after ≈13 months, the boy still remains completely symptom-free [228].

Angioedema. The above-mentioned therapeutic options may be followed. In children with the hereditary form, *danazol* has been demonstrated to be effective at the recommended dose of 20–30 mg/kg/day, with a maximal dose of 600 mg/day [15] for 5 days before and 2 days after the event [35]. Therapy improved serum complement parameters significantly and reduced the frequency and severity of clinical manifestations [70]. Doses of 0.5 g/day of ε aminocaproic acid (EACA) and 1–2 g/day of tranexamic acid are prescribed to prevent episodes in children as needed [35, 69, 70]. Acute, life-threatening edematous attacks are treated by the *administration of C1-INH concentrate,* which achieves the resolution of the edema within several hours [35, 70]. Undesirable adverse effects can be avoided and the *child's quality of life* enhanced dramatically by administering the lowest effective drug dose [70]. In C1-INH deficiency, both primitive and acquired experimental treatment procedures are under study [155]. In cases of laryngeal edema, a tracheotomy will be indispensable. Patients may die as a result of laryngeal edema before a diagnosis is established [247]. Adequate prophylaxis and follow-up care can spare pediatric patients from edematous attacks.

In some patients with Melkersson-Rosenthal syndrome, a remission was obtained with an avoidance diet free of tartrazine and Na benzoate [161], but not in others [142]. Clofazimine, 100 mg, administered orally 4 times weekly for 3–11 months was shown to be effective in several patients [202].

Prevention

A paradigmatic example of *preventive management* is the elimination of stimuli triggering urticaria episodes:

- In *cold urticaria,* cold desensitization by repeated skin exposure to cold until it becomes refractory to challenge has been recommended in motivated patients. A cardinal objective is the prevention of shock reactions during aquatic exposures, including traveling by boat or motor boat, water-skiing and other exposures to cold which lower the body T [233]. In a child with cold urticaria seen by us, protection by a large hat and a scarf was unsuccessful.
- Patients with *cholinergic or generalized heat urticaria* should protect the upper part of their body from excessive heating; also these patients may have recourse to a desensitization with warm baths by gradually increasing water T [44].
- In *solar urticaria* ordinary window glass 3 mm thick will absorb most UV radiation <3,200 Å. Protective garments to cover the skin should be used. Oral β-carotene was useful for type VI of solar urticaria. Types I–V can be prevented, at least in part, by antihistamines or by PUVA therapy [141].
- Subjects with *EIA* should select activities requiring a more modest effort, avoid ingestion of foods and drugs (ASA and NSAID) in the 4–6 h before a planned activity, and carry out physical activity possibly with a partner. Moreover, they should recognize the prodromal signs, to slow down to a minimum or stop exercising [190]. An epinephrine kit (Epi-pen) and medical identification bracelet is mandatory.

In a prospective, DB, parallel-group study of urticaria prevention in 817 children with AD who were 12–24 months of age at study entry, acute urticaria occurred in 5.8% of the children treated with cetirizine, 0.25 mg/kg, and in 16.2% of the placebo-treated children [191].

Allergic Contact Dermatitis

ACD is one of the most frequent skin disorders and the prototype of a delayed type of CMI hypersensitivity reaction: any part of the skin that comes into contact with a relevant sensitizing allergen may be vulnerable. Characteristically, ACD is at first limited to the skin site exposed to the allergen, but the reaction may then spread to other locations. The allergen is brought into skin contact in many ways such as compression, friction, transpiration, humidity and warmth. Lesion severity and persistence are dictated by several factors such as MW, chemical potency, concentration and dose of the allergenic stimuli, site of contact, the frequency, duration and intensity of exposure, and especially the patient's degree of sensitization [82].

Definition

Dermatitis of variable intensity, due to lymphocytes previously sensitized by antigens making contact with exogenous haptens, mostly chemical haptens, at variance with AD, in which allergens arrive by the hematic route. In this reaction, after the first epicutaneous allergen sensitization, Langerhans cells (LCs) take allergens up and migrate from the skin to draining lymph nodes and activate naive T cells in the context of HLA class I or II. Clinical manifestations vary from a transient erythema to edematous papules with vesiculous and occasionally bullous outcome; itching is ACD's distinctive symptom, manifesting with variable intensity [107].

Prevalence

Pediatric ACD is a much more frequent disease than previously reported (Table 5.9). Epidemiological studies supply an ever-growing body of data pushing out the boundaries of the disease, including prematures [76], a *1-week-old neonate* with ACD to the epoxy resin in his vinyl identification band, and a *7-month-old infant* who developed nickel dermatitis to the snaps in his sleepwear [75]. Children as young as 6 months of age may be sensitized to contact allergens with a prevalence of sen-

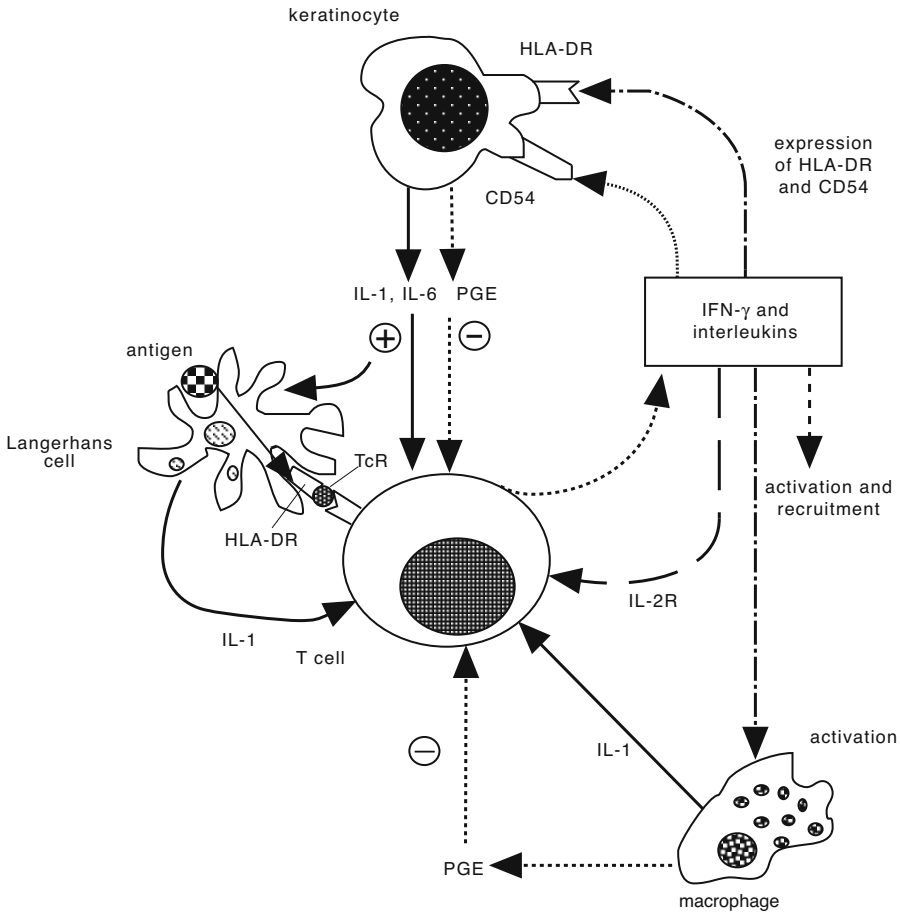

Fig. 8.10.
Cell interactions in ACD.
(Modified from [20])

sitization as high as 24.5% [38]; 43% of children aged 8 (median) suffered from ACD of the delayed type to metals and the like and 6.6% of them to patch-test diagnosed foods, increased up to 20% by an open FCT [154]. The development of contact allergy and ACD increases with age [145, 185] In children aged 3–14, the following positivities were found: 38.8% preservatives, 25% topical drugs and 11%–16.6% fragrances and perfumes [56, 212]. Also, occupational ACD incidence is increased (21.2%) in boys and girls helping their parents in domestic work [7] or work outside the home [85, 199]. These data also complete the ACD natural history in Table 5.9.

Etiopathogenesis

Genetic Factors

Several textbooks assert that ACD is not linked to atopy. On the contrary, atopic sensitization in children and teenagers ranges from 16.7% to 32.6% [7, 56, 85, 199, 212, 214], with peaks of 50% [63], with positive FH between 20.7% [199] and 42.1% [80]. As discussed earlier, a large share of children with AD are also affected with ACD, with a prevalence between 16.7% and 32.4% [7, 56, 63, 85, 212]. Genetics was established by the finding of two monozygous girls with contact allergy, thus suggesting a genetically determined selection process during development of the peripheral T-cell system [206].

Histopathological Aspects

In the acute forms, within 6 h from allergen exposure, perivascular infiltration of lymphocytes and monocytes are seen in the highest dermal layers. Subsequently an intracellular and intercellular edema develops in the epidermis, thus causing spongiosis. Chronic lesions are characterized instead by hyperkeratosis, and in the dermal superficial layers by a dense monocyte and basophil infiltration [107, 138].

Immunological Aspects

Though humoral immunity may participate in ACD pathogenesis, this depends above all on allergen-specific T cell activation stimulated by chemical substances of low MW, which are haptens and therefore need to link with proteins called carriers in the skin before they become antigenic and acquire immunogenicity (Fig. 8.10)

[20]. These circumstances result in a cascade of inflammatory events leading to the development of dermatitis or, after a diagnostic FCT, to a hypersensitivity reaction [20]. ACD can thus be classified as a delayed type of hypersensitivity (DTH) reaction, in other words, a stage of hypersensitivity associated with an increased number of allergen-specific T cells able to invade the peripheral tissues [105]. The series of immune events that induce ACD implies the interaction, at an undetermined site, between T lymphocytes and *epidermal CD1⁺ LCs* (Figs. 7.1, 7.2), functionally immunocompetent ($CD1^+/IgE^+$) cells. Early and important participants in the induction of ADC, LCs act as APCs in the initiation of a type IV immune reaction [207]. Mobilization of dendritic cells (DCs) occurs in response to local generation of proinflammatory ILs such as IL_1 and TNF-α. Activated DCs express high levels of CCR7, HLA antigens, and costimulatory molecules (CD40, CD80, CD86) [33]. Sensitizing allergens contacting the skin activate T lymphocytes. To a subsequent cutaneous contact the duo hapten + carrier is taken up, processed and expressed on the surface of LCs bearing class II HLA-DR molecules [23]. After the allergen-HLA complex presentation, LCs migrate out of the epidermis into the dermis and then into draining lymphatics and on to regional satellite lymph nodes. Within 4–6 h of hapten application, LCs congregate in T-dependent zones; within 18–24 h a great number of LCs are in the draining lymph nodes to present the processed antigen and transfer the sensitization to a large repertoire of specifically sensitized CD4 T lymphocytes bearing CD3 receptors that undergo proliferation and clonal expansion [207]. The antigens interacting with HLA molecules emit the first signal for lymphocyte activation, and the second signal is represented by IL_1 produced by keratinocytes and LCs with the primary function of activating T lymphocytes. This results in the clonal proliferation of antigen-specific memory T cells with the phenotype of $CD4^+$, CD45RO, CD45RA, which yield a number of ILs, including IL_2 and IFN-γ [207]. The coincident presence of both ILs corroborates the conclusion that they are the product of CD4 Th1 specific for contact antigens, in parallel with the delayed reaction of AD [105]. *Keratinocytes* with their HLA-DR antigens and CD54 (Fig. 8.11) act as target cells for activated T cells, and the inflammatory IL they produce attract PBMCs in an allergen-nonspecific way [20]. During the induction phase, the CD4 infiltrated in the dermis proliferate and differentiate into effector cells and release Th1-like ILs (Table 1.10), capable of inducing capillary vasodilation and permeability increase, thus leading to the allergic skin inflammation [207].

Th1 T cells dominate and amplify the generation of cytotoxic allergen-specific CD8 lymphocytes (CTLs), which leads in the final analysis to cutaneous lesions. As seen from studies on the animal model, both mediate type IV immune responses, Th1 with class II HLA, and CTLs with class I HLA. Suppressor CD8 T cells are subsequently generated, although in a lesser number,

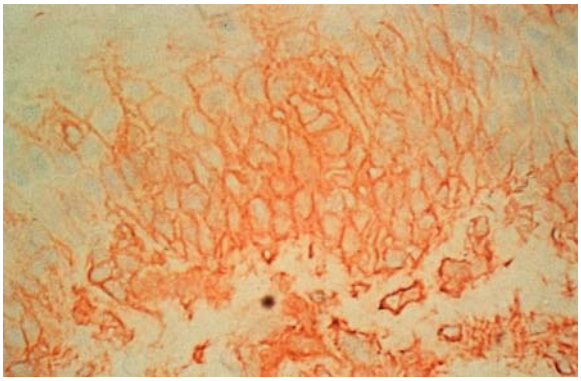

Fig. 8.11. Keratinocytes expressing HLA class II in ACD

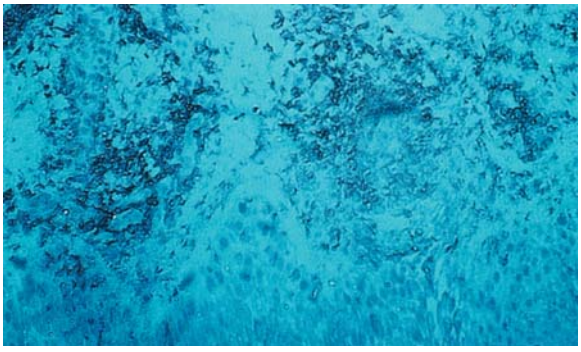

Fig. 8.12. The majority of T cells infiltrating the allergic patch test after 96 h are CD4

thus achieving a balance between sensitization and tolerance, orchestrated by a complex suppressor circuit acting on both afferent and efferent pathways of the DTH reaction [23]. Looked at in more detail, whether sensitization has an effect either on Th1 or Th2 activity depends on the exposure intensity and LC integrity; however, there is no numerical difference between the different T-cell subpopulations in the various phases so far delineated [211]. Intercellular connections are ensured by β1–β3 integrins (Tables 1.45–1.47), which allow cells to migrate into the skin, and IFN-γ-stimulated endothelial cells express CD54, more adhesion molecules and class II molecules [251]. This leads to preferential PBMC migration from the bloodstream to the inflamed skin lesions, and circulating T cells, by expressing their ligands such as CD11a/CD18 and CLA, recognize CD54 on endothelial cell and keratinocyte surface membranes activated by IL_1 and can bind these cells [20, 251]. Moreover, PBMCs of patients with ACD presenting antigens to autologous T cells can stimulate the proliferation of the two different subsets, $CD45RO^+$ and $CD45RA^+$, potentially recognized by two different epitopes. However, $CD3^+$, CD45RA and CD8 T cell responses are absent [23]. $CD45RO^+$ $CD4^+$ T cells stimulated by antigens reach the maximal expression at 96 h (Fig. 8.12), thus suggesting that they are able to induce immediate cutaneous reactions in patch test sites [23].

Modified from [104].
ND not done.

Metachromatic cells are involved in ACD: the cellular infiltrate can contain up to 10% basophils and 40% mast cells, activated by IL released by T lymphocytes, and they amplify the reaction by dilating capillaries [107]. *Basophils* principally are seen transiently: at 48–72 h large numbers of basophils are seen within the skin blood vessels, but their exact role is far from elucidated [107]. *Macrophages* invade both dermis and epidermis also at 48 h, and contribute to calming the reaction by producing either PGE, which inhibit IL_1, IL_2 and NK cells, or LTB_4 inducing T CD8 cells, which further progressively calm the reaction. Therefore both hapten size and its capacity to steadily bind a carrier protein appear to be important factors in immunogenicity [107].

Tables 8.6 [58, 128] and 8.7 [104] show the production of ILs by keratinocytes and LCs [82, 128] and by nickel (Ni)-specific T lymphocyte clones in an ACD response. It is surprising how many ILs are produced by keratinocytes: Ni-sensitive patients produce both IL_4 and IL_5, but the nonallergic patients have elevated levels of IFN-γ. A recent study [82] showed that $IL_{1\alpha}$,and $IL_{1\beta}$ are among the several ILs produced in the skin after contact by an immunizing agent, which potentially primes the synthesis of more chemotactic ILs involved in ACD and IL_{10} [71, 128], which instead inhibits the reaction. In particular the keratinocyte-produced IL_{10} may down-regulate DTH, thus terminating the response, which is instead up-regulated by its inhibition [71]. TNF-α stimulated with UVB propitiates the reaction by its proinflammatory and vasodilatory effects, but may be critical in inhibiting the migration of epidermal LCs [104], which produce few ILs [128]. Chemokines such as RANTES and MIP-1β may recruit a higher level of T lymphocytes, with a further increase in local mediators [203].

A distinctive type of reaction involves *Ni*. Ni-specific T lymphocyte clones recognize the antigen only on the cell surface of LCs in association with HLA class II molecules, whereas they were unable to recognize Ni when presented by monocytes. Therefore, there may be a direct and non-HLA-restricted recognition by T-cell clones; thus Ni might interact directly on the T cell surface structure, with consequent activation and proliferation of these T cells. Since HLA class II molecules are polymorphous and contain mostly three subtypes, all heterozygotic subjects inherit two different alleles for each of these three subtypes, so Ni may be associated with up to six different HLA class II determinants presented by APC, although it is difficult to identify the precise determinant involved [105]. See in the next section that oral Ni administration may have important suppressive effects in the recipients [76].

Etiological Agents

A plethora of compounds hold a top position as ACD causative agents, some, such as dinitrochlorobenzene (DNCB), exercising their action indiscriminately, while others are much more selective. The more frequently induced substances are summarized in Table 8.8 [7, 56, 57, 63, 85, 131, 149, 199, 212], and Table 8.9 [20, 131] shows the sources of sensitization as related to their topography. On the drug panorama, we give concise indications since Chap. 19 discusses the topic at length, and latex dermatitis is analyzed below. We examine the technomarketing particularities related to the most diffused haptens [7, 52, 57, 80, 131, 138, 173, 227].

Data from [131] on 29,499 patients and [57] on 18,822–20,791 (age unknown) [57, 131]; on 1,370 patients from the US and 780 from Canada [149]; pediatric data on 244 nonatopic and 47 atopic children aged 4 months to 16 years [7]; [85] on 69 reactions in 53/214 atopic children and two studies in children aged 3–16 years [56, 199, 212], in comparison with 34 reactions in 28/143 nonatopic children and 47 reactions in 424 schoolchildren aged 7–12 years [63].

Balsam of Peru: vegetal fragrance containing principally benzylbenzoate, benzoic acid, cinnamyl alcohol, eugenol and vanillin. It is used in:

- Emollients, medical creams and ointments, powders, tinctures, suppositories, healing preparations and for burns (due to antiseptic and/or keratoplasty actions)
- Straps and paints due to its adhesive action
- Perfumes and cosmetics (after-shave lotions, brilliantine, creams, face powders, deodorants, infantile cosmetics, lipsticks, lotions, perfumes, soaps, toothpastes, etc.) as fragrance
- Tobaccos
- Drugs (balsamics, cough syrups, emollient lozenges, topical drugs); liquid cement for dentists
- Foods (as aromatizing in food industry) such as aperitifs, baked goods, bitters, chewing gums, candies, chocolates, cola, cocktails, ice creams, orange squash, pâté de foie gras, sauces, vanilla, products containing

Fig. 8.13. ACD provoked by resin

Table 8.9. Location of common allergenic ACD contactants in relation to body sites

Regions	Allergenic substances
Face	Soaps, face powders, cosmetics in general, perfumes, cleansing milks and creams, shaving creams, razor blades, cosmetic lotions used after and before shaving, crash helmets, frames, nebulizer masks, antiallergic masks (Chap. 11), sun creams (hand dermatitis usually appears first), topical medicaments
Scalp[a]	Hair lotions, lacquers, lotions, brilliantine, hair tonics, anti-dandruff products, hair dyes and curling agents, earrings, bobby pins, hair clasps, wig adhesives, hats, caps
Forehead	Cosmetics, hair lotions and shampoos, hat bands, cap bands, anything applied to hair
Eyelids	Eye and face cosmetics and cleansing milks, facial creams, eye shadows and make-ups, eyelash dyes and curling agents, medicaments: collyrium, eyewashes and ointments, contact with fingertips
Ears	Earrings and ear piercing, pendants, earpieces for portable radio, etc., earplugs, hearing aids, earphones and cellular receivers, ear preparations, topical medicaments, medical eardrops
Lips and perioral areas	Ointments in general, lipsticks, lip protectants (both sexes) and lip pencils, chewing gums, toothpastes, mouthwashes, nail polish (contact with fingertips), foods (see contact cheilitis), toilet paper, tobacco smoke, latex, metals, also related to ear piercing
Neck	Perfumes, necklaces (nickel), garments, sweaters
Armpits	Deodorants, depilatory creams, textile fibers, tinctures, topical medicaments, antiseptics
Arms	Watch cases and related watch bands, textile fibers, metals, plants, tinctures
Hands	Cosmetics, lotions, creams and sun creams, metal jewels, metals, plants, cleansing agents, soaps, leather, rubber and latex gloves, metal, rubber and latex handled objects and materials and irritants encountered at work, topical medicaments
Body	Perfumes, bath salts, cosmetics and detergents in general, metal parts of garments (buttons, zippers, etc.), shoulder straps, brassiere clips, textile fibers, leather, rubber and latex dresses, rubber in elastic of garments, dyes, formalin and resins in garments, douche additives, plants, topical medicaments
Genitalia	Infant diapers, briefs, topical antiseptics, antibacterial and antifungal drugs, disinfectants in general, (women) contraceptive creams or jellies, menstrual pads or tampons, preservatives, deodorants, rubber diaphragms (men), remedies, latex condom, vaginal agents used by partner
Anal area	Textile fibers, topical medicaments, suppositories, remedies and ointments
Legs and thighs	Stockings and drawers, leotards, leather dresses, boots, textile fibers, rubber, clips of garters and other metal parts, depilatory creams, topical ointments and medicaments
Feet	Shoes, rubber shoes, shower sandals and slippers, tinctures, shoe waxes, buckles, textile fibers, deodorants, topical foot remedies, plants

Data from [20, 131].

[a] Since the scalp is relatively resistant to dermatitis, hair preparations generally cause dermatitis mostly on the forehead, scalp edges, neck, and sometimes also shoulders, i.e., on hair-free skin.

citrus peels (orange jam, cakes with candied fruits, etc.), confectionery products with spices, perfumed teas

Colophony (Fig. 8.13): a resin obtained from different conifer species, one of its derivatives is turpentine oil. It is found in:

- Electric insulators, pharmaceuticals, soldering materials, such as patches, plasters, and products of common use, including soaps and cosmetics, in addition to adhesives, depilatories, dressings, mastics, nail polish, shoe wax, stickers, tape, varnishes, watercolors; cleaning compounds (furniture and floors), lacquers, surface coating, paints, paper boxes, resins, and printing inks

Turpentine: oils, resins and varnish solvents, is found in:

- Perfumes, bath salts, soaps, shaving-creams, toothpastes
- Insecticides
- Expectorants by mouth, antirheumatic and rubefacient liniments

Parabens mix: substances with antioxidant, antifermentative and fungicidal power, found in cosmetics, drugs and foods as preservatives; are present in:

- Preservatives found in many dermological creams, pastes, face powders, cosmetics, sun-creams, toothpastes, cleansing milk and creams, hair lotions, lipsticks, soaps

Fig. 8.14. ACD provoked by Ni in earrings

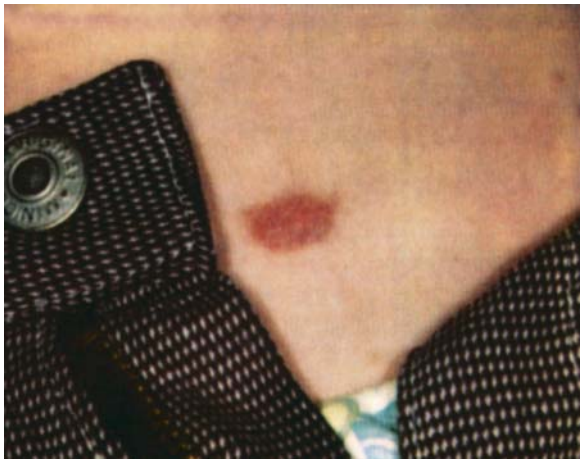

Fig. 8.15. ACD provoked by Ni in fasteners

- Bandages, collyrium, nasal drops, antifungal pomades and for varicose veins, ointments
- Floor wax
- Foods: canned fish, caviar, fruit juices, lemon- and orange-squash, mayonnaise, smoked salmon
- Parabens can also cross-react with compounds of the "para" group (Chap. 19)

Nickel sulfate and chloride (Figs. 8.14, 8.15) is one of the most common sensitizers in our environment contained in nickel-plated manufactured products of common use such as:

- Coins (euro cents), door handles, drawing-pins, earrings, inks, keys, lighters, metallic parts of watch-straps, needles, paper-clips, pencils, pins, safety-pins, scissors, spectacle frames, thimbles, tweezers, utensils, watch-cases, etc.
- Identification bracelets (maternity wards), particular groups of patients, also allergic children.
- Dental prostheses, orthodontic instruments, and low-weight gold alloyed with Ni used in dentistry.
- Clothes accessories such as bobby-pins, buckles, buttons, clips, fasteners, clothing and hair clasps, shoe laces, safety-pins, zippers.
- Costume jewelry since nickel-plating precedes gold-plating (bracelets, earrings, jewelry of white and yellow gold, medals, etc.); some children may be exquisitely sensitive to even Ni traces found in gold jewelry.
- Colorings for cosmetics, for example eye-shadows.
- Curling instruments for eyelashes and hair.
- Door handles, handles of electric appliances, stainless steel pots or enameled pots (especially in blue or green), as well as pottery, insecticides, plastics.
- Dyes, metallic paint, mordents, paints, shoe waxes, wallpapers.
- Young children and girls have a high risk of sensitization at the time of ear, nose, and tongue piercing and subsequently [130] (the Italian press reported on March 12, 2003 the case of a 24-year-old who probably died of a fulminating hepatitis after a tongue-piercing).
- Ni can contaminate foods cooked in chipped pots or pickled in metallic containers or cans.
- Can be found in raw and canned foods, for some of which we give the Ni content in μg/hg [173]: lentils 310, white beans 285, rye 270, peas 225, cocoa and chocolate 220, peanuts 160, raspberry 40, herrings 30, jam 25, potatoes 25, white wine 10, CM and derivatives 5, as well as asparagus, beer, butter, carrots, Brussels sprouts, cabbages, corn flour and whole meal, hazel nuts, margarine, mushrooms, onions, oysters, pears (also cooked), popcorn, raisins, rhubarb, soy, spinach, strawberry, tea, tomatoes, walnuts, yeast (artificial), etc., in addition to traces in cleansing tools.
- It is known that sweating may release Ni ions from metallic objects. The metallic containers for food preservation should no longer affect Ni content, since Ni contact is now avoided by means of an internal coating formed by a layer of acrylic or epoxy polymeric resins, as for enameled pots. Instead, wearing Ni-releasing orthodontic braces induces by immunosuppression tolerance to later Ni contact, provided that fitting of braces is absolutely not preceded by further Ni contacts, for example ear-piercing [130, 221]. We stress that in Denmark *the use of Ni has been banned since June 1989* in belts, buttons, frames for glasses, hair-clips and bobby-pins, costume jewelry in general, watch-cases and related watch-straps, zippers, and any object touching the skin; violation of the ban carries a 1-year sentence of imprisonment.

Potassium (K) *bichromate:* is employed:

- In chromed alloy and manufactures.
- In leather tanning.
- As cloth dye, such as in military green fabric and billiard- and card-tables.
- As anticorrosive in paints, oils and refrigerant fluids.
- As a catalyst in acrylic resin synthesis.

It is contained in:

- Objects of common use such as colored pencils and pens, fragrances and deodorants, magnetic tapes, match

heads, paper money and wall-paper, shaving-creams and razor-blades.
- Bleaches, cleansing creams, detergents in general, floor waxes and other products, porcelain, pots, shoe polish.
- Leather objects, shoes.
- Fixatives, inks, photographic chemicals.
- Rubber objects and artificial flowers.
- Foods in traces (apples, beer, bread, canned cereals, chocolate, eggs, frozen peas, mushrooms, onions, potatoes, plums, raisins, watercress, wholemeal).

Cobalt chloride (CoCl) is found in almost all bichromate materials, moreover:
- In galvanized manufactured products.
- As catalyzing in rubber synthesis, acrylic resins and polyesters.
- As Ni impurities.
- As an alloy in joint prostheses.
- In adhesives, artists' paints, buttons, ceramic and plastic paints, coins, colored pencils, costume jewelry, eye shadows, inorganic pigments in inks, hair dyes, linseed oil-based paints, tattoo pigments, watch straps, wet cement, zippers.
- In Ni-containing accouterments on clothing.
- In anti-perspiration creams, flypaper.
- In vitamin B_{12} preparations and in mineral tablets.
- In foods, namely apricots, beans, beer, beets, bread, cocoa, cabbages, chocolate, cloves, liver, nut, tea, wine [125].

Chrome (Cr) in small amounts is present in cigarettes and in objects of common use:
- Alloys for tooth prostheses, bleaches, cement, ceramic paints, detergents, flypaper, fireworks, floor wax, green felts, matches, military green fabric, pots, razor blades, safety matches, shaving creams, shoe polish, wood ashes and stain, wallpapers.
- As a water and flour pollutant: small amounts are found in mineral waters.
- In foods: apples, beer, cocoa, canned cereals, chocolate, eggs, fish, frozen peas, meat, mushrooms, onions, potatoes, plums, raisins, spices, tea, watercress, wholemeal, wine [125].

In industry:
- As fore-gilding of raw textiles and chrome-tanned leathers (also with Cu and tannins).
- In typo-lithography: auto-implants, fixatives, inks, photographic chemicals, special papers.
- In mechanics: anticorrosive oils and greases, antirust dyes, cooling mixtures for motors, metallic alloys, welding materials.
- In galvanizing processes: aluminium coloring, chromium plating, electroplating, polishing.
- In colors, enamels, dyeing, oil paints and distempers.

Copper (Cu) is a minor sensitizer found in bronze, brass, and other alloy objects, also of common use:
- Pots for polenta, coins, costume jewelry, electric materials, green eye shadow, intrauterine contraceptives.
- Acaricides, antiparasitics, astringents for mouthwash and lotions, fertilizers, fungicides.
- Foods in traces: beer, clams, edible mushrooms, lentils, mussels, oysters, shrimps.

Paraphenylenediamine (PPDA): is employed in:
- Color film developers, inexpensive fabrics and furs, lubricating oils, permanent black or dark hair dyes, dyed textiles, etc.
- As an accelerator and antioxidant: rubber, catalyzers for resin synthesis.
- Antioxidant in gasoline, oils, lubricating, printing inks and cartridges for printers (computer), reagents for photography, lithography and radiography.
- Cross-reactivity with other substances of the para group such as local anesthetics (benzocaine, procaine, etc.), sulfonamide drugs, aniline dyes and PABA (*p*-aminobenzoic acid) used in sun screens (creams, lotions, ointments) and in several cosmetics, including eye shadows, lipsticks, hair balsams, nail varnishes, shampoos. PPDA oxidizes rapidly in contact with atmospheric oxygen, but this reduces its allergenicity only slightly.

Ethylendiamine: stabilizer found in cosmetics and topical drugs (antihistamine ointments, eye drops, nose drops, lotions for itching eczema), in fungicides, insecticides, and preservatives in creams, as a catalyzer for resin synthesis, as well as in anticorrosive and antifreeze agents, solvents, etc. It can cross-react with aminophylline, hydroxyzine, prometazine, etc.

Formaldehyde is a chemical widely used as a disinfectant, while formalin, a 27% aqueous solution, is used to treat allergens to produce allergoids. Formaldehyde antigenicity was recognized as early as 1914 [116]. It is found in:
- Bactericides, denatured alcohol, fabric softeners, fungicides, oral disinfectants, preservatives, and in antitetanic vaccines.
- Cosmetics in general, deodorizers, nail hardeners, permanent fluids, soaps, shampoos, toothpastes, etc.
- Plastic packing (demopac) for foods prepared in advance, from which residual amounts are naturally released.
- Enamels, glues, pastels, tanning agents, tempera painting, in dry-cleaning as a spot remover, in typography, etc.
- Adhesive strips to apply wall-to-wall carpeting, textile finishes.
- Insulating materials, plywood paneling and wrinkle-resistant clothes.

We underline its hidden presence in carpets, cigarettes, insulators, paper tissues and serviettes, towels, and other paper products also for toilet or medical supplies, preservatives employed in the pharmaceutical and other industries, disinfectants also for housework, and as a monomer in butylphenol-formaldehyde resins used in adhesives, corsets, glues, leather goods, products to protect color fading in clothing articles and in underwear elastics or as sizing, crease-resistant and/or waterproof finishes. However, that contained in shampoos

and liquid soaps is a rare cause of ACD since it is rapidly diluted and rinsed.

Mercury (Hg) includes different compounds, all cross-reacting between themselves, employed in medicine and cosmetics:

- Mercurochrome, phenylmercuricborate, etc., are used as disinfectants for small wounds and in lipsticks.
- Thimerosal is a topical antiseptic employed as an ingredient of germicides, cosmetics, eye shadows, preparations for dentists, eyewashes and nasal drops, contact lens cleaning and wetting solutions (Chap. 14), etc., as preservatives in pharmaceutical preparations, including vaccines and sera, and as a rubber accelerator.
- Yellow oxide (HgO) is a topical antimicrobial employed for eye applications and as caustic, cicatrizant, etc.
- Bichloride ($HgCl_2$) is employed in amalgam fillings, contraceptives, electric materials, lubricants, thermometers, etc.
- It is also found in aniline colors, textiles, etc., for leather, felts, furs, wood preservation, in photography and printing.

Topical medicaments

- Benzocaine, a local anesthetic, can be found more or less commonly in medicaments reducing pain, itching, or stinging, cuts, burns, insect bites, rashes, sunburns, toothaches, and in hemorrhoidal preparations, cough syrups, throat lozenges (cross-reacts with PABA).
- Neomycin is present in over-the-counter antibiotic creams, eyewashes, lotions, many skin, ear and nose products, medication powders, ointments and some types of measles vaccines (Chap. 9). It is also a component of deodorants and toilet soaps. Other aminoglycoside antibiotics such as gentamicin, kanamycin and streptomycin may cross-react.

Benzalkonium chloride is a quaternary ammonium cationic detergent with manifold applications as a preoperative skin disinfectant, for disinfection of surgical instruments, and antimicrobial preservative in nasal sprays, ophthalmic medications, solutions for contact lenses (Chaps. 12 and 14), but also in house cleaning products. However, it frequently induces irritant reactions and may cross-react with curariform preparations employed in general anesthesia (Chap. 20).

Disinfectants include (in addition to thimerosal and benzalkonium chloride):

- Betadine, a skin disinfectant used for burn or wound dressings, etc.
- Chlorhexidine hydrochloride, a topical disinfectant found in skin cleaners, gingival washes, cosmetics, deodorants, etc.
- Dequalinium chloride, employed as benzalkonium chloride, is present in throat lozenges.
- Menthol, alcohol extracted from peppermint, is perfuming and revulsive, used also as antipruritic in cosmetics and pharmaceutics or in inhaled medication for respiratory diseases.

Fig. 8.16. ACD provoked by rubber shoes

- Gentian violet, coloring employed also as an antimycotic mostly in topical applications; however, it is sensitizing, and cross-reacts with bright green.

Fragrance mix is a frequent ingredient of after-shave lotions, beauty creams, cosmetics, soaps, sanitary napkins, shampoos, toiletries, toothpastes, and in household products such as deodorant sprays, detergents, polishes, and solvents. It contains cinnamic alcohol, cinnamic aldehyde, eugenol, geraniol, etc.

- Cinnamic alcohol is utilized as a fixative of mixtures based on jasmine, hyacinth, lilac, narcissus and rose perfumes, as deodorant at 12.5 % solution in glycerin and in the soap industry.
- Cinnamic aldehyde is used to give a cinnamon flavor to foods, drinks, pharmaceutical products (it is a valid anti-mold for syrups) and to formulate synthetic perfumes.
- Geraniol is found in flavors used in foodstuffs and soaps, and is also used in the color composition in rose scale.

Rubber additives (accelerators, antioxidants): essentially thiurams and mercaptobenzothiazole (MBT) and benzothiazole bisulfide (BTS) and diphenylguanidine (DPG). They are found in almost all rubber objects, including boots, galoshes, shoes (Fig. 8.16), adhesives, brushes, condoms, elastic bands of all types, especially for undergarments, electric cords, gaskets, germicides, gloves for housework, physicians, and health care workers, inflatable mattresses, insulating tapes, oil, paints, rubber bands, rubber mattresses, soaps, shampoos, tool handles, etc.

- MBT (mercaptobenzothiazole) is a preservative found in disinfectants, fungicides, bactericides (in foods, creams, soaps, sprays), a vulcanization accelerator, an anticorrosive agent in cutting oils such as antirust and antifreeze fluids, and in tires of black color, such as those of cars.
- Thiurams have fungicide actions, and as bacteriostatics are used in foods, soaps, creams and sprays, and in antiparasitics and pesticides.

• DPG, a rubber vulcanization accelerator, is found in boots, elastic bands for undergarments, gloves, preservatives, and elasticized fabrics (with textile fibers interwoven with elastic), etc.

Epoxypolymeric resins are found in adhesives, coatings, dental cements, glues, and in the inner coating of tins for preserved foods.

Ni sulfate reached the highest figures in two cohorts, from 14.9% [84] to 23.7%, with a peak incidence among children aged 1–3 years of 39% [179]. Two children aged 4–6 elicited positive reactions to Ni sulfate contained in medication [47], a 4-year-old girl to Cu present in toys, and a boy aged 11 to turpentine contained in pastels [80]. Several waxes, rubber, spices and flavoring agents provoke contact urticaria and are summarized in the Appendix 8.1 [184].

Allergic Reactions to Ingested Allergens

Several causative agents of ACD can exacerbate clinical manifestations if ingested with foodstuffs [125]:

Co: Absorption in the gastrointestinal tract appears to be particularly rapid, owing to sudden relapses after FCT.

Cr: Even if we ingest 25–300 µg/day, Cr concentration in the organism is low, therefore the role of Cr contained in foodstuffs is controversial.

Ni: High content in the above-mentioned foods. It is estimated that we ingest 150 µg/day of Ni and the absorption in the gastrointestinal tract is 1%–5%, sufficient to aggravate ACD and provoke urticaria and/or wheezing (Ni asthma) [221]. However, it is unknown how much Ni is released by orthodontic instruments and the like [221]; remarkably, oral Ni administration may induce a high frequency of anergic T cells with persistent suppressor activity [9].

Clinical Presentation

ACD is initially located in the skin sites exposed to allergen contact, often a diagnostic distribution, although it may subsequently spread to other sites. ACD can be divided into acute and chronic forms [138].

Acute Forms

At first the lesions appear on the more exposed skin sites, where the contact is easier. Common sites of ACD are under rings, earrings and sites of ear-piercing, spectacle frames, bracelets, necklaces, coins in pockets, jeans studs, and other sites of metal contact (Figs. 8.13–8.16), and clinically the ears, neck, finger interdigital or dorsal aspects, or forearm back, the hand dorsal region, less the palms, face and less obvious sites are the lower limbs. Within 15–20 min of contact the lesion begins to itch. Dermatitis is characterized by macular erythema and papules due to vasodilation, vesicles or blebs related to intensity of allergic reactions and to the tendency to flood from the contact site. The dermis shows perivascular leukocyte infiltration and edema. In some parts, for example, the eyelids, penis and scrotum, both erythema and edema predominate on the vesicles: above all the edema may be particularly intense. Lesions may remain circumscribed or, due to persisting exposure, spread even to far regions by an involuntary contact or in certain cases by self-contact. By progression of the inflammatory reaction, the skin becomes hyperpigmented, small vesicles appear, which result in exudation, transudation, crusting and subsequent scaling. Itching is a symptom invariably present and mostly intense. The dermatitis may appear later, with different localizations, by hand transfer; palms and soles and scalp are frequently spared, due to either the greater thickness of the corneum layer or an increased barrier function [7].

Chronic Form

If allergen exposure persists, the skin undergoes an epidermal hyperplasia evolving into hyperkeratosis and acanthosis when the leukocyte infiltration spreads via the epidermis and basal or corneum layers, then to the features of long-standing AD, with lichenification, scaling, fissuring and crusts [7].

Systemic forms include pompholyx (vesiculous-bullous relapsing dermatitis, limited to fingers, palms or soles), the baboon syndrome (common involvement of the buttocks, accompanied by an eczema-like and symmetric eruption on the elbows, armpits, eyelids and lateral neck region) [138], following ingestion or absorption of Ni, Cr, Co, due to metal prosthesis [7] or provoked by medications first applied topically and then ingested by mouth [227].

Types of ACD

Studies on the prevalence of localization of ACD lesions in two pediatric case reports have recorded the lesions as follows: generalized in 15.8%–22.5% of cases, if localized: face 8.3%–8.9%, face and neck 42.3%, mouth 35%, limbs 35%, upper limbs 25.2%, hands 13.3%–45.9%, lower limbs 3.6%, feet 5.4%–20%, hands and feet 3.3%–8.9% [170, 185, 199]. Other children had foot eczema in 27.7% of cases [7] more often than on their hands [214] and on the hands in 5%–6% of cases [63]. The 13 main types of ACD are as follows:

Diaper dermatitis peaks at age 9–12 months. The skin may become erythematous and scaly and in more severe cases exhibits a papulovesicular or bullous reaction, which extends to external genitalia and buttocks, usually sparing the genitocrural folds. The lesions may spread

beyond the diaper area to the lower abdomen and to the thighs, often complicated by secondary infection. This is certainly the most common contact dermatitis in infants, the prototype of irritant contact dermatitis (ICD), a reaction to the irritant and protracted action of ammonia deriving from urine left too long in the diaper, overly acidic feces, traces of soaps and detergents from an inappropriate cleansing of the diaper area, deodorants and preservatives in the absorbent diapers, ointments and oils, medicated or not, applied several times a day for emollient and anti-irritant purposes, and frictions, washings and wiping, often favored by the occlusive effect of plastic diapers [7]. This dermatitis is commonly treated, over a long period, with various topical medications, some potentially allergizing, for example, casein in a diaper ointment (Chap. 9).

Contact cheilitis is more frequent than stomatitis because the transition epithelium and lesser moistening by saliva facilitate sensitization. Milder cases are caused by lip dryness, chapping and lip licking, and in most severe cases it is intumescent, with erosions and crusts. Cheilitis stems from irritation provoked by:

- Foods, especially artichoke, carrot, cheese, citrus, fennel, kiwi, mango, peach, tomato, fruit juices, etc.
- Topical medications, toothpaste, lip salve, lipsticks, cosmetics.
- Mouthwash and cough syrups, candied fruits and foods containing menthol.
- Preservatives contained even in cold drinks and ices.
- Nail polish, nail enamel and nail hardening for onychophagists; eyelid involvement is unique for nail-polish sensitivity.
- Saliva may be irritant when children lick or bite their lips too often, or suck candies or chewing-gum [172].
- Lip contact with nickel-plated objects [47].

Toothpastes often contain cinnamon, carnation essence, menthol, eugenol, etc. Lipsticks may contain dyestuffs such as fluorescin and eosin, as well as antioxidants, carbamate cinnamon, lanolin, methylethane, oleic alcohol, and perfumes; lipsticks and lip salve contain carmine and lanolin. From cinnamon is derived an oil cross-reacting with balsam of Peru, benzoin, colophony, vanilla and essential oils of orange peel [138].

Contact stomatitis. The skin, differently from mucosa, has several proteins in the keratin layer, which may act as a carrier for hapten-sensitizing molecules. It is characterized by burning, pain, taste reduction up to ageusia and paresthesia. Unlike the substances previously listed, when the contact involves the mouth cavity, the oral mucosa lesions vary from a barely perceptible enanthem up to a dark red coloration with edema and ulceration, which may limit ingestion of foods and drinks, talking, and occasionally breathing. The direct application of offending allergen may provoke local lesions of the urticarial type, generalized and even anaphylactic. Especially at risk in sensitive subjects are the widely used metals in dentistry [6, 224], such as, Ni, Cr (present in wires and alloy) [224], Hg (capping amalgam) [6], further toothpastes and mouthwashes, rubber, essential oils, preservatives, etc. [6]. Recovery is assured by removing instruments with Ni and/or Cr [224].

Other contact dermatitis of the mucosa [138]:

- Conjunctivitis.
- Contact balanitis is a glans pruritic erythema, often accompanied by preputial edema, derived from soaps, products for personal hygiene, condoms and related detergents and lubricants, too close-fitting underwear.
- Contact vulvitis has an onset with pruritus and edematous, erythematous, oozing lesions, limited to the area of contact with the etiological agent, which may become chronic when it persists for a long time. Common causes are soaps, bubble baths (and related additives), hygiene sprays, products for vaginal irrigation if insufficiently diluted or frequently employed, spermicidals, the partner's condom, perfumed toilet paper, too close-fitting sanitary napkins, underwear, and contact with clasps, hooks, and zippers with Ni.

Shoe dermatitis, caused by rubber and tennis shoes, boots, etc., due to a combined action of Cr and Co (tanned leather), Ni (metal decorations) and Hg, present in the upper and/or lining parts. It affects the sole (59%) and dorsum of the feet (41%) and toes (29%), sparing the interdigital spaces [214]. Most often the lesions are symmetric. Common allergens in rubber shoes and boots are thiomersal [214], MBT, BTS [102], thiurams, carbamix [48], mercaptans and PPDA [56], and a shoe glue with 6.2% of reactions [7]. The condition is worsened by excessive foot sweating.

Clothing dermatitis depends on a wealth of sensitizers, including dyes, fabric finishes, mordents, resins, rubber antioxidants, detergents, especially cleansing solutions, synthetic fibers, wool fabric, linen, garments, socks, shirt collars and cuffs, and elastic in garments. Obese children are more at risk. Nitric substances and poorly fixed dyes may be leached out by sweating. Clothing and accessories are implicated in 17% [7] and 56% [56] of pediatric cases.

Dye dermatitis (known since 1938) [86]. As in the clothing dermatitis, the affected areas are those where contact is prominent: neck, trunk, lateral and thigh posteromedial regions, popliteal space, antecubital space, the upper point of contact of stockings, or where other body parts come into contact with bed linen.

Dermatitis from plastic materials particularly include epoxypolymeric resins, diluent and thickenings used in dentistry (epoxyacrylate, methylacrylate and dimethylacrylate metylenglycol) [6]. Artificial nails based on acrylate (similar to that employed in dentistry) can cause long-lasting finger burning, tingling, and paresthesia related to tactile sensitivity [74].

Dermatitis from emollient and emulsifying agents found in cosmetics and topical medications such as oleic alcohol [127].

Dermatitis from topical CSs may be unsuspected, particularly if the medication is being or has been applied for a pre-existing dermatitis, but it is diagnostic when

the initially improved ACD worsens without any apparent cause [2].

Latex dermatitis, latex hypersensitivity (generalized urticaria by a caoutchouc dental prosthesis), has been recognized since 1927 [198]. Natural latex (a variant of the original term "latice," derived from the Latin root *lact*, due to its milky aspect) is obtained from *Hevea brasiliensis*: 17 allergens are listed in Table 1.74 with a MW between 2 and 100 kD (*Euphorbiaceae* family) and 1% from *Parthenium argentatum* [216]. Hev b 12 may be important as a cross-reactive pan-allergen [25]. The basic product contains natural rubber (33%), resin (2%), proteins (1.8%) and water (65%), to which ammonia is added up to 0.6% to prevent premature coagulation during transportation [216]. During the industrial manufacture, many chemicals, such as vulcanizers, stabilizers, accelerators, antioxidants are added [216]. World production is about 6×10^6 tons/year [193]. The worldwide increase in glove production following the advent of AIDS and now the poultry infection precautions has dramatically increased the prevalence of latex dermatitis [216]. All medical personnel at risk, as well as dentists, laboratory and health care workers must wear rubber (latex) gloves to prevent a potential contact with blood or body fluids throughout working hours, thus causing ACD in their patients [193]. For this reason, the use of condoms and diaphragms has also increased, with a great risk of sensitization [193, 218]. Particularly exposed are operating-room workers because, in addition to the gloves, they have contact with catheters, tubes, cannulas, bags for anesthesia, etc. [114]. Among non-health care workers, there are industrial workers, housewives, customers of restaurants and food sales points, as well as consumers if the shopkeepers and dairy workers use latex gloves during their daily work [97].

Pediatric groups at risk are in particular children exposed to some types of latex orthodontic appliance or undergoing surgical procedures, especially children with spina bifida or other urologic conditions, in whom reactions are common, due either to repeated surgery (contact with surgical gloves), or the frequent use of IV infusion sets, catheters and Rx procedures [193]. In children and adolescents affected with myelomeningocele, which is associated with immature defense mechanisms of the mucous membranes [66], the principal risk factors were the number of surgical procedures, atopy and/or sensitization to latex [167]: 60% of children had reactions outside of the operating room environment [112]. Children become sensitized mainly by direct contact between latex particles and blood vessels and open mucosa, whereas in adults the process takes place transcutaneously or by inhalation of aerosol particles [150]. Tables 8.10–8.12 [97, 109] show how latex allergy also develops to an incredible number of objects in common use [126, 132, 218].

Among the population considered to be at risk are health care professionals, where the incidence is between 2.6% and 16.9%, and in atopic babies (2%) [218]. The increased incidence in children of latex allergy has recently been highlighted [112]. Atopy as a factor that facilitates sensitization [66] is present in a large group of subjects who are not at risk (41%–74%) [97, 112, 196]. Latex-specific IgE have been detected in 0.5%–10.2% of atopic children with IgE antibodies ±1,000 IU/ml; almost nobody was informed of any allergy before the visit [3]. SPTs are positive in 3%–6.8% of atopic children and specific IgE (sIgE) are elevated in positive challenges [152]. The determination of sIgE (CAP) shows that 7.2% of 282 children are allergic. In this sample, the incidence among the atopic population varied between 1.69% and 9.5%, depending on the methodology used [66]. The prevalence of IgE-mediated allergy in children with neurological abnormalities is the highest: sensitization is 18%–41%, with peaks up to 77.1% [112, 193]. Alternatively, atopy is present in 49% of sensitized and

Table 8.10. Common latex sources and number of hypersensitivity reactions provoked in 70 patients: sources of clinical and/or IgE-mediated reactions

Sources	No. of patients	No. of reactions
Surgical and household gloves	69	43
Sticking plaster	11	9
Balloons (any type)	8	6
Elastic bandages	6	5
Rubber contraceptives	5	3
Face masks for anesthesia, diving, underwater fishing	3	2
Stretch textiles	3	2
Shoes	3	2
Insulating materials	2	1
Air mattresses	1	1
Sailing equipment	1	1
Stamps	1	1
Colors	1	1

Table 8.11. Common latex sources and number of hypersensitivity reactions provoked in 70 patients: sources of clinical reactions

Sources	No. of patients
Hot water bottle	1
Baby pacifiers	1
Shower curtains	1

Modified from [97].

Table 8.12. Additional consumer products and hospital latex products provoking clinical and/or IgE reactions

Additional consumer products
- Adhesive tapes
- Baby balls and balloons
- Baby bottle nipples
- Boots
- Carpet backing
- Chewing gums
- Condoms
- Diaphragms
- Diazo-sensitized photocopy paper
- Dress padding
- Dress trimming
- Elastic bands
- Elastic or elasticized parts of clothing
- Elastic stockings and socks
- Foam rubber pillows
- Glue and other adhesive substances
- Gummed paper, envelope
- Handlebars (such as bicycle) and wheels
- Medicine dropper
- Paddles (such as ping-pong)
- Pads
- Panty-hose
- Pencil rubber
- Plasters
- Rain wear
- Racquet
- Rubber bands
- Rubber handles
- Rubber key-case
- Rubber soles and heels
- Rubber tires (such as strollers, roller skates, bicycle, wheelchair, etc.)
- Shoes
- Shoulder pads
- Toy balloon
- Toys
- Tires
- Water toys
- Wooden batons

Additional hospital latex products
- Ambu bag
- Anesthesia/ventilation bags
- Bag straps
- Band-aids
- Bands
- Blood pressure cuff and tubing
- Cannula for IV use
- Catheters (such as balloon, rectal, etc.)
- Dilatators
- Elastic
- Endotracheal, nasogastric tubes, etc
- Enema kits
- Gastrogavage kits
- Heating/cooling blankets, pillows
- Occlusive dressing
- Orthodontic appliance
- Rubber parts of medical equipment: stethoscope, otoscope, rhinoscope, etc.
- Straps for masks
- Tourniquet

Data from [109].

30% of nonsensitized patients, with statistically significant differences related to allergic reactions to latex, in 96% and 30% of cases, respectively [193]. The report of one case of anaphylaxis in 646 surgical procedures over 18 years is reassuring [167], but latex-induced anaphylaxis occurred in 10% of patients >5 [124]. A severe anaphylactic shock occurred in an 8-year-old boy who was undergoing elective surgery for an ileostomy [94]. Type IV hypersensitivity to natural rubber latex may be a problem for a proportion of patients with eczema, particularly on their hands [195]. The incidence of latex allergy in the general population is unknown, but it seems to be about 0.001%, with a frequency of 0.125% in unselected surgical patients [218].

The immunological mechanism is IgE-mediated [3, 43, 112, 196], especially in children: serum sIgE are detected to natural latex [97, 196], SPT, ELISA, and RAST. RAST inhibition is also positive. The allergens are usually peptides found in natural latex [193]. Latex exposure may occur by cutaneous, percutaneous, mucosal, parenteral, and respiratory (from inhaling latex glove powder) routes [97]. By the respiratory route, the reaction is materialized within a few minutes with a progression of symptoms from rhinitis, wheezing, conjunctivitis, facial angioedema, to generalized urticaria and symptoms of anaphylactic reaction up to severe generalized reactions (Table 8.13) [160, 216]. Latex allergens in respirable particulate air pollution from tires rubbing on roads is a cause of significant respiratory reactions [239], as also is cornstarch powder on latex products for glove lubrication [205]. Skin exposure induces prevalently ACD symptoms [97, 152, 193], but the latex-fruit and latex-vegetable syndrome provokes anaphylaxis also in children. Anaphylaxis burst occurred within 5 min in a girl playing ball [126], as well as in a girl and a boy playing with a plastic ball in play areas [73] and in allergic adults [25], and facial edema in a boy blowing up a balloon [196]. Recently, a *profilin* has been identified as a component of natural latex, structurally correlated to profilins of different origin found in foods and pollens [220] (Table 1.72), and associated with cross-reactivity between latex, taxonomically unrelated plants and several fruits and nonfruits (Table 8.14) [22, 36, 43, 126, 160, 176]. A latex-fruit syndrome was reported by 55.9% of latex-allergic patients [36]. In Appendix 8.2, we indicate [36] the employment procedures of some extracts: papain and chymopapain are associated with anaphylaxis, as analyzed in Chap. 20.

Occupational ACD. In children of 13–14 years, the hairdressers among them were allergic to PPD, Ni, thiuram; construction workers to Cr, cement, Co; in food industry workers, some were allergic to garlic and Ni; in the footwear industry the problem came from Cr, Co, and Ni; in the ceramic industry it was Co and Ni [85]. Other working adolescents were allergic to metal accessories (37%), medicaments (8.1%), cosmetics (5.4%) and shoes (4.5%) [199].

Table 8.13. Manifestations and differential diagnosis is immediate, delayed, and irritant latex reactions

Clinical manifestations	Immediate type (type I) hypersensitivity	Delayed type (type IV) hypersensitivity	Irritant type
Causative agent	Latex proteins	Accelerators: thiurams, contact with gloves, powder, surfactants, formaldehyde, etc.	Insufficient hand rinsing, rubber additives, glove powder oxidants, formaldehyde, etc.
Atopy	Yes	Yes	No
Pathophysiology	Skin/membrane contact, invasive procedures, injections, allergen inhalation (powder)	Skin contact	Skin contact
Percent (%) of vulnerable subjects	General 0.0001 %, hospital: non-surgical 3 %–5 %, surgical 7 %–12 %	7 %–18 %	100 %
Onset time	Minutes, rarely >2 h	6–48 h after contact	Gradual, over days
Initial reaction	Itch, tingling, burning	Itch, then pain	Itch or erythema
Dermal reaction, acute	Urticaria	Erythema, vesicles or blisters	Scaling, edema
Dermal reaction, chronic	Urticaria, more extensive	Dryness, thickening, scaling, fissuring, peeling crusts, papules, vesicles	Dryness, thickening, fissuring, scaling, crusts, papules, sometimes vesicles or blisters
Limits of the reaction	Whenever part of the body beyond the contact area	Even beyond the contact area	Limited to the contact area
Facial involvement	Diffused swelling, runny nose	Only if face is touched	Only if face is touched
Respiratory involvement	Rhinoconjunctivitis, wheezing	No	No
Systemic involvement	Nausea, hypotension, anaphylaxis	No	No
Life-threatening	Yes	No	No

Data from [160, 216].

Table 8.14. Cross-reactions between latex, fruits, and non-fruits in patients with related allergies

Fruits	
Apple	Passion fruit
Apricot	Peach
Avocado	Peanut
Banana	Pineapple
Cherry	
Chestnut	Non-fruits
Coconut	Alder
Fig	Buckwheat
Grapes	Celery
Hazelnut	Chocolate
Kiwi	Potato
Mango	Pistachio
Melon	Sesame
Papaya	Tomato

Data from [22, 36, 43, 126, 160, 176].

Skin-diver dermatitis is elicited by the equipment (diving mask, fins, etc.). The effect is caused by constituents such as dithiocarbamates, formaldehyde, isopropyl-phenylparaphenylendiamine, mercaptobenzol, butylphenolformaldehyc resin, thiourams, etc. [7].

Diagnosis

In *establishing an etiological diagnosis,* it is crucial to begin with a careful, exhaustive history, the single most important and cost-effective diagnostic tool, including family and personal history, to be completed at subsequent visits. A clinical history of redness, itching, or swelling, or of unexplained urticaria or anaphylaxis after contact with a specific product suggests that a detailed history can be useful for the identification of allergic children. All children and parents should be questioned.

- Does the child have a history of atopic disease?
- What product was there contact with and how often?
- Is a relation with a particular activity or environment suspected?

- Are diapers, chemical products, detergents, cosmetics, ornaments, etc. used?
- Does the infant use rubber pacifiers or do children play ball?
- What type of clothing, shoes, gloves, etc. are used?
- When a latex allergy is suspected, is there a history of allergy to fruits (Table 8.14)?
- What is the course of the disease?
- Have topical medications been applied for an ongoing episode or an earlier skin disease?
- Was symptom onset after ingestion of foods containing substances that formerly induced a skin disease?
- Is ACD caused by cross-reactivity [56]?

The *medical examination* is essential to exclude other skin conditions with lesion aspect and distribution similar to those of ACD. In younger children the diagnosis, apart from diaper dermatitis, is facilitated by the restricted panel of age-related foreign substances to be uncovered:

- Babies starting to crawl may develop leg, knee and elbow dermatitis, by contact with wax or detergents for floors, components of rugs and wall-to-wall carpeting, etc.
- Babies and young children may touch or caress parents, relatives, or baby-sitters who use cosmetics, fragrances, deodorants, etc.

Points to be considered:

- Little girls have ear-lobes pierced for earrings.
- Children and adolescents of both sexes wear jeans with metal buttons or other trimmings.
- Early use of cosmetics, etc. In Belgian participants, the mean age of cosmetic allergy was 12.4 years; however, earlier cases were detected at age 4 [56].
- Topical medications, also for trivial skin lesions or ear pain, are typically used more frequently compared to adults.
- Similarly, orthodontic treatments are more frequent in children.

ACD diagnosis related to lesion topography (Table 8.9):

- *Face and neck* ACD. This localization may disclose diagnostic difficulties because several agents are potentially acting: contact and photocontact substances, cosmetics and costume jewelry should be taken into account [57]. The application of chemical substances to the scalp can induce manifestations in distant sites such as the face, ears and neck. Shampoos and hair gels may provoke helix reactions. ear piercing facilitates Ni sensitization [47] and is a risk factor for AIDS.
- *Hand* ACD. About 50% of cases involve the hand, generally on the back, whereas the wrist is involved when objects are taken. It is chiefly caused by the use of rubber gloves, cleaning products, cosmetics, but any of these substances can be the cause. Hand dermatitis is frequent in girls and boys helping in housework or in family shops (see protein contact dermatitis, PCD), in girls working as apprentice hairdressers, in boys helping bricklayers, mechanics, barmen, and the like [172, 200], and above all the Europeans using Ni-containing coins: euro cents.
- *Foot* ACD. The typical location on the back and at joints does not offer diagnostic problems. Causative agents are those found in rubber shoes, shoe creams (see description of shoe dermatitis in preceding section) or in the coloring agent both of shoes and stockings.
- *Generalized and/or unusual pictures.* These are attributable to ubiquitous substances such as those in rubber (see the related additives) able to produce lesions at several sites, including the face (sponges for make-up, ear plugs, etc.), periocular region (goggles for motorcyclists, swimmers, skin-divers, etc.), thorax and belly (elasticized underwear), genitals (underwear, condom, diaphragm, pessary, etc.), legs (elasticized stockings), and dyes and other cloth constituents often unsuspected and difficult to diagnose.

Particular contact lesions are caused in children and adolescents of both sexes by piercing, at all ages by substances employed for oral and dental hygiene and in dentistry: soaps, detergents, toothpaste, anesthetics, metallic plates and screws, and ear drops in children [172]. Dentists in turn can show symptoms after use of an anesthetic or by contact with instruments cleaned with formaldehyde [6], a hidden allergen which gathers in ear canals or under rings during washing with formaldehyde-based products. Inhalation of related steams may induce face and periorbital swelling [16].

- *Systemic* ACD. It is objectively rare, often dependent on re-exposure to previously used topical medications, thus sensitizing the subjects up to severe systemic reactions [200] by spread of lesions to sites far from the primary exposed region or by oral, inhalation or parenteral exposure to antigens formerly the cause of cell-mediated contact manifestations [227].

Laboratory Studies

Latex allergy. SPT is the diagnostic procedure of choice not only in young children affected with spina bifida, but also in all subjects with positive history due to frequent exposure to latex, in those allergic to mentioned fruits and in cases of urticaria and/or anaphylaxis by unknown causes [196]. Diagnostic screening is complicated by a number of asymptomatic children with SPT^+ [152]. SPTs are efficient in children [152, 193], in addition to prick + prick testing [126, 152], also with gloves (Chap. 6), RAST inhibition [193], useful for the study of crossed allergenicity [115], and challenge tests, which appear to be correlated to RAST [152]. Latex gloves are the source of great heterogeneity: there are significant (sometimes striking) differences between manufacturers and product lines in the amount of free latex protein that can be released from the glove and the number and types of chemicals used in glove production [196]. Among the stabilizers is also casein [133], so CM allergic children may have false positive reactions to casein [133].

ACD diagnosis is confirmed by *patch test* [14, 77]: Finn chambers [14] or True test [2] (Chap. 6), selecting the haptens that more frequently are causes of ACD (standard series) or those potentially relevant in the surroundings of a single patient (special series) [14]. All children with suspected ACD should undergo patch testing. Dentists should undergo a preventive assessment by this method [6] because of the notable spread of Ni-plated instruments . Patch testing is also helpful to reveal possible cross-reactions or concomitant hypersensitivity to additional haptens [149], and to natural rubber latex [195]. False-positive results may depend on aspecific skin hyperreactivity, following a local increase in LC numbers, or particular conditions of both epidermis and vasculature which contribute to a pro-inflammatory cytokine increase [207].

To verify whether trimmings or worn objects contain Ni, some drops of a diluted ammoniacal solution containing 1% dimethylglycoxin can be applied: the Ni presence is revealed by a bright rose dye [138].

Differential Diagnosis

Differential diagnosis includes the following considerations:

- ICD (Table 8.15) [138] differences with ACD are rare, since both haptens and irritants decrease epidermal LC numbers, HLA-DR, CD54 and CD80 expression is diverse, and RT-PCR (reverse transcriptase-polymerase chain reaction) has shown an impressive overlap between ACD a ICD [82]. The main ICD example in children is diaper dermatitis, but one baby had physical irritation from constant friction due to occlusion by abdominal skin on a metal pin causing physical irritation [143]. Several agents (up to 489 in number) [143] are capable of expressing a direct irritant action on skin cells, affecting the hands in 36.3% and face in 26.4% of cases [143]. Their power depends on the chemical nature, concentration, duration of application and individual predisposition. The principal symptoms are a burning sensation (pruritus in ACD), early onset 1 h after contact,

Table 8.15. Comparison of irritant (*ICD*) and allergic contact dermatitis (*ACD*)

	Irritant	Allergic
Clinical morphology	Acute ICD: erythema, edema bullae, necrosis restricted to the area of necrosis	Dermatitis in acute and chronic ACD can be similar to ICD, but lesions are often spreading, papules and vesicles are seen most often
	Decreasing phenomenon	Increasing phenomenon
	Chronic ICD: lichenification	Kinetics of resolution may be slower than ICD during patch testing
	Erythema, scaling, hyperkeratosis, rhagades with less area restriction than acute ICD	
Histology	In acute ICD, necrosis of epithelial cells may by present	Same as ICD; but no epidermal necrosis, neutrophils usually less prominent
	In delayed and chronic reactions, spongiosis, exocytosis, dermal edema and a mononuclear infiltrate; occasionally, neutrophil-rich infiltrates	
Immunochemistry T cells	Predominantly $CD4^+$ T cells;	Predominantly $CD4^+$ T cells, some
	Some $CD8^+$ T cells, activated by IL_2R expression	$CD8^+$ T cells, activated state indicated by IL_2R expression
Frequency of hapten-specific T cells in infiltrate	Not known	Estimated to be approximately 1%
Number of Langerhans cells	No consistent changes	Decreased then recovery
Morphology	Alterations noted, but are highly dependent on chemical	Alterations noted, particularly with high doses of hapten
Accessory molecules		
HLA-DR	Increased	Increased
CD54	Increased	Increased
CD80	Increased	Increased

Table 8.15. (Continued)

	Irritant	Allergic
Cytokine profiles		
TNF-α	Increased	Increased
IFN-γ	Increased	Increased
GM-CSF	Increased	Increased
$IL_{1\alpha,-\beta}$	Not detected	Increased
IL_4	Not detected	Increased at 24 h, absent by 48 h
Chemokine profile		
IP-10	Not detected	Increased
MIP-2	Not detected	Increased
Transgenic mice		
Overexpression of		
CD80 by keratinocytes	Increased	Increased
CD54 by keratinocytes	Increased	Increased
Knock-out mice that lack		
TNF-α R	Not tested	Increased
CD4	Decreased	Decreased
CD8	Decreased	Decreased
CD28	Decreased	Decreased
Clinical manifestations		
Frequency	Several patients	Few patients
Diseased	All exposed	Only sensitized
Extension of lesions	Only the contact area	Beyond the contact area
Onset of lesions	Within a few hours	24–72 h
Aspect of lesions	Erythema, edema	Erythema, papule, itching
	Scaling, bullae, necrosis	Vesicles
Symptoms	Burning, stinging	Itching

Data from [138].

polymorphous aspect with no tendency to generalization, rapid regression after interruption of contact.

- AD is often associated with ACD: Ni is accused in children with a mean prevalence of 4% [47]; the hand eczema appearing as a dyshidrotic vesicular eruption may be largely associated with an atopic condition [63].
- To differentiate from PCD, we mention that the pathogenic agents are protein fractions of animal and vegetable origin.
- Mycotic infections (see above).
- Several cutaneous eruptions such as those of SLE, erythema multiforme, dermatomyositis, viral exanthems, *pityriasis rosea* have mostly a symmetrical aspect rather than eczematous, while ACD has peculiar locations; for example, in feet ACD involves the back (in psoriasis the sole), with a relative sparing of interdigital spaces (unlike viral infections).
- Dyshidrotic eczema often begins with small congested, pruriginous and relapsing vesicular lesions, located on the internal sides of both hands and toes, but then occurs in the soles of the feet and the palms of the hands.

Treatment

Beyond any rigid schema of the inhibiting effects on LCs, TNF-α [128] and UV rays with an IL_{10} mediation could be utilized for therapeutic purposes [71].

Local or general management aims to reduce the clinical manifestations and avoid possible infectious complications; in both cases a preventive ascertainment of the composition of products for topic or systemic use will eliminate those containing sensitizing substances. Treatment of allergic reactions to latex begins with immediate removal of any identified source of latex in direct patient contact. In Chap. 13 we discuss SLIT desensitization to latex. Treatment is similar to anaphylaxis from other causes and may require the use of epinephrine [30].

In case of acute, congested, edematous, exudative dermatitis, local therapy should be limited to hydrophilic packs with watery solutions at ambient T, repeated from two to four times during the day. A number of solutions with antiseptic and decongestant action, without the danger of unwanted allergization, are detailed in Chap. 7, along with water, oil or glycerin pastes, useful in congested and exudative stages, and inert powders in case of intolerance to wet medications. When the acute and exudative stage subsides, lipophilic ointments such as Lassar paste may be appropriate.

In addition, always for topical use, low or moderate potency CSs can be used (Table 7.16) in different excipients (lotions, creams, gel, ointments), for short-term (7–10 days) exclusive application on the involved cutaneous sites in tandem or alternate therapy, taking into account possible contact reactions [2]. Subsequently, topical nonsteroid medications can be used for the same length of time; this combined treatment should be sufficient to return the skin to a normal state. Oral antihistamines may hold promise in relieving itching (Chap. 7). The newer topical immunosuppressors, tacrolimus and pimecrolimus, may be effective in the treatment [118].

Diaper dermatitis, especially in summer, responds to rigorous hygienic measures, which are useful also for prevention: the use of cloth diapers, washed at home exclusively with Marseille soap.

Prevention

A *unique specific management consists in the prevention* of whatever new contact with responsible or suspected substances, especially if they are capable of cross-reacting with other compounds [7], or when feasible substituting, for example, metal wires in orthodontic prostheses with acrylic ones [224], almost always followed by ACD regression. Unfortunately, labels do not fully report product composition [57]: cosmetics, antigens correlated to rubber, textiles and metals are examples. However, several clinics have a complete display of materials that contain the offending allergens, a great aid for the patient, the doctor and the industry, as well as for an exchange of information between experts in the discipline [57].

People allergic to Ni should exclude from their diet the above-mentioned foods and eat small amounts of carrots, cabbages, cauliflower, cucumber, wholemeal wheat or corn, fresh fruits other than pears, and lettuce. Older children should also exclude beer, coffee and wine. Do not cook foods in stainless steel pots, both new and used, in particular foods containing oxalic acid (spinach), malic (apple), or citric (citrus fruit), because the Ni concentration is increased significantly [125]. For metal-induced dermatitis, it is appropriate to prescribe a diet with a low content of foods that are positive to patch testing, which is needed to be supported in children by open FCT (OFC) [125]. For objects of common use and imitation jewelry containing Ni and/or CoCl, replacements are available in brass or low-carat gold, and drawer and utensil handles of nonmetallic material. Alternatives to perfumed cosmetics and household detergents are the *fragrance-free products.* Those who are allergic to these substances should therefore carry out strict dietetic prevention, together with contact prevention, to ensure a clear-cut clinical improvement of ACD lesions [80]. Women have long been encouraged to prefer Ni-free accessories, and men to give up metal watch bands, etc. But is impossible to give up handling metal coins. *We hope that the countries of the European Union (EU) conform to the Danish legislation.* In our opinion, difficulties will be Ni is practically irreplaceable in the alloys encountered *because* since it combines excellent technical properties and low price. Recently, a group of European companies has obtained a Ni-free international patent and the EU has issued directive 94/27 and thereby defined the Ni limit level at 0.5 g/cm^2 for objects in direct and prolonged contact with the epidermis.

People allergic to Cr should employ leather tanned with vegetable systems, by ascertaining whether tannins are present, and those with ACD to dyes should wear white or plant-fiber clothing.

The data available today show which measures should be suggested to patients with ACD to *latex* [109]. Latex avoidance should be advocated for all individuals with a positive skin or blood test or a positive history [30]. Because latex glove antigen content varies among brands and among lots from the same manufacturers [193], the allergics and surgeons can wear polyvinyl gloves, or gloves subjected during manufacture to washing after pressing and in-process steam sterilized for 1 h at 120 °C [216], or powder-free Biogel Skinsense ™N. *In allergic patients,* premedication with H_1 or H_2 antihistamines or prednisone has been used to prevent untoward side effects, but only as a supplementary measure in addition to discontinuing use of latex gloves, since the results are not always effective [30, 193]. In *atopic children,* surgical procedures should be undertaken with the greatest caution since they tend to be sensitized even by the slightest contact with latex [3, 126]: in children with spina bifida, latex contact should be avoided from birth [193]. In particular, pacifiers should be banished [109], surgeons should manipulate latex gloves outside an allergic patient's room to avoid airborne transmission of latex particles [112], which are also spread by the cornstarch covering gloves and other objects [205], during surgery catheters in silicon (silastic) and for medications tapes and bandages with acrylic adhesives should be preferred [112]. Latex allergy should be investigated not only in multioperated patients but also in children with severe AD, fruit allergy and with urticaria or anaphylaxis by unspecified causes [196].

A new form of treatment consists in asking a latex patient to wear a latex glove for increasingly longer times, or in a type of SLIT desensitization (Chap. 13).

Protein Contact Dermatitis

Definition

PCD is an exquisitely occupational dermatitis seen in individuals exposed to animal and/or vegetable foods: cooks, veterinarians, slaughterhouse workers, housewives, boys and girls helping in family business, etc. [184]. PCD occurs as a chronic eczema accompanied by erythema, swelling and itching on fingers. Immediate recurrences in the same sites are frequent following contact with the causal agent.

Etiopathogenesis

PCD is another area of increasing interest with only a small rate of patients with positive family and/or personal history for atopy [186].

The causative agents are protein fractions of animal and vegetable origin, handled for a more or less protracted period, but the precise pathogenetic mechanism is as yet largely unexplored [1]. It is proposed that apparently unaffected skin facilitates the passage of protein substances via the epidermis, thus producing a spongiosis, an intercellular edema of the skin's spongy layer. Histological studies have revealed the outcome of these lesions, including superficial vesiculation, parakeratosis and lymphomonocyte infiltrate localized in the superficial dermis and in the perivascular seat. The mononuclear infiltrate delineates full-blown T lymphocytes with a clear-cut CD4 prevalence on CD8 T cells. Immunohistochemical studies show an increase in the number of LCs in the vesicles, epidermis and superficial dermis [186].

The list of foods, fruits, and vegetables identified as etiological agents is remarkably long: see Table 8.16 [1, 186].

Clinical Presentation

The vesiculation starts suddenly after contact with the causative agent, also following a long period of manipulations without lesions [186]. After contact, prominent erythematous, pomphoid and vesicular manifestations appear within a few minutes on the back of the hand and/or fingers, with progressive spread of erythema, accentuation of vesiculation and itching [131].

Diagnosis

SPTs are the diagnostic tests of first choice. The reactions show within 10–30 min, small vesicles that are sometimes dyshidrosiform, combined with erythema, and notably itching [131]. Better results are obtained with the prick + prick test, or the similar SAFT (skin applied food test) by employing fresh and raw foods [1]. The RAST may be reliable.

Differential Diagnosis

As discussed earlier, the offending agents are protein fractions of common foods, which distinguish PCD from the haptens responsible for ACD [186].

Treatment

There is no specific management. Affected subjects should protect their hands with polyvinyl gloves that cover the lower forearm or, if possible, should change jobs [1].

Phytodermatitis

Phytodermatitis is a particular type of contact dermatitis caused by plants, especially by chemical substances present in the leaves, stems, flowers, pollens and roots, particularly essential oils, components of the oleoresinous fraction, containing in turn phenols, aldehydes and aromatic alcohol, terpenes, hydrocarbons, aliphatic and aromatic esters, and kinones. The dermatitis is distinguished by the lesions provoked by irritant effects, particular to some plants such as *Urticaceae,* and by injecting histamine, serotonin and acetylcholine at the contact site, often leading to linear or figured aspects and bullous or pomphoid eruptions elicited by toxins of further plants, including *Compositae,* crucifies, lilies and *Ranuculaceae* (directly or following plant cutting) [7].

Allergic Phytocontact Dermatitis

Several agents cause plant contact dermatitis:

- *Catechols,* belonging to the family of phenols, are among the more widespread allergens in the plant world, equipped with an elevated sensitizing power. These include eugenol, used in dentistry and the manufacture of soaps, perfumes and carnation oils; vanillin; pentadecilcatechol, a potent allergen of the *Rhus* genus, including *Rhus toxicodendron,* or *R. radicans* and *R. vernix*, by far the most common cause of plant contact dermatitis in the US, where they are called poison oak, poison ivy and poison sumac, and are a frequent cause of ACD in children via pets, mainly long-haired dogs, which rub against the plants and transmit oleoresin to newborns and children.
- *Terpenes* are contained in citrus, celery, chrysanthemums, and other products such as resins and balsams.
- The plants of the *Compositeae* family (chrysanthemums, pansy, ragweed, sunflower), those of the *Alstroemeria* genus and *Hydrangea* species, and hepatica contain sesquiterpene lactones yielding extended contact phytodermatitis on exposed skin sites, especially in florists [2]. The *pollens* are common causes in the fall season via their allergenic fractions, the oleoresinous and hydrosoluble protein, which by inhalation can cause respiratory allergy. These conditions are differentiated from *photodermatitis* by the season and the lesions with shaded instead of clear-cut limits [7].

Allergic Photodermatitis

Definition

Allergic photodermatitis is kind of CMI to chemical substances that become antigenic when activated by sunlight. When skin is exposed to UV rays, cutaneous symptoms of various types may appear during a time when a patient is exposed to different exogenous or endogenous substances or is taking an offending medication topically, but most often systemically [58, 174].

Prevalence

It is connected principally with newly introduced medications and chemical substances. The manifestations have alternating phases, in epidemic form when a new therapeutic agent is commercialized. Generally as soon as its photosensitizing potential is ascertained, the product is withdrawn and the prevalence abates.

Pathogenesis

UV rays are divided into UVA, with bands comprised between 400 and 315 nm, UVB between 315 and 280 nm, and UVC of <280 nm [58]. UV rays can induce phototraumatic reactions (basically solar erythema) and photodynamic reactions, further classified into phototoxic and allergic variants [58, 174].

Photoallergic Reaction. This immunologically mediated photosensitization is activated by longer wavelengths (UVA 320–450 nm), which alter molecular structure, thus leading to a type IV sensitization. The radiant energy absorbed by a chromophore, for example the photoantigen, produces photochemical changes resulting in a photosensitized molecule, then conjugated with a protein carrier to occasion a complete allergen, against which is directed the immune response mediated by T lymphocytes, as in ACD [58]. In predisposed subjects, symptoms develop after a persistent exposure to sensitizing substances continuing for an adequately long period (up to 1–3 weeks). The wavelength of UV light is elicited by offending chemical substances. The causes are cosmetics based on natural perfumes such as bergamot (Fig. 8.17) and sandal oils and synthetic perfumes (musk and coconut), fragrance ingredients and lotions containing musk ambrette, dyes such as eosin used in lipsticks and the like, known photoallergens in sunscreen products such as oxybenzone, or correlated to PABA and methylcoumarin, disinfectants (halogenate salicylic-aniline: bithionol, fenticlor, etc.) [58, 215], and foods (Table 8.17) [173].

Phototoxic Reactions. The cause is a foreign chemical substance reaching the skin either exogenously or endogenously in combination with exposure to a sufficient amount of UV rays, in this case UVB rays, which activate nonimmunological cell damage. The pathophysiological mechanism of phototoxic drugs involves absorption and accumulation of UV energy in the skin. Photo drugs or their metabolites may combine with dermal proteins, acting as haptens solely when a significant dose of UV rays (285–310 nm) is present. When this dose is higher, it is likely that the energy modifies the drug to form reactive metabolites that combine with skin proteins, thus also expressing in this case a complete allergen. The period necessary to sensitization development may range from weeks to months, critical for cross-sensitizations, often triggered by low allergen doses. When it is all put together, the dependable molecule amplifies the skin sensitivity to UV rays. Phototoxic effects occur by damage to the DNA chain such as by psoralens [174]. Systemic medications and chemical substances more frequently incriminated are coal tar and derivatives, cyclamates, demeclocycline, doxycycline, griseofulvin, hexachlorophene, phenothiazine, psoralens, sulfa drugs, tetracycline and derivatives, thiazide, and photosensitizing substances such as furocoumarins (including psoralens), employed for their antimycotic action [138].

By a similar mechanism, *phytophotodermatitis* may develop after contact with plants containing natural furocoumarins, diffused in numerous vegetables: *Umbrelliferae* (celery, parsley, etc.), *Rutaceae* (citrus fruit), legumes, and *Moraceae* [174].

Clinical Presentation

- *Photoallergic reactions* (Fig. 8.17) are elicited after re-exposure to both the photoallergen and radiating energy, taking the aspect of an urticarial eruption appearing after several minutes, or erythematous, edematous, eczematous or exuding, also involving parts of the body not exposed to the sun (≥24 h).
- *Phototoxic reactions* are manifested 5–18 h after the first sun exposure and reach their maximal effect after 36–72 h. Their typical aspect is characterized by hyperpigmentation, erythema, and vesicles. The flare-ups develop in cloth-covered sites not exposed to UV radiation and that are distant from those initially involved.

The clinical picture is therefore various. In certain cases, the reactions to UV rays produced by photoallergens may persist, even after prolonged abstention from sensitizing substances (for example, ambrette) [58], or after eradication of the plant.

Contact photocheilitis is induced after sun exposure by dyes based on fluorescin, eosin, erythrosine, or on above-mentioned natural furocoumarins and psoralens.

Diagnosis

The diagnosis, when not evident from a careful history and clinical examination, requires photopatch testing, which reveals several photoantigens including methylcoumarin, ambrette and oxybenzone [58, 223]. However, the EU has prohibited using ambrette in cosmetics and

Data from [58, 174].

has introduced for furocoumarins a limit of 1 mg/kg in sun-tan lotions and in sun-tanning products in general.

Differential diagnosis takes into account, in addition to phototoxic reactions (Table 8.18) [58, 174], the extended contact phytodermatitis caused by *Compositae* pollens, which differ from photodermatitis since they occur in the fall season and produce the lesions with shaded instead of clear-cut limits.

Treatment

No specific management is available. When it is possible to detect an eliciting substance, allergen prophylaxis is crucial. Patients should avoid sunlight exposure while taking implicated drugs. If necessary they can protect the exposed sites with sunscreens that do not contain PABA esters [215]. Topical treatment is based on packs to alleviate pruritus and burning, and topical CSs if erythema and edema appear not to resolve, rigorously avoiding topical antihistamines, a cause of (photo)allergic reactions when applied on the skin.

Contact Dermatitis by Seawater Organisms

Contact is with toxic proteins of some *Coelenterates,* echinoderms, molluscs, sponges, seaweeds, cercariae, and fish of various types. *Coelenterates* are provided for attack and self-defense with nematocysts containing venomous urticating substances capable of remaining on the skin surface or penetrating it. Symptoms consist, in addition to urticaria and ACD, of linear erythematous or edematous eruptions that are either vesicular or hemorrhagic and toxic reactions. The forms stemming from jellyfish are characterized by erythematous wheals appearing within a few hours, subsiding spontaneously after a few days. Echinoderm prickles elicit pain, burning, erythema and edema; pain is live, pyrotic if caused by venomous substances emitted also by morays, skates,

scorpion fishes, etc. Systemic symptoms induced by *Coelenterates* consist of nausea, asthenia, ataxia, muscle spasms, paresthesia, vertigo, etc. [7]. Lesions by *Coelenterates* should be treated with seawater or salted water, because fresh water is hypotonic and induces nematocysts to burst; it is sufficient to disinfect with alcohol. The more severe fish dermatitis and lesions should be cleaned with seawater then applying a tourniquet; application of hot water (>50 °C, but in practice up to the degree of tolerance) helps to inactivate the poison. Depending on the circumstances, we suggest instituting a local or systemic treatment. Echinoderm dermatitis is best treated by surgically removing the prickles or by dipping in hot water. Prophylactic approaches include the use of suitable shoes in shallow water and avoidance of touching such types of fish.

Allergic Vasculitis

Allergic vasculitis, or hypersensitivity vasculitis, affects small-caliber vessels: this vasculitis is most frequent in children, also considering the objective rarity of this allergy section [34]. The allergic origin with CIC deposits is hypothesized after the report of several immunological dysfunctions and the histological and immunological aspects similar to those seen in experimental models of Arthus reaction and acute serum sickness [34].

Definition

Allergic vasculitides in children is primarily characterized in histopathological terms by inflammation of vascular walls, possibly associated with necrosis and subsequent occlusion of vessels [24]. They are included in a heterogeneous group of vasculopathies involving arteries with different locations and diameters, veins and capillaries, whose vessel walls have in common the typical lesions of necrotizing vasculitis, or are *leukocytoclastic,* always associated with inflammatory cells and perivascular infiltration of polymorphonuclear (PMN) leukocytes.

Classification

Several classifications based on morphology and clinical features have been proposed [11]. However, it has thus far been impossible to formulate a global classification that takes into consideration all anatomical, clinical and etiopathogenetic characteristics. Both the etiology and clinical features are entirely different, due to a spectrum of varying causes: Table 8.19 [11, 17, 34, 122] classifies the principal allergic vasculitides in children. Contrary to adults, children suffer above all from SHS and to a lesser extent from hypersensitivity angiitis [31].

Table 8.19. Main types of allergic vasculitis in children

Primary allergic vasculitis
Acute hemorrhagic edema of infants
Giant cell arteritis
Granulomatous arteritis
Wegener's granulomatosis
Churg-Strauss syndrome
Hypersensitivity angiitis (with no apparent cause)
Younger children
Kawasaki syndrome
Polyarteritis
Schönlein-Henoch syndrome
Older children
Polyarteritis nodosa, classical
Polyarteritis nodosa, cutaneous
Polyarteritis nodosa, infantile
Temporal (giant cell) arteritis
Takayasu's arteritis
Secondary allergic vasculitis
Associated with infections
A. Microbial
Brucella, Yersinia, Rickettsia
Mycobacterium leprae
Mycobacterium tuberculosis
Mycoplasma pneumoniae
Streptococci, staphylococci, etc.
B. Viral
Cytomegalovirus
Epstein-Barr virus

HIV
Hepatitis B virus
Rubella virus
C. Parasites
Plasmodium malariae
Toxoplasma gondii
Disimmune disorders and syndromes
Chronic atrophic polychondritis
Cogan's syndrome
Congenital deficiency of complement components
Cryoglobulinemia
MacDuffie's syndrome
Associated with autoimmune disease
Behçet's syndrome
Dermatomyositis
Lupus erythematous, systemic
Rheumatoid arthritis
Scleroderma
Sjögren's syndrome
Other associations
α-1-Antitripsin deficiency
Contact agents
Cow's milk proteins and other foods
Cystic fibrosis
Drugs
Hemorrhagic rectocolitis
Insect stings
Physical agents (cold, heat, etc.)
Sarcoidosis
Serum sickness

Data from [11, 17, 34, 122].

Prevalence

A study referred to by Athreya [11] points to a 4% incidence, probably an underestimate because only academic centers were involved in this data collection, and pediatricians usually see and treat cases of SHS and Kawasaki syndrome, the most common vasculitides.

Histological Aspects

Dermal inflammatory phenomena are localized prevalently among capillaries; therefore the vasal endothelium plays a crucial role in these cases. The vessel wall becomes a target of immune processes, characteristic of vasculitis [34]. The vasal lesions affect the superficial dermal capillaries; endothelial cells are the seat of edema restricting the vessel lumen. Thus the wall is thickened, infiltrated by fibrin deposits that extend to adjacent connective tissue, leading to fibrinoid necrosis, which derives its name from its tintorial affinity with fibrin, characteristic of necrotizing vasculitis. A perivascular inflammatory infiltrate complicates the wall lesions, which, along with edema, are responsible for the infiltrated character of the purpura, including various amounts of PMNs, whose nuclei undergo pyknosis and disintegrate to so-called nuclear dust. PMN cell decay is known as *leukocytoclasis,* inconstant but with a great diagnostic value [34]. The infiltrate may also include intact eosinophils and mast cells, associated with PMNs; however, PBMCs could be recruited before PMNs. Vasculitis is a cause of dermal hemorrhages, clinically corresponding to purpura, more rarely of local ischemia, responsible for more or less ulcerate bullous lesions. Yet the pattern is not always that of a typical form [24].

Pathophysiological Aspects

CICs have a key role in the pathophysiology of leukocytoclastic vasculitis; additional elements confirm that these vasculitides depend on type III immune reactions, based on serum anticomplement power, hypocomplementemia and above all the observation, by direct immunofluorescence, of complement and/or antibodies in the vessel walls. CICs are not always demonstrable in the vessels; on the other hand, even if CICs are detected in numerous pathological conditions, only occasionally are CICs demonstrated in some forms of vasculites, or there is a parallel between CIC titer and the outcome of vessel lesions. Both antigens and antibodies found in the vessel walls are rarely detected [34].

PBMCs infiltrate in some vasculites, chiefly lymphocytes and partly monocytes, by lysosomal release of digestive enzymes that attack first the adventitia and then the media coat of vessel wall, thus destroying the cellular matrix of these vessels and surrounding tissues. In the absence of PMN and CIC markers, the interference of CMI is also probable: active cells may be NK cells with perforins, T lymphocytes with direct cytotoxicity and/or DTH reactions, leading to increased vascular permeability and the accumulation of more leukocytes and proinflammatory molecules [24]. These pathogenetic models postulate that the endothelium suffers passively from the insult favored by complement activation, resulting in the production of complement breakdown products (C3a, C5a) that are chemoattractants to PMNs and PBMCs. Usually, endothelial cells are protected from potential damage originating from CICs activated by several regulating molecules at various levels of the complement cascade; consequently 90% of CICs are eliminated by the liver (Kupffer and endothelial cells) and to a lesser extent by the alternative pathway. Similarly, if CICs react directly with erythrocytes CIC–erythrocyte complexes are transported to the liver, thus decreasing the risk of epithelial damage [11]. Conversely, the endothelium could also actively contribute to the development of vasculitis in the general context of inflammation [24].

Immunopathogenesis

Although etiopathogenesis remains in great part barely recognized, recent work speculates that CICs, after binding to endothelium, increase synthesis of adhesion molecules on the cell surfaces. Leukocytes carry integrins and selectins, and endothelial cells add CD54 and CD106 to the selectins [78, 148], which are crucial for leukocyte migration between endothelial cells, as analyzed in Chap. 1. A new mechanism mediating the unmatched pathogenetic processes of diverse types of vasculitis is essentially the formation of anti-endothelial cell antibodies (AECAs), CIC deposition and T lymphocyte adhesion to the vascular wall. Several other mechanisms may play a major part, including the release of antibodies against antigens located in the surrounding sites, phagocyte adhesion and complement dysregulation at the tissue level [24]. It is tempting to speculate that CD4 activation by antigens presented by APC in association with HLA class II molecules mediates B lymphocyte activation with subsequent production of ANCA (anti-neutrophil circulating antibodies), formation of CICs and complement activation attracting PMNs also recruited by chemokines (Fig. 8.18) [177]. A set of Aab directed against PMN proteinase 3 (PR3) such as the c-ANCA (cytoplasmic ANCA) have been implicated in the pathogenesis of Wegener granulomatosis with a remarkable predictive significance, thus embodying a key diagnostic role [122]. That these c-ANCA recognize PR3, p-ANCA (perinuclear ANCA), MPO (myeloperoxidase) and the elastase, shown also in patients with polyarteritis nodosa, Kawasaki syndrome and SHS, where they are of IgA class, supports the hypothesis that clinically different disorders might have a

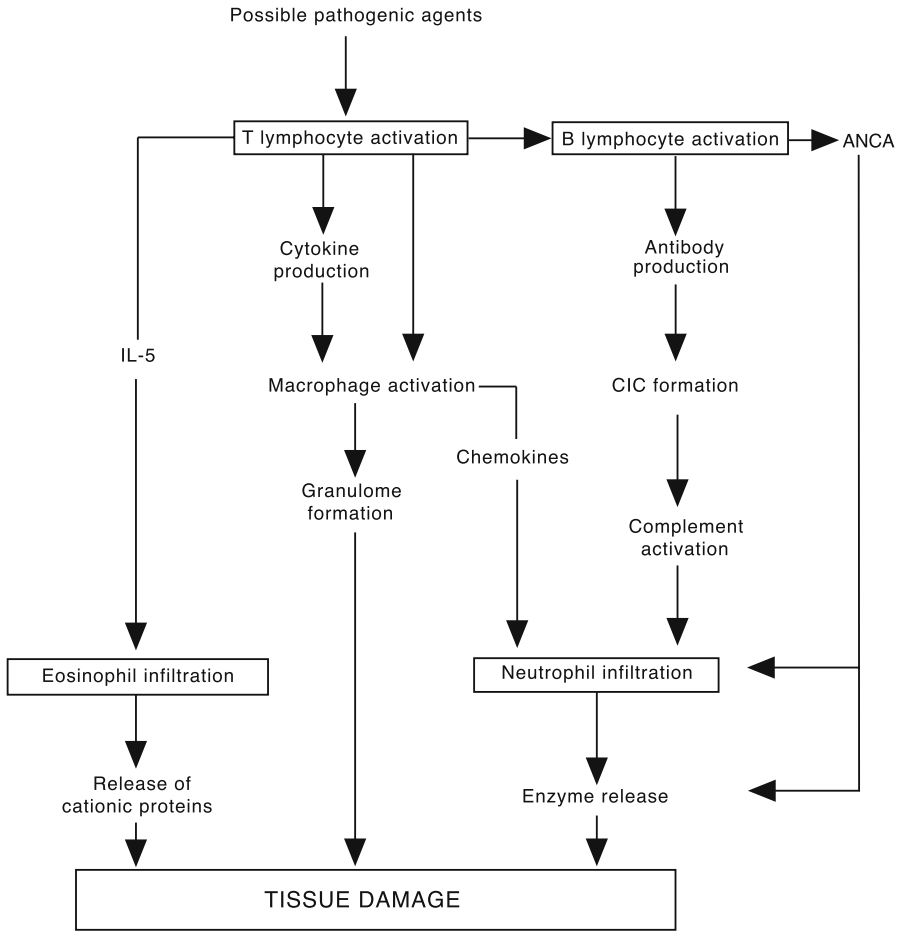

Fig. 8.18. Possible pathogenic events responsible for tissue damage during vasculitis. (Modified from [177])

common pathogenesis caused by antibody-mediated PMN activation [79], and by ANCA involvement in pathogenesis.

Microbial or viral infections may foster TNF-α production and thus the expression of ectoplasmatic antigens such as PR3 and MPO on PMN membrane and epithelial cells [177]. Both proteins and enzyme recognized by ANCA have also been found on granulocyte surface, and are therefore more easily attacked. In addition it is likely that ANCA antibodies bind PMN expressing PR3 on surface, thus causing degranulation with release of free O_2 radicals and lysosomal enzymes on surrounding epithelial tissues, or alternatively bind enzymes released by cells damaged by the inflammatory process, facilitating their transport to the tissues where the enzymes cause further damage [79]. In parallel, the ANCA/PR3 interaction induces, by mechanisms not yet fully understood, an increased CD62E and CD106 expression, which attaching to epithelium modulates the adhesion of PMN [177], CD54 and CD102 [78, 148], which bind their contrareceptors CD11a/CD18, CD11b/CD18 and CD11c/CD18. In this model, the integrins are necessary for leukocyte adhesion to endothelium. Figure 8.18 shows the tissues damaged by a complex interaction of cells, with a prominent role played by eosinophil cationic proteins. Additional etiological factors to be considered are genetic and local factors (lesions differentially affecting one organ rather than another), etc. [122].

Clinical Presentation

Vasculitis disorders share cutaneous and visceral symptoms [34].

Cutaneous Symptoms

Cutaneous vasculitis is a condition characterized by infiltrated palpable purpura (erythema not fading on vitropression), with predilection for the lower limbs, with tendency to symmetry and worsening following orthostatism. Of 130 children, 116 had SHS and14 had hypersensitivity vasculitis [32]. The often associated lesions are mostly polymorphous, erythematous or maculopapulous, well circumscribed, occurring in crops, have dimensions from a pinpoint to several cm, often evolving to form hemorrhagic blisters or necrotic ulceration, lasting from 3–10 days, and affecting in par-

ticular the lower limbs and feet. Certain lesions may complicate the diagnosis such as well circumscribed ecchymotic spots, erythematous papules (palpable purpura), often with an annular arrangement appearing as a polymorphous erythema, which are able to transform into nodules, vesicles, blisters, and/or become necrotic. Preferred sites are gravity–affected areas such as lower half of the legs and buttocks, but also forearms and hands, although in severe cases the face and trunk may be involved. Subcutaneous nodules are small, stiff, often short-lived, most often located on the back of both hands and feet, elbows and knees. Less frequent is *livedo reticularis*. Generally such lesions are asymptomatic, but can be accompanied by pruritus, burning sensation and pain [34].

Additional Symptoms

Articular manifestations are the most frequent and renal lesions condition the prognosis. No relationship is apparent between extension of cutaneous lesions and presence or not of renal manifestations.

- *Musculoskeletal apparatus.* Arthralgias are usually present in >40% of cases.
- *Kidney.* Renal lesions should be investigated, although it has been suggested that the prevalence is not 25%–40% of cases, but <1% of children develop persistent renal disease [11]. Proteinuria is usually associated with microscopic hematuria: symptoms may persist or subside; however, <0.1% develop renal insufficiency. Renal biopsy results are discriminatory as far as the type and severity of injury are concerned.
- *Gastrointestinal tract.* Abdominal pain with nausea and vomiting are frequent (15% of cases); rarely does an occlusive or hemorrhagic syndrome develop.
- *Central nervous system.* Rare associations include hemiparesis, neuropathies and migraine.

Prominent Vasculitis Syndromes in Children

As shown by Table 8.19, the main types of primitive allergic vasculitis in children that most frequently have an immune pathogenesis are the following:

SHS, or anaphylactoid purpura, is the most common among *leukocytoclastic vasculitis* patients, with an estimated annual incidence highest between the ages of 4 and 6 years (99.3×10^5) [81]. SHS peaks preferentially between 4 and 7 years (or between 5 and 6), with a greater prevalence in males and in fall season and in winter [98, 245]. The SHS annual incidence may be 12.9×10^5 children <17 years of age [245]. However infants aged 5–24 months have been reported [5, 188]. It is an immune-mediated disease, paradigmatic of cutaneous necrotizing or leukocytoclastic vasculitis, of small dermal and visceral vessels (<0.1 mm in diameter), which appear to be infiltrated by PMNs with nuclear fragments in various stages of necrosis, releasing proteolytic enzymes resulting in damage to vascular endothelium [11]. The inflammatory and thrombotic process is likely correlated to increased biosynthesis of vasoactive prostanoids [210].

A pediatric study has focussed on the action of these molecules and demonstrated a significant increment of thromboxane A_2 (TXA_2) and PGI_2 in acute stages correlated with the degree of clinical severity [210]. The TXA_2 increase is consistent with platelet activation; a lesser portion derives from activated PMNs and macrophages, while the PGI_2 increase seems to reflect endothelial cell damage by local inflammatory and thrombotic process [210].

The prostanoid, the main metabolite of arachidonic acid, is a product of vascular endothelium and has potent anti-aggregate effects on platelets. It is a vasodilator and inhibits the TXA_2-induced platelet activation on vascular lesions. PGI_2 of endothelial cells influences the interaction between vasal walls and leukocytes, blocking their adhesion after stimulation [210]. Prostanoid synthesis in the vascular cells can be induced by PAF and IL_1, both CIC-stimulated, thus confirming the CIC activity in immune-mediated vasculitis [235]. In the acute stages of SHS, a PGE_2 increase has been shown, probably derived from PMN and macrophage activation. Examined in greater detail, it is unclear whether its action amplifies or suppresses the inflammation characteristic of SHS [210]. On the one hand, it is an active mediator in inflammation, by promoting blood afflux in the inflamed area and thus leukocyte infiltration; on the otherhand, it exploits a local down-regulation by inhibiting lymphocyte activation and antibody and IL production.

In conclusion, both TXA_2 and PGI_2 increase allows a correlation of SHS with other affections and syndromes characterized by an increased interaction between platelets and vascular walls, so that a parallel between a wide spectrum of causes and a virtual uniformity of responses may be advocated [210]. The deposition of IgA and C3 in the small vessels of the skin and renal glomeruli is characteristic. Recently deposition of IgA has been shown in the intestine as well [106]; therefore SHS is considered an IgA-mediated vasculitis of small vessels [11]. The main clinical manifestations outlined in Tables 8.20 and 8.21 [5, 188] show that the skin manifestations, edema and purpura of both scalp and limbs, are characteristically seen in infants, while in older children the frequency of articular (arthritis may be the initial manifestation) and renal complications is increased [5, 188]. The SHS hallmark is the purpuric rash, first macular and then erythematous maculopapules, with hemorrhagic elements (petechiae and ecchymosis), involving symmetrically the lower limbs (Fig. 8.19), associated with edema of the scalp and/or extremities. Depending on the age, abdominal pain and migratory articular manifestations are more or less frequent, the onset of glomerulopathy may even be long after SHS

Table 8.20. Clinical Schönlein-Henoch syndrome manifestations in children aged 0–8 years

onset. In cases not complicated by nephropathy, the prognosis is good after 24 years of follow-up; however, long-term follow-up of all patients who had severe renal symptoms at onset is needed during adulthood [171].

Hypersensitivity angiitis is another leukocytoclastic vasculitis, clinically similar to SHS, occurring mostly in children, excluding those cases in which the specific allergen (drugs, microbes, virus, insect stings, pesticides, etc.) is easily identifiable. Clinical manifestations include fever, myalgia, and arthralgias without frank arthritis and visceral involvement, and may sometimes resemble the SHS limited to the skin, with which it has in common the character of acute phases *(one-shot disease)*. The small vessels are involved, arterioles or venules, with a variable degree of vessel wall necrosis, localized and rarely occlusive. The cutaneous lesions are typically small hemorrhagic papules, usually in sloping areas and at a similar stages of development. Inflammatory cells are usually PMN [72, 122].

Acute hemorrhagic edema of infancy (Fig. 8.20) is a disease with a benign course characterized by a suddenly occurring cutaneous vasculitis in children aged 4 months to <2 years in good general condition. Large purpuric lesions are distributed on the face, auricles and lower limbs, associated with limb edema, or they are segmental, thick or soft [153]. In some cases, extended trunk lesions may suggest a differential diagnosis with fulminant purpura. Progression is spontaneous and favorable within 2–3 weeks [83, 120, 182], or after a 7-day oral CS course [87]. Vasculitis, essentially cutaneous of the leukocytoclastic type, a (very) young age, the topography of lesions, peripheral edema and common absence of arthralgias and internal organ complications (in any case benign) are diagnostic [83, 98, 120] and should be evaluated as a benign SHS variant [182].

Kawasaki syndrome [108] is the most frequent vasculitis in infancy after SHS. An epidemiological study on

Fig. 8.20. Acute hemorrhagic edema of infancy. The condition subsides spontaneously and is not associated with severe, systemic complications

Fig. 8.21. Kawasaki syndrome: scaling of the toes

105,755 cases reported over 35 years ago in Japan [217] showed a prevalence of 4.5–8.5 cases $\times 10^5$ aged <5, with the youngest patient aged 26 days, 0.006% of infants aged 30 days and 1.67% aged 3 months. Among newly treated children aged <5 years, the incidence was 102.6×10^5 in 1995 and 108×10^5 in 1996, with a male-female ratio of 1.37 [244]. The estimated annual incidence was 5.5×10^5 in children <5 years, and was highest in Indian subcontinent Asian children (14.6×10^5) [81]. The incidence rate in Korean children <5 years was ($\times10^5$) 73.7 in 2000, 90.8 in 2001, and 95.5 in 2002. The mean age of onset was 30.5 months [162]. This is a multisystem disorder causing substantial symptoms of vasculitis and mucocutaneous lesions with desquamation, after 2 weeks, beginning at the nail-pulp junction (Fig. 8.21). It is another CIC-induced one-shot disease, characterized by a polyvasculitis of small and medium-sized vessels, especially affecting medium-sized arteries, with a predilection for coronary arteries with thrombosis and formation of aneurysms [72], a particular risk for infants aged <6–12 months [178]. Ongoing antibody synthesis may foster inflammation involving

Table 8.22. Main immunological changes in Kawasaki syndrome

Activated B cells
Activated T $CD4^+$ increase
Ongoing antibody synthesis
Expansion of TcR Vβ2 and Vβ8 regions
Microbial superantigens secreting toxins
Monocyte-macrophage activation inducing:
IL_1, IL_6, IFN-γ, TNF-α raised expression
IL_2R and CD45RO on CD8 raised expression
Endothelial cells expressing HLA class II antigens, CD54, CD62E
Circulating autoantibodies and CIC
Suppressor/cytotoxic T $CD8^+$ decrease

Data from [21, 123, 147, 165, 235].

all three layers of the vascular walls, thus destroying the internal elastic lamina: Table 8.22 [21, 123, 147, 165, 235] reviews the many immunological features consistent with the pathogenesis. Another area of intensifying interest is the demonstration that ILs linked to AECA favor endothelial cell migration, thus modulating the worsening of vascular changes [180]. The changes are multiplied by the high levels of adhesion molecules on endothelium, including CD54, CD102 and von Willebrand factor [78, 148]. Recent data have revealed toxins acting as superantigens (SAs) on Vβ2 and Vβ8 [51, 123, 243], produced by microorganisms of the respiratory or gastrointestinal tracts [51, 147], in particular by *Staphylococcus aureus* and *Streptococcus pyrogenus* secreting TSST-1 (toxic shock syndrome toxin-1) and SPEA/SPEB (staphylococcal pyrogenic exotoxin A and B), respectively [123]. A result still to be weighed is whether CD45RO expression is raised solely on CD8 T cells [165]. There is a tempting suggestion that the intestine encourages causative agent entry such as microorganisms [147, 243] that are producers of toxins with SA properties (Table 8.22). A novel human coronavirus, designated "New Haven coronavirus" (HCoV-NH) was identified in 8/11 infants with Kawasaki disease. Human coronaviruses (HCoVs) have attracted renewed interest because of the emergence of a novel HCoV associated with severe acute respiratory syndrome (SARS). The median time between the onset of fever and the diagnosis of HCoV-NH was 5 days; 7/11 infants and 19/22 control subjects had respiratory symptoms that were consistent with an upper respiratory tract infection (URTI) [68]. Table 8.23 [189] outlines the chief diagnostic and associated symptoms. Useful diagnostic markers could be CD8 T cells [147, 165] and IL_2R for early diagnosis [21].

Polyarteritis nodosa (PAN), divided into classic, infantile and cutaneous PAN [122], is among the least common in childhood. This is another disease that differs in presentation and etiology from that seen in

Table 8.23. Main diagnostic criteria for Kawasaki syndrome and main associated criteria

Main diagnostic criteria
Patients should have at least 5 or 6 main symptoms with exclusion of other diagnosis:
1. Fever with sudden onset, lasting ≥5 days
2. Bilateral nonsuppurative conjunctival hyperemia
3. At least one change of the lips and oral cavity, including hyperemic or dry fissured lips, erythema of the oropharyngeal mucosa, strawberry tongue
4. At least one change in peripheral extremities, including edema of the hands, feet, or both, or erythema of the palms and soles, scaling beginning periungually or generalized
5. Polymorphous rash, especially of the trunk, with varying characteristics, without vesicles or crusts, often itching
6. Cervical lymphadenopathy, not purulent, usually unilateral, ≥1.5 cm
For the diagnosis, in addition to the fever, the child must meet 4/5 criteria
Main associated symptoms (in order of incidence)
1. Urethritis
2. Arthritis or arthralgia
3. Cardiac involvement, especially myocarditis or pericarditis
4. Aseptic meningitis
5. Diarrhea
6. Gallbladder hydrops
7. Obstructive jaundice

Data from [189].

Table 8.24. Hypocomplementemic urticarial vasculitis: clinical aspects

Lesion characteristics
Small wheals
Evident central clearing or dusky coloration
Persistence greater than 24 h
Residual pigmentation following regression
Painful, burning or pruritic lesions
Alternatively, presence of palpable purpura, nodules, ulcers
Clinical aspects
Recurrent, widespread urticarial lesions
Association with arthralgia, arthritis, abdominal pain, fever
potential involvement of synovia, kidneys, gastrointestinal and respiratory tracts, eyes and/or CNS

Data from [135, 226].

adults. More frequent is cutaneous PAN, manifested by purpura, edema, linear erythema, tender palpable nodules, high fever, arthralgias and myalgias, without important organ system involvement. It has a chronic course and a better prognosis than the systemic variants [11, 72, 98]. Biopsy reveals a focal necrosis and inflammation of the walls of small and medium-sized arteries that tend to occur in a segmental way and particularly involves areas where arteries bifurcate [98].

Other types of polyarthritis vasculitis include *Wegener granulomatosis,* featuring the formation of granulomas around blood vessels, with typical lung and kidney involvement, which is currently classified as one of the ANCA-associated small-vessel vasculites distinguished by its predisposition to affect the upper and lower respiratory tracts and kidneys clinically and histologically by the presence of necrosis, granulomatous inflammation, and vasculitis [246]. The presence of PR3, normally restricted to neutrophil α granules, has led to the hypothesis that ANCA-induced neutrophil activation is central to a chain of events leading to T-cell activation and a CMI response involving macrophage activation, and that PR3 expression may be abnormal. The cause may remain unknown, but circumstantial evidence suggests the potential roles of ANCA and infection in the pathogenesis [246]. Recurring infections of upper airways and respiratory infections are prominent clinical manifestations, along with cough, fever, weight loss, arthritis, neuropathy, rash, and splenomegaly. ANCA-associated glomerulonephritis has been diagnosed in 20 children, the youngest aged 11 years, but early recognition and aggressive treatment of these children may prevent end-stage renal disease [219].

Churg-Strauss syndrome, an allergic granulomatous vasculitis also affecting small and medium-sized vessels has a predilection for lungs characterized by AR and/or asthma and presents with fever, headache, myalgia, weight loss, and peripheral blood and tissue eosinophilia exceeding 1,500 cells/m^2. The systemic vasculitis may involve the skin, heart, and peripheral nerves. Kidneys are spared or only mildly affected [122]. Recently three cases have been reported: a 15-year-old girl with catastrophic gastrointestinal vasculitis and multiple colonic ulcers with active bleeding [124], a 10-year-old girl with acute abdominal pain, bloody diarrhea, pulmonary infiltrates, a 6-year history of severe asthma, and marked eosinophilia [26], and a boy with poorly controlled bronchial asthma, AR, recurrent sinusitis and several episodes of hemophthisis since the age of 9, who developed purpuric skin lesions, generalized soreness, and symptoms of mononeuritis multiplex at age 11 [234]. These cases demonstrate that the prognosis is poorer in children than in adults [124].

Table 8.25. Histopathology of hypocomplementemic urticarial vasculitis compared with acute and chronic urticaria

Manifestations	Urticarial vasculitis	Chronic urticaria	Acute urticaria
Inflammatory cells	Predominantly PMN	Predominantly monocytes	Few PMN and monocytes
Location	Perivascular and within vessel wall	Perivascular few within vessel wall	Perivascular
Leukocytoclasis	Yes	No or minimal	No
Endothelial cell swelling	Yes	No or minimal	No
Leakage of erythrocytes	Yes	No or minimal	No

Data from [27, 226].

Fig. 8.22. Acute urticarial vasculitis

Wholly particular is *hypocomplementemic urticarial vasculitis,* of which eight pediatric cases are known [39, 55, 135, 232], including 2 identical twins [241] and a girl with SLE [55]. Concordance in identical twins may suggest that the pathogenesis of the disease involves abnormal genetic immunoregulation [241]. CIC-induced pathogenesis has an Arthus-like pattern; there is selective depression of Clq binding IgG and lesser depression of C2, C3, C4, but the levels of Clr and Cls are almost normal [135, 232]. Cl, C3, C4, properdin, IgM, IgG and fibrin are often present in vascular cells and basal membrane. When complement is activated, C3a and C5a are released. These anaphylotoxins with chemotactic action induce *de novo* synthesis of chemokines and ILs and mastocyte degranulation with consequent increase in vascular permeability, followed by LTB_4 release. In both ways, PMNs are recruited, resulting in the tissue damage described above. Clinical features are those of leukocytoclastic vasculitis: clearly delimited erythematous and edematous macules are seen, and are characterized by their relatively fixed aspect, tendency to purpura, are only slightly pruritic, and the possible association with systemic manifestations or an inflammatory syndrome [27, 135, 226]. The lesions resemble urticaria and typically persist for more than 24 h [55]. Tables 8.24 and 8.25 [27, 135, 226] outline the clinical and diagnostic symptoms of urticarial vasculitis, characterized by a wide spectrum of symptoms that may lead to a more severe clinical course that is life-threatening to children, including severe anemia and renal insufficiency [135], and hycomplementemic histopathology, compared with acute and chronic urticaria [27], is useful for the differential diagnosis.

Acute urticarial vasculitis related to postinfectious or drug-induced hypersensitivity starts as transient infiltrated purpura (Fig. 8.22), 2–3 weeks after antigenic aggression; several secondary types of vasculitis are induced by food additives [173, 223], CM proteins [34], other foods and vitamins [173].

Diagnosis

Vasculitis assessment should include history, physical examination, and some of the following items:

- Age and epidemiology, in order of frequency SHS (Tables 8.20, 8.21), Kawasaki syndrome (Table 8.22), leukocytoclastic vasculitis, hemorrhagic edema (Table 8.19) and urticarial vasculitis (Tables 8.24, 8.25), the last being most unusual in this age range
- Recent treatment with potentially implicated drugs
- Palpable purpura
- Maculopapular erythema
- Possible biopsy

Laboratory studies (complete blood count, ESR, CRP, platelet count, kidney and liver function studies, T subpopulations, AECA, ANCA, lymphocyte antibodies, etc.)

Table 8.26. Frequency of c-ANCA, p-ANCA and anti-MPO in several disorders

Disorders	c-ANCA	p-ANCA	Anti-MPO
Polyarteritis			
Classic PAN	Uncommon	2+	2–3+
Microscopic PAN	2–3+	2–3+	2–3+
Churg-Strauss syndrome	Rare	2+	2–3+
Wegener granulomatosis	4+	1+	1+
Generalized			
Active	2+	–	?
Remission	3+	–	?
Limited			
Active	2+	–	?
Remission	2+	–	?
Polyangiitis overlap	1+	1+	?
Idiopathic necrotizing and semilunar-type glomerulonephritis without immune deposits (pauci-immune)	1+	4+	4+
Inflammatory bowel disease			
Ulcerative colitis	Rare	2–4+	Absent
Crohn's disease	Rare	Absent	Absent

Data from [11].

are useful to confirm the diagnosis. Table 8.26 [11] gives the frequency of c-ANCA, p-ANCA and anti-MPO in several vasculitis.

Treatment

The reader is referred to reviews on therapeutic details [11, 226, 235]. Intravenous immunoglobulins (IVIg) were administered to two children aged 2.5–3.5 with Kawasaki syndrome associated with severe AD at the dose of 4–6 g daily for 5 days with remission of hyperthermia (Chap. 7). The IVIg positive effect, to be started promptly and continued for the 5 days of Kawasaki syndrome [244], lies in the inhibition of endothelial cell migration with destructive effects [180], likely favoring the reparative phase.

Pediatricians and Other Cutaneous Allergies

This chapter presents pediatricians with a large number of different diseases and syndromes of childhood, the background to a very extensive and differentiated task. This includes several kinds of foods, additives, drugs, and insects that induce urticaria and the countless and dissimilar physical forms, as well as foods and inhalants inducing angioedema. Since urticaria covers a clinical spectrum, it should not be surprising that several skin disorders have urticarial lesions. ACD involving young children is provoked by buttons, clasps, jewels, cosmetics, topical medications, and the ubiquitous latex with latex-fruit and latex-vegetable syndromes and even in the materials employed by dentists. The most important preventive measure for patients with latex allergy or at risk for it is minimizing direct exposure to latex products, most notably latex gloves. Recent operating room studies indicate that simple preventive measures can dramatically reduce intraoperative reactions [30]. Although rare, the different forms of infantile vasculitis are undoubtedly a challenge for most colleagues. The clinical and laboratory findings are variable, frequently nonspecific or overlapping. Therefore early and correct diagnosis is imperative, but one should never delay initiation of treatment, while trying to finalize the diagnosis. These disorders are therefore found in several chapters of infantile allergy and immunology and will put to the test more than ever not only the diagnostic and therapeutic skill of pediatricians, but also their cooperation in light of understandable parental anxieties. With treatment methods designed both to avoid side effects and limit costs, effective approaches will be centered. However, clinical experience will untie several Gordian knots, thus justifying neither frustration nor polypragmatism, especially when faced by the tempting plethora of current therapeutic options.

Food Allergy

One Allergy, Several Allergies

Food allergy (FA) was born as cow's milk (CM) allergy (CMA). Only humans began and continue to use milk of other animals to nurse offspring, although Hippocrates recorded gastric upset and hives due to CM and proposed dietetic measures. The use of animal milk to feed children began spreading around the mid-eighteenth century, with a preference for ass or goat's milk rather than for CM [249]. In parallel, the consequent decline in breast feeding became evident from the fifteenth to nineteenth centuries: perhaps "nine months of blood, nine months of milk" [95] were too heavy. Subsequent discoveries in the fields of microbiology and medicine provided a more thorough basis for development of substitutes for breast milk (BM). Comparisons against the advisers of bottle feeding were requested, with unhappy results [95] and also differences in mortality among the BM-fed infants compared to non-BM-fed infants were worthlessly pointed out [249]. Even if at the start of the 20th century the first cases of anaphylaxis [436], one of which was fatal [161], and of CMA [196] were documented in the German literature, artificial feeding increased like an avalanche in the 20th century [249]. This massive progression was also based on data giving the impression that BM did not transfer any immune factor to neonates, although in 1892 Ehrlich had demonstrated the contrary [144]. In the last decades there has been a positive promotion of BM feeding in different countries, and supporting studies since 1985 have again reaffirmed BM supremacy and the several problems connected with CM [538]. Newborn BM feeding is confused with the history of mankind and probably found its first application in the garden of Eden: perhaps for this reason BM feeding has always retained an absolute pre-eminence. For centuries, BM has been the only way of feeding human newborns, and CMA was virtually unknown in infants [64]. It is significant that BM was classically defined as a natural feeding, while CM is mentioned as an unnatural or artificial feeding [95]. Certainly, the occurrence of symptoms stemming from eating foods different from BM, and especially of CM, dating back to ancient times is striking, whereas only in 1918 was it reported that a girl had the so-called BM allergy (BMA) [470]. This is decidedly another demonstration that BM is the ideal food for neonates, and although in the past it was recommended since it provides practical, economical, nutritional, physiological, and psychological benefit, we can say that every day a further protective factor is added to the long list of BM's documented advantages (Table 2.12). Clearly, throughout history not all neonates and infants had BM available, so their mothers were compelled to select a more easily achievable and/or economical substitute: thus the onset of CMA.

Adverse reactions to foods are frequent and common causes of childhood morbidity, and one of the best-known and most frequently encountered problems in current infant feeding practices. However, they are surrounded by considerable controversy to the point that some standard textbooks in pediatrics either avoid mentioning FA altogether or only refer to it in passing in relation to gastrointestinal (GI) or skin symptoms; at times only a few lines are devoted to FA, but no mention is made of CMA, so the frequently divergent attitudes toward FA often result in its underdiagnosis by some allergists or its overdiagnosis by others. In 1980 *Allergies to Milk* was published [23], and in 1982 the specific use of a homemade diet based on lamb meat with CMA infants was first reported, originally devised in 1973 in the Division of Pediatrics of Rome University [403]. What is surprising is that casein may remain active for 2,500 years [110] and egg for 500 years [12]. This chapter also includes oral allergy syndrome (OAS) and bird-egg syndrome.

Definitions

Among the clinical manifestations arising after a food ingestion we include *food anaphylaxis,* a severe classic, hypersensitive reaction, and *FA,* based on a clear cause–effect relationship between food ingestion and onset of allergic manifestations. A reaction to a food allergen by DBPCCT (double-blind, placebo-controlled challenge test) illuminates the pathogenesis [322, 413]. Although the immune reactions can be of varying types, the only immune mechanism to demonstrate FA *is IgE-mediated.* All non-IgE-mediated forms are defined as *pseudoallergic (PA) or food intolerance* [10, 334, 519] (Chap. 10). Actually, FA can be defined as the only allergic disease with a homogeneous etiology, since the causative factors are solely foods or their handling. FA children may be cured by oral desensitization in 84.6 %–87.5 % of cases [380].

Prevalence

Epidemiological estimates are highly variable in children: the values we have ascertained have a mean of 6.6% (Table 5.1) for FA and 2.42% for CMA (Table 5.2). However, in other studies done in selected children to be analyzed below, the positivity rate is much higher, with a prevalence of 23.5%. Usually, elevated values are lowered by DBPCCTs or open food challenge tests (OFCs). Table 5.5 shows that FA's onset is in the 1st year of life in 52%–100% of cases. In a prospective study on children aged 3–6 years, 28% were thought by parents to have had an adverse food reaction, only 8% had their symptoms confirmed with OFCs [257] and in DB trials [41]. In adults, DBPCCTs have corroborated 1.4%–1.8% of the presumed 19.4% [524]. In a similar study on 1,759 infants followed up from birth, the prevalence was 6.7% in 117 children manifesting symptoms indicative of CMA, but only in 39 of them (2.2%) was the diagnosis confirmed by FCTs [224]. The *onset age* is certainly a very significant factor: CMA began on average at 2 months with immediate reactions [140] and 57% of cases occur *in the first 3 months of life*, 75% *in the first 6 months* and 97% in the first 2 years [111] (Table 5.3 and Fig. 7.38). Several investigators rank CMA in first place [47, 140, 224, 397] among allergies, others egg allergy [26, 111, 178, 203, 237, 339, 449]. In 544 children with FA, the highest prevalence of FA was in the range of 1–3 years, for egg, peanut, and CM [386]. A double allergy has been reported, for example, 37% of egg-sensitized children were also CM-sensitized [449].

New sources of increased prevalence have been recently theorized, including characterization of additional allergens (Table 1.74), genetic modifications of natural foods, reports of countless cross-reactions (presence of common epitopes) [81], introduction of exotic fruits, etc., with multiplication of sensitization processes. The potential danger of transgenic foods (Tables 1.78, 1.79) seems to be increased, while genetics has been usefully applied to rice [525]. From this viewpoint, the increasingly more widespread practice in maternity wards of administering unnatural formulas to neonates instead of colostrum (Table 2.19) has facilitated the rise of FA prevalence in geometrical progression.

Pathogenesis

Immune Mechanisms

Foods making up a typical diet consumed by human beings are usually ingested daily, to the point that during a lifetime some 150 tons of food and fluid reach the gut, which has a total surface of about 400 m^2, thus being the largest immunologic organ of the body, and should protect the host against a wealth of foreign substances, while accepting and absorbing various nutrients to feed the host [200]. The gut is an extraordinary organ that has to accept these large amounts of nutrients daily while recognizing and reacting to harmful materials. It is surprising that only few foods are responsible for allergic sensitization. The foods as yet characterized have several allergenic proteins, but very few of them act as major allergens. Moreover, some foods retain their allergenicity irrespective of how they are consumed, fresh or cooked, etc. [1]. If FA first shows up as CMA, the first foreign protein consumed early in life, the following definitions should be retained:

More pathogenetic mechanisms may mediate allergic reactions, either immediate or delayed.

Multisensitizations may lead to different types of immunological activation in the same individual.

A different temporal modulation of external or internal factors may up-regulate the immunogenicity of food proteins.

Our understanding of the basic mechanisms underlying FA is still very limited. There are two important prerequisites: the antigen (a protein with a molecular weight of 10–70 kD) should be capable of crossing the protective mucosal barrier, thus triggering a potentially damaging immune response. In neonates and infants, the pathological transport of antigenic macromolecules through the small intestine may cross the mucosal barrier. The controlled uptake of these macromolecules results from the interaction of several immunological and nonimmunological factors within the lumen and on the mucosal surface [508]. Normally, the specific suppression mediated by T cells shoulders the burden of maintaining the host in a state of non-allergy, and numerous defensive components (Table 2.11) consolidate the epithelial barrier, where IgA antibodies predominate [508]. Several functions of the immune system are virtually immature (Chap. 2), a transient deficit in IgA is present and also the defense by antigen-specific CD8 T cells is deficient [461]. CM as such or contained in adapted formulas is able to induce lesions in a quantified way [24, 477]. These interwoven factors in neonates and infants are found to overlap and vary in genetically established and other occasional and environmental settings, which ultimately act as triggering events: in this way the differences can be explained in both the clinical course and histological patterns, explaining the difficulties met in establishing the diagnosis.

Despite considerable advances in the understanding of allergic responses, the mechanisms regulating GI allergy are not very well understood. The role of specific cells and their mediators in the development of food hypersensitivity reactions continues to be the focus of much debate. Several different immunological mechanisms and various pathogenetic hypotheses have in turn been proposed to explain the intervention of other types of immune reactions [10].

Cross-reactions among food (and inhalant) allergens are a new immunological variant of the pathogenesis. Precise identification of cross-reactive epitopes would

represent a significant advance in the problem of FA, since it would facilitate the choice of hypoallergenic substitutes for the treatment and prevention of FA. Table 1.73 offers a wide selection of cross-reactions among allergens. Table 1.72 details the spectrum of profilins, with an additional mixture of food (and inhalant) allergens, which can also cross-react among themselves. Both occurrences will be highlighted throughout the text, specifying their relative weight.

Type I–IV Pathogenic Mechanisms

As regards the mechanisms involved in the pathogenesis of CMA, varying immunological theories have been postulated, including types I, III, and IV of the well-known Gell and Coombs classification. Therefore, the differences in the clinical course, histological picture, various prognoses, and difficulties in the diagnostic procedure have been explained.

In *type I reactions* there are no doubts: this is the only mechanism that can be demonstrated with substantial evidence. Reactions mediated by mast cells of intestinal mucosa induce mediator release, thus resulting in many clinical manifestations acutely arising after food ingestion, with exclusive localization in the intestine (inducing vomiting and diarrhea), or other sensitized organs including bronchi, skin, etc., with a different expression depending on the amount of antigen that reaches mast cells of other areas [327]. This mechanism is self-maintained, since type I reactions raise mucosal permeability favoring the uptake of ever-higher doses of antigen in both the intestine and the circulation.

Type II reactions occur when specific antibody binds to a surface tissue antigen or hapten associated with a cell and induces complement activation. The products of complement activation promote the generation of several inflammatory mediators, which then leads to subsequent tissue damage. These reactions are explained by the likelihood that a mechanism mediated by antibody-dependent cell-mediated cytotoxicity (ADCC) plays a pathogenetic role in CM-induced enteropathy [410] and a case of antibody-dependent thrombocytopenia after drinking CM [145].

Type III reactions could be responsible for many GI manifestations on antigen exposure within the first 24 h or a few days: in 80%–90% of all children by the age of 3–4 years after CM ingestion, a CIC (circulating immune complex) deposition in tissues has been shown, a sign that CICs are not necessarily the cause of mucosal damage, nor are they correlated with disease [457]. In contrast, CIC levels are elevated in subjects with CMA [372]: this is an Arthus-like reaction with a local effect. CIC microprecipitates passively deposited beneath endothelium of vascular structures of target tissue may provoke acute inflammatory reactions in the gastroenteric mucosa, and reaching the cutaneous superficial microcirculation they cause edema and infiltration of dermal papillae [275]. Macromolecules escaping defense mechanisms face IgA and IgG blocking. Given that IgA antibodies as well as IgE are strategically positioned in the GALT (gut-associated lymphoid tissue), normally in excess of IgA, it is likely that an adequate part of antigen is neutralized *in situ* [508]. Unmodified CICs cross the intestinal epithelium and the IgA barrier, pass through the intercellular junctions, enter the portal circulation and reach the liver, where a part is conjugated with IgG of splenic derivation, but antigen-IgG CICs are cleared by Kupffer cells of the liver. The remainder of CICs bind IgA and form antigen-IgA CICs, and are eliminated by biliary salts; thus symptoms decline and pathological lesions regress [275]. Therefore, antigen-IgA CIC levels in normal subjects appear to be necessary for the induction of specific low-dose tolerance to food allergens [275]. In allergic subjects and with specific IgE (sIgE), eating an offending food may cause a passage of proteins in the circulation greater than that in normal subjects, thus resulting in antigen-IgG or -IgA CICs in a greater amount when compared to controls [96]. We stress that *in infants of a few months the levels of IgA and IgG are low*, hence antigen-Ig CICs are damaged, with the result that macromolecules taken up unmodified are sensitized by allowing the access of minute amounts of allergen at the next contact, with the possible outcome of allergic symptoms [367]. IgE and IgG CICs, in direct correlation with symptom development, are detected in the serum of subjects with FA, however without a support in other subjects with similar manifestations, but negative RAST [96]. Obviously, a straight correlation between food ingestion → CIC increase → appearance of symptoms in the absence of IgE is largely conjectural. Recently the role played by CICs has been re-evaluated after the report of a woman with recurrent urticaria-angioedema, bronchospasm and high levels of CICs in the peripheral blood. These CICs contained antibodies against bovine serum albumin (BSA), and a BSA-free diet induced a rapid CIC clearing with levels returned to normal, but BSA addition to the diet led to reappearance within 24 h [298]. In conclusion, the presence of food antigen-antibody CICs has been demonstrated in FA subjects and in nonsensitive and healthy subjects.

Type IV reactions rely on the more likely hypothesis that postulates that type IV immune reactions do not cover the entire spectrum of CM reactions, since children with CMA may manifest type IV symptoms of delayed hypersensitivity and lack of increased levels of sIgE to CM [275, 508]. On clinical grounds, it is characteristic that late responses to CM occur even after 15 days [82, 328]. Relatively little is known about these reactions: the specialized structures of Peyer's patches (PP) are important in a controlled antigen uptake from the gut lumen, as a cluster of lymphoid cells and in the induction of humoral immune responses [103]. An in vitro lymphocyte proliferation or interleukin (IL) generation by lymphocytes handling food allergens has been demonstrated in children with atopic dermatitis

(AD) and FA [445], especially in younger ones, but cannot be considered as specific, since it is also demonstrable in healthy subjects [245]. In children with CM enteropathy, activated $CD4^+$ are observed in the lamina propria of small-bowel mucosa, much more abundant in comparison to controls, which may play a role in contributing to mucosal damage [349], likely IEL (intraepithelial lymphocytes) and lamina propria cells emigrated from peripheral blood and activated by orally administered antigens [366]. These $CD4^+$ increase in the lamina propria after a FCT [366] or normalize with treatment, but regress to pretreatment levels after challenge [349, 366]. However, even if we can expect that CD4 are active [445], it is still difficult to accept the interference of IL_2 and IFN-γ Th1 producers [280]. The experimental demonstration of the type IV immune mechanism is complex: on histopathological grounds, an increase in cryptic hyperplasia and villous atrophy, epithelial lymphocytes and PBMCs (peripheral blood mononuclear cells) are observed in the lamina propria; along with a notable rise in the number of cells with IgG and IgA antibodies, is seen during relapses, thus leading to the hypothesis of a consistency between those immunohistological findings and the existence of III and IV type reactions [384]. TNF-α induced locally by PBMCs after FCT with CM is co-responsible for epithelial cell damage, especially when these cells function as a barrier: TNF-α acts in synergy with IFN-γ to increase gut permeability [208]. Mucosal damage is severe and extends to the entire GI tract even if the small bowel is involved more. The crucial role played by T lymphocytes has been widely investigated in intestinal explants of fetuses of different ages [310]: epithelial lesions and even explant destruction after mitogen stimulation are observed only in the mucosa of fetuses populated by T cells at age 14–20 weeks. Activation of T cells results in local IFN-γ production and an increase in HLA-DR expression by a tenfold increased rate of crypt cell proliferation, as well as of IEL numbers [311], so that after a 3-day culture the explant mucosa resembles that seen in untreated celiac disease (CD) [310].

The development of a protective or allergic response depends on which T lymphocyte subset has been activated by antigen molecules. However, the delayed maturation of suppressor CD8 T cells plays a role of primary importance in the pathogenesis. A IL_4^{++}, IFN-γ^{--} pattern (Table 1.10) follows Th2 T-cell activation, which stimulates IgE-mediated reactions, but if Th1 T cells are activated a reverse pattern and an isotype switch to IgG and IgA antibodies predominate. Recent reports demonstrating an *IFN-γ total absence in children with CMA at 13–23 months* [466] have confirmed similar cord blood (CB) results (Chap. 3). This explains why Th1 are deficient and express *no suppressor protective function*, and this maturation delay may be another pathogenetic cornerstone since it persists as an IFN-γ deficit in CM-intolerant children [465, 466]. Such deficits are added in a negative sense, because CD8 expresses

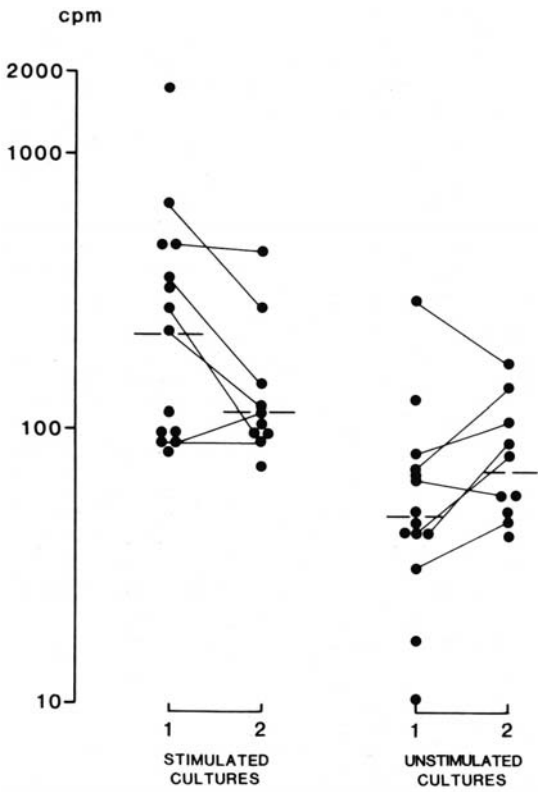

Fig. 9.1. Change in CM-induced lymphocyte proliferation from day 1 (before the food challenge, *1*) to day 8 (after the food challenge, *2*) in children with CMA and gastrointestinal symptoms. Lymphocytes were induced by CM (*stimulated cultures*) or cultured in the absence of CM (*unstimulated cultures*). *Dots* represent individual children, those *interconnected* were evaluated in both cases. *Horizontal lines* indicate geometric mean ($p<0.05$). *cpm* Count per minute

IFN-γ by immune deviation [222]. IL_4 was also wholly absent from the scene [465, 466], recalling previous discussions in Chap. 4. T lymphocytes and ILs generated appear to be dysregulated: at 2–44 months of age both the number and/or function of CM-specific circulating lymphocytes are reduced (Fig. 9.1) [467], and it is therefore likely that these dysregulations also compromise the humoral arm [244]. Although cell-mediated immunity (CMI) mechanisms contribute to several forms of adverse food reactions, there has been no clear-cut and objective demonstration of a food CMI disorder.

Food antigens are the main allergens that cause allergic reactions during infancy and childhood. An important role in the pathogenesis of FA is attributed to food-specific T-cell reactivity. Both in allergen-stimulated PBMCs and at the clonal level, it has been shown that the food-specific T-cell response in patients with FA is Th2-skewed when compared to that of food-tolerant individuals. Because the Th2-like T-cell ILs are important in the pathogenesis of allergic inflammation, these results have suggested a key role for allergen-specific T cells in FA-related symptoms. Recently, CM-specific T cells from

infants with CMA have been shown to express significantly higher levels of CD25 and CD30, both more important T-cell activation markers than CM-specific T cells from infants without CMA. Expression of CD26, a marker of Th1 inflammation, was lower than in normal controls. Following stimulation, antigen-specific T cells from children with FA display an increased expression of cell-surface markers of activation, compared with children without FA [435]. Although it is known that activated T cells of the human intestinal lamina propria are in general high producers of IL_{10}, almost no IL_{10} could be measured in the activated milk-specific T-cell lines. A similar low release was found for TGF-β, both of which contribute to tolerance development in the mucosa.

New insights have been provided into the molecular mechanisms involved in allergic responses of the GI tract. A critical role of *eotaxin* was demonstrated in regulating allergen-induced eosinophil trafficking to the lamina propria of the GI tract, also in the absence of the major eosinophil growth factor IL_5. In the absence of IL_5, allergen challenge promoted partial eosinophil accumulation into the small intestine and a decline in circulating eosinophil levels [542]. Therefore, the accumulation of GI eosinophils is antigen induced, can occur independent of IL_5, and a molecular mechanism explains the dichotomy between peripheral blood and tissue eosinophilia. Furthermore, eotaxin is identified as a critical regulator of antigen-induced eosinophilic inflammation in the GI tract. Eotaxin-1 appears to be more ubiquitously expressed in the GI tract compared with *eotaxin-2,* which is *a potent chemoattractant for eosinophils,* predominantly expressed in the jejunum. By combining the results of comparative experiments between eotaxin-1 and eotaxin-2, both chemokines were demonstrated to have comparable activity in the GI tract [542]. In conclusion, the finding that peripheral blood and tissue eosinophilia can be dissociated in the absence of eotaxin indicates that the relative balance between the expression of eotaxin and eosinophil IL_5 can have profound effects on the relative distribution of eosinophils. As a corollary, underexpression of IL_5 relative to eotaxin can lead to GI tissue eosinophilia in the absence of circulating eosinophilia. Intriguingly, agents that block eotaxin and/or CCR3 may have beneficial effects on modulating eosinophil-associated GI allergies [221].

Humoral Mechanisms

Immune exclusion against CM proteins and tolerance acquisition suffers from significant antibody reduction in infants with CMA (mean, IgA 19%, IgM 15% and IgG 27%) and of IgAs (specific) against β-lactoglobulin (βLG) and casein (11% and 5.5% compared to 60%–50% of healthy controls) [256]. In egg-allergic children, the lymphocyte capacity of producing anti-OVA (ovalbumin) IgAs is deficient up to the 6th year, thus explaining the early onset of CMA [357].

A possible IgG-mediated pathogenetic mechanism has not been confirmed in humans: antigen-specific IgG bound to mast cells are reported in certain patients who release antibodies to pertinent allergens; however, these IgG are characterized by scarce concentrations and short-term effects: thus they fail to play a specific role [429]. Even if IgG_4 show a blocking action to antigens via CIC generation, preventing antigens by competition from reaching target cells or organs, they are present both in healthy and in allergic subjects, so that increased concentrations could exemplify a normal response to antigens, and no pathogenetic role whatsoever has been conclusively ascribed to IgG_1 [59, 212]. The response of involved organisms to a chronic antigenic stimulation is mainly upon IgG_4. This restricted response may be associated with the significant aspect that IgG antibodies may have a protective role for damage due to CIC formation and complement activation when the response is primarily IgG_1 and IgG_3 [96]. Others have not confirmed an IgG protective effect in the first years of life, despite elevated IgG titers in CB and/or in maternal blood [117]. Moreover, anti-CM and anti-egg IgG titers decline in the first 6 months of life, to rise over the subsequent period: an increase in anti-CM IgGs (specific) is a normal event, whereas that of anti-egg IgG is surprising, since eggs are introduced later [117], so we may hypothesize that small doses of egg white presumably found in BM may stimulate an IgG response. However, IgG_4 and IgE immune responses seem to run parallel in some cases, due to a common dependence on Th2 cells.

IgE hyperproduction in atopic children is probably caused by a stimulating effect of IL_4 and IL_{13}, but IgE have been found in CB only in 0.5% of newborns (Table 3.2). However, some infants have elevated titers already in the first months of life, levels that often develop prior to weaning, likely to be in connection with anti-idiotype antibodies from BM.

IgE antibodies to foods are detected soon after birth and develop high titers during the 1st year of life. Based on the data [105, 111], it is not unexpected that high titers of IgE to foods are detected in 14% of infants at 3 months of age and in 31% of infants of 8 months [203]. A transient IgE antibody response to foods is also found in 8% of normal infants, in comparison with 19%–48% of infants at high risk (HR) of atopy [203]. Thus, IgE antibodies to CM and egg white appear frequently in both normal and atopic infants, but elevated titers are found only in atopic infants, thus indicating that predisposed infants are less capable of suppressing IgE antibody responses. However, low levels should not be overlooked, since they can cause severe anaphylactic reactions, whereas moderate titers are often consistent with tolerance acquisition [117]. It is plausible that a massive antigenic load on the GALT favors not only IgE antibody formation, but also formation of IgA, IgG and IgM antibodies with a likely blocking capacity; however, the

titers are very low at the age 7 months [256]. Moreover, the scales may turn to one side or the other depending on the prevalent IL pattern or involved T-cell subpopulation to which sensitized cells are exposed [245].

In conclusion [117]:

The IgE antibodies:

- They are predictive of atopy.
- They appear early and frequently in young infants both in atopics and nonatopics.
- They often appear during breast feeding and before the introduction of causative foods into the diet.
- They are present independently of breast feeding duration and frequently even when breast feeding is exclusive.
- They appear less often in the offspring of nursing mothers on a restricted diet than in the offspring of mothers on an unrestricted diet; however, the effect is limited to the restriction period.
- The IgE response often persists even when all further contact with the allergen is stopped.
- High IgE levels occur in infants with current or future atopy [117].

The IgG antibodies:

- There are mainly maternal antibodies during the first months of life and antibody levels in the infants are not affected by dietetic restrictions during pregnancy and/or lactation.
- Infants with IgE hyperproduction have high IgG concentration, but type I allergy is an IgE prerequisite.
- IgG_4 levels are often increased more than IgG_1 levels: there is a correlation between IgE and IgG antibodies for the same food, contrary to inhalant allergens.
- High IgG concentrations of egg appear to be a good prognostic sign in children with AD [118].
- lgG_4 therefore have no role in pathogenetic mechanisms of FA [117], nor do convincing reports prove an lgG_4 protective function [429], because lgG_4 levels rise during responses to food proteins [212, 429], but no difference in the IgG antibody level was found in patients with positive or negative response to CM challenge [56, 211].

The IgA antibodies:

- Secretory IgA (sIgA) of the intestinal surface and, in lower numbers, IgM antibodies, provide a specific response to the antigens taken up, a response absent in the neonatal intestine where no such antibodies are found.
- The IgA and other BM factors protect newborns from allergic sensitization and thus from FA, especially in infants at risk of atopy, on condition that nursing mothers do not ingest potentially sensitizing foods during breast feeding.
- Antigen-IgA CICs avoid antigens reaching their targets by the same IgG mechanism; however, they have a negligible diagnostic value for an individual patient [275].

Therefore, even if a correlation between IgE and IgG_4 levels has been put forward there is no proof that IgG_4 plays a role in FA pathogenetic mechanisms, nor does a protective function appear to be documented. It can be hypothesized that high IgG_4 levels represent an epiphenomenon of IL_4 that stimulates B lymphocytes to selectively produce IgE and in concomitance IgG_4, likely exemplifying a chronic antigenic stimulation of an immune system not fully controlled and/or subjected to excessive exposures. More important are IgA antibodies that reach breast-fed neonates and infants [275] who are protected from food allergens: only half of infants have measurable levels of IgA anti-CM and/or anti-egg, which are not correlated with IgE and IgG concentrations [203]. In other studies this parallelism is present [117]; anti-food IgM antibodies do not pass the placenta and have a low weight in BM.

Since FA depends on an IgE-mediated mechanism, it is unclear how a sensitization to food proteins is mediated by non-IgE antibodies or how such antibodies interact with the immune system [10].

In Utero Sensitization

The human fetus is able to produce IgE antibodies early (Table 2.3), which cannot act against the fetus. Maternal IgE do not pass the placenta (are absent in CB), which can be traversed by substances with immune properties. Interestingly, the first exposure can be *in utero,* due to intrauterine exposures. The fetus is capable of responding to food antigens ingested by the mother by mounting type IgE antibodies: in the amniotic fluid and CB IgE to CM, egg and wheat have been detected, surely of fetal origin, since the mothers of such children are RAST-negative to the same foods (Chap. 2). Transplacental exchange of immunogenic cells occurs in both directions, an explanation of a possible pathogenetic role of foods ingested by pregnant mothers and transported across the placenta [325]. It has been hypothesized that fetal sensitization is induced by anti-idiotype maternal antibodies, including IgG antibodies directed towards food antigens. The anti-idiotype antibody anti-food antigens, capable of recognizing idiotopes within the paratope, may replace the antigens, mimicking their functional properties, be transmitted to the fetus across the placental filter, and act as antigens in neonates and infants [330] with consequent priming of anaphylactic reactions at the first food administration. Ratner has demonstrated the possible *in utero* sensitization to CM proteins of guinea pigs and postulated that a similar process might even occur in humans [400], a potential explanation for a fetal sensitization to foods previously ingested by the mother, even if these foods are not eaten during pregnancy. No study aimed at verifying the effectiveness of allergy prevention by a CM- and egg-free maternal diet during the last trimester of gestation, not even a randomized study over 5 years, found statistically significant differences on the onset of atopic manifestations in the newborns as related to maternal diet [156]. A fetus of 10–20 weeks already responds to IgE

Table 9.1. Timing of sensitization through breast milk in babies apparently fed only breast milk

Authors/ Reference	No. of babies studied	Age at onset of symptoms	Incriminated foods ingested by the mother (no. of cases)	Tests done and no. of positive tests

and to a wide spectrum of antigens, inhaled or ingested by mothers during pregnancy, as discussed in Chap. 4. Lastly, CM supplements given in neonatal nurseries are detrimental for *in utero sensitization* in addition to being a risk factor for persistent CMA at age 2.0 years [odds ratio (OR), 3.2%; 95% CI, 1.4–7.8], and early sensitization to egg (OR, 2.8; 95% CI, 1.2–6.6) [408].

Postnatal Sensitization

When human neonates leave the sterile intrauterine habitat, they face a biological status of immunological deficit (Tables 2.1, 2.2); nevertheless a defense barrier should be rapidly organized. In 1918, Talbot [469] reported the development of AD in a 3-week-old exclusively breast-fed infant, obviously a reaction to a food that was never eaten: the atopic manifestations cleared when milk chocolate was completely eliminated from the mother's diet. In the reports *emphasizing BMA,* βLG may be responsible: elevated βLG levels in the milk of several nursing mothers and the serum of their children were found 1 h after BM ingestion [317]. An infant has reacted with vomiting and diarrhea to BM containing βLG levels of 740 pg/ml [17]. More precisely, βLG has been found in BM with frequencies of 18% [462], 44% [314], 47% [238], and 68% [17] of cases; high βLG titers (up to 800 µg/l) have been associated with symptoms of CMA in one child [17]. However, CM hydrolysate formulas (HF) contain even higher βLG rates, contrary to BM [451]. The response depends on the child's immune status: if the child is healthy the allergens will be tolerogen, if atopic, the child will not be tolerant, and the more severe the atopy, the more sensitive the child will be to the allergens. IgE were positive to CM and egg before the official introduction into the diet in 14% of 65 infants aged 3 months [203], and OVA may be detected in the serum of exclusively BM-fed and egg-allergic infants [93]. Actually, BM sensitization is limited to 0.042% of cases [89]. Table 9.1 [77, 92, 101, 124, 176, 225, 301, 307, 361, 400, 444, 469, 510] shows that 153 children have been studied with skin prick tests (SPTs), RAST and OFCs. Minimal doses of heterologous proteins in BM are sufficient to act subsequently as a booster dose, triggering in infants even an anaphylactic shock, frequently labeled as BMA, whereas it is caused by hypersensitivity to CM proteins ingested by their mothers [301, 314] (Table 9.1). Before diagnosing a BMA, one should recall the studies reporting that the exposure to small doses of allergens can sensitize a predisposed individual [247, 248].

The pathogenetic effect of small sensitizing doses disseminated in neonatal nurseries (Chap. 3) agrees with the results of several studies supporting the hypothesis that CMA is significantly more frequent in children who received CM supplements in a period of particular vulnerability, in comparison with infants exclusively fed BM since the first hours of life [78, 86, 225]. Significantly, *only the 39 infants with adverse reactions*

to CM were fed CM supplements in the first 3 or 4 days of life [224]. Evidently, if neonates with atopic predisposition were not fed potential allergens early in life, the development of an atopic disease would be postponed and the included risk lessened [93] (Chaps. 3 and 24). We are a long way from seeing a complete picture, but the drop in sIgA antibodies in both colostrum and milk in mothers of neonates who will be affected with CMA later on compared to mothers of nonallergic children is significant [431].

Immunology of the Gastrointestinal Tract

To understand how foods, necessary for a child's normal development, provoke lesions in different organs, they should be viewed as a "non-self" that GALT must transform into small molecules to make them immunologically tolerable. When in particular conditions the foods deliver antigenic characteristics, they become capable of stimulating the immune responses, including a high molecular weight (MW) of proteins by which are formed macromolecules; other crucial functions are carried on by microbes, viruses, enterotoxins, etc. [348] (Fig. 9.2) [340].

The GI tract is composed of four concentric layers, which from the lumen inward are the *mucosa* (epithelium, lamina propria and muscularis mucosa), *submucosa, muscularis externa* and *serosa,* specialized tissues containing lymphocytes, macrophages, mast cells [327], and eosinophils [542]. From an immunological point of view, the GI tract can be described as an epithelial tube separating intraluminal immunogenic peptides from immunoreactive cells and antibodies residing in the

lamina propria. T lymphocytes found in the lamina propria and between epithelial cells form a diffused lymphoid tissue, which has effector functions for the GALT efferent arm [440]. The greatest lymphoid organ of the human body playing a central role in the intestinal immune function includes:

- PP and appendix
- Lymphocytes and plasma cells of the lamina propria
- Solitary lymphoid follicles
- IELs
- Mesenteric lymph nodes, which differ from other lymphoid organs because they do not possess capsule and afferent lymphoid vessels

The sIgA antibodies predominate in the GI tract and are a major characteristic of the human GALT [440] (Fig. 9.3) [343].

Lymphocytes

In the adult intestine (about 9 m long), there are about 10^{10} lymphocytes/m, a striking feature when one considers that all immunoglobulin-producing cells in bone marrow, spleen and lymph nodes combined are as high as 25×10^{10} [310]. The majority of B cells are committed to IgA synthesis and undergo an isotypic switch so that sIgA production in both PP and lamina propria is promoted rather than the IgM isotype [333]. Almost all T cells in the intestinal epithelium and connective matrix of lamina propria use an α/β TcR, and only 10% of epithelial $CD3^+$ are γδ, characterized by a Vγ1/Vδ1 gene rearrangement and in the bloodstream by Vγ9/Vδ2 [310]. About 50% of IEL T cells and 80% of lamina propria T cells are $CD45RO^+$ memory cells; lymphocyte and immunoglobulins (Igs) are summarized in Tables 9.2 and 9.3 [310, 333, 460]. Notably, $CD8^+$ may be positioned nearer epithelium, while $CD4^+$ are found more centrally, in the villi. This location supposedly has the goal of regulating immune response to soluble antigens in the gut [490]. The presence of T lymphocytes is not imperative for the mucosal integrity of GALT: this is supported by the morphologically normal mucosa in infants with SCID (severe combined immunodeficiency) without B and T lymphocytes [457]. As regards lymphocyte circulation (Fig. 1.12), PP B cells, if sensitized, migrate to mesenteric lymph nodes, where they differentiate, returning to colonize even distant mucosal sites including breast [185] (Fig. 2.18).

Table 9.3. Immunoglobulin distribution in the human intestinal tract

Location	IgA	IgA_1	IgA_2	IgM	IgG
Gastric body	74	80	20	12	14
Antrum	80	85	15	8	12
Duodenum/jejunum	70	70	30	17	4
Ileum	80	55	45	11	5
Colon	90	38	62	6	4
Rectum	ND	45	55	ND	ND

IgA, IgM and IgG antibodies are expressed as a percentage of all Ig-containing cells; IgA_1 and IgA_2 antibodies are expressed as a percentage of IgA-containing cells.

Macrophages

Leaving aside their functions, in the GI tract macrophages are located in subepithelial sites, superficial epithelium, and under the PP dome and reside around efferent lymphatics. Scarce in IELs, these cells are more abundant in the lamina propria, where 80% of cells expressed by HLA-DR antigen have a dendritic cell (DC) appearance, whereas in the colon 60% show phenotypic features of macrophages [311]. Strategically located beneath the surface epithelium, in addition to classic defensive phagocyte functions, they show little evidence of providing costimulatory signals for T lymphocytes [202]. Many of these cells express large amounts of HLA class II antigens and other surface markers associated with phagocyte activity and participate in mechanisms of nonspecific defense, but produce low levels of IL_1 and IL_6, necessary to the local differentiation of B cells. Although macrophages might present antigens to $CD8^+$ IEL in a DQ-specific fashion, they express few activating signals to lamina propria $CD4^+$, since they produce little or no CD54, which is important for T-lymphocyte adhesion via interactions with CD11a, leaving T cells in an antigen-independent state of anergy [442].

Dendritic Cells

Interdigitated in T zones, DCs of oral epithelium, similarly to cutaneous DCs, act as antigen presenting cells (APCs), independently of their origin and antigen administration route [484].

Mast Cells

Distributed throughout the length and breadth of the human GI tract, small in size with a rapid turnover, mast cells increase in number in FA [15]. Mucosal mast cells are T cells, whereas peritoneal mast cells are TCs (Table 1.27) and also may participate in the host defense, because mast cells may recruit inflammatory cells to the site of parasitic infection, etc., but food-sensitive subjects have exhibited food-specific, mast cell-dependent reactions upon ingestion or direct exposure to the appropriate antigen [15]. Mast cell immunological function has been appraised both in children undergoing FCTs, in whom histaminemia underlies degranulation (and that of basophils), and by measuring mast cell protease, a specific marker of cell secretion, or tryptase [365]. T mast cells, localized predominantly in the lamina propria (20,000/mm^3), facilitated by both LPAM-1 (lymphocyte Peyer's patch HEV adhesion molecule 1) and MAdCAM-1 (mucosal addressin cell adhesion molecule-1), are juxtaposed to a true network of neuropeptides, where substance P (SP) operates, and work as sensory receptors of the so-called *enteric mini-brain,* transmitting information on the microenvironment to peripheral nerves and CNS [132]. Data circulate in a bidirectional way, thus also the CNS, through its neurotransmitters, can send impulses to the periphery, where SP is able to evoke mast cell degranulation via subliminal stimuli [132] (Fig. 9.4).

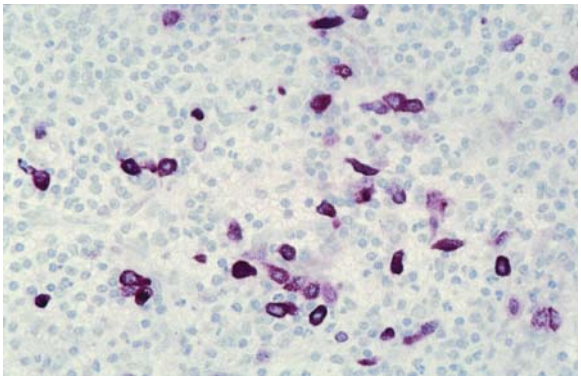

Fig. 9.4. Mast cells in normal intestinal mucosa

Eosinophils

Children with CMA frequently have eosinophilia during CM feeding, with this sign present in 33%–50% of children [385]. Prominent eosinophil infiltration is seen in several diseases to be discussed. New insights have been provided into the molecular mechanisms involved in allergic responses of the GI tract. In the genetic absence of the chemokine eotaxin, constitutively expressed in the GI tract as a key regulator of eosinophil circulation during GI allergic processes, eosinophil recruitment into the small intestine was reduced. A critical role of *eotaxin* was demonstrated in regulating allergen-induced eosinophil circulation to the lamina propria of the GI tract, also in the absence of the major eosinophil growth factor IL_5. Interestingly, in the absence of IL_5, allergen challenge promoted partial eosinophil accumulation in the small intestine and a decline in circulating eosinophil levels. Therefore, the accumulation of GI eosinophils is antigen-induced, can occur independent of IL_5, and a molecular mechanism explains the dichotomy between peripheral blood and tissue eosinophilia. Furthermore, eotaxin is identified as a critical regulator of antigen-induced eosinophilic inflammation in the GI tract. Eotaxin-1 appears to be more ubiquitously expressed in the GI tract compared with eotaxin-2, which is an eosinophil chemokine, induced by IL_4 overexpression. By combining the results of comparative experiments between eotaxin-1 and eotaxin-2, both chemokines have been demonstrated to have comparable activity in the GI tract [542].

Mucosa

The intestinal mucosa quantitatively makes up the largest mediator organ of humoral immunity. GALT discriminates between potentially pathological and harmless stimuli: in one part it elaborates suppressor activity to neutralize ubiquitous antigens, in the other it is capable of responding adequately to stimuli by producing antibodies interacting with potential pathogens, which are eliminated without concurrently eliciting inopportune inflammatory reactions. GALT responses are able first to block the way to and then to eliminate antigenic macromolecules [51].

Epithelium

The intestinal epithelium alone includes 25% cells of lymphatic origin: it is constituted intrinsically by columnar cells capable of absorbing foods, muciparous calyciform cells that produce intestinal mucus and IELs [440]. The effector functions carried out by these cells are exclusion, transport, breakdown and antigen presentation, bidirectional transport, and antibody secretion [311]. The human intestinal epithelium, including the cells overlying PPs, express HLA-DR antigens as PPs, which may therefore *play a role in antigen presentation to the local immune system* by epithelial cells, but rarely in the normal subject [311]. Even if important costimulatory molecules of B cells such as CD80/CD86 and CD54 are absent, it is believed that epithelium is the preferential afferent mode of intestinal immune responses, by taking polypeptides up and activating the CD8: the key ligand is gp180 (CD45RO) of IgSF (immunoglobulin superfamily) [254] (Table 1.4). Instead, in experimental animals the increment of HLA-DR expression, modulated by local IFN-ɣ production by mucosal T cells, up-regulates the enterocyte capacity of to act as APCs [536].

Peyer's Patches

Described in 1667 [386], PPs (Fig. 9.5) are well developed in fetal life and increase in number and size progressively from 50–100 in neonates to 200–300 by late adolescence [311, 460]. The most prominent PP feature is the follicle center, containing centrocytes and centroblasts [185]. The specialized dome epithelial cells derive from Lieberkühn crypts adjacent to the follicles, are part of follicle-associated epithelium (FAE), with a possible function of separating PPs from enteric lumen [311]. PPs are located in the human ileum, but mainly in the mucosa and submucosa, in an immediately subepithelial position, and reach the length of several cm [185]. More precisely, in contrast with various animals, in humans they are of a higher number and size in both the ileum and jejunum, where the follicles number between 10,000 and 20,000. The ileal PPs undergo

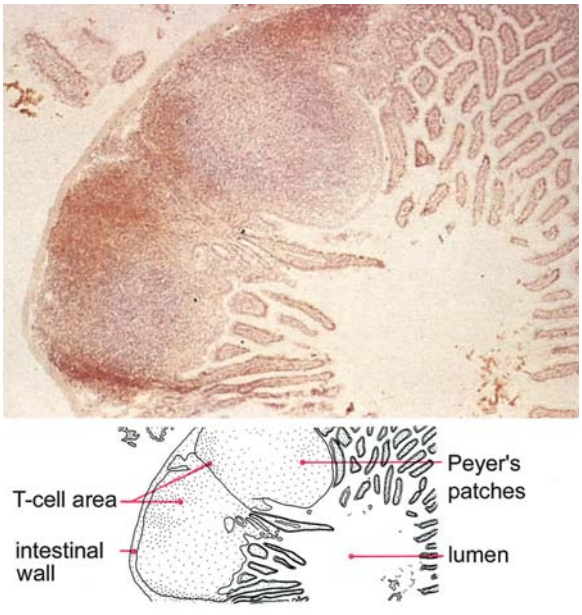

Fig. 9.5. Peyer's patches in mouse ileum, T-cell areas are stained *brown*

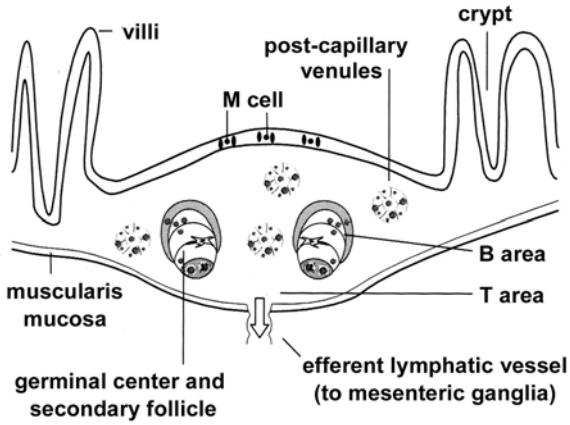

Fig. 9.6. Structure of Peyer's patches

an involution in a way similar to the thymus, whereas jejunal PPs persist in humans throughout their lifetime [185]. Interestingly, *PPs develop during fetal life* when the gut lumen is sterile, thus suggesting that foreign antigens are unessential to start both B cell colonization and expansion within PPs [185]. In humans, PP architecture is comparable to that of lymph nodes, with similar B- and T-dependent areas; the lymphoid follicles with B cells (60%–70%) express sIgA, sIgM and plasma cells, encircled by T lymphocytes (25%–35%) with prevalent CD4 phenotype [461] (Fig. 9.6).

FAE is a one-cell-thick lining layer with fewer villi compared to the epithelium of the surrounding intestine; calyciform cells are few in number and the SC (secretory component) is not seen [327]. On entering the lumen of the small bowel, immunogens present in the gut are sampled by way of specialized M cells (Fig. 9.7), overlying the dome of lymphocytes, which are extremely efficient at sampling antigens infiltrated in the lumen of the small bowel to deliver such antigens to underlying antigen-specific B cells, which are thus transformed into antibody-secreting plasma cells if the appropriate costimulatory molecules are also present [461]. However, B cell activation, as reflected by germinal centers, is not apparent until shortly after birth (Fig. 1.5). M cells are rare in humans, despite countless studies in rodents [185], but are believed to play a key role in the induction of mucosal immune responses, since in the PPs antibody responses against food or microbial antigens are induced [185]. Non-self substances are taken up by M cells, which differ from other mucosal epithelial cells since they have few microvilli, have a poorly developed glycocalyx and no lysosomal organelles [508]. Such data support the view that M cells are especially well adapted for microorganism and endoluminal peptide uptake, which are then transported directly to mucosa-associated lymphoid tissue (MALT), in that since they are probably HLA-DR$^-$, they are unlikely to play a role in antigen presentation [311]. Recent reports stress that M cells are important as a route of antigen entry into GALT. Unlike

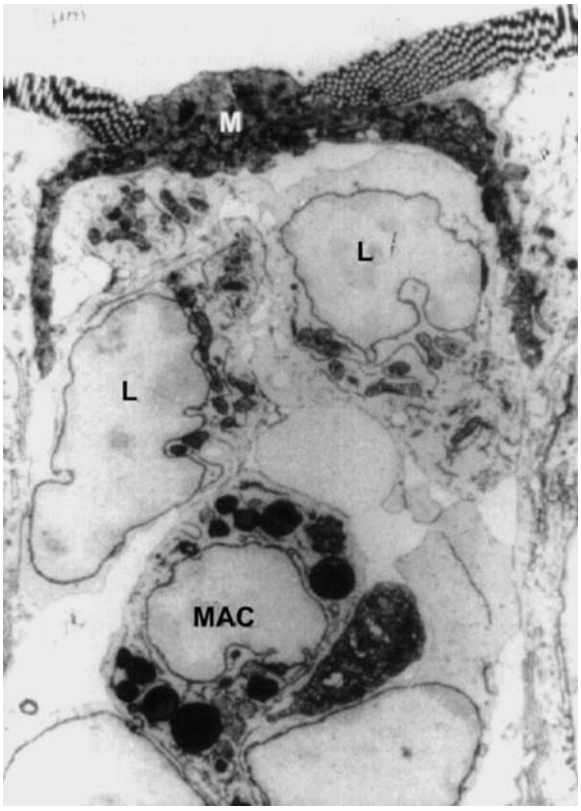

Fig. 9.7. M cell ultrastructure. *M* M cell, *L* leukocytes, *MAC* macrophages

the intestinal epithelial cells that take up soluble antigens, M cells are extremely efficient in sampling and transporting particulate antigens, and their surface appears to be specialized for endocytosis of antigens, which are then processed and presented to immunocompetent cells such as CD8 localized nearby [254]. DCs are present in normal PPs, follicular DCs (FDCs), and macrophages express the HLA class II molecules necessary to present macromolecules to B and T precursors, with consequent activation of these cells. Therefore, the PPs would be for food allergens an inductive site for lymphocyte activation [334].

Antigens of the GI mucosa, via intracellular uptake and ensuing digestion or via intercellular spaces (Fig. 9.8), gain access to PPs, thereby stimulating the local immune system [508]. In turn, B and T lymphocytes reach PP subepithelial and interfollicular zones through small postcapillary vessels of the HEV (high endothelial venule) type [442]. MAdCAM specific of MALT (Table 1.45) is expressed on HEVs of PPs and mesenteric lymph nodes; naive T cells also require CD62L to adhere to HEVs [254]. PPs may have the function of bringing circulating CD4 into contact with intraluminal antigens, and consequently their priming associated with expression of functional CD40 in ileal PP B cells may occur after B cells able to respond are selected, and their expansion is modulated by a combination of

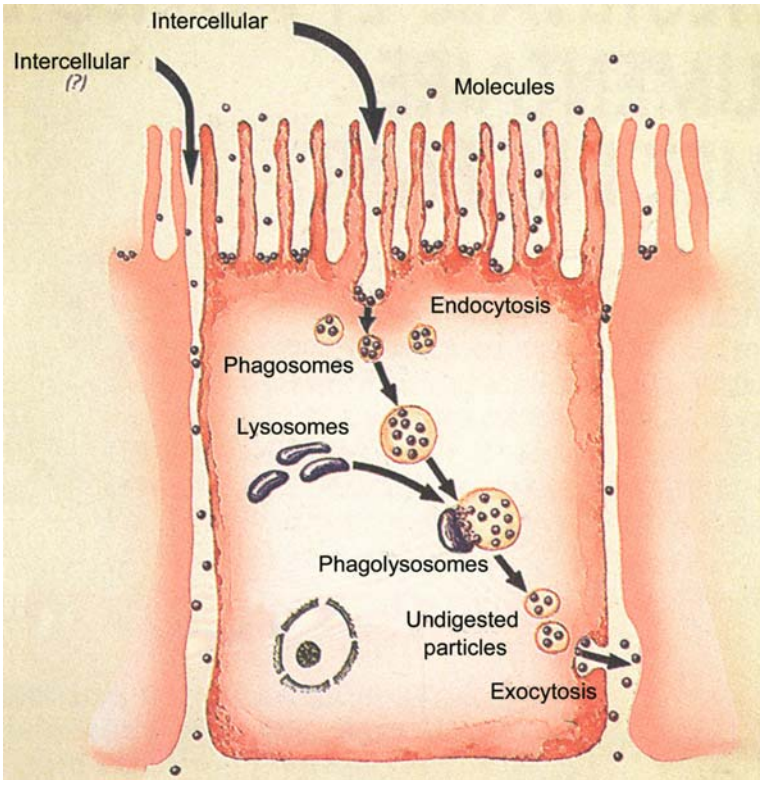

Fig. 9.8. Antigen uptake by enterocytes

ILs in concert with CD154/CD40L [185]. Another prospect is that interactions between B cells and T cells induce the latter to migrate to the periphery via efferent lymphatic vessels, mesenteric lymph nodes and the thoracic duct, consistent with their known migration route. Returned to their final stage, the lamina propria of the intestinal wall, or other secretory areas, CD4 T cells may induce B lymphocyte differentiation in plasma cells-IgA when antigen priming first occurs in the GI tract [275] (Fig. 1.12). B follicles are also found in the colon, but aggregates of follicles akin to those seen in small bowel PPs are not seen in the colon, nor has their function been widely scrutinized [185, 311].

Lamina Propria

Early in life, the lamina propria is infiltrated with B lymphocytes in large numbers committed to IgA synthesis (Tables 9.2, 9.3) and plasma cells (in decreasing order) IgM, IgG, IgE, IgD [457]. The sIgA are the majority, 70%–80%, of all GI Ig-producing cells; the remaining include sIgM and IgE, which amount to 5%, so it can be estimated that ≈80% of all Ig-producing cells of the body are localized in the GI mucosa [51]. In humans, sIgA number some 10^{10}/m of small bowel [51] (Fig. 9.9). Contrary to airways, tonsils and lymph nodes, where IgA predominate, IgA_2 are more numerous (60%) [333]. However, the majority of IgA secreted by plasma cells are dimeric: J-chain expression is more prominent in

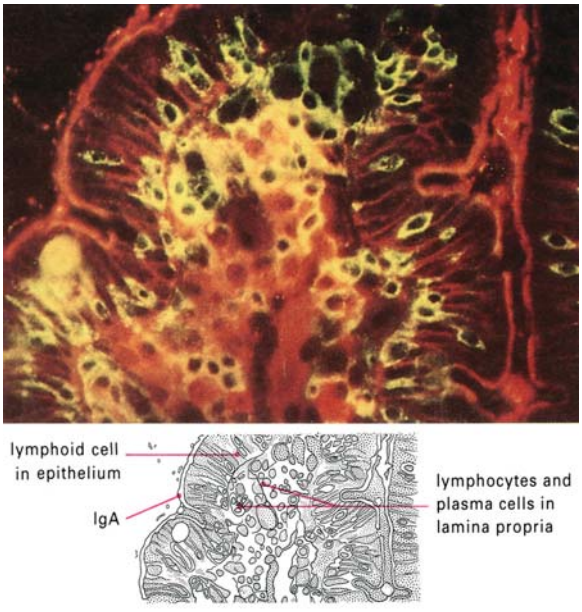

Fig. 9.9. Section of human jejunum showing lymphoid cells stained *green*, in the mucosal epithelium and in the lamina propria. A red fluorescent anti-IgA conjugate stains the plasma cell cytoplasm in the lamina propria and detects IgA in the surface mucus

IgA_2 (100%) than in IgA_1 (88%) [268]. Recently, SC has been found to be a key factor in sIgA and sIgM generation: their expression may be marked by IFN-γ, IL_4 and

TNF-α [442]. IL_4–IL_6 act as B cell terminal differentiation factors [442]. T cells and activated macrophages secrete sIgA and sIgM, which are then actively transported during mucosal reactions. The IgA activity is known to ensure the first line of defense in the context of immune homeostasis [508]: in selective IgA deficiency, IgM dominate in the GI mucosa and IgG are not increased. The sIgA transported in the intestinal environment, once SC binds polymeric IgA, is carried into epithelial cells by pinocytosis. The complex is then transported in vesicular form across the cell to the luminal border. Given its unique structure, sIgA is less susceptible to proteolytic digestion and retains most of its functional capacity while passing along the GI tract [310, 348]. Two different subsets of T lymphocytes are visible, but $CD4^+$ predominate in the lamina propria and in mesenteric lymph nodes [244]. There is lymphocyte differentiation with specific and nonspecific mechanisms either cell-mediated with induction of IgA-specific CD4 and of IgG-specific suppressor CD8, or humoral with B lymphocyte activation and proliferation and IgA raised production [440]. Resident T cells may induce an isotype switch in B cells, so that IgA synthesis is prominent on IgM isotype. Moreover, T cells with Fc receptors for IgA may help commit B_{IgA} development into true plasma cells, a *crucial event in neonates and young infants with no lamina propria IgA* [244]. T and B cell collaboration is underlined by CD2–CD58 interactions, a means of control of IgE synthesis independent of the classic CD40–CD154 interaction (Fig. 1.22a). At this level, the $CD4^+$-to-$CD8^+$ ratio is about 4:1, as in peripheral blood [310]. Roughly one-half of CD8 T cells have cytolytic function and express CD28, 10% are $CD25(IL_2\text{-R})$; very few CD16 are associated with NK cells and CD49a/29 or VLA-4 [244, 310]. In light of these data, lamina propria T lymphocytes possess specific features that distinguish them from subsets localized in other organs and tissues. Homing receptors bind T cells selectively to PP HEVs: this binding is mediated by $\alpha_4\beta_7$ (LPAM-1), with an α chain homologous to α_4 of CD49d/29 (Table 1.45), expressed also by IELs, notably a MAdCAM ligand [202]. The MAdCAM–CD49d/β7 couple is sufficient for this circulation; however, CD62E is absent [254]. The weight of β7 integrin is such that it is expressed in addition to mast cells by human B lymphocytes when they migrate to the lamina propria for terminal differentiation, and the critical role of $\alpha_4\beta_7$ in the existence of GALT should be recognized [504]. In allergic subjects, CD4 is already activated, as demonstrated by T cells expressing IL_2 receptor mRNA (CD25), by HLA class II raised expression and even higher expression of IFN-γ, IL_4 and IL_5 mRNA [245]. CD4 T cells are demonstrated in vitro; there is a reason lamina propria CD4 express more helper activity than suppressor activity as compared to CD4 of other tissues. This activity is exercized upon B lymphocytes, thus modulating in particular local IgA production [202]. Lamina propria contains many mast cells of the mucosal type [15] and can be infiltrated by neutrophils, eosinophils and macrophages.

Solitary lymphoid follicles, presumably functional PP equivalents, are disposed throughout the entire GI tract, especially in colon and rectum; on the whole, they averaged $9/m^3$ of large intestine, usually with germinal centers.

Intraepithelial Lymphocytes

The IEL population (Table 9.2) is not homogeneous: the epithelium lining the enteric mucosal surface contains up to 20% nonepithelial cells, the greater part of which constitute the IEL population, residing in the basolateral surface of epithelial cells that make up intestinal villi, in the interstitial spaces between epithelial cells. IELs can also interact with immunogens that can cross to the epithelial cell surfaces, since they first encounter the myriad of antigens present in the GI tract. Although quantitatively fewer than lamina propria lymphocytes, they are consistent in number, in that in normal humans one of every 5–8 enterocytes and 9–40 out of 100 epithelial cells are IELs, whose numbers increase in inflammatory states [202]. IELs express $\alpha_E\beta_7$ integrin recognized by CD103 (Fig. 9.10), whose expression is amplified by TGF-β1. IELs adhere to epithelium by heterotopic adhesion between CD103 and E cadherin on epithelial cells [254] (Table 1.51). The $\alpha_E\beta_7$ integrin is the only one expressed also by pulmonary IELs and is known to mediate a double T homing. In the IEL subpopulation of the normal human small bowel, 70%–80% are CD8 T cells expressing the CD45RO and CD45RA markers, thus suggesting that they are activated or memory T cells, more than 15%–20% of cells with the CD4 phenotype, half of lamina propria CD4 [51]. $CD2^+$ and $CD3^+$ (Fig. 9.11) are 5%, $CD3^-$, $CD4^-$, $CD8^-$, $CD7^+$ in an unspecified share and CD49a/29 50% [202]. B lymphocytes are virtually absent. CD8 T cells could display a CTL activity, but have phenotype of memory cells, divided between CD45RO and CD45RA [195] (Fig. 9.12). Most human CD8 employ the TcR αβ, but their mediation of oral tolerance is an unproved hypothesis [51]. Animal studies have delineated the IEL effector functions, including NK activity, specific cytotoxicity, IFN-γ secretion, and an intraepithelial increase in HLA class II expression [442].

The heterogeneous IELs are further distinguished by their usage of TcR chains: the thymus-dependent IELs express the TcR αβ chains and thymus-independent IELs express TcR γδ chains (Tables 9.2, 9.3); the latter are few (10%–20%), equally divided between $CD8^-CD4^-$ and $CD8^+$ [202]. Epidemiological evidence suggests that γδ TcR carry on a mucosal defensive function. The γδ IELs also mediate a contrasuppression supporting IgA responses [51], so that IgA antibodies escape suppression as part of a defense system and can confront antigens through interactions between IEL γδ and lamina

propria $CD4^+$ cells, resulting in an increased production of sIgA [172]. HLA-unrestricted IELs recognize antigens different from αβ TcR, and consequently they could possess an antigen-specific regulatory function [172]. The γδ IELs can regulate the mucosal IgA response, a finding further supported by γδ-knockout mice, which show a pronounced decrease in IgA plasma cells in the GI mucosa and of serum IgA levels [254]. Moreover, γδ may be especially active in the first line of defense against pathogenic microorganisms, function as a protective barrier to antigenic stimuli, or may be scavengers that participate in the elimination of stressed or damaged epithelial cells [442]. In children with CMA, an increment of γδ IEL was shown, characteristic but nonspecific in CD children [278]. Moreover, epithelial expression of IL_7R is up-regulated on γδ IELs stimulated by IL_2 and IL_7 or SCF (stem cell factor) for which IELs express a c-kit receptor [51].

Mesenteric Lymph Nodes

Mesenteric lymph nodes are an integral part of GALT, although actually situated outside of the GI tract. Once activated by immunogens, leukocytes in the gut mucosa can drain to the mesenteric lymph nodes, from which they can gain access to the peripheral circulation. Activated leukocytes also can recirculate back to the mucosa, in that these nodes lie in a vital area for lymphocyte recirculation. Mesenteric lymph nodes also play a cardinal role in the synthesis and maturation of IgA antibodies, also receiving lymph from the whole GI tract via lymphatic vessels running along mesenteric arteries. Germinal centers are more evident in the nodes subjected to antigenic assault. The lymphocytes are mostly naive T cells, a group of immune cells ready to support the weight of immune responses to a new antigenic contact; IL synthesis favors IL_4 with the role of increasing the proliferation of both T and B cells, but inhibiting B-cell differentiation, at the same time encouraged by the low level of IL_2 and IFN-γ activity [245].

GALT Regulation of Effector Functions

GALT is one of the more sophisticated homeostatic mechanisms mainly supporting the immune protection of babies in the first days of life, from systemic and abnormal immunological reactions to a great number of new food antigens, thus promoting a certain degree of oral tolerance. Such specific mechanisms should ensure a strong local defense at the same time, and meet the possible danger represented by the systemic invasion of macromolecules and CICs. Consequently, the GALT is exposed to an unremitting flow of non-self substances with antigenic activity. GALT's crucial function within the MALT is as a central organ with interactions also with other MALT organs such as bronchus associated lymphoid tissue (BALT): for example, oral vaccines are produced to protect children from respiratory infections. Animal studies disclose that oral immunization with *Haemophilus pleuropneumoniae* has been shown to result in an increase in the number of lymphocytes in the bronchoalveolar lavage fluid (BALF), deriving from the migration of gut lymphocytes to the airways [137].

Similarly, the analysis of the distribution of T cells specific to *Pseudomonas aeruginosa*, following intestinal immunization of rats with killed *P. aeruginosa* strains, has shown that T cells appear in PPs, mesenteric lymph nodes and blood and can be found in lung tissues following challenge with live bacteria. Hence, bacteria-specific lymphocytes migrate from the gut to airways, where they reside until re-stimulated by antigens [137]. The same mechanism may be operating in food-induced asthma: food absorption is potentially amplified by the permeability increase common in these cases, which permits allergen passage into the bloodstream and the subsequent action upon the airways. A contrary case may occur, that GI allergic diseases may be related to inhalant hypersensitivity, as in a 5-year-old Der p-sensitized girl who responded with morning vomiting to nocturnal house dust inhalation [434]. Fecal Der p allergens, which to a large extent yield an enzymatic activity, are synthesized and secreted into the alimentary canal, and may prompt an inflammatory response in a nonspecific and nonimmunological way.

The important GALT functions carried out in the host defense or food tolerance are summarized in three closely interrelated mechanisms: immune exclusion, immune elimination and immune regulation.

Immune exclusion is mediated by sIgA, along with aspecific mechanisms that have not yet been elucidated, and has a double objective: sIgA antibodies activate only the alternative complement pathway and are protected from proteolysis by SCs, have the task either of inhibiting the adherence of microorganisms and non-self macromolecules to the mucosal surface or of preventing both contact and ensuing absorption of antigenic molecules through epithelial cells [333], as indirectly confirmed by an increased antigen absorption in individuals with selective IgA deficiency [51]. The process operates in tandem with hepatic clearance cleansing the antigens that have entered [461]. B lymphocytes, after the isotype switch in B_{IgA}, leave the PP and via the lymph and the circulation populate the GALT, where they produce IgA polymers with the J-chain, subsequently handled by SCs at the mucosal level [333]. The predisposition of the immune system to activate chiefly the local IgA response following stimulation by intestinal antigens could prevent severe local changes [440]. Therefore, it is not without significance that IgA has the same antigenic specificity in the whole context of secretory areas: this aspect of the immune response confirms the prevalent concept, which identifies GALT as a sole secretory organ being part of MALT [348].

Immune elimination represents the *second line of defense* to non-self substances that have penetrated the GALT barrier, made up of mucosal IgG and IgM and RES (reticuloendothelial system) cells, including Kupffer cells: humoral responses are mainly based on the action of secretory antibodies, that is, surface IgA and in small part IgM. In adults, IgA are the most numerous and most important of surface Ig classes (Table 1.15), whereas in neonates both sIgA and sIgM are insufficient. No different is the case of 7.6-month-old infants with CMA with antibody levels significantly lower than in healthy infants, thus confirming that IgA serum levels against CM proteins are inversely correlated with the clinical expression of atopy [256]. The elevated IgA_2 resistance to bacterial proteases is a prominent characteristic [333]. Macromolecular ingestion via CD4 T cells stimulates IgA synthesis, thus reducing antigen absorption, and antigen-specific CD8 T cells suppress antibody responses able to activate the complement cascade. Consequently, the antigen cannot link to the specific antibody and since complement fixation is not evoked, no CIC formation and inflammatory processes are triggered [461].

Immune tolerance or *immune regulation* is a specific state of immune hypo- or non-responsiveness of lymphoid tissues against particular antigens determined by prior exposure, and the substance in question is defined as a tolerogen [311]. Experimental evidence on intestinal immunoregulation, because of obvious ethical considerations, comes from laboratory animals; however, there are valid reasons to demonstrate that such mechanisms also operate in human beings [228]. We mention in this context that Dakin was the first to describe the American Indians practice of chewing and ingesting *Rhus* leaves to prevent a severe form of contact dermatitis induced by poison ivy [114], and Besredka demonstrated in a classic experiment that guinea pigs tolerated orally administered CM and were unaffected by sensitization and anaphylaxis when the same food was parenterally injected [33]. Chase established the bases of oral tolerance, which was also named after Sulzberger, who observed that feeding the hapten picryl chloride leads to suppression of responses against a second parenterally administered antigen if the oral antigen was re-fed along with the parenteral antigen [348]. Mice ability to develop tolerance has been shown to occur at around 4 days of life, although a transient defect in the capacity of developing tolerance takes place when mice are weaned [348]. In oral tolerance, studied in man to a limited extent, intact proteins entering the circulation usually cause no clinical response, because T-cell clones responsible for these responses were eliminated or inactivated by a previous contact with the same antigen: this may be the consequence of an encounter in the fetal or early postnatal life, or exposure to very high antigen concentrations *(high-dose tolerance),* or continuous presence of very low antigen concentrations *(low-dose tolerance)* [461]. Tolerance can be typically evoked also by lower doses than the immunogen doses (on the average 100-fold lower [460].

Additional experimental *studies on oral tolerance* have investigated the pronounced antigenic trend to evoke antigen-specific suppressor T cells in PP: it is unclear why suppressor circuits originate in the MALT/GALT system more rapidly than elsewhere; the hyporesponsiveness could be linked to T lymphocytes, in that

B cells remain potentially reactive to T cells transferred from an intolerant animal [460]. It is significant that in normal mucosa, the *antigen-nonspecific* suppressor cells play such a relevant role in the suppression of responses to specific antigens, even if this hypothesis does not receive much support: it has been shown that in animals genetically unresponsive to lipopolysaccharides (LPs), able to elicit in B cells the differentiation into antibody-secreting cells, the mechanism of oral tolerance is inhibited; as a consequence following an OCT (oral challenge test), the responses to selected antigens are increased and those of suppressor T cells wholly absent [461]. The failure of oral tolerance may have an immune background, as demonstrated by a decreased tolerance in autoimmune mice strains: thus we can speculate that an inappropriate reactivity to one or more antigens may condition the development of autoimmunity [461]. The demonstration that PPs contain suppressor cells of IgM and IgG responses, but help IgA function, has shown which mechanism might explain the coexistence of two apparently unrelated responses, a local immune stimulation and a systemic hyporesponsiveness (oral tolerance). Thus, host responses to enteric antigens involve the suppression of IgG systemic responses and concomitant induction of local mucosal IgA responses contributing to tolerance [508]. Low colostral and BM sIgA levels are atopy-associated [431] and in children with an active FA, IgA responses increase only when clinical tolerance to food antigens is acquired [249].

Oral Tolerance: Experimental Data

In normal subjects, the absorption of antigenic molecules via stimulation of inhibiting T cells leads to suppression of IgE synthesis, which is controlled throughout life [222]. In this model, *allergy can be defined* as the consequence of an immunodeficiency that interferes with the mechanisms regulating IgE suppression, which may likely lead to a breakdown of this protective immune response, thus resulting in an immediate hypersensitivity reaction and in clinical injury to the gut [457]. The antigen's foreignness is not exclusively correlated to the chemical structure or molecular conformation, depending in certain cases on the genetic background of both the donor and recipient [460]. Thus, the *antigen immunogen power* also depends on a comparison between the two genomes, and recipients should possess genes capable of recognizing antigens: when a strain is unable to respond to immunogen antigens of another strain, oral tolerance may be under the control of different genes [348]. Acquisition of tolerance and conversely development of food sensitization are therefore a multifactorial process including numerous variables, many of which can be investigated only in experimental conditions.

Minimal proportions (10^{-4}–10^{-7}) of ingested foods reach the circulation of normal infants undegraded after passing across the gut barrier and are eliminated without eventful sequelae [457]. The background of these neutral effects is to be found in states of normality, when a reduced amount of antigen passes across the barrier, but is blocked by IgA and undergoes an intraluminal digestion; as a consequence, only a small portion reaches the portal circulation by perabsorption. However, the low quantity of initially produced IgE antibodies is unable to saturate the metachromatic cells and induce their degranulation, so a repeated oral intake of food proteins commonly induces the development of a *specific immunological tolerance*. It is believed that when no tolerance develops, as caused by lacking or deficient IgA antibodies and/or elevated IgE titers, increased numbers of antigenic macromolecules would cross the barrier, thus making alimentation quite inconceivable [413]. In normal subjects, oral tolerance is ensured by several immune and nonimmune mechanisms, which in the first stages of extrauterine life undergo a progressive physiological maturation [78].

Role of antigen presentation

The epithelium of intestinal villi expresses HLA class II along the brush border and laterobasally, and is therefore in theory capable of taking up and presenting intraluminal antigens to T cells [51]. It is not surprising that APCs play a crucial role in regulating the immunological consequences of antigen uptake. Such a capacity was initially suggested by the fact that agents activating RES appear to enhance APC activity, by preferentially interfering with the generation of CD8 subsets, with a subsequent negative effect on tolerance [348]. Intriguingly, feeding one novel antigen to naive mice will transiently activate RES and inhibit induction of tolerance if mice receive a second antigen [198]: similarly AD may develop after introducing several food solids in the first 4 months of life (Table 4.30). The role of agents capable of activating APCs has been reinforced by IFN-ɣ administration in mice that abrogates induction of oral tolerance [536].

Role of processing and oral tolerance

In mice the processing of food antigens by the gut is necessary for the generation of oral tolerance: if mice are given OVA by other parenteral routes, OVA isso non-tolerogen that it induces DTH (delayed type hypersensitivity) suppression in recipients [53]. Even if studies are mostly done in mice, oral tolerance is induced if foreign antigen is processed by enterocytes associated with HLA class II molecules and presented directly to lamina propria T lymphocytes or IELs via the TcR–CD3 complex, *bypassing APC processing*. In this case, T lymphocytes do not receive a second costimulatory signal via CD28-CD80, but tolerogen (Fig. 9.13) [460]. If there is GALT immaturity of primitive or secondary permeability changes [460], greater in CM-fed compared to breast-fed infants [512], increased amounts of antigen may saturate the scarce M cells and

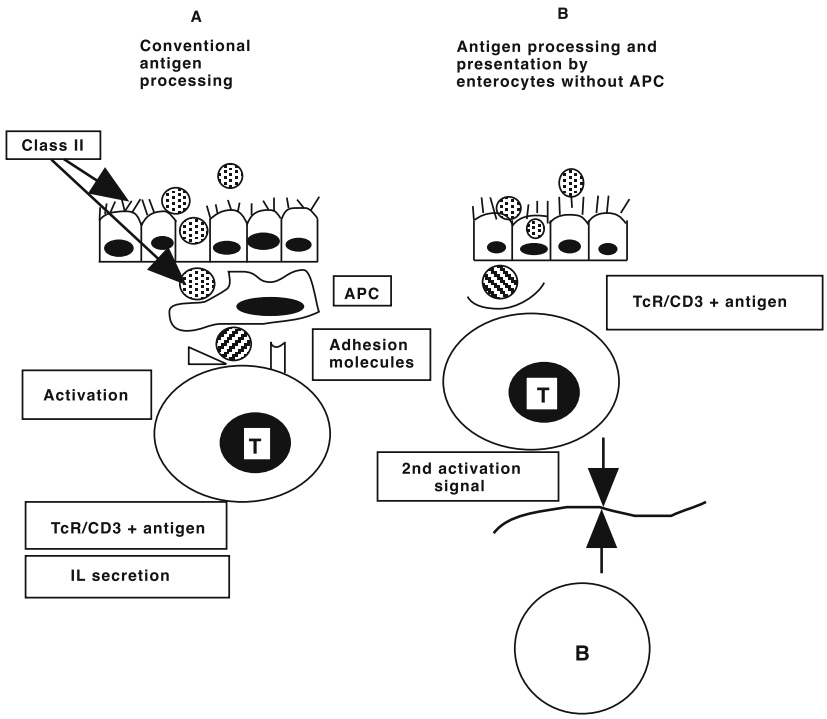

Fig. 9.13 a,b. Tolerance induction. **a** Prevention of oral tolerance: the conventional antigen presentation leads to T-cell activation. **b** Induction of oral tolerance: the antigen is processed by enterocytes and presented directly to T cells. B cells are not provided with a second signal and T cells receive a tolerogenic signal. The role played by Th2 T cells is unknown. (Modified from [460])

by extracellular passage may bypass enterocyte-mediated processing. Unprocessed antigens could be presented to lymphocytes by activated APC in association with HLA class II. In conclusion, instead of tolerance, immune responses are activated that are associated with local anaphylaxis [457].

Suppressor T cells and oral tolerance

Systemic tolerance represents a complex phenomenon involving all types of immune responses, including control of CD4 and CD8 lymphocyte stimulation, antibody regulation and production, and DTH responses; therefore IgE antibody regulation acquires a specific influence [457]. A single feed of antigen proteins induces a systemic hyporesponsiveness of IgM, IgG and IgE responses, as well as of CMI, apparently following suppressor CD8 activation, which may be depleted by cyclophosphamide, with consequent tolerance inhibition [348]. A putative role is assigned to most human CD8 (of IELs) with TcRαβ in the induction of clonal anergy in CD4, thus mediating oral tolerance [51]. However, the full T-cell activation with IL generation and related proliferation requires two signaling events, one via TcR and the other via a receptor for costimulatory molecules. Without the latter signal, T cells mount only a partial response and, above all, are subjected to clonal anergy and do not produce IL_2 on restimulation, leaving them in an antigen-independent state of anergy [442]. Conversely, subepithelial macrophages (APCs), expressing HLA-DQ [51], may activate $CD8^+$ T cells but negate stimulatory signal to lamina propria CD4 T cells [442]. The prominence of CD8 equipped with IFN-ɣ is the cornerstone of immune deviation [222]. However, CD8 T cells are nonexistent or scarce in the neonatal period and later, but IFN-ɣ treatment strongly enhances epithelial HLA expression in mice enterocytes, thus enabling antigen presentation to T cells, and modulating suppression of oral tolerance [536]. Moreover, suppressor CD8 inhibit only systemic T responses and not the humoral responses [348].

Clonal anergy or suppression

Whether at the base of tolerance there is a suppressive [222] or anergizing mechanism [329], the anergy thesis seems to prevail; therefore T suppressors are not necessary to mediate anergy [329], so T lymphocytes that have made tolerogen become capable of suppressing the responses to other antigens that are different from the disease-inducing antigen (bystander suppression) [336]. Small intermittent doses foster active suppression, linked to low antigen dose administration, with high doses causing anergy [329]: thus high doses are required to obtain anergy of B_{IgE} and T cells [200]. As yet, high doses have been fed to infants without appreciable positive effects. The relatively short duration of anergy induced in the neonate by a sudden large intake of antigen could, however, impair the development of necessary suppressor activity or tolerance, a result not without significance in neonatal and infant feeding, since the breakdown of anergy might endanger the MALT homeostasis in response to dietary antigens [200].

In children, tolerance induction is also linked to normal T lymphocyte activity [457]. Instead, a *defect of T-suppressor function* may recur in early infancy, especially when food antigens, always different, come into contact

with the gut mucosa, exhausting the still maturing immune reactive potential. However, oral tolerance is able to reduce the Th2-like profile and enhance the Th1-like profile by inhibiting IL_{10} and TGF-β mediators [38], thus protecting the child from the development of IgE-mediated allergy. Interestingly, after development of CM tolerance, CD25 and CD30 expression was decreased, whereas CD26 expression was increased to normal levels [435]. Although it is known that activated T cells of the human intestinal lamina propria are in general high producers of IL_{10}, almost no IL_{10} could be measured in the activated milk-specific T-cell lines. A similar low release was found for TGF-β, both of which contribute to tolerance development in the mucosa. In this study, CM-specific T cells in children with CMA displayed a clear Th2 profile, and released Th2-like T-cell ILs, especially IL_{13} that promote an allergic response, but failed to release Th3 ILs important for the development of *oral tolerance* [34]. However, Tr1 (T-regulatory 1) and Th3 cells, which are potent sources of TGF, are generated in mucosal lymphoid tissue in response to low-dose antigen and mediate bystander tolerance within the GI tract [450]. The establishment of tolerance during the neonatal period and its relationship with the genetic determination of any individual immune system and the pertinent maturation highlights that *the first years of life may be the most critical in the risk of sensitization.*

Oral Tolerance: Factors that Condition Its Induction and Maintenance

The acquisition of oral tolerance is likely a multifactorial process modulated by many variables [105, 383, 457].

Genetic background

As underlined in Chap. 4, neither in children with CMA, nor in their parents has an association been found with HLA-A, HLA-B, HLA-D and HLA-DR haplotypes, but with HLA-DQ. Evidence for linkage and allelic associations for CMA was not found. We add that a putative immunodeficiency marked by very low levels of T lymphocytes has not been confirmed using more sophisticated methods. The hypothesis of a deficit of IgA evoking a local transient immunodeficiency has been confirmed; however, it should be emphasized by the significant report of reduced concentrations of IgA-secreting cells at diagnosis, which increase during the follow-up, especially in tolerant children [233]. Concerning the low IgA levels, age has a pronounced effect on the response increase, which might be due to a dissonance between essentially low serum levels. Experimental evidence suggests that *infants developing CMA during breast feeding come from a selected population* [225].

Age at first antigen exposure

Children aged 1–3 months (58.4% of cases) had clinical symptoms of CMA [140]. HR neonates or infants are highly vulnerable and susceptible to sensitizing influences. Five out of nine infants developing CMA during breast feeding were from a HR population [225]. With a reduced oral tolerance at the base of infantile CMA, the acquisition of tolerance dependent on the first exposure to food antigens is of paramount importance [199]. It is also believed that the digestive and immunological immaturity of early life induces systemic CD8 T lymphocyte tolerance, but B_{IgE} cells priming at systemic and mucosal sites [228, 416, 508]. Since IgE antibody production depends on the amount of absorbed antigens, in mice as in humans, antibody responses may be suppressed by relatively high doses of food proteins, but primed by the early introduction of low doses [198, 460]. Neonatal rodents were sensitized during the first 1–3 days by a dose of CM or OVA able to induce tolerance in adult animals; however, induction of tolerance could be demonstrated before weaning and before gut closure [413, 509]. Consequently, if the multiplied ingestion of proteins in sensitized animals leads to secondary acquisition of tolerance, repeated doses would be more effective in suppressing hypersensitivity reactions [348, 460]. Giving CM in the first hours or days of life has a sensitizing effect [86, 225, 413, 437]. The selective deficit of oral tolerance is correlated to age in infants, but it is not of a quantitative type, because it can be corrected by transferring mature lymphocytes [383]. This deficit may be correlated *to the inability of an immature immune system to respond appropriately to gut-derived tolerogen stimuli;* and a further deficiency, irrespective of the age, may occur at weaning [413].

Nature of antigens

The larger prevalence of clinical reactions to certain foods is more likely a reflection of infant feeding routine than to be correlated with specific food sensitizing properties [66]. The *allergenicity of food proteins* is wide, as well as their *antigenicity*: evidence suggests that many proteins and antigenic substances are taken up and processed in the GI tube, or modified by industrial manipulations and by such modifications new epitopes may be unmasked, either newly formed or made more accessible [479]. CM antigenic modification (by heat or enzymatic digestion or both) reduces in part, but never totally abolishes the potential allergenicity/antigenicity of the starting proteins; therefore the immunogenicity of modified proteins cannot be excluded completely [63]. Moreover, protein antigenicity may be increased or diminished while being transported via living membranes, and vary from protein to protein, apparently in correlation to specific host conditions and/or to genetic, ambient, adjuvant, and similar effects. The ability to induce an immune reaction is in part *a function of antigen MW:* several antigens with well-defined physicochemical traits are proteins with a high MW; however, small molecules are allergenic, whereas macromolecules such as polyvinylpyrrolidone are not allergenic. Furthermore, an elevated MW is overall a property to promote

allergenicity, which also depends on amino acid (AA) sequence [1]. In several cases, molecules of low MW introduced by the parenteral route may be eliminated so rapidly, especially by urine, that they cannot be an effective allergenic stimulus, whereas other smaller and less immunogen molecules may act as *haptens,* which, by combining with host proteins, confer to these proteins a specific immunogen power [1].

Dose of antigen

The bulk of evidence shows that small doses (ng or µg in rodents, mg in humans) are more sensitizing than larger doses, a µg total dose in rodents primes for ensuing immune responses, whereas mg quantities are able to suppress humoral and cell-mediated responses [348]. In mice the dose required to elicit systemic sensitizations is 1–50 µg protein [348], which affects T-cell responses more than humoral immunity [383]. It is therefore noteworthy that low doses may prime children to develop AD [248]. The dose also depends on the *ideal size* of an allergenic protein, with a MW between 10^4 and 10^6: within these limits is found the MW of main food allergens, including casein, βLG, α-lactalbumin (ALA), Gad c 1, and egg white and tomato glycoproteins (Table 1.74). However, *there is no obligatory minimal limit expressing a protein immunogenicity*, because very small peptides and other molecules, as noted above, may act as haptens. Some CM-protein HFs also have a MW under 1,500 D, compared to allergenic substances with a high MW [297], but small peptides, with a MW of about 3,000 D such as glucagon with only 29 AAs and a MW of 3,000 D, insulin at 3,800 D and in some cases 1,000 D, may retain allergenicity by particular AA sequences, for example, Asp-Glu-Leu-Lys- and Asp-Glu-Asp-Lys- [1]. As a consequence, the allergen physicochemical characteristics are not related to MW. Therefore, immune reaction to a definite food results from IgE antibodies binding to epitopes on allergenic molecules, irrespective of two identical epitopes.

Thermostability

High temperature, in addition to reducing food allergenicity, changes the biological value, in a variable fashion for each component of highly sensitizing protein fractions, without forgetting that in given cases, heat-induced changes may make heated proteins more allergenic than raw proteins, not subjected to industrial treatments. CM proteins are both thermoresistant and thermolabile, for instance casein is stable at 100 °C, and its antigenicity remains unchanged after being heated at 121 °C for 15 min, whereas boiling whey proteins for 30 min reduced immunogenicity [297]. However, it remained dormant for 2,500 years. Infants still react to heat-treated whey proteins. Other allergens are inactivated by digestion, or during cooking. Raw fish, fruits and vegetables may result in sensitizing, but are tolerated when cooked [23]. Each rule has its own exceptions: Küstner, in a classic experiment, reacted to cooked fish, not to raw fish (but did not specify the fish species in question) [395]. Thus cooking formed or made accessible a new antigenic epitope in fish. Patients may have fierce allergic reactions to raw but not to cooked apples, carrots, and potatoes [1].

Concentration of given allergens

Allergen concentration in intestinal lumen is correlated with the degree of macromolecular absorption, which has its weight, as demonstrated by the high incidence of rice allergy (which would normally have an essentially low allergenicity), as in the Chinese and Japanese populations, who eat a high quantity of rice daily [1]. Eighty percent of CM protein is casein and 12% is βLG [297]. Also, CM's intrinsic characteristics, including its widespread use, and early and regular ingestion, are all factors incrementing CM's antigenic power [23], so that infants who are bottle-fed in early life are exposed to a massive and rapid allergen intake at each feeding, which is able to overcome the immune, anatomical and enzymatic barriers, thus representing the first cause of some cases of sensitization [440].

Frequency of antigen administration

Intermittent exposure of breast-fed infants to low doses of a CM formula was correlated with increased IgE production, but continuous and higher-dose exposure to the same formula induced IgG instead of IgE antibody production [163]. Low CM uptake before breast feeding was commenced exposed HR infants to an increased risk of allergic sensitization [225] or to a significant increase in total IgE levels [437].

Antigen transmission

When a sufficient concentration of molecules comes into contact with the cell membrane, invagination occurs at the epithelial membrane and small vesicles are formed. Subsequently, macromolecules migrate within membrane-bound vesicles to the supranuclear region of the epithelial cell where the vesicles coalesce to form large vacuoles. Within these structures, enzymatic degradation occurs; however, allergenic proteins tend to maintain their immunogenicity while submitted to different food transformation stages. Many food allergens, in addition to being thermostable, are acid-resistant (such as tomato), thus undigested macromolecules may escape breakdown and migrate to intestinal mucosa in an immunogen form [275, 440]. The organism is not always capable of eliminating food allergenicity; therefore the *immune barriers* are interposed (Table 2.11), so that peptides are eliminated by binding to BM sIgA [440]. Regardless of such immunological and nonimmunological defenses, there is no complete exclusion of non-self materials, also because normally between the gut lumen and internal ambient of the host there is an exchange of large or small molecules: in this process, both the antigen concentration and exposure timing

concur to establish the antigen load to which the gut is subjected [383].

Antigen absorption
As discussed in the previous section, oral tolerance to antigens taken up reflects the type of processing to which antigens were subjected in the intestine; it is therefore conceivable that any factor that alters the amount or chemical nature of the antigen absorbed from the gut will influence the related immunological consequences. This result can be connected with disorders causing increased permeability to macromolecules in several pediatric conditions such as Crohn's disease and CD, and the resulting increment of antigen-specific antibodies [348].

Antigen persistence
This depends on multiple parameters including antigen nature, structure, presentation and introduction route, host characteristic (metabolism, digestion, immune reactivity, age, etc.). For example, polysaccharide antigens have been found in the tissues 6 months after their introduction, but others, chiefly soluble proteins, are cleared within a few hours [1].

Immunological status of the infant and GALT
During alterations of local or systemic immune system immunocompetence, oral antigen administration increases the rate of secondary sensitization in infants such as viral infections of the respiratory tract. The underlying pathogenetic mechanisms could be represented by:

- Interference with the GALT immunoregulatory functions, such as immunosuppression
- Intestinal mucosa loss of integrity, by physiological or inflammatory causes and/or increased macromolecular absorption into the circulation (Table 2.23)

In the first case, the suggested hypotheses are supported by studies in the animal model [413]; in the second case it is stressed that *in the first weeks of life*, up to gut closure at about 3 months of age, the intestinal and/or immune system immaturity is combined with the deficit involving IgM antibodies from exocrine secretions, salivary sIgA and serum IgA. The mechanisms responsible for antigen macromolecule exclusion and elimination are immature [508]. In newborns, both increased permeability of the intestinal barrier, by altered chemical composition of epithelial cell membrane [413], and *microvillous membrane immaturity,* by tangible lowering of the proteinphospholipid ratio, are all factors resulting in increased antigen attachment and transport [413]. During intestinal absorption, exocyted antigens bind to IELs with the net result of eliciting immune responses [508]. In the vulnerable neonatal period, the development of a protective local immunity is important; however, if sufficient amounts of undigested macromolecules pass into the circulation and if a subject is genetically predisposed, in concert with insufficient mechanisms responsible for oral tolerance, allergic sensitization may develop from the first months of life [440].

Several studies have focused on and demonstrated or not the *increase in intestinal permeability* depending on the method used [138]. The results do not clarify how much such an increase plays an effective role in CMA development in children: the increase in protein endocytosis noted during the CMA initial period seems to be rather a secondary effect of an abnormal immune response leading to mucosal inflammation and impairment of endocytic process [209]. Children with positive FCTs to CM (34%) have serum ALA significantly higher than those with negative FCTs (66%) [253]. The authors hypothesize that in children with CMA, an increased macromolecular absorption depends on small intestinal mucosa damage caused by FCTs, or on incremented passage also during the elimination diet [253]. Another group of infants was evaluated by the lactulose/mannitol test, administered in concomitance with FCTs to CM (before and 3 days after), thus confirming an increased intestinal permeability to antigen macromolecules, evidencing in particular an identity of alterations whatever the manifestations (cutaneous or GI), and suggesting that an increased permeability could underlie a multisensitization [239]. Moreover, agreeing indirectly on the preceding results [209], it was shown that increased permeability is not a primary alteration somehow underlying CMA pathogenesis, but rather an epiphenomenon probably correlated with an altered protein uptake [240] or a local hypersensitivity reaction of intestinal mucosa [460] that amplifies epithelial dysfunction [409]. Intestinal permeability is increased in synergy by PBMC-released TNF-α and IFN-γ in children with CMA following CM challenge [208].

These data show that in CMA there is an abnormal passage of allergens secondary to altered immune response to allergens. Interestingly, experimental animals made hypersensitive to one food and challenged locally in the gut also absorb an unrelated "bystander" antigen: an increased lactulose/rhamnose urine excretion was demonstrated only when both sugars were administered together with the challenge antigen [460]. In infants with active CMA, the jejunal epithelium shows an increased transepithelial βLG [397] and horseradish peroxidase (HRP) transport [208]. However, the increased HRP absorption in an either intact or decayed form [208] might imply an intrinsic defect of metabolic functions of the epithelial cells and their degradation functions. This is a growing field of study and is easily understandable, owing to reflexes that are also preventive.

Finally, there are *numerous pathological causes of increased absorption of food macromolecules* [275] (Table 2.23). An increased permeability may be correlated with alterations of GI mucosa mainly consequent to acute diarrhea, also in children not affected with FA [240].

Cow's Milk Allergy

Allergen Characteristics

Among the foods most frequently responsible for sensitization, some are raw allergenic (carrot), others cooked (fish) etc. Moreover, denaturation processes caused during digestion modify the protein specificity of some products of digestion, which may be different from that of initially ingested proteins [1].

In thoroughly studied foods, numerous substances have been found to be potentially capable of priming for immune reactions, but only one or a few of several proteins are essential causes of sensitization and are called *major allergens*; less important allergens are called *minor allergens*; a high degree of *cross-reactivity* should be kept in mind. The structural and immunogenic characteristics have been identified and exhaustively studied only in a few food allergens, but those so far classified correspond roughly to the principal foods responsible for FA in children (Table 1.74).

CM immunogen characteristics are shown in Table 1.75. CM contains at least 25 separate protein components, equal to 3.3 g/dl (2.8–4.1 g/dl), all virtually unknown to the neonatal immune system, provided with several epitopes and an implicit sensitizing capacity [23]. The serum proteins that can cause hypersensitivity reactions are βLG, casein with 5 genetic variants, ALA with two variants and a polypeptidic sequence in common with egg white lysozyme and BSA (Table 1.75). The treatments to which CM is subjected (pasteurization, boiling, sterilization) modify the thermolabile immunogen components (serum albumin, ALA, Igs), but not the thermoresistant components, provided with a greater sensitizing power (caseins and βLG). The reactivity of circulating IgE against CM proteins detected by immunoblotting has provoked immunological responses in 12 children as follows: α-casein 12, κ-casein 11, β-casein 8, γ-casein 7, ALA 6, βLG 5 [402]. It is likely that techniques of CM isolation and modification elicit the appearance of new epitopes not identifiable with native proteins, since studies on βLG have provided interesting observations on the structural bases of βLG allergenicity and antigenicity (Chap. 1). ALA is absorbed up to serum concentrations of 10–1,000 μg/l of human milk/kg bw. Thus an infant weighing 10 kg may have a serum level from 100 μg to 10 mg (about 0.1–10 μg/ml), both titers being elevated in these infants. Therefore, CM products are potentially capable of provoking sensitizations in children drinking CM and of triggering immune reactions in sensitized children [23]. An unusual type of sensitization may derive from bovine antibodies found in commercial pasteurized CM specific to or cross-reacting with xenogenic products, including rye grass pollen, wheat, Der p, proteins, and *Aspergillus*, likely leading to the production of anti-idiotypic antibodies and anti-food antigens [107].

Clinical Manifestations

Hypersensitivity reactions to foods induce onset of cutaneous, respiratory, and GI symptoms. We divide the clinical manifestations attributed to CM by systems. The symptoms and disorders sometimes believed to be caused by CMA are numerous, but almost none of them are pathognomonic of CMA [23].

- *Systemic:* hypotension, shock
- *GI:* colitis, irritable bowel syndrome (IBS), flatulence, diarrhea, abdominal pain (colic), gingivitis, malabsorption, nausea, constipation, stomatitis, vomiting
- *Respiratory:* extrinsic allergic alveolitis, recurrent respiratory infections, upper airway obstruction, recurrent pneumonia (Heiner syndrome), rhinitis, serous otitis, sinusitis, laryngeal edema, pulmonary hemosiderosis, chronic cough, bronchitis, wheezing, dyspnea, recurrent fever
- *Cutaneous:* alopecia, angioedema, dermatitis herpetiform, eczema, urticaria, purpura, erythematous macular rash
- *Hematological:* iron-deficiency anemia, thrombocytopenia, gross/occult bloody stools
- *Urinary:* albuminuria, cystitis, enuresis, minimal lesion glomerulonephritis, nephrotic syndrome
- *Central nervous:* migraine, epilepsy, attention deficit hyperactivity disorder, restless legs syndrome, chronic fatigue syndrome, tension-fatigue syndrome
- *Ocular:* keratitis, uveitis
- *Various:* rheumatoid arthritis (seronegative), diabetes mellitus, recurrent periostitis, SIDS (sudden infant death syndrome), etc.

In the first part of Table 9.4 are listed the clinical manifestations that are more clearly related to CMA, assessed according to the prevalent immunological mechanisms [413]. The second part is based on nonimmunological criteria, but the literature is not unanimous [23, 430]. Figure 9.14 [29, 66, 86, 182, 200, 225, 237, 293, 339, 349, 439, 456, 500] summarizes the analysis of 13 studies done over about 40 years with the prevalence of more common symptoms and relative ranges. Around 2.5% of neonates experience hypersensitivity reactions to CM proteins during the 1st year of life [439]. In 27 infants with CMA associated with AD [86], at the first CM feeding anaphylactic shock occurred in 4 cases (14%), urticaria-angioedema in 9 (32%), vomiting in 7 (25%), abdominal pain and diarrhea in 6 (21%), respiratory symptoms in 3 (11%), AD worsening in 8 (29%), alone or associated. A 3.5-month-old child seen by us experienced a generalized edema. In 115 infants [92], 41.5% reacted with AD worsening, 16.5% with GI symptoms or with bronchospasm or wheezing, 12.5% with urticaria, 6% with anaphylactic shock, and 6% with angioedema alone or associated with other manifestations. OFCs provoked urticaria in 73% of 467 children aged 3 years (median) [453] and children as young as 8 weeks reacted to CM challenges [237].

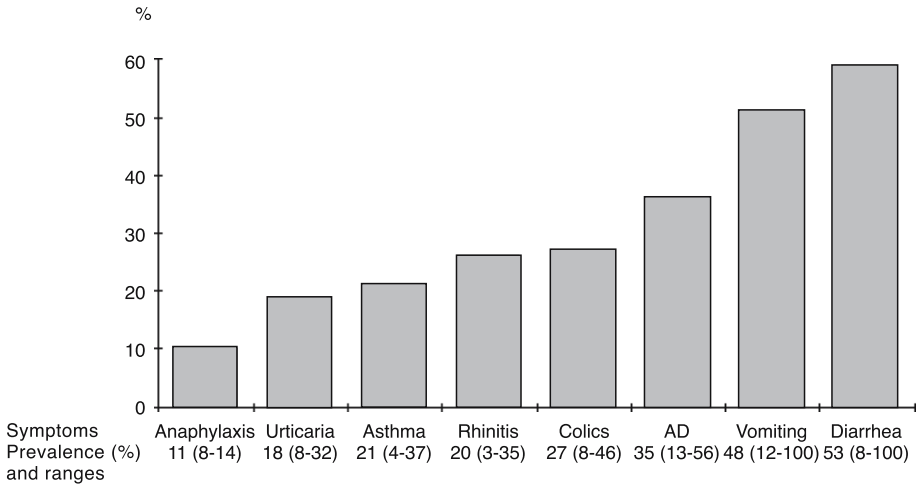

Fig. 9.14. Prevalence of clinical features of CMA. Division between systems: gastroenteric, 45.5%; skin 27.5%; respiratory, 23.5%. AD. (Data from [29, 66, 86, 182, 200, 225, 239, 293, 339, 349, 439, 456, 500])

Table 9.4. Clinical manifestations attributed to CMA

On immunological basis: unanimous
1. Type I: IgE-mediated reactions
a) Systemic
Anaphylactic shock
b) Gastrointestinal
Early-onset enteropathy
Nausea, colic, diarrhea, vomiting, abdominal pain
Allergic eosinophilic gastroenteritis (some forms)
c) Cutaneous
Atopic dermatitis, erythema
Urticaria-angioedema
d) Respiratory
Wheezing, sneezing, cough, rhinorrhea
Rhinoconjunctivitis
2. Type II: Cytotoxic reactions
CM-induced thrombocytopenia
3. Type III: By immune complexes
Celiac disease
Colitis syndrome
Dermatitis herpetiformis
Enterocolitic syndrome
Malabsorption syndrome
Pulmonary hemosiderosis
Sideropenic anemia, sometimes with occult blood loss
4. Type IV: Cell-mediated hypersensitivity
Celiac disease
Dermatitis herpetiformis
Enterocolitic syndrome
Malabsorption syndrome
Pulmonary hemosiderosis
On nonimmunological basis: not unanimous
Attention deficit hyperactivity disorder[a]
Crohn's disease[a]
Eosinophil enteropathy[a]
Gastroesophageal reflux[a]
Infantile colitis[a]
Insomnia[a]

Modified from [371].
[a] Included in the text.

Some authors have reported CMA-related symptoms in children 0–3 years old divided by systems, as shown in Table 9.5 [87, 106, 177, 178, 323, 351, 439, 456, 491, 517]. The mean incidence of GI symptoms is 50%, and 34% when GI symptoms alone are taken into account. Cutaneous symptom incidence is 50% (31%–94%) and the highest rate is encountered in infants 1–6 months of age [275]; in others [224, 456] the incidence is up to 64%–84%, but the groups are less numerous and their age went up to 3 years [224]. The incidence of respiratory symptoms is 19%, but considering only children of 0–1 years, incidence is 13.6%. The incidence shows that *the GI tract is not the only shock organ* [23], but there is always a disagreement due to the known differences among studies [145]. We note that symptoms vary according to age and add that foods follow the same pathway and are often involved in exercise-induced manifestations [270].

The manifestations attributed to CMA [66, 430] and reported in Fig. 9.14 are somewhat typical of FA: they can be local or systemic, the entrance route of allergens is usually oral, but can be inhalatory or by skin contact (Table 7.22). In infants, the pattern of GI involvement is prevalent, sometimes up to atrophy of mucosal villi, but often rhinitis with chronic nasal obstruction can be complicated by otitis, sinusitis, asthma; more rarely recurring respiratory symptoms are recognized, as well as urticaria and AD onset after CM feeding [145]. Risk factors are acute infectious episodes which potentially induce lesions in genetically predisposed children, likely leading to an increased permeability with consequent CMA [240, 509]. Among the patterns reported in Fig. 9.14, GI symptoms are probably the most frequent in absolute terms when we reckon that late onset reactions occurring in 50% of patients involve mostly the GI tract [145].

GI gastrointestinal.

Systemic Manifestations

Anaphylaxis

Anaphylactic shock, the most dramatic symptom of allergy, was the first to be connected with CM in 1905 [161]. The onset of this severe manifestation is usually within a few minutes, but the frequency varies in the literature from one series to another, from zero to 33 % of cases, especially in infants with prevailing GI forms; in Fig. 9.14 the incidence is 11 %. Very typical is the *anaphylactic shock by CM* at the first time CM is met by infants after a more or less long period of exclusive BM feeding, or after low doses: as soon as food touches the lower lip [86, 88], the reaction ensues in infants with pruritus and edema of lip, tongue, palate and pharynx and cutaneous symptoms, including erythema, urticaria, angioedema. and pruritic morbilliform rash [86]. Such reactions may be followed by more severe symptoms such as tachycardia, pallor, cramping, vomiting, diarrhea, shock and respiratory insufficiency due to oropharyngeal angioedema or wheezing and, especially in older children, symptoms of other systems, for example urticaria-angioedema, bronchospasm, nasal obstruction, etc. [145]. The chronology is suggested by Fig. 9.15 [340]. To these cases we add CM-induced anaphylaxis/shock in three infants [41], a child of 4 years [43], a 6-month-old boy [470] and two patients aged 2–17 years [41]. Some children may experience generalized nonfatal anaphylaxis following CM intake [424]. Infants undergoing shock often have elevated IgE levels and should not be subjected to CM challenge [54]; even a SPT should be done in clinical setting and very prudently [92]. A useful model of intestinal anaphylaxis has investigated OVA-sensitized animals to study the effects of repeated daily feeding of OVA antigen. After OVA feeding, serum mast cell protease II (MCP II) levels increased ≈16-fold of normal on the 1st day, and two- to fivefold the normal level by re-feeding OVA in the subsequent 4 days. If OVA feeding was discontinued for 9 days, re-feeding increased serum MCP II levels only fivefold the normal level [55]. This study supports the assumption that a 2-week course of complete food allergen avoidance is necessary to elicit unmatched responses to an OFC.

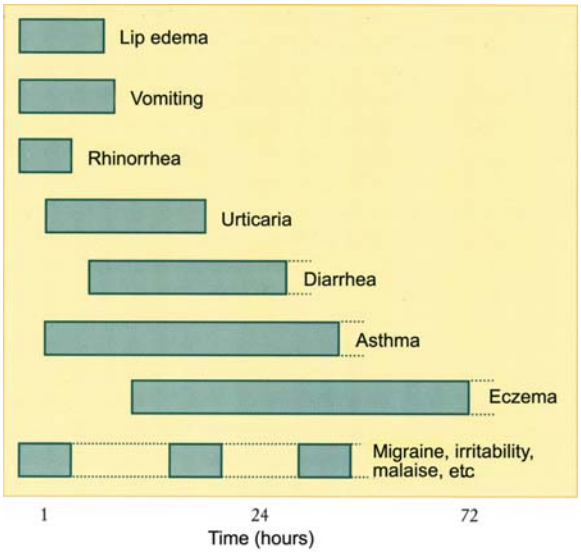

Fig. 9.15. Chronology of clinical manifestations

Gastrointestinal Manifestations

CMA-Induced Enteropathy

CMA is very frequent in babies: two types of clinical manifestations are evident [165].

The acute onset form (80% of infants) [66] is observed in the first 6 weeks of life and is characterized by diarrhea and vomiting in 59% of cases [224]. In 40 infants, the onset was acute in about 75% of babies [131], diarrhea and vomiting were noted in 67% of 54 babies [281], a more dramatic onset was observed in 42 babies, with 93% diarrhea and 71% vomiting [351]. In a series of 100 infants with CMA, 53 had a history of diarrhea and 53 of vomiting, acute diarrhea was more common than chronic [186]. Diarrhea is severe and persistent, the stools being frequent and loose, mucous and watery, with occult or overt blood [186] (a sign of inflammatory colon involvement), often associated with *persistent vomiting* (the second manifestation in order of frequency), appearing within 1 h after the meal. The *diarrhea* may be of short duration (above all when CM is readily eliminated from the diet), or prolonged and resistant to treatment. Severe and/or protracted diarrheal forms may be complicated by dehydration, damaged intestinal mucosa, electrolyte imbalance, weight loss, and malabsorption, accompanied by transient intolerance to several foods before an exact diagnosis is assessed [23, 281, 392]. The diarrhea-vomiting-dehydration association may resemble neonatal necrotizing enteropathy [66, 509]. *Abdominal pain* (gas colic) is present in 26% of infants: the child is awake, or wakes up due to apparent abdominal cramping that does not subside with common medications; crying is unremitting. Often the clinical picture induces us to suspect an intoxication and in extreme cases, even an invagination. Moreover, *systemic symptoms* may be present such as fever and abdominal distension along with projectile vomiting, which may even mimic an acute abdominal obstruction. At variance with other causes of the child's vomiting, *pallor* and shock (and metabolic acidosis) usually accompany vomiting, a cause of massive fluid loss [66]. *Growth arrest* may persist as the only symptom of CMA in 76% [351] to 100% [66] of cases, later complicating the clinical picture, with malabsorption and hypoproteinemia due to allergic gastroenteritis. In more severe cases, protein loss across the intestine may lead to edema, hypoproteinemia or hypogammaglobulinemia, malnutrition, etc. [293], resulting in misinterpreting the diagnosis in some cases.

Table 9.6 outlines the clinical features of 41 infants with chronic diarrhea by CMA, hospitalized in our department between 1973 and 1976 [66], in whom GI symptoms with growth failure had a peak of 100% during the disease. CM elimination and institution of an oligoantigenic diet with lamb meat led to diarrhea vanishing within 1 week and the infants throve again within 2 months. In 21 children with BMA, the symptoms were suggestive of atopy (Table 9.7) [93]. Frequently, following virus-induced mucosal damage after episodes of chronic postinfectious diarrhea, or enteropathies of varying pathogenesis, a *transient lactase deficit* is caused, thus CM may slow down the normalization of intestinal biological functions, with no influence, however, on the child's growth [492]. The differential diagnosis with acute viral enteritis may be demanding in these infants. Likely due to an incorrect treatment of the re-feeding phase more often following viral infectious episodes characterized by profuse and watery diarrhea, especially in younger infants. CM exclusion from the diet does not always induce an immediate resolution of symptoms. The possible elimination of other foods in sequence may imply fallacious diagnostic conclusions as an outcome [54]. Such incentives may be supported by the abatement of symptoms after substitution of CM formula with a soy protein formula (SPF) but the caveat may be that the possible resolution of postinfectious disturbances can erroneously be seen as indirect proof of a possible allergy, not only to CM, but also to other foods previously reintroduced without success [54]. However, lactose intolerance would cause similar symptoms and would improve with dietary changes [439].

Table 9.6. Clinical features of 41 infants with CMA-induced chronic diarrhea

Clinical features	No. of cases	(%)
Onset age 3 months (median)	41	100
Diarrhea	41	100
Growth arrest	41	100
Vomiting	19	46
Bloody stools	8	19
Colic	5	12
Shock	5	12

The studies are ordered according to the year of publication.

Table 9.8 [106, 178, 224, 237, 323] shows the time between the first CM exposure and onset of related allergy: 1 week was sufficient in 42% of cases.

The late onset disease manifests itself several weeks to months later with vague symptoms, generally including failure to thrive, abdominal distention, wasted buttocks, and voluminous, bulky, fatty stools. Even if diarrhea is protracted, steatorrhea is rarely observed, as in the early-onset disease. *Malabsorption* is very usual, likely resulting in growth retardation and malnutrition. In addition to CM, egg, wheat and soy have been implicated with lesser incidence [413]. If gluten already has been introduced into the diet, the picture can sometimes be easily mistaken for gluten-sensitive enteropathy (see "Celiac Disease"), with an *anatomical-pathological pattern* characterized more frequently by subtotal villous atrophy and increased lymphocyte and eosinophil mucosal infiltration; similar histological patterns have also been demonstrated for others forms of FA [89]. *On the scanning electron microscope,* lesions apparently particular to CMA with GI expression are observed, consisting of patchy losses of glycocalix, not covering microvilli homogeneously, leaving them furred and short, a finding missed at standard histological or radiological examination [492].

Colic

Infantile colic, a common problem during the first months of life in otherwise healthy, thriving infants, is of unknown origin. It usually begins in the first 4 months of life and occurs in about 20% of infants. It is a poorly defined syndrome of paroxysmal activity characterized by inconsolable crying, drawing up of the legs, abdominal distention, excessive gas, etc. In children who are exclusively fed BM, several investigators consider colic to be connected with CMA, due to bovine or other foreign proteins present in the maternal diet that escape complete digestion, enter the circulation, and are transferred into BM [17, 272], likely dependent on an IgE-mediated hypersensitivity, which may be a pathogenic factor in some infants [168, 237, 303]. A recent study does not support an association with markers of allergy [100]. CMA has been implicated: colic recedes after dietary CM elimination from the maternal diet, but the effect is only transient [229]; in other cases clinical improvement was obtained with a casein HF [168].

Colitis

The onset of colitis is usually from the first weeks of life to the 6th month, never beyond 10 months: it is frequent in the first 5–6 months of life [217, 367, 492]. Several studies have confirmed that it is caused by CMA [217, 492], or by soy, beef, and other food antigens present in BM, most cases are in BM-fed infants [186, 193, 250, 313], in one study up to 50% of cases [362]. The onset in infants <1 week of age may result from transplacental fetal sensitization by exposure to CM antigens *in utero* [201]. Family history (FH) is positive in 60%–92% of cases [186, 217, 250, 286, 313, 367]. The onset may be acute (<6–12 h after the first CM feeding) [362] as occurred in 36%–92% of cases, with frequent diarrhea containing blood and mucus, vomiting, cramping, weight loss and eosinophilia in 14% of cases [367]. Furthermore, onset may be insidious and protracted, especially if enteropathy and malabsorption are associated, with a clinical picture similar to intractable diarrhea [16]. The symptoms are severe [201]; low doses of CM precipitate bloody diarrhea [217], as well as 5 ml CM or one tin of beef broth [250]. Colon biopsy studies show eosinophils and epithelial cells, as well as alterations of the intestinal mucosa, and although inconstantly, they show IgE plasma cells in the lamina propria, but no lesion characteristic of ulcerative colitis (UC) or CD [250]. In these infants, the age-related titers are low in IgA in 48% and in IgG_2 and IgG_4 in 50%–72% of cases, thus hypothesizing an immunodeficiency [367]. The diagnosis is made when the disease responds dramatically to CM dairy elimination, hematochezia resolves within 72 h and symptoms relapse within hours or days after FCT [186], aided by sigmoidoscopy showing an

erythematous mucosa alternating with patchy zonal lesions of normal aspect, and presence of specific markers of an acute inflammation [217, 250, 313, 492]. A toxic dilatation of the colon in a preterm baby [201] and other macroscopic anomalies in up to 83% of children have been observed [367]. Owing to the marked presence in the lamina propria of more numerous eosinophils compared to controls, prevalent in the colon [313, 362], the syndrome has also been called allergic proctitis [273]. The differential diagnosis includes CM- and/or soy-induced enterocolitis and acute infectious colitis, whereas in the protracted forms the differentiation with chronic inflammatory enteropathy is unreliable [362]. Avoidance of CM and other causative foods leads to a rapid clinical improvement in 77% of cases [367]; however, lesion repair requires months [413].

Eosinophilic Gastroenteritis

Approximately 50% of cases are caused by food allergy and intolerance. Clinically it is characterized by anorexia or early satiety, nausea, vomiting (which can be blood-streaked), postprandial abdominal pain resembling colic, diarrhea, growth retardation or failure to thrive, occult or gross blood in stools, eosinophilic infiltration and peripheral eosinophilia, with histological patterns of colitis, enteritis and gastritis [211, 212, 294, 338, 345, 414, 426]. Some infants and children experience iron-deficiency anemia and generalized edema secondary to hypoalbuminemia dependent on protein-losing enteropathy, but not rarely clinical symptoms, including vomiting, diarrhea, abdominal pain, and growth retardation [345]. Four diverse forms may be related to the predominant layer involvement [338, 340]:

- Mucosal involvement, the most common [345] with steatorrhea, hypochromic anemia, hypoproteinemia and malabsorption
- Muscular involvement, especially of smooth muscles with weight loss, pyloric stenosis, partial obstruction of the large intestine due to gut thickening and rigidity, wholly overlapping with CD
- Subserosal involvement, the least common [345], principally with eosinophilic ascites
- A form combining the features of the above

Another classification, more suited to children, includes only two classes [426]:

- Early onset of symptoms, SPT and RAST negativity, rapid response to CM elimination and outcome toward tolerance
- Late onset, positivity of laboratory testing, ineffectiveness of CM elimination and trend to chronicity

The first class recalls early onset CMA, in which children gradually experience tolerance to sensitizing foods [165, 212, 339, 426].

The IgE-mediated disease (50% of children) is characterized by high IgE levels, sensitization to numerous food and inhalant allergens, peripheral eosinophilia [338, 345, 494] and deficient IFN-γ and IL_2 expression by T cells, which in the intestinal mucosa is 10- to 1,000-fold higher compared to resting blood T cells [245]. In a 6-year-old boy with asthma, but with positive sIgE for CM and egg, a massive extracellular major basic protein (MBP) deposition caused a broad geographic erosion in the gastric body and antrum [277]. In other cases, likely those that are not IgE-mediated, CIC-induced complement activation or IL release by activated lymphocytes denotes a massive eosinophil infiltration in lamina propria of gastric antrum and distal small intestine [54, 345]. The diagnosis is based on the demonstration of eosinophil infiltration in biopsy specimens [294, 345]. The differential diagnosis is with several disorders of peripheral eosinophilia [338] (Table 6.15), considering that eosinophil is a normal constituent of GI tissues [362], and with GER (gastroesophageal reflux), which may be suspected by sharing the unsuccessful specific treatment [263]. Management is by elimination diets, which gives appreciable results [145], especially if based on FCT results [245]. Ten children with an apparently mucosal layer disease failed to thrive despite medical therapy, but symptoms were greatly improved after 5–8 weeks of an AA-based formula with rice [263].

Hemorrhagic Gastritis

The prevalence is unknown and both clinical and histological findings are not well defined. In some cases, characterized by predominance of vomiting, a severe antral form is observed, with an evident eosinophil infiltrate and elevated concentrations of IgE plasma cells [492]. Other cases are associated with the hypertrophic pyloric stenosis, thus raising the suspicion that the disorder is FA-related [186]. Two young babies have experienced hematemesis caused by an eosinophil erosive gastritis or an eosinophil gastroenteritis, which disappeared after CM withdrawal [147, 207].

Vomiting

In the first months of life, persistent vomiting is a typical symptom, never isolated, since it is frequently associated with other GI symptoms, in particular with diarrhea (26% of cases) [281], common in very young infants [392]. Vomiting occurs in enterocolitis, allergic colitis, malabsorption and eosinophil gastroenteritis [23]. It is a very frequent symptom, especially in infants with CMA, likely causing severe metabolic alterations, including dehydration with electrolyte loss; the younger the child the greater the severity. The differential diagnosis includes a wide spectrum of disease: it may lead to a suspicion especially of GER and hypertrophic pyloric stenosis (Table 6.5).

Iron-Deficiency Anemia

Microscopic intestinal blood loss has been recognized for many years and it is considered an expression of a CMA enteropathy. However, iron loss occurs in a substantial group of infants, causing a true deficit in some infants; older children are asymptomatic, although they appear pale and are hypoproteinemic [186, 463]. Certain cases with severe anemia (Hb <7 g) may be associated with generalized edema, abdominal distention, hypoalbuminemia and show an increase as much as 4- to 7-fold of fecal Hb [23]. The relationship with CM has been shown by CM-fed infants of 5–8 months who excreted significantly more Hb than did formula-fed controls [539]. However, it is disputed that the anemia subsides solely with iron therapy, thus excluding immunological mechanisms [23]. Intestinal biopsies of children with severe anemia and hypoproteinemia revealed no histological or immunological abnormalities [186].

Respiratory Manifestations

Heiner Syndrome

This uncommon syndrome, described in CM-fed infants of 13 days to 6 months, consists of chronic symptoms of the lower airways or recurrent disease, characterized by persistent or recurrent pulmonary infiltrates, probably caused by CIC deposits [204]. Additional findings upon several organs may include serous or recurrent purulent otitis media, diarrhea, vomiting, anorexia, poor weight gain, anemia, eosinophilia, and high titers of serum precipitins to CM. Pulmonary hemosiderosis may ensue because of bleeding from the alveolar capillaries and should be suspected when hemophthisis and anemia are present [204]. Most symptoms improved strikingly with a CM-free diet since the disorder may be a result of CMA [480]; in some cases egg and pork have been suspected [296]. Infiltrates apparent on chest X-rays resolved within 4 weeks [495]. IgG, IgA and C3 deposits were demonstrated in immunofluorescence studies on lung biopsies [296]. Antigen–antibody complexes and lymphocyte-mediated immune reactions to CM are postulated in the immune pathogenesis based on the presence of high serum levels of CM-specific IgG antibodies and in vitro proliferative responses of lymphocytes to CM antigens [55].

Asthma

Infantile asthma associated with IgE-mediated CMA is present chiefly in the first 2 years of life, with a 4%–9% prevalence, which increases by taking into account cases of wheezing by mechanisms of the delayed type, and decreases in older children. Figure 9.14 shows a 21% prevalence with a 4%–37% range (see "Association with Asthma"). Severe asthmatic episodes with loss of consciousness and death also depend on *inhalation of CM proteins* by patients with CMA [489].

Rhinitis

Rhinitis can be referred to CMA, especially in infants. The prevalence in children is between 3% and 35% (mean 20%) (Fig. 9.14). Usually it is accompanied by other manifestations and not only respiratory symptoms [23].

Additional Respiratory Symptoms

The following respiratory symptoms have been described [23]:

- Recurrent bouts of cough, dyspnea and fever with a clinical picture similar to that of CF or of foreign body aspiration
- Recurrent pneumonia as such, or associated with chronic diarrhea, in which not only CM but also pork, peanuts and soy have been incriminated as causative allergens
- Extrinsic allergic alveolitis manifests itself with recurrent bouts of difficult breathing, mild chronic respiratory distress, and serum precipitins to CM and egg [495] (Chap. 11)

The prominent characteristic of these syndromes and symptoms appears to be the overlapping clinical manifestations [463]; it seems logical to advance that it consists of one syndrome with a wide spectrum of manifestations, with different degrees of severity and chronicity. Solely from the 2nd year, when the classic acute enteropathy becomes rare and fades away, the diverse syndromes can be independent.

Other Food-Induced Manifestations

Cutaneous Manifestations

CM, egg, peanuts, and nuts are responsible for cases of contact urticaria, less frequently for acute urticaria and/or angioedema: typical is the case of fish [83, 112] (Fig. 8.3). Urticaria and shock due to CM are reported also in infants 4–6 months of age [187]; however, the prevalence is unknown. A young girl seen by us manifested erythema and edema shortly after having been caressed by fingers wetted by CM, or using a CM-containing ointment. Acute urticaria-angioedema may be an early sign of an impending anaphylactic reaction and is often related to food ingestion immediately prior to the symptom onset [145]. A ten-month-old girl seen by us because she was CM-allergic also developed urticaria and edema after her brother kissed her while eating a CM-made ice or drinking CM. It is believed to be the

most common manifestation of IgE-mediated FA and its cause–effect relation with the incriminated food is obvious when symptoms appear within minutes [10].

AD may be present in 50% of children within the first 2 years of life, then the prevalence decreases clearly; the differential diagnosis should take into account all the affections indicated in both Chaps. 7 and 8.

Dermatitis herpetiformis may be mistaken for AD and in 85% of cases is associated with CD, also because of a genetic predisposition denoted by HLA haplotypes in 80%–90% of patients [55]. The diagnosis is based on IgA, C3 and polymorphonuclear (PMN) leukocytes found in the dermoepidermal junction; IgA deposits contain J-chains that indicate its origin in the gut [414].

Colitis Induced by CM and Other Foods

CM- and soy-induced colitis are clinically and histologically similar: endoscopic examinations of colonic mucosa show analogous features in both conditions [55]. Colitis presents in the first months of life in infants, typically secondary to CM and soy hypersensitivity, but these infants usually do not appear ill and are detected because of the presence of gross or occult blood in their stools [186]. Some infants have normally formed stools, lesions are confined to the colon and consist of mucosal edema with evident eosinophil infiltration and IgE antibody increase in the epithelium and lamina propria [55]. In older children, other foods are incriminated such as egg, wheat, fish, molluscs, and nuts [145]. The manifestations are not specific, including fever, vomiting, chronic diarrhea, leukocytosis, carbohydrate intolerance, metabolic acidosis, dehydration and sporadic shock [106, 392]. A subset of children may manifest diarrhea and transient carbohydrate malabsorption, with most of them experiencing alteration of the lactose tolerance test and a rise in fecal carbohydrates as well as PMN elevation in many [392]. In chronic cases, anemia and/or hypoproteinemia may be apparent [55]. DBPC-CT studies are absent; however the disorder generally resolves after 6 months to 2 years of allergen avoidance [55].

Enterocolitis Induced by CM and Other Foods

Food protein-induced enterocolitis syndrome (FPIES) secondary to food ingestion and not specifically IgE-mediated [224], has a probable CD4-mediated pathogenesis [349]. Infants of 1 week to 3 months generally present symptoms in response to food proteins passed in BM or to CM [392, 448] but none of 14 infants developed FPIES during exclusive breastfeeding [358]. Usually the symptoms are isolated to the GI tract, such as protracted vomiting and abundant diarrhea, and can be dramatic enough that some infants may progress to severe illness [358, 392]. The condition can be misdiagnosed as a mucosal enzyme deficiency [178, 392]. Intolerance, in addition to CM, may be to soy [392], which, when employed after severe lesions of the gut mucosa due to CM ingestion, perhaps due to a 30-kD component from soybean, may induce in these infants or young children clinical manifestations similar to CMA [90]. In 14 babies aged <1–7 months at initial diagnosis, 71%–80% with FHA the reactions were to rice (71%), oat (64%), barley/pea/string bean (14% each), squash, sweet, potato, poultry (7% each), >1 grain 50% [358]. In older children, the reactions are more frequently to egg or wheat in 37% of cases [281], but also to peanuts, nuts, chicken, turkey, rice, gluten, sweet potato, squash, string beans, peas, beef, pork, fish, and goat's milk [145, 178, 358, 392, 448, 414, 486, 492]. Among the triggers, oat is a prominent (64%), but hitherto unrecognized cause [358]. The OFC with a SPF was positive in 20.9% of 43 infants with non-IgE-mediated intolerance to CM and/or soy, to both foods in 13.9% of cases [60]; clinical intolerance to soy was noted also in 11.5% of 35 children with malabsorption and CM intolerance [281]. The symptoms can occur within minutes or can sometimes be delayed up to several hours after a FCT [193, 234, 392]. The diagnosis cannot rely on RAST results [84] or SPTs [55] in these children with GI symptoms caused by CM and/or soy intolerance [33]. Thus, the diagnosis is based more usually on symptom resolution within 72 h of elimination of the offending food and on the relapse within 1 h after its reintroduction. FCTs should be done in a medical setting because the symptoms are severe, consisting of protracted vomiting, dehydration, acidemia, hypotension, and anaphylactic shock in 15% [182, 486] to 57% of cases [358]. After the challenge, a biopsy of proximal jejunum reveals hemorrhage, and histology shows flattened villi, edema, increased eosinophil counts (in some cases), and infiltration of PMNs in the lamina propria; the superficial epithelium appears to be abnormal, and in the inflammatory infiltrate both IELs and plasma cells in the lamina propria are increased [384]. Jejunal biopsies disclosing an increased infiltration of mucosal lymphocytes and eosinophils may be wholly similar to biopsy findings in eosinophil gastroenteritis, especially of the first type [294]. Scanning electron microscopy shows poorly visible microvilli because of patchy losses of glycocalix, which leaves villous height abnormally low, with adjacent areas markedly flattened and deeper crypts resembling the ultrastructural pattern of stage II CD, up to total upset of cellular architecture [384, 391]. Villous height is significantly lower than it is in controls, 250 µm vs 380 µm [349]. An increased number of IgA and IgM antibodies in the lamina propria after challenge with SPFs confirms the affinity with CD, and establishes that a similar immune mechanism is potentially involved in soy enteropathy, as confirmed by the local mast cell activation: in biopsy specimens, food antigen-induced mast cell degranulation correlated well with OFC results, but not with SPT and RAST results [186, 430].

Therefore, SPT and RAST negativity in these infants shows that *IgE-mediated hypersensitivity plays no role* in SPF-induced enteropathy, as demonstrated by lack of evidence of IgE pathogenetic involvement [58], and of subjects with IgE-mediated reactions [60]. Breast feeding appears to have an important protective effect against CM and soy-induced enterocolitis [349]. The mainstay of dietary treatment is the oligoantigenic diet with lamb meat [80], whereas casein [16, 264] and whey protein HF are not always reliable, as seen in three infants with chronic diarrhea and dehydration [229, 477], in two of whom notable histological lesions were detected [477].

Celiac Disease

Celiac disease is a common chronic inflammatory disorder of the small intestine with a multifactorial etiology. HLA is a well-known risk factor, but other genetic factors also influence disease susceptibility. Although gluten is a necessary factor for disease development, it is a hereditary condition with a genetic risk of 15% between first-degree relatives, and monozygotic twins showed a concordance of 70%–100% [476]. The analysis of involved genes showed that the strongest linkage with disease was to the HLA *locus 6p*, indicating that *11q*, *5q* and also *2q* are true susceptibility *loci* in this disorder [350]. Chromosomes *15q* and *19q* have also been implicated [537]. The mean incidence in Europe is from 1:4,000 in Greece to 1:300 in Sweden; in northern Europe, 95% of CD patients are positive to *DR17* and *DQ2* alleles; more recently a closer association has been described with *DQA1*0501* and *DQB1*0201* [306]. Roughly 75% of children in central Italy have an association with HLA-DR7 and ≈50% with HLA-DR17 [476]. The *DR7* allele exists in a heterozygous (HET) combination with either *DR3* or with *DR5* [476]. The study of HLA haplotypes reveals that the *DR7* allele is a linkage disequilibrium with *DQA1*0201* and *DQB1*0201* and *DR5* with *DQA1*0501* and *DQB1*0301* alleles; thus individuals with the HET combination to *DR5/7* have the same combination of *DQ* (*DQA1*0501*, *DQB1*0201*) alleles [476]. The enteropathy, which results in malabsorption, is suspected when children present with diarrhea (or steatorrhea) and weight loss 1–6 months after introduction of foods containing *gliadin, the alcohol-soluble portion of gluten* found in wheat, rye, barley and oat [306], with the previously reported histology. Gliadin is responsible for immunopathological alterations, with a shared AA sequence homology with human adenovirus 12. The immunopathogenesis remains unclear; it is likely that in the lamina propria the gliadin antigen is presented to HLA-DQ restricted CD4-gliadin-specific T cells [306], thus leading to the known cascade of events. Also involved is a type IV CMI mechanism. Gluten ingestion induces proliferative activation of TcRαβ CD8 and γδ CD8 IELs [194]; IEL TcRαβ CD8 T cells are markedly increased and express many $CD45RO^+$ memory cells, as well as TcRγδ CD8, thus demonstrating their role in pathogenesis, which is also indicative of the disease [51]. γδ IEL density was significantly greater than in children with CMA [278]. There is hyperactivation of mucosal T cells and release of ILs, which probably contribute either to the increased imbalance of B-cell response or to crypt hyperplasia and enhanced epithelial permeability and HLA class II and SC expression [51].

Urine mannitol and lactulose have been measured as noninvasive means of evaluating the state of the GI mucosa [501]. Subtotal atrophy of the intestinal villi, the classic hallmark of the disease, is not a universal finding, because some patients have subtler lesions that may make diagnosis difficult. Indisputable evidence that the lesion is gluten mediated in theory would require obtaining a biopsy specimen before treatment, another after withdrawal of gluten from the diet, and a third after gluten challenge. In children, obtaining serial biopsies is only reasonable in doubtful cases or in very young children [501]. However, a gluten challenge to establish the diagnosis should not be performed in children, because a relapse may be expected at a much lower gluten load than previously presumed [291]. Gluten challenge significantly increases anti-WGA (wheat germ agglutinin) and anti-gliadin (AGA) antibodies [158], but not anti-βLG and anti-OVA [157], and IgG and IgA levels are not increased, thus showing that the celiac lesion may be a mitogenic response induced by WGA [158]. For a less invasive diagnosis in children who are ≤2 years of age, AGA IgA are measured in the saliva, with a 90% specificity [190], or in the serum (in 98% of patients after the first biopsy and in 81% after reintroduction), or IgG and IgA together (specificity 94% and sensitivity 89%) [157]. In older children, AGA IgA are measured, then anti-endomysial antibodies (EMA) [501] and tissue transglutaminase C (tTG) [288]. tTG has recently emerged as an outstanding tool for diagnosis: in a study in children using human recombinant tTG, specificity was 100%, and sensitivity was 95% [501]. Starting a gluten-free diet (including all foods of the same family of wheat) induces a decrease in antibody levels also to other foods [157]. However, this diet should be continued throughout life [288].

Crohn's Disease

CD is the principal chronic inflammatory condition and affects infants and adolescents, potentially involving every part of the GI tract. The relations to allergy are sporadic, but based on the improvement of symptoms with an elemental diet.

Gastroesophageal Reflux

GER in infants presents with various symptoms, including emesis, anemia, esophagitis, hematemesis, failure to thrive, near miss SIDS and respiratory symptoms, recurrent vomiting, and colic [167]. The possible clinical overlap with CMA symptoms [167] or eosinophilia [263] makes GER an underdiagnosed condition [167, 263].

Insomnia

Approximately 10% of children aged <1 year and 20% of those 2 years of age suffer from insomnia. There is a growing trend to consider insomnia secondary to intolerance (more than to allergy) to CM: however, 42% of young atopics suffer from the same discomfort [258]. Often a 4-week elimination diet under medical supervision, with the assistance of a diet diary, gives positive results. Attention should be paid to the spontaneous resolution related to environmental measures or the sleep routine. Therefore, both diets and FCT should be limited to not otherwise assessable infants.

Recurring Stomatitis

The lesions are seen in up to 20% of children, consisting in superficial ulceration in the oral mucosa, with itching and burning, attributed to local contact with CM, but also apple, citrus fruit, tomato, pineapple, bananas, and walnuts are incriminated [23].

Ulcerative Colitis

UC is limited to the large bowel. CM has been implicated as a triggering factor in several cases, also because CM ingestion causes clinical flare-ups. However, CM elimination is followed only rarely by the resolution in stabilized cases (see Chap. 18 also for CD).

Vasculitis

In infancy Schönlein-Henoch syndrome is better known, but the etiology is scarcely understood: CM is one of the numerous provoking factors (Chaps. 8 and 19).

Allergy to Other Foods

Dannaeus and Inganäs [118] have studied food effects on diverse systems: lemon, tomato and cereals induce only cutaneous symptoms (in 100% of cases), while all remaining foods induce both cutaneous and GI symptoms, but respiratory symptoms are provoked only by CM, egg and fish (8.5%–50% of cases). Furthermore, numerous histamine-rich foods or with histamine-releasing power are responsible for pseudoallergy (PA) (Chap. 10).

Prevalence

The results presented in Table 9.9 are based on 18 studies in 4,657 selected children of 0.1–19 years, with a thorough evaluation and a proper diagnosis of reactions to several foods [28, 29, 46, 48, 61, 111, 177, 178, 203, 225, 237, 257, 270, 323, 397, 416, 520] and are compared to the results of 456 positive FCT in children and adults from three US centers [48] and of 404 European children and adults [520]. The results based only or mostly on parental reports [40, 211] have not been included since they are not comparable with other results. Some foods, also studied in children of a different age, have a wide frequency range, especially egg (7.3%–85%), peanuts (3.9%–31.4%), wheat (1.1%–23%), fish (2.4%–20%), chicken (1.1%–15%), and beef (0.5%–6%). Pork and shrimp are included in five and six studies, respectively, potato in two, and remarkable rates of 3%–30% for orange, 0.6%–9.5% for apple and 0.8%–19% for tomato were found [224]; the records of peach and almond [270] and the logical differences between younger and older children [47, 224, 316] are reported. In babies with an onset age <12 months, the prevalence is highest [322], while at 36 months there are numerous reductions compared to the total [224]. Severe reactions such as anaphylactic reactions are triggered by egg, peanuts, fish, molluscs, nuts, and spices [340]; shock and urticaria are triggered by peach, wheat and egg in young infants [187]. A case of anaphylaxis and a cutaneous reaction to egg [41] and cutaneous, GI, respiratory reactions to peanuts, peas, beans, herbs, vinegar, ketchup, and shellfish [43] have been reported. Numerous cases of food anaphylaxis are discussed in Chap. 20.

Allergy to Single Foods

See Table 9.10 [19, 415] and Table 1.74 for the allergens.

Egg

The prevalence of allergy to egg in selected children is 26.4%, higher than that of CM (23.5%). IgE-mediated allergy was present in 10/191 unselected infants aged 1 year (5%), none of whom had elevated CBIgE levels [267]. The most sensitizing proteins are in egg white, containing 23 glycoproteins, the principal proteins are, in order of frequency [218], OVA (Gal d 2) (54% of total), ovotransferrin (Gal d 3) (12%), ovomucoid (Gal d 1) (11%), ovomucin (1.5%–3.5%), lysozyme (3.4%) and Igs (4%). The egg yolk proteins are lipovitellin, lipovitellinin, livetin (α, β and γ) and phosvitin. The main aller-

In the study by Høst et al [186], cases of CM intolerance were not taken into account because at 3 years no child was still CM-intolerant. In three studies, the diagnosis of CMA was made with food challenge, but parents reported for other foods [216] or SPT and sIgE were employed [47, 206]. Studies based wholly or mostly on parental reporting were not included. The means were not calculated for foods rarely reported. Cod was almost always reported for fish.

H history, *TH* telephone history, *SPC* skin prick tests, *IgE* total IgE, *sIgE* specific IgE, *OPC* oral provocation challenge, *OPB* idem in double-blind, *M* median, *ND* not done; *NS* not specified, *CM* cow's milk, *CMA* cow's milk allergy, *OFC* open food challenge, *BFC* double-blind food challenge, *m* months specified; * See the text.

Table 9.10. Examples of common food families

Animals
Mammals (meat/milk)
Cow, goat, lamb, pork, ram, rabbit, sheep, squirrel, venison
Birds (meat/egg)
Chicken, duck, goose, grouse, hen, partridge, pheasant, squab, turkey
Fish
Anchovy, barracuda, bass, bluefish, buffalo, bullhead, butterfish, carp, catfish, caviar, chub, cod, croaker, cusk, drum, eel, flounder, hake, haddock, halibut, herring, mackerel, mullet, perch, pike, pickerel, salmon, sardine, shad, snapper, sole, sunfish, trout, tuna, weakfish, whitefish
Shellfish
Arthropoda (crustacea) Crab, crayfish, lobster, prawn, shrimp
Mollusks Gastropoda: abalone, limpet snail Bivalve: clam, mussel, oyster, scallops Cephalopoda: octopus, squid Others: cockle, conchs, polyp
Vegetables
Caper Caper
Compositae Artichoke, camomile, chicory, dandelion, endive, escarole, head lettuce, leaf lettuce, oyster plant
Grass Barley, buckwheat, corn, oats, rice, rye, sorghum, sugar cane, wheat
Ginger Cardamom, ginger, turmeric
Laurel Avocado, bay leaves, cinnamon, camphor
Legumes Acacia, alfalfa, broad beans, black-eyed pea, kidney bean, lentil, licorice, lima bean, mesquite, navy bean, peanut, pea, senna, soybean, string bean, tamarind, tragacanth
Lily Asparagus, chives, garlic, leek, onion
Mint Marjoram, mint, peppermint, sage, savory, spearmint, thyme
Mustard Broccoli, Brussels sprouts, cabbage, cauliflower, celery, cabbage, collard, horseradish, kohlrabi, mustard, radish, rutabaga, turnip, watercress
Parsley Anise, caraway, carrot, celery, coriander, cumin, dill, fennel, parsley, parsnip
Potato Capsicum, chili, eggplant, pepper (green, red), potato, tomato
Sunflower Jerusalem artichoke, sunflower
Fruits
Actidine Kiwi
Apple Apple cider, pear, quince, vinegar
Beech Beechnut, chestnut, chinquapin nut
Birch Filbert, hazelnut
Cashew Cashews, mango, pistachio
Citrus Grapefruit, lemon, lime, mandarin, orange, tangerine
Gourd Cantaloupe, cucumber, honeydew, muskmelon, Persian melon, pumpkin, squash, watermelon, zucchini
Grape Champagne, grape, raisin, vinegar
Mulberry Breadfruit, fig, hop, mulberry
Musa Banana
Myrtle Allspice, cloves, guava, pimento, pomegranate
Nuts Brazil nut, nutmeg, pecan, walnut
Orchid Coconut, date, vanilla
Papaw Papaya
Pineapple Pineapple
Plums Almond, apricot, cherries, nectarine, peaches, plums, persimmon
Rose Bigarade, blackberry, citron, dewberry, loganberry, medlar, raspberry, sorb, sour cherry, strawberry, youngberry

Data from [19, 415].

Table 9.11. Allergy and multiple allergy to cereals

The reduction of incidence by DBPCFC was remarkable [488].
[a] By OFC.

gens, resistant to denaturation and therefore potent allergens, are Gal d 1, recently considered as immunodominant in man [30], Gal d 2 and Gal d 3; Gal d 3 allergenicity is lesser and that of lysozyme is mild. Even if the sensitization is due usually to egg white, small amounts of Gal d 1 and Gal d 2 are also found in egg yolk, and several responses to OVA may be due to contamination of Gal d 1 traces [30]. Egg has been shown to be the most common food to cause allergy, and to be responsible for IgE-mediated symptoms, including urticaria-angioedema, rhinorrhea, wheezing, AD and GI symptoms, as well as severe asthma after remaining dormant for 500 years [12]. Also known are its histamine-releasing properties. No differences are found between cooked and raw egg: the allergens have a stable sensitizing power after heating at 100 °C for 20 min [526]. Egg sensitization may derive from BM, inadvertent inhalation of small amounts of allergen in kitchen fumes (Table 7.22), school floors in up to 41% of cases [139], and from cross-reactivity among eggs of various birds (see below). An unusual case was that of a boy who reacted while in a room next to the kitchen where the mother was cooking with eggs [22].

Egg allergy, often associated with other allergies, can elicit highly variable symptoms. In four pediatric cohorts (160 children), egg provoked cutaneous symptoms in 45%–78%, GI symptoms in 50%–56% and respiratory symptoms in 8%–39% of the children, solely urticaria in 25%, and associated symptoms of the three organs in 41% of cases [112, 166, 328, 481]. In 467 children [453], the rates were 90% cutaneous (84% of urticaria), 20% GI, and 15% respiratory symptoms. Egg allergy was present in 30% of children with AD and FA, FCTs with egg were positive in 45.8% of children with immediate, delayed, or associated reactions [328], or immediate reactions in 72% of cases [453]. In 324 children followed up from birth for 4–15 years and investigated with RAST and Phadiatop Paediatric, 135 (41.6%) at ≤18 months had at least one positive test, 66 to foods (49%), 70% of whom reacted positively to egg and 15% to CM [449].

Cereal Grains

About 40 protein allergens are known, half of which are common to wheat and barley (allergen Hor v 1); others are found in rice. These allergens are found in both the flour and bran. More precisely, the seeds contain four protein fractions: the more antigenic are glutenins, which form 30% of proteins, and globulins [531]. A wide cross-reactivity is seen among cereals, so children sensitive to wheat are also sensitive to other antigens [379], following the taxonomic relations in the following order: wheat – rye – barley – rice – corn – sorghum; but the primary reactivity is more evident between wheat, barley and rye and between rice and millet [531]. Cereal is allergy not always isolated: apart from the related pollens (see below), multisensitization is frequent (Table 9.11) [379, 399, 488]. Children allergic to cereals have SPT+ to rice, corn, millet and buckwheat, thus indicating either a cross-reaction or a true sensitization, since such cereals are suggested as an alternative to children allergic to wheat and the like [488]. The high number of SPT+ in one trial is astonishing, although reduced with DBPCCT [413], and 57.1% of children were positive to six cereals in another trial [379]. Children with positive SPTs to wheat have associated positivities to other cereals in 59%–77% of cases [379]. In younger children, the incidence rises during their growth: among 66 children at about 18 months of age only three (4.5%) were positive to wheat, but after 18 months there were 14 (21.2%) [449]. Symptom location is also diverse, only respiratory in one cohort [481], cutaneous in 86.4% of cases (73.3% AD and 13.1% urticaria) and GI in 13.4% (10.5% diarrhea and 2.6% vomiting) [379]. In an OFC,

there were no respiratory symptoms (Table 9.11). Interestingly the reactions were immediate in 35%, delayed in 61% and associated in 4% of cases [399].

Wheat

The mean prevalence of wheat allergy is 7.8%. Wheat proteins include six main fractions: gluten, albumin, starch, euglobulin, pseudoglobulin and gliadin; α-gliadin is involved in CD. Hydrosoluble fractions (albumin and globulins) are more often responsible for type I reactions, located in the GI tract. Gluten is an elastic protein used as "glue" for baked goods [531]; 11.7% of 102 children who were RAST+ to wheat were also strongly positive to grass pollen [126]. Generally, children allergic to wheat are also allergic to rye and barley, belonging to the same family, *Triticum* [488]. In Europe, wheat allergy is rather frequent, in other countries it is less so, and in statistics wheat comes after fruits and vegetables, or is absent, except in Nordic countries and USA where corn flakes are more often consumed.

Corn

Corn originates in North America: the US produces 50% of the world's corn. It is credited with a relatively low degree of correlation with other cereals, although corn and rice allergens appear to be similar [531]. An insoluble 50-kD protein present in corn flour may act as an allergen in IgE-mediated FA to corn products, because of its stability to cooking and digestion [376].

Rice

The mean prevalence of rice allergy is 5.5%. Rice allergy is more frequent in Chinese and Japanese populations, because rice has been eaten in high daily amounts for centuries, to which the immune tolerance should be established with time. Japanese investigators have identified 16-kD allergenic proteins in both the glutelin and in globulin fractions of rice [511]. Cross-reactions with wheat, rye, corn and rye pollens are known [126, 488]. In Western countries, five anaphylactic reactions (vomiting, diarrhea and shock) in infants 3–10 months old have been reported in the last 20 years [16, 49, 229, 473]: in two cases the FCT was positive [16] and in one lesions similar to enterocolitis were observed [49]. A 4-month-old girl had vomiting, urticaria and shock [230]. Other children had immediate reactions to rice ingestion with shock, but SPTs to rice were negative [102]. In 7% of children, SPTs were positive, whereas DBPCCTs elicited no clinical manifestations [421], corresponding to positive SPTs in 5.3% and 6.8% of two other cohorts [177, 178]. More often, children with enterocolitis show wheat intolerance.

Barley

Barley may induce reactions because its protein antigens are the same as those in wheat, and barley protein fractions show a strong biological cross-reactivity particularly with rye [413].

Oat

Oat-related allergens react slightly with wheat, rice and barley [413].

Fish

The mean prevalence of fish (cod) allergy is 8.0%. The best known and best characterized fish is the cod Gad c 1 (*Gadus callarias*) allergen, which has been purified until the crystalline form was obtained [1]. It is a protein of the parvalbumin group, which controls the flow of Ca^{++} into and out of muscle cells and contains 113 AA residues and one glucose molecule [531]. It is highly resistant to proteolytic digestion and stable when heated to 100 °C for 10 min [1], thus making Gad c 1 a potent food allergen. Parvalbumins are sarcoplasmic proteins from muscle tissue of fish and amphibian; thus Gad c 1 is found in all fresh- and saltwater fish. RAST-inhibition studies have shown allergenic differences of various fish species with Gad c 1 [374], as confirmed by immunoblotting, demonstrating a 13-kD band in several fish species, corresponding to Gad c 1 [32].

Fish allergy seems to be more frequent in European countries with allergy onset in the first 6 months of life in 24% of cases and in the second 6 months in 51% of children [374]. Fish often induces IgE-mediated reactions: urticaria-angioedema (92% of cases), AD (18%), asthma (inhalation during cooking) (14%), vomiting or diarrhea (11%), up to systemic anaphylactic reactions [374]. In 88 children, 60% of those allergic to fish reacted with angioedema [83]. Since the age of 17 months (mean), 21 children aged 2–12 years affected with AD, asthma and asthma and/or rhinitis, when ingesting fish (regardless of which fish was actually eaten) reacted with generalized urticaria and/or angioedema in 85.7% of cases, vomiting in 19% and respiratory symptoms in 4.8%, as well as two cases of OAS (oral allergy syndrome) [112]. All these children had sIgE to 4–7 fish species. Allergic reactions were associated with airborne fish particles: interestingly, when the same children were exposed to *inhalation of fish particles* at a mean age of 7 years, they reacted with cutaneous symptoms (urticaria isolated or associated with angioedema) in 57.1% and respiratory symptoms (wheezing, rhinoconjunctivitis) in 56.6% of cases. Most reactions occurred at home (53.8%), in the kitchen (26.9%), in a fish-shop (15.4%), at the restaurant (3.8%); in 22.2% of cases reactions stemmed from cross-reactions. Methods

of exposure included cooking vapors or fumes from boiling or frying fish and simple exposure to fish [112]. Smelling the fish odor provoked anaphylaxis in two young children seen in our department. Another child tested positive to cod with a wheal = 7 mm diameter, although we prepared a solution 1:10 with saline to test him.

Precisely the fat-poor species, which are commonly prescribed to infants, are the most sensitizing: *Merluccius merluccius* or hake (95%), *Lepidorhombus whiffiagonis* or whiff (92%), cod (91%), *Glyptocephalus cynoglossus* or witch flounder (90%), *Solea solea* or sole (82%). The least sensitizing was *Thunnus alalunga* (albacore) (21.5%) [374]. Children with cod allergy have SPT positive to eel, dentex, sole, perch fish (PF) (85% of cases) and tuna (55%) [127]. Studies with RAST inhibition that have evidenced cross-reactivity of fish-related allergens reported the following data:

- With cod: eel 89%, dentex 75%, PF 72%, sole 66%, tuna 45%
- With dentex: eel 83%, PF 68%, sole 64%
- With eel: PF 79%, sole 75%, tuna 51%
- With tuna: PF 50%, sole 46% [128]
- With salmon: swordfish and sole 50% [374]

Similarly to what was demonstrated for the legume botanical family, fish allergy is often species-specific, and therefore the reactivity to one type of fish does not warrant automatic dietary exclusion of all related fish species [374], as demonstrated by cod-allergic children who tolerated other species [1, 127], despite cod's widespread use and its extended cross-reactions. Canned tuna and salmon, perhaps as a consequence of a prolonged exposure to heat during the production, could be less allergenic than those cooked conventionally [32]. Canned tuna could contain peanut oil and CM [175]. Similarly to egg, RAST-inhibition studies have found Gad c 1 up to 80%–85% in carpeted and noncarpeted schools [139].

Shellfish

Shellfish can be divided into molluscs and crustaceans. These are among the main nonimmunological mast cell activators (Chap. 10); moreover, several highly sensitizing allergens have been identified and characterized by CRIE (crossed radioimmunoelectrophoresis), which very frequently elicit immediate hypersensitivity reactions: 23 to freshwater crawfish and 17 to sea crawfish. Cross-reactions have been found between mollusc-allergic patients and those allergic to crabs, crayfish and shrimp, thus showing common epitopes [526]. Shrimp-allergic patients have sIgE and/or IgG_2 and IgG_4 [346], with elevated levels compared to controls, which tend to persist at length, even if eliminated from the diet [346]. Therefore, elevated IgG_4 levels may reflect a prolonged exposure to mucosal allergens and a normal response to dietary allergens [346]. Interestingly, there is extensive allergen cross-reactivity (Table 1.73), there is a 75% risk in shrimp-allergic patients with crab and lobster [447], as well as with inhalants (Bla g) [113], and recent discovery that Pen a 1 and Met a 1 are tropomyosins involved in actin activation during muscle contraction, shared with Der f 10 (Mag44) and with several food allergens, which may yield severe reactions in those allergic to dust mites, and with a number of other allergens. Finally, a 3-year-old child suffered anaphylaxis after having eaten shellfish [43].

Molluscs

A major cause of adverse food reactions, molluscs include the Gasteropoda (limpets, snails, whelks), Pelecypoda (bivalves) (clams, mussels, oysters), and Cephalopoda (octopus, polyps, squid). IgE-mediated reactions are more frequent to clams, mussels, snails, and oysters. Snail allergy seems to prevail in Der p-sensitized patients and aggravates their asthmatic symptoms [483].

Legumes

Legumes (peanuts, fava beans, lentils, soy, beans, peas, etc.) possess thermoresistant antigenic proteins; cross-reactivity is rather frequent but rare in children. Legumes cause sensitization and allergic symptoms via ingestion (more common), inhalation and cutaneous contact: rhinorrhea and bronchospasm have been reported by inhalation of cooking vapors of chickpeas and lentils [321] and urticaria due to contact with someone eating peanuts (Table 7.22).

Peanuts (*Arachis hypogaea*) are an annual herb of leguminous papilionates, the seeds or fruits of which are one of the most allergenic foods in children. Moreover, they have the property of cross-reacting with chestnut, hazelnuts and other nuts belonging to different botanical families, more rarely with their similar botanical families. Seven peanut allergens (Ara h with a MW between 15 and 63.6 kD) have a protein content varying from 25% to 28%, with three major groups classified as arachin, conarachin (globulins) and albumin.

Peanut reactions (14.8%) are becoming increasingly more frequent, and from the US peanuts have reached a worldwide diffusion with a prevalence that has tripled in the Isle of Wight, up to 3.3% in 1996 compared to 1.1% in 1994 [188]. Peanut allergy has its onset in childhood, in 92% of cases from 1 to 7 years [155]. More precisely, 16.9% at age 1, 27.7% at age 1–3, 39% at age 3–6 and 46.2% at age 6–15, showing a pattern of increase according to the child's age [397], but before 12 months of age it has been reported between 18.3% and 80% (Table 5.5), and up to 100% of cases [155]. Severe reactions have been reported within a few minutes of inges-

tion [155], anaphylaxis, respiratory distress and angioedema *in three children aged 2–3* [43] and acute anaphylaxis, also fatal [424, 528] (see "FA-Caused Death" and Chap. 20). Attention should be paid to numerous *hidden sources* including foods and vitamins for infants and chocolate-containing foods (see Chap. 24). Some authors have found a high incidence of sIgE to peanuts in children without a known exposure [541] and a fact arousing concern, peanut residues in *foods declared as peanut-free,* but contaminated by previously processed peanuts [262]. Fifty-eight percent of children followed up for 5 years experienced adverse reactions from accidental peanut exposure. Regardless of the nature of their initial reaction, the majority with subsequent reactions experienced potentially life-threatening symptoms. The group with isolated skin symptoms (22%) had lower serum peanut-specific IgE levels than the group with respiratory and/or GI symptoms (78%) [485]. Peanuts are often at the heart of a multiple sensitization with varying types of nuts, and many adults have positive SPTs to inhalants [155]; pollen-allergic children also have sIgE to peanuts (23%) [126]. In addition, there is a controversy on the allergenicity of skin preparations containing peanut oil (Chap. 24).

Soy (6.4%) has a protein content of 32%–42% with two protein fractions, globulins and a whey fraction: the main globulins separated by ultracentrifugation are 11S (glycinin), 7S (β-conglycinin), 15S (aggregated glycinin) and 2S (in the whey fraction), the most thermostable and immunogenic [528]. Three glycoprotein allergens, Gly m 1, Gly m 2 and Gly m 3, were identified. Immunological studies show that a birch pollen-related protein from soy, SAM22 (Gly m 4), might cause adverse reactions up to *systemic allergic symptoms* to soy in patients with high IgE titers to Bet v 1 [271]. Examining Table 1.72, we see that both Gly m 3 and Bet v 1 are *profilins,* therefore the two profilins may cross-react and trigger severe clinical reactions. Banana, apple, tomato, fennel, and celery are other food profilins; however soy, either natural or as a GMO (genetically modified organism), is everywhere, and we name only soy lecithin. By the calculus of probability, it is 10- to 100-fold more probable that a Bet v-1-allergic individual eats soy than fennel. In addition, in a study of ten children aged 1–4 with IgE (mean) at 1122.6 UI/ml, the link between CM and soy was found in a 30-kD component from soybean (Table 1.74) cross-reacting with CM caseins. Thus, the molecule could be involved in allergic reactions observed in soy-fed children exposed to CM-containing foods and in CMA children exposed to soy-containing foods [406]. Children without high IgE titers, and no sensitization to birch or to glycinin run no risks. We discuss below several hypersensitivity reactions in infants and young babies [413].

Pea allergens (2.5%) have been studied less extensively, their allergens, PR-1 and PR-2, are found in the hydrosoluble albumin fraction [528]. A cross-reactivity has been observed with the seeds of soy and white beans [532]. This allergy is found in 14% of pollen-allergic children [126] and in a child with CMA [433].

Lentils are allergens that are very common where they are widely eaten: in Spain they are fourth among the causes of hypersensitivity in children; in India they are ranked fifth [532]. Allergic reactions to lentils start usually before 4 years of age; oropharyngeal symptoms and acute urticaria are the most common symptoms through ingestion, and symptomatic reactivity to chick peas is frequently associated [375]. In Chap. 20 we report a case of anaphylaxis to lentils.

It has been demonstrated that legume allergy is not extended to the entire botanical family. In a study on 69 children with positive SPT response to one or more legumes [31], only in two cases did the initial symptoms reappear after DBPCFC with more than one legume; therefore it is unnecessary to eliminate all legumes from the diet. More demonstrative is that, despite the elevated frequency of positive SPT response to peanuts and soy, only 2%–3% of such positive responses have been confirmed by DBPCFCs [46, 421]. Bock and Atkins [46] studied 32 children with peanut allergy confirmed by DBPCFCs and found that ten (31%) had a positive SPT response to soy, but only one (3% of those with peanut allergy) had a clinical reaction to soy. Among 113 children with AD evaluated with DBPCFCs, only one (0.8%) had clinical allergy to both foods, despite 19% reacting to peanut and 5% to soy [421]. In conclusion, clinical hypersensitivity to one legume should not mean that it is sensitizing to the entire family to which the food provoking symptoms belongs; the possible sensitization should be verified by a DBPCCT.

Potato and Related Foods

This family includes the tomato, potato, eggplant, capsicum, etc. Only a glycoproteic fraction of 20 kD of the *tomato* (7.2%) has been isolated with allergenic properties, stable at acid and neutral pH, and thermoresistant. Characteristically, ripe tomatoes are more allergenic than green tomatoes [10]; many 25-mg/kg glycoproteins are found in ripe tomatoes. Isolated allergy is uncommon; 40% of 102 pollen-allergic children were also allergic to tomato [126]. Symptoms linked to its histamine-release power are frequently appreciated.

Potato has seven allergenic fractions at a MW of 16–65 kD, one of which is thermolabile and disappears after cooking at 40 °C, and is usually responsible for symptoms when it is peeled or eaten raw [505]. Nevertheless, a 5-month-old girl experienced anaphylaxis when eating cooked potatoes for the first time [99]. Cross-reactivity is possible with birch pollen [135] and latex (Table 8.14).

Apple and Related Foods

Apple (4.7%) allergens are the pulp proteins, commonly found in fresh fruit juice; they are less resistant and disappear after 48 h if the fruit is stored at ambient T or at + 4 °C. Such allergens are not stable in solution and are easily oxidized, thus explaining why the prick + prick (P+P) method is preferable [135] (Table 6.10). Some varieties express a marked capacity of IgE-mediated binding to an allergen of 18 kD, Mal d 1 [497, 498], more evident in pollen-allergic patients due to cross-reactions with Bet v 1 (birch) [499], Bet v 2 (profilin) [141], Api g 1 (celery) [132], Pru p I (peach) [482], latex (Table 8.14), carrot and potato [135]. SDS-PAGE (sodium dodecylsulfate-polyacrylamide gel electrophoresis) studies have established that 100 g of Delicious apple contain 1–5 mg of Mal d 1, so a mouthful of about 10 g contains 0.1–0.5 mg of Mal d 1, which should be less sensitizing than Bet v 1 [497].

Plums

Peach, apricot, cherries, and plums can induce severe reactions in the pediatric age group, above all when ingested by children sensitized to birch pollen, and can cause cross-reactions with latex (Table 8.14). Pru p I of *peach,* which is mostly in the skin, causes labial and lingual angioedema and/or perioral contact dermatitis and cheilitis, oral and pharyngeal pruritus and rhinoconjunctivitis in many patients [270]. The risk of reactions in peach-allergic children to apple, cherry, pear and plum is 55% [447]. Bet v 1 and Bet v 2 cross-react with Pru av 1 and Pru av 4 (cherry). The study on plum cross-reactions to other fruits (see OAS) has disclosed common epitopes [377], and a case of shock has been reported [413]. Commonly, children may be sensitized to other fruits of this family (Table 9.10) or to strawberries, which in children frequently provoke cutaneous symptoms induced by aromatic substances or dyes [534] and have a direct action on mast cells. sIgE were demonstrated against a 30-kD allergenic epitope present in peach, strawberry, banana, tangerine [503], cherries [377], and kiwi [502] (Act c 1) (Table 1.74). A case of anaphylaxis in a child eating kiwi for the first time was reported to us.

Citrus and Related Fruits

Lemon, lime, orange, tangerine, and grapefruit contain terpene bodies in the skin and pulp (d-limonene, carotene) and can provoke hand dermatitis, *citrus* contact dermatitis and cheilitis and laryngeal edema, possibly related to toxicity of peel terpene bodies or to pesticides (Chap. 10). *Orange* (11.5%) is the cause of anaphylactic reactions, eczema, asthma or urticaria due to seed proteins [534]. In children with FA and inhalant allergy, sIgE to *grapefruit* have been detected [534]. Both citrus fruits and the parsley family contain natural furocoumarins causes of phytophotodermatites (Chap. 8).

Musa and Gourd Family

There is cross-reactivity between banana (1.2%), members of the gourd family (Table 9.10) and profilins (Table 1.72); *banana* induces symptoms in allergic individuals to ragweed pollen because of common epitopes, and latex (Table 8.14).

Cashew

Cashew falls within the hidden allergens: two adolescents died after ingesting foods containing cashew as an undeclared ingredient [424]. *Mango* provokes anaphylaxis and ACD. *Pistachio* antigenic fractions have marked cross-reactivity with mango and cashew [160].

Parsley and *Compositae* Family

Celery, carrot, fennel, coriander, etc. are prominent (Table 9.10). Subjects allergic to *Compositae* have experienced anaphylactic shock by ingesting celery or mustard (Chap. 20). Recently, *celery* allergen Api g 1, with a MW of 17 kD, has been defined [142] by immunoprint inhibition shows shared allergenic 17-kD epitopes with carrot and birch [206]. Analyzing cross-reactivity between celery, carrot, cucumber and watermelon, immunoblotting has demonstrated that all share a 15-kD protein [252]: in both cases the MW recalls that of profilins. Moreover, celery, carrot and anise share allergenic epitopes with fresh vegetables [535]. Api g 1 is part of the profilin family and has antigenic similarity with apple, peach and potato [381]. Celery can elicit cross-reactivity with *parsley,* cabbage, cauliflower and broccoli [535], less often with carrot, cucumber and anise, thus forming the celery-carrot-mugwort-spices syndrome [521].

Nuts, Pine Nuts and Seeds

Walnuts (Juglandaceae) are biologically related to American nuts or pecan (*Carya illinoensis*), and Brazil nuts (*Bertholletia excelsa*) have several 5- to 50-kD antigenic proteins [13]. Patients allergic to birch, alder and hazelnut pollens experience evident reactions after ingesting hazelnuts and occasionally apple or other rose fruits [533]. Generally, pollen-allergic patients report hypersensitivity to walnuts and hazelnuts more frequently than non-pollen-allergic patients [533]. Sensitization to hazelnut was associated with reactivity to birch pollen in 4/11 children [164]. Cases are known of severe reactions to Brazil nuts within 3 min of ingestion,

with cutaneous (angioedema and generalized urticaria), respiratory and systemic symptoms as severe as anaphylaxis [13], caused even by involuntary ingestion [528]. Walnuts provoke fatal anaphylaxis (Chap. 20) and asthmatic manifestations after DBPCCT [359]. Cross-reactions are also frequent: in a group of children, one reacted to DBPCCT to five nuts, one to two nuts and 12 to one nut each; two reactions were positive to pistachio and one to hazelnuts [46]. The risk of reaction in walnut-allergic patients to Brazil nut, cashew and hazelnut is 37% [447]. In the US, cases of systemic reactions and *pine nut anaphylaxis* have been reported in adults (Chap. 20). Two young Spanish girls had two or three repeated episodes of anaphylaxis after eating small amounts of pine nuts, correlated with this nut only after the last episode [231]. Pine nuts are almost unknown in the US, while in Mediterranean countries they are widely consumed as such, or employed in confectionery, sauces and dishes, and are pressed to extract oil.

Cases of anaphylaxis, angioedema and generalized urticaria have been reported to be provoked by *sesame* seeds utilized for vegetarian and health foods, hamburger, salad dressing, as well by bakers [533].

Mustard and Related Foods

Two types of *mustard* allergy, black (*Brassica nigra*) and white mustard (*Sinapis alba*) are implicated. The known allergens are Bra j 1 of *Brassica juncea* and Sin a 1 of *Sinapis alba*, which have elicited type I reactions as well as anaphylactic and type IV (contact dermatitis) reactions: cases of anaphylaxis in children were generated by mustard addition to sausages and sandwiches [344]. *Cucumber* induces sIgE in patients with FA and reactivity to common epitopes of ragweed has been described, as well as to banana, melon and zucchini [150].

Additional Foods

IgE-mediated reactions have been made known to camomile, sunflower honey, muskmelon, pomegranate, kiwi, uncommon fruits (raspberry, cranberry, red and black currant, etc.) and exotic fruits [205, 283, 502, 516, 520], which should be eaten with precaution by children with diagnosed allergy to foods or pollens, because of possible cross-reactions. *Honey* may include pollen allergens: 10 g may contain from 20 to 10,000 pollens [205] and trigger mild [283] to severe symptoms such as generalized pruritus, vomiting and diarrhea [205]. Allergy to other vegetables utilized in bakeries, including sunflower and flaxeeds have been reported [520], and anaphylaxis following ingestion of meat containing papain employed to tenderize meat [534]. Furthermore, the *cross-reactivity* between banana, cucumber, melon and zucchini with ragweed and of almond, apricot, cherry, and peach with birch is widespread [381]. Patients allergic to melon have a 92% risk of reactions to avocado, banana and muskmelon [447]. *Camomile* may cause symptoms in *Parietaria*-allergic subjects and royal jelly in *Compositae*-allergic patients (ragweed and mugwort) [532], the latter up to asthma and anaphylaxis [475]. Cross-reactions are known between *Compositae* and sunflower pollens [159], which have a partial allergenic identity with sunflower oil and mugwort pollens [260], as well as in patients with profilin-modulated allergy to various fruits, between latex and banana, avocado and coconuts (Table 8.14) and other fruits and vegetables [141]. Additional cross-reactions are with poppy seeds and sesame, kiwi, rye and hazelnuts [502] and bird derivatives with chicken egg (see "Bird Egg Syndrome"). We underline that *sunflower* is a cause of cross-reactions [159]. In an infant 6 months old, it caused severe symptoms; the infant ended up in hospital every time he received cereals with sunflower oil [169]. Since the use of this oil continues to propagate, the potential sensitization to mugwort pollens should be taken into account [260].

The medical literature over the years has attributed a varied spectrum of symptoms to *chocolate* consumers. The case of Talbot is well known [469]. Several children had many positive SPTs but DBPCFC to chocolate was negative in all subjects [61, 270]. Since no immunological pathogenesis has been demonstrated, the term "intolerance" is more accurate, and is relatively frequent in children, especially in atopic children, while the hypothesis of cross-reactions between legumes and chocolate belonging to the same botanical family has not been validated [31]. In 4/57 children 1–5 years of age, affected with FA (CM and/or egg) with SPT+ to both chocolate and legumes, and one to legumes, the OFC was negative in all. In the control children, there was one positivity to legumes (p=0.01). Since the 4 children had SPT+ also to legumes, a cross-reaction between chocolate and legumes is very rare, so these data do not warrant dietary elimination of plain chocolate. The cases reported are likely due either to chocolate's pharmacological properties (Chap. 10) or to other constituents, including aromatizing substances (cinnamon, vanilla, nutmeg), soy lecithin (emulsifying and anti-oxidant), cocoa butter and other vegetable fats such as oleic acid. Moreover, nitrogen residues, tyramine, histamine-releasing substances, balsam of Peru, Ni sulfate up to 220 mg/hg, bichromate K, CoCl, Cr (traces) and latex are found (Chap. 8). Hidden CM has been detected in chocolate stemming from contamination by previously processed food items, but CM in plain chocolate is generally not reported on the label and it is unknown whether substituting cocoa butter with different oil types is devoid of risk.

Table 9.12. Prevalence of asthma in children with FA

Authors	Reference	No. of cases	Median age or range (years)	Asthma (%)	Diagnosis
Oehling et al	[363]	284	2–8	8.5	OFC
Onorato et al	[370]	300	6.5*	2	DBFC[a]
Novembre et al	[359]	140	5	5.7	OFC
Meglio et al	[328]	70	2	13.1	OFC
Bock	[43]	279	0.4–19	2	DBFC
Salob	[412]	15	11	6	NS
James et al	[242]	88	7.5	14.8	DBFC
Cantani et al	[86]	213	3	6.6	OFC
Carroccio et al	[98]	91	0.2	8.8	DBFC[b]
Mean				7.3	

NS not specified, *OFC* open challenge, *DBFC* double-blind challenge.
The studies are ordered according to the year of publication.
[a] The six patients with asthmatic reactions were children, whose median age is shown.
[b] Four children reacted to ass milk and four to a casein hydrolysate formula.

Multiple Food Sensitizations

Multiple food sensitizations, contrary to what is commonly believed, are rare [47, 82, 83, 421, 449]: arguments have been put forward that assume that children with several positive SPTs and RASTs should not endure rigid diets that eliminate a wide spectrum of foods. To assess food polysensitization properly, it is necessary to schedule children for FCTs to each suspected food, excluding those with a convincing history of prior life-threatening reactions. These observations underline the difference between humoral (RAST positivity) and clinical sensitizations (FCT positivity). Borderline cases are reported in Chap. 16. The prevalence is highest for 2-food hypersensitivity (24.6%) than for 3-food (7%), 4-food (2.9%) and 5-food (1.8%) hypersensitivity. In 88 children [83], 25 (28%) were sensitized to CM and egg and 4 (4.5%) were also sensitized to wheat. Polysensitivity (especially toward CM, egg and wheat) was recorded in 29% of children [69], and in 43/115 (37.4%) children: to CM, egg and wheat in 27 cases, CM and wheat in 8, CM and egg in 8 [92]. In 128 children affected with AD associated with FA (lasting 1–5 years) [82], we did P+P tests with vegetables and fruits: FCTs were positive to citrus (62%), potato (12%), tomato (24%) and peanuts (11%), whereas no child positive to other foods reacted to a pertinent FCT. Therefore it would be unwise to make a diagnosis of multiple sensitization based only on pseudo-positivity. In 63/113 children with AD associated with FA who underwent elimination diets based on history and positive SPT and/or of sIgE, 20 children (31.7%) reacted to 3 or more foods: 12 of them to 3 (CM, egg, wheat or soy), 5 subjects to 4 foods (the above plus wheat), and 2 children to 5 foods (the above plus fish); in only two children 3 foods (CM, egg, wheat) were eliminated to obtain improvement of cutaneous symptoms [421]. In the study of Bock and Atkins, 52/480 children (11%) reacted to two or more foods, and 10/52 to three or more foods [47], while in 46/66 children with sIgE reacted to egg; 30%–37% also had sIgE to CM and wheat [449]. In 71 subjects with a mean age of 18 years, with FA onset after the age of 10 years, the main SPT results and FCT results were as follows: peanuts, 46 (22%), orange, 21 (6%), carrot, 9 (4%), tomato, 17 (2%), wheat, 10 (2%) and apple, 8 (2%); soy and chocolate yielded negative results [270].

Association with Asthma

Many children react to CM and to FCTs with respiratory symptoms, as results from a meta-analysis on the prevalence of asthma in children with AD and FA (46.8%) have shown (Table 7.10). Respiratory symptoms in Fig. 9.14 were induced only by CM, while, as seen in Table 9.12 [43, 86, 98, 242, 328, 360, 363, 370, 412], asthma has been noted in 7.3% (range, 2%–13.1%) of 1,480 children with FA, but it was also produced by other foods. Our data show that 23/94 children (24.5%) (median age 36 months) with asthma and sensitization to CM demonstrated by positive SPT, RAST and DBPC, reacted with bronchospasm to the administration of CM and five to CM-derived formulas: in five children asthma appeared after administration of very small doses of CM on the lower lip [86]. In a selected group, 5 of 20 children (25%) reacted with asthma to DBFC to CM and HFs [396], and a young woman reacted with asthma to egg proteins that had remained dormant for 500 years [12]. The association of 57%–83% cases of asthma with severity of FA reaction has been demonstrated in 293 children [312]. Many children with

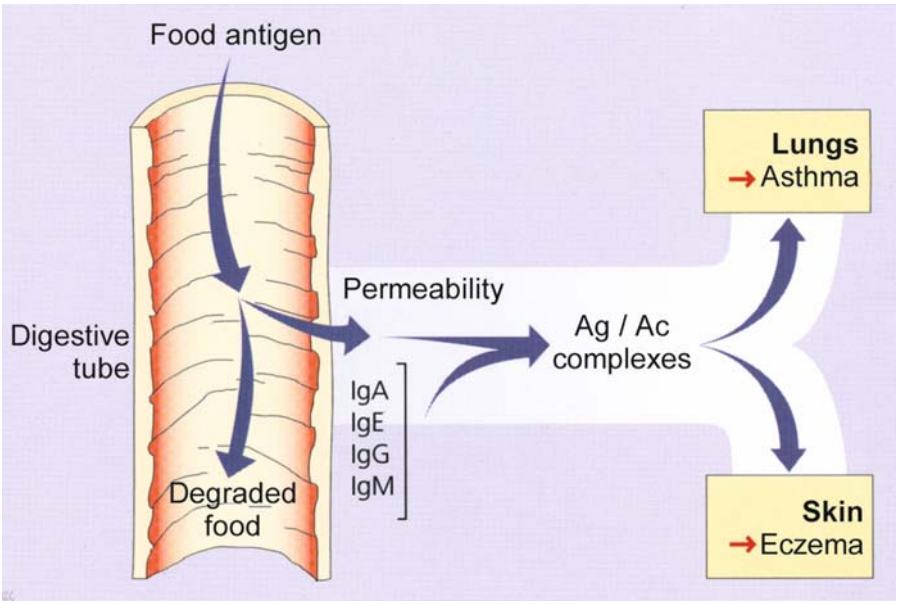

Fig. 9.16. Food allergy and asthma (or atopic dermatitis)

recurrent wheezing that had begun during the first few weeks of life required frequent emergency room visits and even multiple hospitalizations, until elimination of CM from their diet resulted in complete wheezing remission [23].

From the Heiner study it is known that CM [204] or other foods are able to induce respiratory symptoms immediately, due to inhalation, for example of cooking vapors or fumes [112] ingestion during FCTs [88], or exercise, sometimes with fatal effects [424, 528]. A 7-year old boy reacted with wheezing to inhalation of peanut and shrimp [470]. Food and inhalant allergens can share common epitopes, either totally such as garlic powder, crabs and shrimp and fish, or partially such as *Compositae* pollen and related honey, bromelin from pineapple, as well as common epitopes shared by mugwort with celery and tomato with grass pollens [381]. The prevalence of food asthma in children is at the limit of asthma associated with more frequently responsible foods, in order of frequency: peanuts, CM, egg, nuts [44], CM, egg, peanuts [359, 420], CM, peanut, egg [453], egg, shellfish and CM [364], fish [112] and hidden foods [340]. A monosensitization may be present in 77% of cases in a cohort of 163 wheezing children with 56%–83% positive FH of atopy (FHA) and multiple food sensitizations; sIgE were positive to one or more foods, depending on age: 4% <2 years, 24% between 2 and 4 years, and 31% ≥4 years [394]. Cross-reactions are more frequent in older children and adolescents: snail-sensitive individuals experience bronchospasm in 100% of cases and have the highest IgE levels [364] with possible cross-reactions to mites [340] (see OAS). In four OFC/DBPCFC studies in children with FA that we examine below, the rate of respiratory reactions is 28%–59% [47, 55, 242, 416].

To explain the pathogenesis of such episodes, it is hypothesized that the airway uptake of ingested food proteins takes place in two ways [50] (Fig. 9.16) [340]:
1. Across the epithelium, transported by M cells, reaching the respiratory tract systemically (and via the skin)
2. Aspiration and inhalation of food substances, without doubt the less plausible, but it deserves attention

In the first case, food allergens are able to pass across the mucosa at any point of the GI tract, as a result of increased permeability, then into the circulation, thus reaching distant organs, including the skin and airways. These diverse passages could interfere with food immunogenicity and as a result the epitopes can be broken down or hidden epitopes can be uncovered (Fig. 1.18). As a consequence, food immunogenicity is reduced or raised depending on cross-reactions between food and inhalant allergens [381].

Three distinct patterns can be envisaged [50]:
1. Food-induced asthma, caused by adverse reactions to foods, whatever mechanism is involved, immunological or nonimmunological
2. Asthma with FA, in children presenting with both asthma and FA without a confirmed causal relationship between asthma and FA
3. Asthma due to FA when children present asthma and FA causing respiratory symptoms

In conclusion, the respiratory reactions observed during FCTs may be classified as belonging to the second category.

The association is more convincing in the following conditions [540]:
- FH positivity
- Age up to 3 years

- Wheezing present in the first months of life, often in connection with bronchiolitis, especially by RSV (respiratory syncytial virus) or other viruses
- Coexistence of other affections, such as rhinitis, abdominal pains, and above all AD
- Elevated concentrations of total IgE (>1,000 UI/l), especially when concordant with SPT positivity, anaphylactic or urticarious symptoms and/or asthma less controllable by appropriate treatment
- Positive RAST to foods
- Immediate symptoms following FCTs

Asthma may occur in connection with exposure to pollens cross-reacting with foods. The best proof is the remission of respiratory symptoms by an elimination diet and the relapse by DBFCs [50].

Diagnosis

Diagnosis of FA is very challenging and is often not as simple as it might look [19], as we have detailed in Chap. 6, especially the rare compliance (voluntary or involuntary) to elimination diets. A presumptive diagnosis of FA based on medical history, SPT and RAST is acceptable in selected cases of severe anaphylaxis after eating specific foods, when one is in a hurry [82]. The diagnosis is structured on a series of diagnostic procedures outlined in Fig. 9.17.

A detailed evaluation of cutaneous lesions is done before and after the elimination diet, as described in Figs. 6.2, 6.3, 6.19. Additional tests that may be required in selected cases will be elucidated in "Other Diagnostic Tests."

When *history and clinical picture* have yielded valuable clues to a thorough diagnosis, an immediate type is almost always suggested, so that the necessary steps can be initiated. When these first indications are missing (such as in a mute history) or are directed to a food intolerance, the next step consists of seriously considering that children continue the same *diet followed up to the moment of the visit* over 2–4 weeks, with parental help when possible.

A *diet diary* is frequently utilized in adjunct to the medical history to provideg a sequential record of all foods ingested for a specified period and to detect the possible presence of further complaints [23]. Parents are instructed to record serially in a notebook, over a predetermined period and at every meal, the type, time and quantity of suspected foods ingested, specifying the composition of commercial products. They should record the symptoms that occur, even if apparently modest (pruritus, erythema, worsening of lesions, etc.), indicating the day, time and the place if different from the child's home. The symptom occurrence or exacerbation requires returning to the previous diet. The diary is reviewed periodically by the pediatrician or allergist to determine whether there are significant relationships [23, 54]. When unusual and/or apparently severe reactions occur, the parent should inform the doctor quickly: he or she will decide whether or not to change the prescriptions. The partial or complete remission of symptoms shows that these were elicited by one or more eliminated foods. The diet diary is important in that, contrary to history, the symptoms are recorded *on a prospective basis* and therefore independently of poor child or parent memory [59].

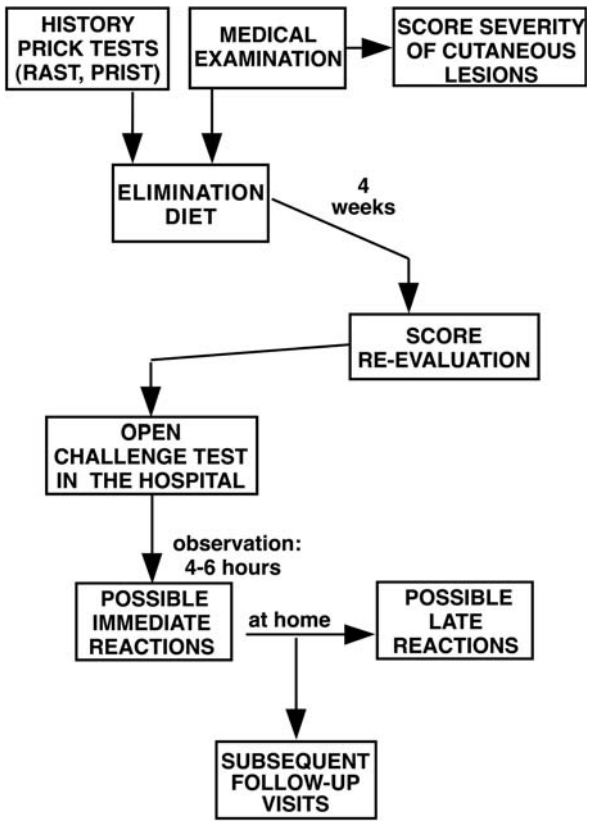

Fig. 9.17. Diagnosis of food allergy

If both pediatrician and allergist agree SPTs, PRIST, and RASTs are done, requiring the number of strictly indispensable allergens. Such tests are a complement also because the results often cause a *diagnostic discordance,* since the auxiliary test negativity and the positivity of clinical data are suggestive of a food intolerance: try in this case the prick by prick test. At the subsequent visit, the results are examined: if the cause–effect relation between administration of one or more foods and recurrence of symptoms is evident, or if these were continuative, or the diary gives eloquent indications, a diagnostic elimination diet is commenced.

The easier cases to resolve are those with mono- or bi-sensitization; provided that the suspected foods are ≤3; their staggered reintroduction should induce the pertinent symptoms, thus confirming the diagnosis.

As mentioned in Chaps. 6 and 7, the *current knowledge limits*, on practical grounds, the *value of SPTs and*

Table 9.13. Sensitivity and specificity of SPT and sIgE in pediatric trials

Allergens	Sensitivity (limits)	Specificity (limits)
Skin prick tests		
CM	0.28	0.80
Egg	1.00	0.25
Peanut	1.00	0.50
Tomato	1.00	0.66
Various	0.00–1.00	0.63–0.90

Various	0.67–0.77	0.71

Modified from [37].

RAST in the diagnosis of FA, whereas *the necessity of FCT is clear* [179, 270, 328]. An interesting study has meta-analyzed the results of pediatric trials employing DBPCCTs, by examining SPT sensitivity and specificity in five trials with 340 children and of sIgE in four trials with 204 children, as seen in Table 9.13 [37]. The comparison with the data of Table 6.19 shows that SPTs for foods have the greatest specificity, but lack sensitivity, whereas sIgE fare well only with cod [37]. In the "immediate reactor" children, the diagnosis made by a SPT ≥4 to CM was confirmed by a parental challenge [212]. Thus, RAST and SPTs, even if they can yield helpful clues for the diagnosis, should not be the only procedure to exclude or incriminate a food as the cause of symptoms or to select the type of elimination diet, neglecting clinical history, medical examination, food diary, and FCT convincing data.

Diagnostic Elimination Diets

The choice of a diet to start adequately represents a crucial moment for the diagnosis of FA. When data are fulfilled, univocal, etc., or have clear-cut indications, a diagnostic elimination diet is prescribed, which, if followed completely free of any type of the offending allergens, will provide clear improvement of symptoms, and to their relapse after reintroduction of incriminated food. This type of 4-week diet involves omitting the food (or foods) identified with sufficient certainty, inviting the parents to continue to record on the diary the frequency and severity of adverse reactions. The elimination diet is simpler in infants, because only one food is substituted, but is more complex in weaned babies, since the suspected foods to be eliminated are more numerous the food requirements and more differentiated.

Several different elimination diets have been proposed [19]:

Conventional diet. If symptoms occur the foods that more frequently cause symptoms in infants are avoided: CM and dairy products in children eating only CM, also eggs and the foods in which they are incorporated if reactions occurred after their introduction. Otherwise, epidemiological data may be followed based on age: if the child is <6 months CM and egg are avoided, if the age is >6 months often a multiple sensitization exists, hence also wheat, fish, etc. are avoided, always evaluating the specific case and the data on the prevalence.

Advantages: good compliance, minimal financial impact, a good approach when the offending food is not identified but the symptoms are frequent or persistent; thus FA is highly suspected.

Disadvantages: the diet may include sensitizing foods, the effects may be appreciated only after weeks or months, nutritional imbalances may occur, and this diet may be monotonous, thus reducing compliance.

Specific diet. The foods clearly correlated with the symptoms and their onset are eliminated, and by its greater specificity better results are obtained; however, the foods to be avoided are incorporated in common processed foods.

Advantages: most effective, especially in very sensitive children, usually easy to prepare, good compliance, absent or minimal nutritional derangements and financial impact.

Disadvantages: the elimination of highly diffused foods such as CM, egg, wheat, fish, etc., can be problematic, other members of the same food family may need to be avoided, younger babies may be provided with a substitute formula.

Elemental diet. This is suitable for polysensitized children with rather severe symptoms, but for a limited duration, because the formulas without animal or vegetable proteins, replaced by synthetic AA, are thus very hypoallergenic (HA). They often provoke diarrhea secondary to carbohydrate malabsorption due to a 16% carbohydrate content. Because of its look, smell and taste, this diet cannot be proposed to children, especially to infants and older children who prefer fasting to the point that this diet must be administered by *nasogastric tube* [481]. Recent AA products are much better tolerated (see "AA Formulas").

Advantages: easy to prepare, nutritionally adequate, ideal being least allergenic, best for children highly sensitive to several foods, but for a limited duration until the symptoms abate.

Disadvantages: expensive, poor palatability and compliance, monotonous, dietary restrictions at times lead to rebellion, obviously children aim at satisfying their hunger, with understandably irreparable results.

Rotation diet. This might be used in children sensitized to more foods, but to a slight or moderate degree, or to children not able to follow an elimination diet correctly. Members of the same food family are eaten separately: the prerequisite is that, based on food families (Table 9.10), the members of the sensitizing family are eaten at intervals of not less than 1 day; no food may be eaten more often than once in 4 days. This diet is varied and seems to be fairly agreeable. It is based on the principle that allergy to one member of a food family may result in a variable degree of allergy to the other members of the family; however, as regards legumes and fish, this theory finds no confirmation in recent studies [31, 32].

Advantages: satisfactory control of symptoms in children with mild or moderate sensitivity to several foods, reasonable diversification of foods, children may follow tabulated diets.

Disadvantages: necessity of knowing food families and adopting an efficient planning, difficulty of retracing the foods eaten, the sensitizing foods may be masked in processed food products or restaurant servings, etc., unsafe for highly sensitized children, probable failure when the responsible allergen is shared in sufficient quantity in several foods of the same family, and sporadically will trigger subclinical disease by continued intake of small amounts of allergen, adverse reactions to ingestants may require long-term treatment of some children.

Oligoantigenic diet based on foods known to be oligoantigenic: our experience began with the 41 children affected by chronic diarrhea by CMA, hospitalized in our division (Table 9.6), utilizing the effective *homemade meat-based formula* (HMMBF) (Rezza's diet) reported in 1973 specifically for children with CMA [403]. It is prepared with *lamb meat,* fresh or frozen lean meat (free of fat and tendons) that is cut into small pieces, boiled and minced, then mixed with the other diet components (Table 9.14) [80, 403]. We suggest using only one cereal, rice, to avoid a simultaneous exposure to more allergens; Ca (500–1,000 mg/day) must be added to the formula. The HMMBF offers a great advantage since it can be *personalized* by adding other foods gradually (see "Treatment") depending on child age, clinical severity and FCT results [89].

Table 9.14. Composition of home-made lamb-meat diet (Rezza's diet)

Food	Dose	
Lamb (fresh)	g	100
Olive oil	g	40
Rice flour	g	70
Ca	mg	500–1000[a]
Vitamin D	U	400
Water up to	l	1

Cut fresh or frozen lean lamb's meat (free from fat and tendons) into small pieces, boil in a double boiler and mince the lamb meat, then mix it with the other diet components. One liter is for four servings.
Data from [80, 403].
[a] For children aged 0.1–7, see Tables 9.23, 9.24.

The HMMBF (Table 9.15) [80, 403] has an adequate nutritional value, provides 310 kJ/l, (741 calories/l). We have calculated the nutritional value [80], comparing it with ESPGAN guidelines for infant formulas (Table 9.16) [80, 151]. We stress its pleasant taste, the adaptability to individual needs, also in younger infants, and the low cost of its constituents [66]. Lamb meat may be substituted with rabbit, or horse meat, lean pieces of pork, or with chicken [80] (3.1% in Table 9.9) or turkey *only if children are not egg-allergic.*

Rezza's diet is not devoid of a virtual antigenicity (Table 9.17) [80]; however, as far we know no case of lamb allergy has been reported, not even in countries where lamb meat is greatly consumed such as New Zealand, likely because lamb AA sequences are not able to form reactive epitopes. Even if the ovine meat contains serum albumin, this has an elevated thermolability and is denatured by cooking [403], thus explaining its

Table 9.15. Composition of Rezza's diet (per liter)

Foods	g	Calories	Carbohydrates g	Fats g	Proteins g	Ca mg	Fe mg	Na mg
Lamb meat	100	121.7		4.6	20	10	2	100
Olive oil	40	360		40				
Rice flour	70	259	58.8	0.7	4.6			
Calcium	0.5[a]				500			
Total		740.7	58.8	45.3	24.6	510	2	100

If the rice flour is Ca-enriched, calculate the dose for 70 g and subtract it from Ca addition.
Data from [80, 403].
[a] Tables 9.23, 9.24.

Table 9.16. Comparison between Rezza diet and ESPGAN guidelines on infant nutrition

	ESPGAN	Rezza' diet
Energy (kJ)	268–301	310
Proteins	1.2–1.9	2.0
Fat	2.7–4.1	4.5
Carbohydrates	5.4–8.2	5.9
Na (mEq/l)	<12	4.3
Ca (mg/dl)	40	31
Vitamin B_1	0.4	0.12
Vitamin B_2	0.6	0.2
Vitamin PP	3	4.9

Grams per decaliter when not otherwise stated.
Data from [80, 151].

Table 9.17. Advantages of HMMBFs (Rezza diet)

1. Adequate nutritional value
2. No cross-reactivity with CM proteins
3. Lower antigenicity than that of CM proteins
4. Hypoallergenicity
5. Nutritional adequacy
6. Easy availability
7. Pleasant taste
8. Low cost
9. Adaptability to individual needs

Modified from [80].

use in CM-free diets [182]. In one trial, the lamb meat diet was changed in 7.7% of cases [517], but it is unknown whether by a doctor, or the family, or for reasons of poor compliance, or intolerance to ingredients not included in the original diet [403]. Seven reactions to lamb reported in 97 children came from *parental diagnosis* [40], and in most studies reported in Table 9.9, no reactions were found [48]. The total rate of 0.8% is validated by 5% of positive SPTs [178], but when SPT+ to lamb are verified by DBPCCT, they become negative in 100% of cases [416]. For pork (Table 9.9), there is a 2.9% rate in positive SPT, RAST and clinical history [178, 339] but, controlled by FCTs, it is reduced to 0% [416] or to 2% [421]. A reaction to cooked and roasted pork has been documented by OFC (RAST was negative) in a 4-year-old boy with AD and Der p sensitivity [319]. However, some reactions are usually due to the additive penicillin, which is not inactivated by cooking, since it is thermostable [519].

HMMBFs can be used in a number of situations [80].

- *Symptoms of IgE-mediated CMA:*
  - Vomiting
  - Diarrhea
  - Angioedema
  - Urticaria
  - Asthma
- *AD*
- *Intolerance to CM:* used both in diagnosis and treatment of adverse food reactions

Advantages: nutritionally adequate and not allergenic, can be utilized also in children 8–9 years of age, almost always with a good rate of compliance [309], especially since it is personalized and has good palatability, minimal financial impact;
Disadvantages: before personalization it might cause monotony and noncompliance in older children.

In conclusion, depending on the disorder and the age, we suggest the specific diet or the lamb meat diet.

Observations on Diagnostic Elimination Diets

The success of dietary regimens depends on a wide spectrum of factors, including the identification of offending allergens, child compliance, the child's ability to maintain the elimination diet and the assumption that no other factors provoke similar symptoms. For example, if a child reacts to CM the symptoms are resolved after an appropriate diet, he (or she) is diagnosed as having CMA. If instead the child is affected with lactose intolerance she (or he) could suffer from similar symptoms and likewise improve with dietary changes, or could be affected by PA and the symptoms would not change [54].

In the first days of the elimination diet, some concern may arise because of the refusal of new or different foods, even with wholly palatable diets, or a kind of deprivation syndrome or an unexpected worsening of symptoms, which can occur when introducing unrefined sugar, or compensating the possible poor food intake with an increased water supply: this is an example of how important the doctor–family relationship can be. Schoolmates may taunt a child compelled to follow a CM-free diet with their own snacks. Results may be discouraging in cases started after 6 months of age, owing to the frequency of polysensitizations at this age, which a correct and suitable elimination diet is not always able to cope with if specific needs are not taken into account. Especially in weaned children, emotional problems may arise due to negative feelings likely aroused by the diet's impact; thus it is natural that compliance is poor. Mothers are often astonished when such diets are proposed, but they can overcome the problem quickly by discovering that desirable meals can be prepared while following their child's tastes, by varying the procedure of food cooking. Furthermore, families are often confused by opinions that contradict the use of dietary restrictions in growing children, but this misconception can be

averted by either calculating the differentiated calories using Table 9.16 or monitoring the child's weight and height in the Appendices 6: 1–4.

After having correctly followed the diagnostic elimination diet for the prescribed period, the skin lesions are again evaluated:

1. *If the result is positive* (resolution = no relapse), the child is followed up, deciding after 6 months whether SPTs should be repeated.
2. *If the result is negative* and the symptoms persist (are unchanged) or recurrent after an initial resolution, a more restricted diet is resumed for other 3–4 weeks. Then the second diagnostic phase is started, to ascertain that it is not:

– A food intolerance or a PA by additives (Chap. 10)
– Too short a period of elimination
– An elimination diet not maintained exclusively free of all forms of the incriminated allergen.
– A possible persistence of sensitizing allergens
– A food regularly consumed or belonging to the same biological family (Table 9.10)
– Non-food factors

Therefore, in children not improving after a strict diet, the final decision agreed on between both pediatrician and specialist is a FCT in an asymptomatic period, indispensable for diagnostic evidence (Fig. 9.17), also in view of a possible oral desensitization (Chap. 13) in children aged >3 years.

Recent revelations of cattle testing positive for mad cow disease (also known as bovine spongiform encephalopathy, or BSE) in several European countries may continue the practice of recycling nonedible sheep and cattle tissue for animal feed instead of the usual fodder [116]. Moreover bovine meat should not be utilized in allergic children in that it contains cross-reacting antigens with those of CM and BSA found in CM [181]. Bovine meat may induce allergic sensitization [433] as in 11/335 children with CMA: 8 reacted to beef during DBPCFC, and 3 tolerated beef in a DBPCFC and well-cooked beef in an OFC but *reacted to ingestion of less well-cooked beef* [514]. In 12 children with *positive beef-specific IgE* (median 6.23 kU/l, range 0.83–36.6 kU/l, the rate of FH of beef allergy was 67 %. Of the 5 children who underwent OFCs, 3 were positive and 2 tolerated the beef administered [371]. Such results agree with subsequent data that extend beef allergenicity to that of veal when the sensitization involves CM serum albumin and βLG [519], whereas homogenized meat was less sensitizing or thermo-denatured [371] when the meat was well cooked and not rare [514]. The major allergen of bovine meat has been isolated and purified [522], and shows epitopes cross-reacting interspecies with sheep, dog, cat, horse, guinea pig, etc., but *not with lamb* [522]. Children subjected to antibiotic therapy may react by eating *antibiotic-treated meat* and vice-versa.

Food Challenge Test

Pathogenetic Mechanisms

We have mentioned previously a mechanism underlining FCT: intestinal mast cell histamine and tryptase release may be useful in selected cases. A study in 20 children 1–14 years of age [365] has shown significant differences between positive and negative FCTs and immediate and late reactions: histamine levels in positive FCTs were increased about threefold 2 h after FCT and nearly doubled after 4 h. Similarly, raised histaminemia levels matched immediate reactions, raised tryptase levels indicated after 2 or 4 h of IgE-mediated mast cell activation. The interesting reactions are immediate reactions: in children with suspected allergy but not with immediate reactions, only histaminemia was raised, thus suggesting a basophil activation, whereas histamine levels were not significantly increased in children with negative or positive, but not immediate reactions [365]. As a corollary, sIgE antibodies often are not correlated with FCT results [279], and are more often found in children with immediate reactions to CM and/or to egg [103, 284, 398], whereas a lymphocyte proliferation in late-onset reactions was always more evident [398] with suppression of IgE synthesis by IFN-γ [284]. Promising pathogenetic and diagnostic signs were recorded by evaluating circulating eosinophils and ECP levels [354, 464] (see "Other Diagnostic Tests"). Recently, FCT has been shown to trigger systemic release of IL_{10} in atopic children (mean 15 months) with FA, and this IL_{10} up-regulatory effect may reflect a reactive state against the release of inflammatory ILs in children with AD and FA [468].

Challenge Procedure

The provocation test can be done by three modalities:

- *Open food challenge* (OFC) test (both the doctor and the patient know which food shall be tested)
- *Single-blind challenge test* (the doctor knows, but the patient does not)
- *Double-blind challenge test* (neither knows)

FCT is *performed in a fasting state and on an ongoing elimination diet*; if the diet has been stopped, the food to be tested shall be eliminated for 7–14 days prior to challenge [20].

The technique tests foods in the natural state, one at a time, beginning with the most important food. There are no coded rules for the amount of food and the administration rate during the challenge, but it is suggested to start with very small doses to be augmented gradually, also because *after eliminating the offending allergen from the diet, the child may become more reactive* to the point that angioedema and anaphylactic shock occurred after reintroduction of foods previously eliminated [119] in children who had never had such severe reactions [328].

In the majority of cases, *an OFC is done especially in infants and young children* [29, 111, 224, 275], since at this age the symptoms are objective and the effect of suggestion is unknown [21]. Moreover, if FCT is conducted in young children with care and adequate observation, the results of open and double-blind FCTs coincide [255].

A *single-blind FCT* may be employed in infants up to 2 years, but can be utilized in difficult cases such as in weaned babies when diagnostic issues may be essential, or emotional components prevail, or FCT is refused for fear that an agreeable food may be prohibited; but is also useful to escape the parents' emotional influences and their beliefs.

In our opinion, a *double-blind FCT* should be performed in selected cases, chosen by pediatricians among the children with uncertain results, or not diagnostic, even if certain investigators, above all Sampson [415], assert the necessity, for a definitive diagnosis, of performing a DBPCFC, undoubtedly a sophisticated method that often appears to be a necessary prerequisite for publication in international journals [21]. FCTs performed without obstacles certainly contribute to decreasing the number of children labeled as true allergic and, more importantly, the number of parents skeptical of the validity of this diagnostic method [255].

Points to be considered.

- FCTs should always be performed under qualified medical control *in a clinical setting* (university, clinic, hospital, etc.), only if trained medical personnel (preferentially insured) and appropriate equipment for treating systemic anaphylaxis are available, especially if IgE-mediated reactions are suspected, which is entirely unpredictable even in the case of negative history. The practice of instructing parents to perform home challenges should not be undertaken because potentially severe reactions can result [120]. Anaphylactic shock occurred in four children [119] and immediate severe reactions in 18 children [328]: only a drop of CM may trigger such reactions [41, 86, 88].
- A FCT should not be performed in children with prior severe manifestations after eating the food that is to be tested, or with a SPT or RAST highly positive to the food in question. FCT is also not recommended in infants with a severe malabsorption syndrome (unless growth is improved) and in children with lactose intolerance (primary or secondary) or intercurrent infectious illness [21].
- Parents should be informed about possible severe reactions and give their written informed consent (Appendix 6.7). They discontinue antihistamines at least 7 days before the test, minimize corticosteroid use. In case of doubt, FCTs can be repeated in a single- or double-blind format.

Procedure of Open Challenges with CM, Egg, Wheat, and Fish

We follow the following procedure, record-chart in hand (Fig. 9.18) for young children undergoing an OCT by using standardized low doses [472], very low at the start (Fig. 9.18):

1. Check child's personal history and medical examination.
2. A drop of fresh CM, or of an emulsion of raw egg, or a bit of bread or fish (not lyophilized), depending on the food to be tested, are put on the inner border of the lower lip [88]. The drops of CM put on the inner border of the lower lip have been evolved as a labial food challenge (LFC), a neologism indicating an alternative to the FCT [88]. However, LFC is a nonexistient test [397], since we first reported this part of FCT in 1989 [328]. *Using small doses* minimizes the danger of potential immediate severe reactions.
3. After 5 min, 5 ml of fresh CM, or 1 ml of an emulsion of raw egg, or 5 g of bread or fish are administered.
4. After a further 30 min (provided that no immediate reaction arises), the last dose is given, that is 100 ml of CM or half-boiled egg, or 100 g of bread or 80 g of fish.
5. Other foods are similarly tested.
6. After the last administration, the child is observed for 4–6 h (always under strict specialist control in hospital).
7. At the end of observation is again visited.
8. If everything is fine the child is discharged.

If any symptom secondary to FCT is observed, the FCT in hospital is terminated. Others [224] have administered increasing volumes of CM every 2 h, if after the fourth dose (80 ml) no symptoms appeared, the FCT in hospital was terminated. More precise are the doses in milliliters such as successive doses of 0.1, 0.3, 1.0, 3.0, 10.0, 30.0, and 100.0 ml [103, 404]. It is also necessary to evaluate the rate of positive results. In 501 children aged ≈13 months, 992 FCTs were done (OFCs in children aged <1 year and DBPCFCs in children aged >1 year), and only 445 (44.8%) true FCTs but also 10/354 (2.8%) placebo FCTs were assessed as positive [103].

Immediate reactions are defined as those occurring within minutes to 2 h from the first food ingestion, and *late reactions* when the first symptoms occurred after 4 h or more; however, others report that acute reactions develop within 1 [466] or 2 h [56] of commencing the procedure. Goldman et al [182] have suggested doing three subsequent FCTs; however, several authors [20, 21, 224, 353, 439] have not conformed to this proposal, in our opinion also for ethical reasons. In very sensitized children or with severe symptoms, we suggest diluting 1:10 a drop of CM as the first dose, continuing every hour with the following doses: one diluted 1:1, one undiluted drop, ten drops, 10 ml, then 100 ml if no reaction has occurred; the use of reduced doses should be weighed by the doctor caring for these children.

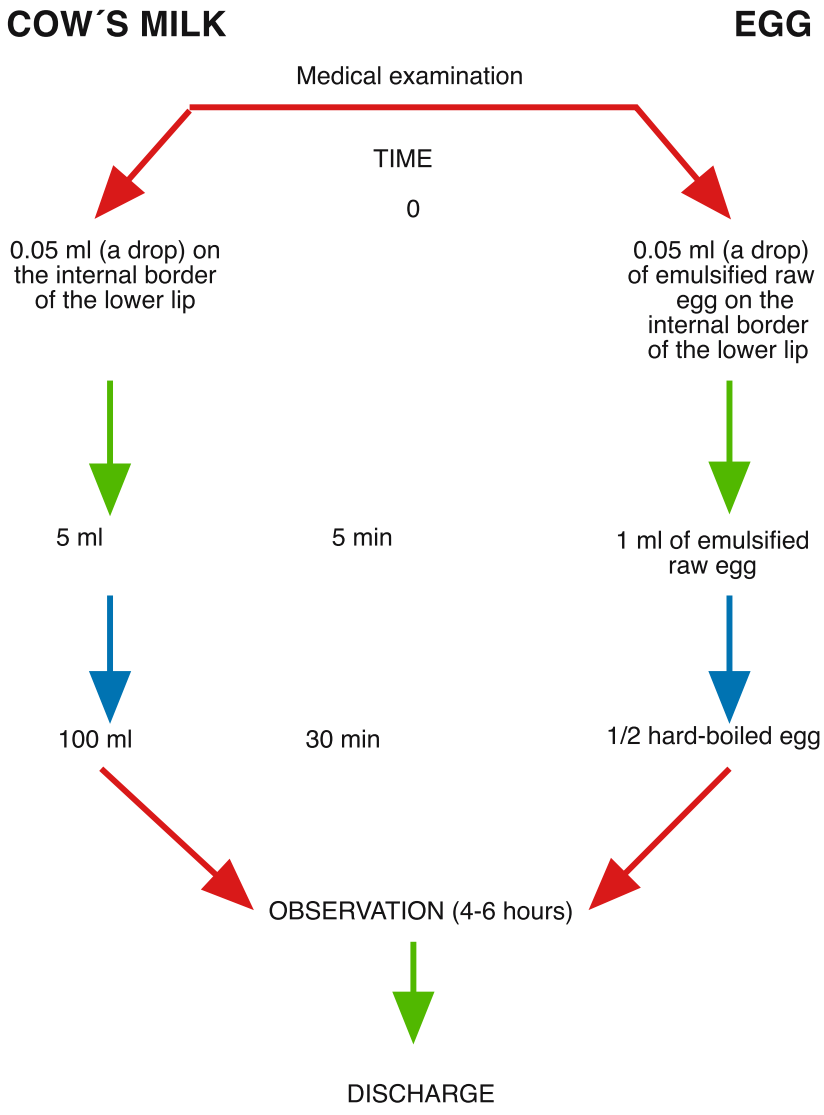

Fig. 9.18. Guidelines from our department for food challenge tests. Note that following the same indications, wheat, fish, peanut, chocolate, etc. can be tested. Appropriate mixtures can be prepared, checking the proportions of food amounts to be tested

Problems may arise in defining the FCT duration and dose chronology since several authors, us included, establish the start of symptoms from the first dose, Bock et al [48] from the last dose, so that different evaluations result, especially if foods are administered on subsequent days, as suggested: day 1, 5 ml, 10 ml, 20 ml, 30 ml, and 60 ml at 30-min intervals; day 2, 120 ml; day 3, 240 ml as a single morning dose up to a normal intake on day 4 [40, 211, 335, 453], so the late reactors [40, 212] react clinically 20 h or more after the normal doses administered on days 3 and 4. In this way, a normal CM intake was only started on days 3 and 4 of the procedure, thus failing to detect immediate responders usually reacting within minutes. Recently, FCTs were done every 48 h, by administering CM, egg, wheat and soy with 20-min intervals in 7 different steps [103]. The duration may also vary from 0.5 to 7 days [248]. Niggermann et al [353] suggest intervals of 15–30 min between doses and agree with us in concluding everything in a single day but extend the observation period to 24 h, and in considering the moment of the greatest dose as the check on late-onset reactions. More similarly, the procedure may last from ≤2 h to ≥24 h [320]. DBPCFCs may be done in two stages: the first day to CM or placebo; if no symptoms ensue, the next day the child begins challenges over a week [18], likely while hospitalized. Several authors have considered as positive the reactions occurring within 24 h [456], or within 3 [21, 517], 7 [40, 212] or 9 days [212]; others judge the FCT as negative only when no reaction occurs within 1–2 weeks [21].

Goldman et al [182] have measured the time elapsed between the start of FCT and the onset of symptoms: 1 h in 39% of cases, 1–5 h in 21%, 6–11 h in 10%, 12–24 h in 17%, 1–3 days in 11%, and 7 days in 1% of cases; so 77% of cases occur within 24 h. However, especially in children with AD, late-onset reactions to egg arise over 3 h to 5 days, reactions to CM over 4 h to 15 days (Fig. 9.19) [328]. There is a difference between immediate and late onset reactions [316]; the first figure refers to immedi-

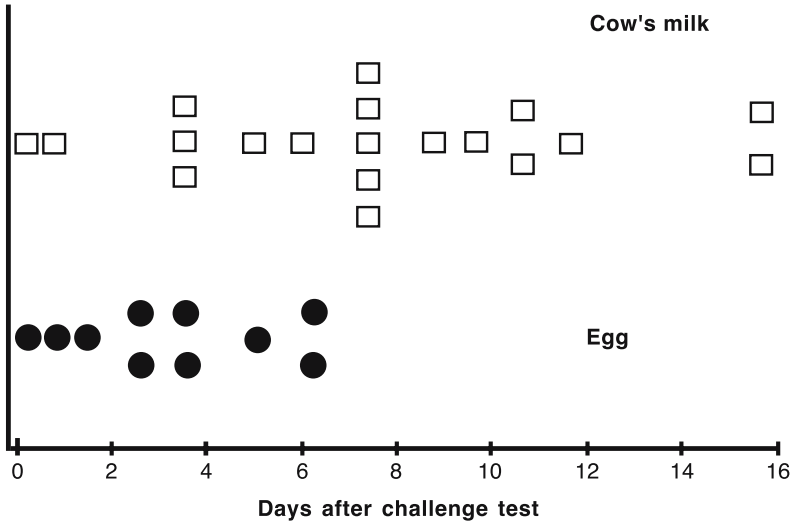

Fig. 9.19. Onset (days) of late reactions after challenge test with cow's milk or egg. (Data from [328])

Table 9.18. Symptoms provoked by OFC/DBPCFC

Authors (reference)	No. of children	Age (years)	Characteristics	Symptoms (%)		
				GI	Cutaneous	Respiratory
Sampson [416]	160	M 5.3	AD + food allergy	43	79	28
Burks et al [57]	46	m 5.7	AD + food allergy	30	96	52
Bock et al [47]	480	3–19	AD + food allergy	56	62	39
James et al [242]	320	M 4.4	AD	41	75	59

M median, *m* mean, results are >100 because patients have manifested more symptoms. The mean shows the following rates: GI 42, cutaneous 78 and respiratory symptoms 44.5.

ate, the second to late-onset reactions, with relative minimal and maximal limits in parentheses:

- Dose-inducing symptoms: 16 (range, 6–27) to 86 ml (range, 70–104)
- Cumulative dose until symptoms: 27 (range, 8–47) to 200 ml (129–270)
- Time from FCT commencement until reaction: 2 (range, 0.1–5) to 31 h (range, 15–46)
- Time from last dose until reaction: 0.3 (range, 0.1–0.4) to 16 h (range, 6–27)

Early reactions were also defined as clinical symptoms occurring within 120 min after administering the highest dose, late reactions as symptoms occurring after 2 h [103]. Late reactions also occurred after ≥5 days [320]. We record many immediate and late onset reactions. The challenge results include the following symptoms (Tables 9.18, 9.19) [44, 47, 57, 175, 242, 416, 420].

GI: nausea, vomiting, abdominal pain, diarrhea (33%); cutaneous: pruriginous, erythematous and morbilliform rashes in the preferred sites, lip edema, rarely urticaria (99%); respiratory: rhinitis, laryngeal edema, wheezing (12%).

Food responsiveness in provoking *respiratory symptoms* has been shown in 121/205 children (59%) with nasal symptoms in 70%, laryngeal symptoms in 48% and bronchial symptoms in 27% of cases [420]. Comparing these data to Bock and Atkins' [47] and Bock's [44] results in asthmatic children, we find differences related to egg and peanuts. In 279 subjects aged 3–19 years [44] with food asthma, 40% had asthma as one of the symptoms noted, 2% asthma as the only symptom. In the first row of Table 9.19, SPT results parallel to Sampson's DBPCCT results [415] are listed: the highly reduced rates are self-evident. In children with AD and FA, immediate or late onset reactions were found in 87% of cases in cutaneous reactions: more precisely, worsening cutaneous lesions, 49%, pruritus, 46%, rash or erythema, 43%, urticaria, 23%, wheezing, 15%, lip edema, 8%, diarrhea, 6% and vomiting, 3% [328]. Relative to DBPCCT, Bock and Atkins [47] and Sampson [415] have recorded, respectively, *4.6% and 1.8% false-negative and 0.9% and 0.5% false-positive results.*

If challenge is positive, on discharge the parents are instructed to continue the administration of foods at home (150 ml of CM, or one-quarter of a hard-boiled egg, or 150 g of bread or pasta or 80 g of fish twice a day) always completing the food diary recording:

- Amount and time of foods ingested
- Occasional breaking (other foods and/or medications)

Table 9.19. Symptoms provoked by OFC/DBPCFC related to the foods tested, divided into overall and respiratory types

Foods (%)	Sampson [416]		Bock et al [47]	James et al [242]	Bock [43]	Sampson et al [420]
Type of symptoms	Overall				Respiratory	
Egg	56	38	25	46	19[a]	51
CM	24	11	23	19	27	28
Peanut	51	24	24	6	28[a]	6
Wheat	15	4	2	5	3[a]	5
Soy	25	5	6	8	3	5
Fish	28	7	3		3	
Nuts			10		15[a]	

In the first row of Sampson's data [416] the SPT results for the same foods are shown.
OFC oral food challenge, *DBPCFC* double-blind, placebo-controlled food challenge.
[a] Shows monosymptomatic patients in Bock's data.

- Ambient and/or emotional variations
- Any late events [328]

Whenever possible, it is useful that the pediatrician observe and diagnose these late-onset reactions. To record the possible onset of reactions, the children return for two visits, after 3 and 7 days or 7 and 15 days. FCT is concluded after 1–2 weeks. The results may be summarized as:

1. Negative → free diet
2. Positive → therapeutic elimination diet
3. Positive, but with other suspected foods → another FCT with an interval of at least 7 days
4. Borderline → repetition of OFC or in single- or double-blind fashion

Procedure of Single- and Double-Blind Challenge

The differences in single- and double-blind challenge tests are:

- Blinding the test to the patient and/or doctor
- The necessity of disguising the food.

The food can be made unrecognizable in various forms, but there is no general agreement on how color, odor, taste and vehicle to be used can be dissimulated in such a case. We disguise CM by mixing it with soy (if children are not sensitized) and other foods diluted in fruit juices prepared at the moment, including nonoffending fruits such as pear, orange, grapefruit, and pineapple; carob powder and syrup are good disguises for cocoa [21]. To disguise peanut and soy the procedure is rather difficult, since different varieties exist of both foods [472]. *Freeze-dried substances* are often utilized. This procedure offers advantages since a whole egg is equivalent to 5 g of freeze-dried food and 30 ml of CM to 3 g [48]. Several foods may be given in a freeze-dried form; however, the presence of additives or preservatives in this test material should be taken into account. The calculation of how much freeze-dried food is equivalent to fresh foods is not always easy. The preparation in opaque capsules with progressively increasing doses of freeze-dried substances certainly ensures blindness, but only older children are able of ingest them. On the one hand, the oropharyngeal mucosa absorbs allergens, as demonstrated by reactions we have observed in the first minutes of an OFC [41] and by test negativity in children with OAS; on the other hand, no explanation can be found for different symptoms recorded after absorption of the capsule in various segments of the GI tract [192]. Therefore, we recommend that blind testing, provided that it is technically feasible, be performed with fresh foods also in older children. However, a 14-year-old boy reacted to DBPCCT with liquid CM and not to that with CM in a capsule [261]. If these manipulations are strictly necessary, it is preferable to apply to specialized structures. In case of negative DBPCCTs, repeating the procedure in the open is suggested to rule out a false-negative reaction [48], which occurs in 3.2% of cases [47, 415]: a 12-year-old boy with CMA and exercise-induced asthma has reacted negatively to two DBPCCTs with CM but with anaphylaxis after eating pancakes made with CM before engaging in exercise [261].

Evaluation of Food Challenge Testing

Our experience shows that there are advantages and disadvantages to carrying out or interpreting the results of challenge testing, which must be examined in relation to SPT and RAST predictive values (PV).

Advantages

The problems related to low sensitivity and specificity of other diagnostic tests are definitively eliminated.

It is the only very helpful test in determining true clinical FA as a food responsibility to a specific pathology (see AD), to get rid of psychological influences and misconceptions on the part of both children and parents.

Positivity rules out clinical food reactivity, and negativity needs to be confirmed by an open test, the cases of false negativity being uncommon and difficult to resolve (see Chap. 6).

It allows a widening of diets that otherwise would be too punitive, leaving children free from unnecessary and harmful food restrictions, thus preventing prolonged use of an inappropriate diet, likely inducing malnutrition [516].

It avoids the assumption that a child is recognized as intolerant only because of persistent SPT positivity.

Disadvantages

It is necessary to perform FCTs in a clinic or hospital setting, with medical personnel and suitable hospital equipment for potential emergencies.

Immediate reactions consequent to FCT are also frequent in children never manifesting such reactions.

Medical history is generally an unreliable indicator of a possible onset of such reactions, notwithstanding a history of negativity.

SPT- and RAST-positive PV (PPV) is rarely helpful to predict these reactions (because of a number of false-positive results that coincide with FCT negativity; however, SPTs and RAST may be a useful means of investigation, especially SPTs, when the onset of severe immediate reactions is suspected by their high *negative predictive value* (NPV).

In our studies related to *immediate and late reactions,* the RAST, PPVs and NPVs are lower than those of SPTs, which similarly were demonstrated to be more specific and less sensitive (Table 6.19).

The absence of immediate reactions following reintroduction of a given food does not exclude the chance of recording late onset reactions (over 4 h, but sometimes over a few days). However, before a definitive diagnosis, each child should be followed with assiduity also in the period subsequent to FCT itself.

A positive FCT merely indicates a cause-and-effect relationship, regardless of the underlying mechanism. A meta-analysis found that DBPCFC results were positive only in 20%–36% of suspected foods in eight pediatric studies [21].

Further Points to Be Evaluated

Hill et al have suggested that a SPT response ≥4+ is equivalent to a positive FCT [212]. More precisely, this equivalence is seen when skin wheal diameter is >8 mm for CM and peanut, >7 mm for egg, smaller in children aged <2 years: 6, 5, and 4 mm, respectively, with a 100% specificity [453]. Among the children seen by us, a 7-year-old male had SPTs positive for ALA (3 cm), β-LG (2.5 cm), casein (12 mm), an 18-month-old child with a SPT = 14 mm to egg-white and a 6-month-old girl with a wheal of 1×1 cm to egg yolk and another with a SPT negative to CM, but with a 2-cm wheal with P+P and CM diluted 1:1 with saline. Another child severely allergic to fish, tested positive to cod with a wheal of 7 mm, *although we diluted the allergen 1:10 with saline*. A group of 11 children had SPTs positive to CM of 8–16 mm [164]. These children have FA and do not need to be subjected to a FCT.

Moreover, for a number of food allergens (CM, egg, peanut, fish), it was possible to define positive DBPCFCs as IgE-mediated, which occur with 95% certainty [419].

Positive results of APT (atopy patch test) to foods in combination with measurement of sIgE serum levels to foods has been suggested to further reduce the need for DBPCFCs in children with FA [404]. Serum food-specific IgE is a useful test for diagnosing symptomatic allergy to common foods such as egg, CM, and peanut since the use of sIgE values could reduce the number of DBPCFCs we need to perform by 40%–50%. If the food-sIgE level is <0.35 kUA/l for egg, CM, and peanut and the SPT response is negative, the FCT can be performed at home unless there is a *compelling history of reactivity.* If the CM-sIgE levels is <15 kUA/l but ≥0.35 kUA/l, we would need to perform some form of CM FCT to determine whether the child is truly reactive to CM [419]. In infants aged ≤1 if sIgE levels for CM are ≥2.5 kUA/l, the FCT *should not be performed* because of sIgE high PPV (positive predictive value) (90%) [174]. Notably, by analyzing the different cutoff points of the sIgE for CM, 2.5 kUA/l had a PPV of 90% and 5 kUA/l had a PPV of 95% [174]. For wheat and soy there is no clear relationship between sIgE levels and the probability of positive FCTs [103].

FTCs, even if they may be inaccurate in FA, are without doubt more reliable than accidental exposures to foods, also hidden, to which children may run into at home or at school, where they are not under their parents' control. The classmates of a severely CM allergic child seen by us waved their snacks in front of him. Therefore, a clinician seeking to avoid nonessential and potentially hazardous FCTs [119] while avoiding unnecessary diet restrictions has a test with a high specificity such as SPTs [453]. Similarly, DBPCFTs may be viewed as unnecessary given an IgE test result above the PV [174].

Surprisingly, children with negative SPTs had positive FCTs [453], and children with positive SPTs had negative FCTs [419].

We continue to observe, for the most part differently from other authors, late reactions not preceded by immediate reactions, with onset even after several days. We deem that only some authors [31, 40, 52] confirm this result. Late onset reactions starting even after 1–2 weeks occasion a controversial issue in the literature since the experiences of each group vary.

Children, once returned home, may find several random and aspecific environmental factors such as changes in emotional or climatic conditions that cannot be verified at a distance which may challenge the diagnosis of delayed reactions. Nor is it always feasible to draw the attention of the family doctor to monitoring and recording such reactions.

In a subset of children with frequent patch test reactivity and total IgE correlated with IL_{10}, a possible explanation of delayed reactions are low IL_{10} concentrations [468].

Physical exercise, including sport, after FCT are firmly discouraged.

Other Diagnostic Tests

Several diagnostic tests are frequently utilized in scientific studies. We do not suggest their use in clinical practicebecause they are poorly standardized, expensive, and more appropriately reserved for the research setting.

- *Intestinal biopsy* may conceptually be an additional diagnostic aid designed to supply helpful indications such as pathognomonic alterations of FA, particularly in cases of CMA with prevalent GI symptoms and for the diagnosis of malabsorption.
- *Peripheral eosinophilia and ECP serum levels.* The count of peripheral eosinophils may be another diagnostic aid, even if aspecific, provided that an elevated number of cells is seen, as well as a significant variation at the start of FCT and soon after, as with ECP at the beginning and 24 h after (Fig. 9.20a) [464], with positivity in children with cutaneous, but not with GI symptoms [354, 464]. However, the ECP increase is transient (Fig. 9.20b) [464].
- *Fecal determination* of ECP, TNF-α and of α-1 antitrypsin widen the diagnostic spectrum being raised before FCT and notably reduced after FCT [316].
- *In total or specific IgG antibodies* and related subclasses, elevated levels are not diagnostic [117].
- *Lymphocyte stimulation test* (LST) and inhibition of leukocyte migration (ILM). Several recent studies have aroused interest for LST [2, 279, 280, 445]: in addition to critical examination of diet results [2, 446], LST is suggested for CMA with prevalent GI symptoms and with late-onset reactions to FCTs (48 h) [279, 280] but not for egg [445] and is not correlated with RAST [279, 280]. It is a time-consuming method and rarely diagnostic, in that doubts have been expressed, either on the technique or the chance of achieving standardization [493]. ILM appears to be equally time-consuming and of scarce practical utility because of excessive variability and rare reproducibility [493].
- For *evaluation of GI mucosa permeability,* the lactulose and mannitol permeability test (LMPT) can be employed as an absorption index of large and small molecules, respectively, and is based on the differentiated assimilation of both sugars. LMPT use can evidence the relative, potential alterations, with consequent digestion of macromolecules (increases after CM load in children with CMA) [239, 341] (Fig. 9.21) [340]. Others have pre-

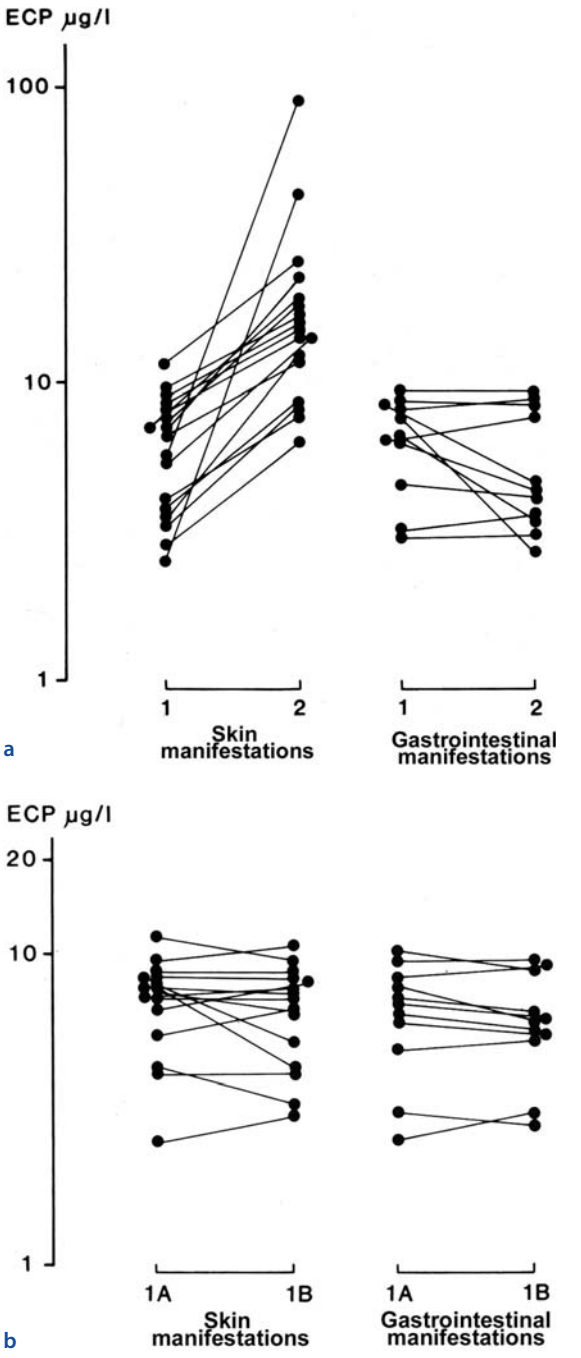

Fig. 9.20. **a** Serum ECP levels (µg/l) before CM challenge (*1*) and 27±6 h later (*2*) in CMA children with skin and gastrointestinal manifestations. During the challenge ECP levels increased from 6.2 µg/ml (mean) to 20 µg/ml (mean), but only in CMA children with skin symptoms (p=0.01). **b** Serum ECP levels (µg/l) taken in two different occasions (*1* and *2*) with an interval of 2–4 months remained unaltered in CMA children with skin and gastrointestinal manifestations

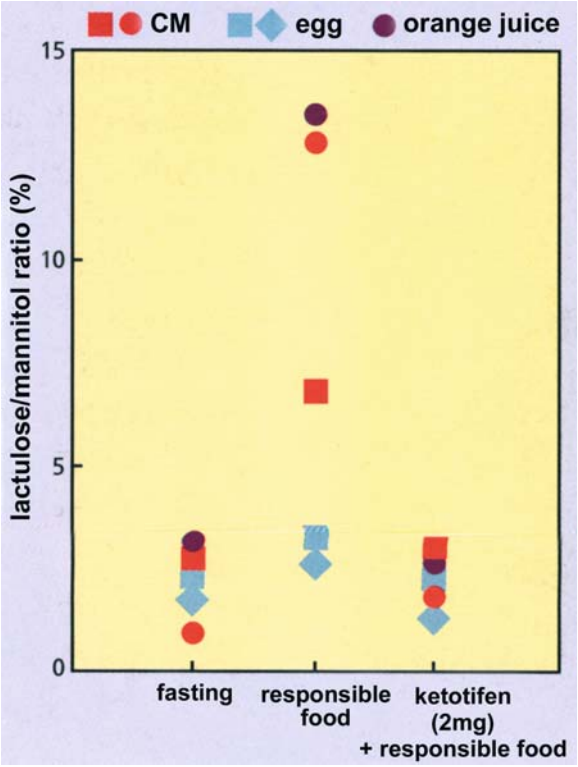

Fig. 9.21. Permeability of the gastrointestinal mucosa as shown by lactulose:mannitol ratio. The patients were tested with CM, egg and orange juice. The ketotifen protective effect is shown

ferred PEG (polyethylene glycol) or OVA [340]. Such methods are subjected to a basic criticism: too different and too small molecules are used in comparison with food macromolecules (PEG, lactulose) or heterologous molecules (OVA), which have immunogen properties and/or may cause CIC formation, and therefore are laborious to determine [340]. The method employing ALA seems to be more useful [253]. The efficacy of this in vivo noninvasive method is demonstrated in the biological diagnosis of BMA [124] and HF allergenicity [24].

Advantages of the Permeability Test

- This is primarily a research procedure more than a clinical tool. A demonstration of its application comes from the above-cited studies, even if further data is needed.

Disadvantages

- More useful in other clinical conditions, such as CD and Crohn's disease
- Necessity of protracted urine collection
- Necessity of employing endoscopic techniques for lactulose and mannitol test, and radioisotopes for EDTA (ethylenediaminetetraacetic acid) and/or PEG

In conclusion, the test is sophisticated, not standardizable, and therefore not of immediate widespread use in clinical practice.

The *differential diagnosis* with other GI disorders is outlined in Table 6.5, structured according to age, as well as CMA diagnosis, also taking into account lactose intolerance that may mimic CMA symptoms and PA [54]. A high incidence of IgE-mediated FA may be found in CD [304]. Enteric infections are capable of disclosing a previous CMA but not evidently clinical, which is revealed by acute gastroenteritis [509]. Münchausen syndrome by proxy should not be neglected (Chap. 16).

Dietary Treatment

It is not known whether diet changes can aid in permanently eradicating FA. Shinoda et al [446] investigated the effect of elimination diets on T cell responses to OVA in hen's egg-sensitive AD patients. The proliferative responses of the patients' PBMCs and $CD4^+$ T cells with monocytes decreased with an egg elimination diet. Similar proliferative responses to a recall antigen and phytohemagglutinin did not decrease after the same elimination diet. The investigators concluded that elimination diets may help reduce the responsiveness of food-sensitive T cells. It has been demonstrated [2, 445, 446] that parallel to good diet results in children with FA (CM and egg), AD and RAST+ [2], both sIgE and proliferative responses of antigen-specific lymphocytes statistically decrease [2, 445], contrary to RAST– children [2], so RAST can be useful to monitor diet effectiveness. Because of diet-positive effects, antigen-stimulated $CD4^+$ express IL_2 and IFN-γ (Th1-like T cells) in the skin and FcεRII on B cells [280], while $CD4^+/CD45RA^+$ increase, which may suppress the ongoing immune responses [446].

Based on FCT results, individualized diets can be prescribed based on the exclusion of sensitizing foods, which, if well conducted, may yield objective results (Fig. 7.40). FA treatment consists in the elimination of these foods: when the causative food is not a source of indispensable nutrients, it can be easily eliminated according to the characteristics reviewed in Tables 9.20 and 9.21 [80]. Success depends on several factors that may be determinant: it is necessary to specify the diet duration and restriction, adopting measures to prevent the detriment caused by inadequate preparation of formulas [516] (Table 9.22) [92, 276], which may also consist in growth retardation and hypothyroidism, reversible after appropriate diets [285]. Compared to controls, children on a diet may show a significantly reduced quantity of Ca and Zn [373], or 25% less Ca compared to the age-related requirements [276], which makes it necessary to oversee the Ca recommended levels (Tables 9.23, 9.24) (Appendix 9.9).

7. Malnutrition (see Chap. 21)
8. Failure to thrive

Data from [92, 276].

Over the past several years, the number of special formulas has been progressively increasing, but no specialized sources have updated pediatricians and allergists with information on the nutritional adequacy and therapeutic efficacy of such products [276]. Both pediatricians and allergists should therefore develop a critical sense to choose the right formula. The properties of an adequate diet are principally those exposed by Table 9.25 [80], above all the compliance on which depends the child's acceptation.

In Chap. 6, we mentioned nonatopic children who, as a result of erroneous or superficial interpretations, were started on diets by their family, and allergic children put

Modified from [80].

on diets without medical prescriptions. An investigation reports that >50% of 73 children followed diets based on information from the media, books, magazines, radio or TV (51%), friends and neighbors (32%), general practitioners (27%), district nurses or health visitors (20%), personal observations in five cases, and from psychologists, homeopaths, herbalists, or schoolteachers in six cases. Potentially dangerous practices were suggesting goat's milk even to a 4-month-old baby or very restricted diets. Fortunately, no growth retardation, failure to thrive, or nutritional deficiencies were observed [513]. In children with reactions to CM and egg, one-third had strict dietetic limitations on the intake of these foods, which in 20% were unwarranted, and more than one-third of children with confirmed adverse reactions lacked pertinent diet restrictions, in both cases as decided by their parents [143]. A 2.7-year-old child on a highly restrictive diet after a DBPCFC was put on a free diet and 3.5 months later had a fourfold normal weight gain for his age and twofold normal height gain for his age [276].

CM-Free Diets

If CM is the only offending allergen (and the cause-effect ratio is evident), an adequate food substitute is necessary, as indicated by Tables 9.20 and 9.21. The first choice is age-based: an infant is obviously nutritionally vulnerable because CM normally gives almost all necessary nutrients (proteins, carbohydrates, lipids and Ca). In the first weeks of life, CM is a food that represents the main source, when not exclusive, of nutrients of high biological value. From 0.5 l of CM, a two-year-old obtains 100% Ca and riboflavin, 50% protein and 24% energy of the age-related RDA [183]. The high nutritional value is associated with a low cost. CM can be eliminated from the diet of children aged >2 years, without nutritional problems, provided that selected foods, including meat, egg, fish, legumes, etc., supply all necessary nutrients to satisfy daily food requirements [183]. Different measures may be taken, but they should be balanced to be in keeping with the prerequisites established by ESPGAN [151] for correct and adequate infantile nutrition (Table 9.16). Additional parameters to be considered are symptom severity, number of potentially sensitizing foods, alerted by physical examination and previous investigations, family involvement, and availability to observe a diet seriously. Problems may still arise, since an alternative formula represents the only alimentary source and infants should receive all nutrients necessary to a rapidly growing organism, while ensuring good tolerance to ingredients and osmolarity [516]. Consequently, the immunological tolerance is strictly related to the nutritional component and only secondarily different factors acquire relevance, including the infant's and family's compliance [276]. The child's age will determine the diet to prescribe.

Appendices 9.1 and 9.2 summarize the dietary products that must be eliminated in children allergic to CM and/or egg proteins and the dietary products and ingredients for children with potential hidden forms of CM and/or egg proteins [27, 516].

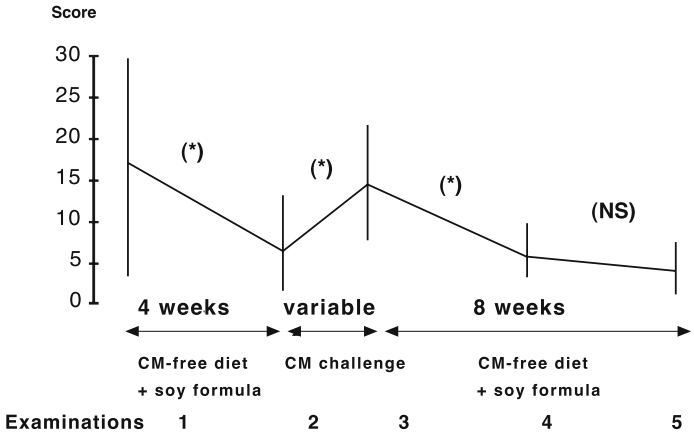

Fig. 9.22. Severity score (mean±SD) of AD in 17 children aged 5–15 months before and after soy-formula feeding and before and after CM feeding. *M* mean, *SD* standard deviation, *AD* atopic dermatitis, *CM* cow's milk, *NS* not significant; * $p<0.001$. (Data from [85])

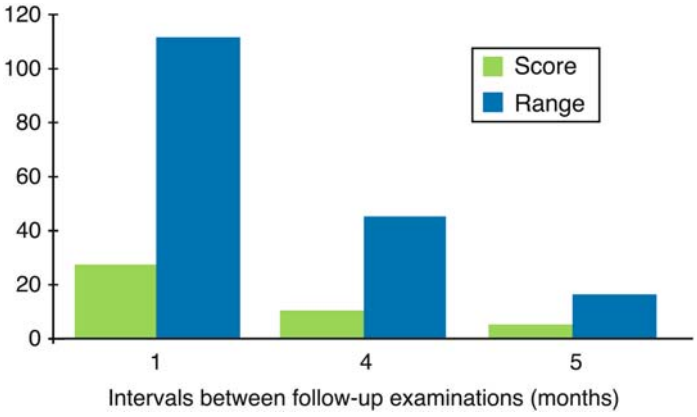

Fig. 9.23. Score severity of skin lesions (geometric mean + ranges) in 17 soy-formula-fed children with atopic dermatitis. $p=0.0003$ between *1* and *4*, 0.0002 between *1* and *5*, 0.000 between *4* and *5*. (Data from [85])

Infant Feeding

The following alternatives to CM can be considered:

1. Breast milk
2. Soy protein formulas
3. Hydrolysate protein
4. HMMBF
5. Amino acid products
6. Goat's milk
7. Mare's milk
8. Ass's milk

Each of these will now be reviewed in more detail.

BM can be highly advantageous when the baby is breast fed and the mother still has BM (homologous proteins) (Tables 2.12, 2.13, 2.20, 2.21). The nursing mother should follow an oligoantigenic diet limiting or excluding ingestion of CM and eggs and completing her diet with Ca (Tables 9.23, 9.24).

Soy protein formulas (SPFs), utilized for many centuries in the alimentation of Chinese and Japanese children [215], were first used to feed US babies with CMA in 1929. Worldwide experience has now accumulated on SPF; we were among the first Italian pediatricians to employ SPFs. Analyzing the paper by Atherton et al [14] studying children with AD on a CM- and egg-free diet, in 14/20 a significant improvement in cutaneous lesions was noted while children were on a SPF diet, which were reduced to 1/20 when they were changed to a common diet. In a study on 17 of 21 SPF-fed children, similar effects were noted on a FCT with CM (Fig. 9.22) [85] and a marked improvement in the cutaneous score when the diet was resumed (Fig. 9.23) [85]. SPFs currently commercialized (Appendix 9.3 shows the composition of the most common SPFs) respond to nutritional criteria of the American Academy of Pediatrics (AAP) [5] and contain purified soy proteins, that is limited to those with the least sensitizing power. The protides are mixtures of vegetable oils (corn, soy, coconut) with unsaturated fatty acids and mean chain triglycerides. The fat is a mixture of vegetable oils, and carbohydrates are represented by maltodextrins, corn, starch, or saccharose, and the RDA of vitamins, minerals and trace elements are usually added, thus forming a sufficiently balanced food [89]. Therefore, the SPFs presently marketable, given the percentage of various nutrients, caloric supply and the described integrations, ensure a valid alternative to CM [64, 73, 85, 89] and, as we were the first to demonstrate, support *adequate normal growth* [85] and a normal bone mineralization [337]. Moreover, SPFs *do not induce immunological deficiencies* even when they are employed since birth and over long periods [71]. Since SPFs are *lactose-*

Table 9.26. Results of studies employing challenge test to soy

Author(s)	Reference	No. of children	Age (years)	Challenge type	Reactions to soy (%)
Sampson et al	[415]	204	5.2 (M)	DBPCFC	5

The studies are ordered according to the year of publication.
DBFC Double-blind food challenge, *DBPCFC* Double-blind, placebo-controlled food challenge, *M* median, *NS* Not specified, *OFC* Oral food challenge.
[a] In the study by Klemola et al [274] 5/8 children manifested immediate reactions (urticaria, erythema, and three out of eight delayed reactions; two more children reacted to soy formula as reported by parents who refused DBPCFC studies. The authors considered these as "probable adverse reactions to soy." One child out of eight had positive soy-specific IgE.

free, they are also useful in primary or secondary lactase deficiency and galactosemia [89]. Current formulas are fortified with L-methionine and contain added taurine and iron; and *carnitine,* necessary to mitochondrial oxidation of long-chain fatty acids and essential fatty acids and nucleotides, has been added to some SPFs in the same amount as that found in BM [64].

SPFs have the advantage of offering proteins with which the child has never come into contact [64]. A favorable case may also be that of a sensitization (often of the humoral type) [90], limited to 0%–6% when not evaluated by SPTs and/or sIgE levels, but by DBPCFC or OFC, which was done in 13 trials, in addition to Cant et al, who performed the test in the mother [77]. In Table 9.9, outlining the data of 18 trials, the incidence of soy intolerance varies from 0% to 36%, with a mean of 6.4%, whereas CMA intolerance is 23.5%, as much as 3.7-fold higher [89]. In 12 trials (Table 9.26) [27, 45, 48, 61, 75, 146, 179, 270, 274, 315, 397, 415] *involving 3,649 children,* the mean is 2.7%. Dean et al used a modified RAST [130] and found a 6% prevalence in children with CMA. In 317 children with a median age of 12 months (range 6–120 months), the prevalence of SPF humoral sensitization was 22%, but only ten children (3.1%) responded positively to FCT [179] (p=0.0001) (Table 9.26). RAST has yielded a PPV of 0.06% [179]: as demonstrated in Chap. 6, RAST is also unfit for wheat. In addition, the rate of false-positive SPTs to soy may be as high as 67% [31]. Four cases of anaphylaxis have been reported in children [25, 119, 315, 347], in addition to three poorly documented cases [331, 496, 415]. A child was reported to be fed Sobee [347], which was particularly antigenic [89, 140]. These are a few episodes compared to innumerable children who were and are SPF-fed, a conclusion reinforced by >200 Italian [62] and 1,450 pediatricians throughout the world [251] who have never seen a case of soy-induced anaphylaxis. To our documented invitation to revise their position papers [89], the AAP concluded that the majority of neonates with certain and IgE-mediated CMA can eat SPFs [5], thus in 97.3% of cases. The AAP concludes that most *infants with documented IgE-mediated CMA fare well on isolated SPF* [5] and others add that SPFs are the *first-choice alternative* in such infants [274, 530].

As certain authors stress that "soy protein is as allergenic as CM proteins", it is necessary to state that Eastham et al [140] studied soy *antigenicity,* in that they measured hemagglutinins to soy and to CM, which mainly belong to IgG antibodies [85], as acknowledged by the AAP, affirming that "recognizing that soy protein is antigenic does not mean that soy protein is highly allergenic" [5]. To prove SPF allergenicity, either the capacity of triggering IgE-mediated reactions in sensitized individuals or the existence of peptides with a high MW should be demonstrated [82]. Instead the authors discussing soy allergy [152, 154, 223, 428, 441 and references in 89] quote Eastham et al [140], and stress that soy is as "allergenic" as CM, alluding to studies based exclusively on clinical history and parental reports (never on FCT), which preposterously provoke reactions in

30%–40% of children. Through the meta-analysis of 18 different epidemiological studies (Table 9.9), we conclude that in five studies restricted to history [177, 178] and parental reports [40, 211, 237], the prevalence is 35%, in the remainder <3% [89], thus agreeing with the studies of Table 9.26. The studies with high frequencies [40, 177, 178, 211, 237] do not involve children with colitis and/or enterocolitis, in whom the AAPSNAD (AAP Subcommittee of Nutrition and Allergic Disease) found values of 8%–14% [273]. Therefore, SPFs are indicated at least in these children in the remaining 86%–92% of cases. See "Legumes" for the discussion on soy-CM casein cross-reactions. Some quoted studies failed to employ FCTs also for historical reasons: in the first one [177], there is a retrospective prevalence of 36%, but the intolerance could be due to other substances included in the formula. In the second [178], the authors noted in the five children that when one proprietary preparation was not tolerated, a second one was, suggesting either that the soy protein had been denatured in one and not in the other, or that other ingredients in the formula had caused symptoms. Interestingly, IgE antibodies to a liquid soy formula were significantly higher than IgE to a powdered soy formula: as a consequence, some children may be sensitized, and others receive an epitope-free formula [41]. In another study, 7/20 children were intolerant to CM and soy [237] as stated by parental reports, but 6/7 had multiple sensitizations. Thus the prevalence of monosensitization was *5%*. In studies by Hill et al, the SPFs used up to 1985 contained sucrose, to which many of the infants studied were intolerant [211]. Therefore, Hill et al never stated that 50% of the children with CM intolerance were also reactive to soy. In one review [223], only the studies with a mean incidence of 30% [40, 177, 178, 211, 237] are cited, and the challenge-based trials are neglected (Table 9.9), except one in children on a gluten-free diet [281]. A 30%–32% rate may also depend on a modest [131, 193, 392] or inappropriate sample building, [1] with 20% of OVA-positive "negative" controls [392]. In the studies summarized by Zeiger et al [530], 59% of cases are based on history. In two studies in infants followed up for 2–3 years, 5.1% [224] and 6.6% [203] experienced adverse reactions to soy; however, at 2–3 years of age the prevalence faded, thus demonstrating that the possible allergy is a transient phenomenon. Freier et al [170] utilized SPFs in infants aged >6 months without recording undesired reactions [170].

The presumed soy allergenicity has been widely emphasized by placing it on the same line as goat's milk [4, 136]. Based on our experience [73, 85, 89] and others' [130, 145, 270, 397], there are no scientific data to compare soy allergenicity to that of CM. Surprisingly, either a RAST+ of 22% [179] or SPT+ of 21% [315] and 25% [416] are reduced by FCTs to 2.5%, 6.1% and 5%, respectively, which accounts for the statements highlighting SPT and sIgE [179, 224]. In other words, SPTs suggested an incidence of soy sensitivity as much as 5-fold higher than that shown by DBPCFCs. Even if in children 4 years of age SPT+ prevalence to soy was 0.1% [191], this is not synonymous with soy allergy [216]. The studies restricted to history [177, 178] have a 25% rate of errors and/or forgetfulness (Chap. 5) and the reactions reported by patients [40, 211, 237] are reduced by FCT to 8% [41, 257]. As previously underlined, the prevalence in small cohorts of *infants and children* [407] at a mean of 2 years of age *with intestinal symptoms* is different: 19.3% [61, 131, 193, 281, 299, 351, 358, 385, 392, 396, 425, 530]. Table 9.27 deals with very small selected populations of children, only 7–18 children in 5 studies [131, 193, 299, 358, 392]; the figures vary considerably, from *0% to 57.1%*. In three studies, the results totalled zero, and the diagnosis was made with DBPCFC [299, 396, 425], and in another there was a 14% incidence, but the DBPCFC was done only in 47% of children [530]. Considering the three DBPCFC studies done in these cohorts of children, the incidence of soy-induced reactions falls dramatically to 4.6%, with SPFs defined as a safe alternative for children with CMA [425]. We deem that, to ascertain the true prevalence of soy in CM-induced enterocolitis and colitis, more studies based on DBPCCT and wide pediatric case records are necessary to avoid type II errors. In 392 children aged 0–3 months without CMA soy prevalence (PTC) was 0% and in 191 aged one year it was 1.6%. FHA was positive in 66% of the whole group [269].

In conclusion, the unnecessary restriction of soy may result in a significantly more limited and inconvenient diet, since soy is ubiquitous in prepared foods: soy-based drinks, yoghurts, and ices offer palatable alternatives for CMA children [31].

Experimental data show that no fatal anaphylactic reaction was set off by soy proteins in soy-sensitized guinea pigs (only nonfatal reactions in 30% of cases), contrary to CM in βLG-stimulated guinea pigs (80% fatal and 20% nonfatal reactions [387]), data supported in rabbits by the lesser allergenicity of soy proteins compared to casein [108]. Soy-sensitized guinea pigs undergoing a type IV challenge with soy protein have exhibited no adverse reaction [432] (see the next point below).

Among *hydrolysate formulas* (Tables 9.28 [68], 9.29 [80] and 9.30 [36]) [74, 90] defined as HA, that is less allergenic than CM normal formulas, there are several types deriving from casein or whey proteins, or formed by casein and whey proteins or soy and pork collagen. Table 9.30 specifies the brandnames with which they are available in European and North American markets and Appendices 9.4 and 9.5 specify their components. We were the first to report five exclusively BM-fed infants aged 3–8 months (median, 5 months) with IgE-mediated CMA, who experienced anaphylactic reactions when first fed a small amount of a *whey HF* (WHF), Alfa-Rè (HR). All infants had AD during BM feeding, positive SPTs and RAST for CM proteins and HR; total IgE levels ranged from 45 to 2,990 IU/ml (Table 9.28) [68]. Subsequently, the infants were success-

fully fed a SPF [68]. Remarkably, a recent paper demonstrating that even following a blind FCT, the safety of an *extensively casein hydrolyzed formula* (ECHF) (Alimentum, A) in children with CMA [417], corresponding to AAPSNAD prerequisites, provided a safe formula in 90% of babies with CMA (tolerance, 90%; confidence intervals, 95%) for 18 months [4, 273]. This was followed by the documentation of the first case of generalized reactions to the same formula in a 7-year-old girl with IgE-mediated CMA who did not tolerate even another ECHF (Nutramigen, N) and three EWHFs (extensively WHF): HR, Good Start (GS) and ultrafiltrated GS, whereas the girl had no reaction to a SPF [9].

Several papers have proved in vitro and in vivo and with SPT/FCTs the allergenicity of such formulas in children with demonstrated CMA.

In a group of children with immediate-type CMA, Oldæus et al studied the positivity of SPTs to Nutramigen employing casein/whey HFs with an increasing degree of hydrolysis: none of the 15 children (median age, 8 years) had positive SPTs to the regular, high-degree casein HF; however, 5–7 out of 15 (33.3%–46.6%) reacted to the intermediately hydrolyzed preparations [369]. Rugo et al [407] used SPTs, RAST, RAST inhibition and titrated provocation tests in 8 children (aged 5 months to 9.5 years) with known CMA using single-blind challenge tests. Five out of 8 children (62.5%) reacted to a high-degree WHF with symptoms similar to those induced on challenge by whole CM, 4/8 to EWHFs, 4/8 to a whey ultra-filtrated formula that was not marketed; 1/8 manifested only perioral urticaria on challenge with the soy/collagen HF, and none of the children reacted to N and Pregestimil (P).

In 20 children positive to DBPCFC to CM, RAST-inhibition results revealed the following trend: CM > PWHF (partially whey hydrolyzed formula)/EWHF > soy + pork collagen formula and > AA formula [355]: RAST and RAST-inhibition show that 1%–4% of children with CMA have IgE anti-CM against one or more HFs [197]. sIgE directed against P, N and HR were found in 6/13 infants aged 3–32 months with high serum total IgE and CMA as diagnosed by an appropriate challenge [390].

The allergenicity of several infant formulas was investigated using RAST and RAST inhibition on the sera of 15 children (mean age, 7.5 years) with known CMA. RAST was >3rd class to several formulas in 10/16 children (62.5%): seven to the only high-degree WHF (PJ), one to N, two to P and soy formula, and three to Pregomin (PR). The RAST inhibition results were in agreement with those of the RAST [129]. EWHF Nutrilon Pepti (NP) was tested in 32 children with CMA, for comparison with EWHF Prophylac (PH) and PWHF Nan HA (NHA). SPTs were, respectively, positive to the three HFs in 19%, 15%, and 32% of children [180].

A new ultra-filtrated product was investigated in 66 children with CMA (mean age, 1.9 years), who tolerated it on OFC, except four, only one of whom was positive at the first rechallenge and negative at the final one. However, of the 35 subjects with IgE-mediated CMA, 11% (3/28) had positive SPTs and 6% (2/35) sIgE to the formula. The authors suggest performing a rigidly controlled OFC in children with immediate reactions to CM before starting any such formula [192].

Immunoblotting and monoclonal antibodies were used to evaluate the reactivity of circulating IgE of 12 CMA children with residual intact proteins and peptides present in 6 HFs, 8 reactions to HR, 5 to H and PJ, 5 to Nidina HA (NI), three to N and one to PR were recorded [401]. The use of immunoblotting and monoclonal antibodies may evaluate the antigenic activity of CM protein HFs.

Reactions to ECHFs made known since 1944 [181] are summarized in Table 9.31 [7–9, 16, 24, 35, 42, 76, 98, 121, 125, 170, 173, 281, 301, 324, 356, 368, 385, 389, 393, 396, 405, 411, 423, 432, 441, 452, 477, 487, 506]. The reactions observed by Sampson et al on the whole were 28 to N and A; in particular 7 children manifested a classic IgE-mediated reaction to challenge, 9 had what was called a convincing history of immediate reactions because of enterocolitis symptoms, and 10 children with non-IgE-mediated eosinophilic gastroenteritis reacted to casein formulas (Sampson, personal communication).

Additional *reactions to EWHFs and PWHFs* are summarized in Table 9.32 [7–9, 24, 68, 76, 91, 115, 125, 149, 180, 210, 230, 274, 326, 396, 417, 440, 452, 477]. Results of challenge tests in babies tested with CM or NI were similar [91]. The age of the children involved ranged from 15 days [7] to 15 years [26]. As many as 30% of children were intolerant to extensive and 40% to partial HFs [530].

A more severe case is that of an infant with AD fed a soy formula from the 33rd day of life [471]: since no benefit was observed despite normal growth, at the age of 7 weeks, 12 h after the last SPF feeding, GS was introduced, but at the second feeding the baby exhibited dyspnea and diarrhea, and at the third feeding a severe anaphylactic shock with respiratory distress, subsequent cardiac arrest, and death ensued at the 21st h of admission. Postmortem examination showed signs of the shock with GI hemorrhage, necrosis of the Sanarelli-Schwartzman phenomenon type and congestion and edema of pulmonary alveoli. We ask *a posteriori* why a HF was administered whose HA designation had been removed from the label in 1991 [149].

It is also possible that HFs can induce, in addition to immediate reactions, intestinal lesions that both SPTs and DBPCFC fail to detect, while they can easily be documented with light microscopy. In short, two babies aged 15 days and 10 weeks were fed an EWHF and were affected with diarrhea → remission for 10 days → recurrence → resolution when put on a BM diet. The intestinal morphology improved; however, following an OFC with the EWHF showed congestion and inflammatory infiltration of the chorion of a lymphoplasmacytic type, and increased numbers of IELs [477]. Such lesions

are sometimes discrete, and useful for diagnostic purposes only when they are compared to a previously regular biopsy (which is rarely performed in normal conditions) [477]. Therefore we are confronted with elusive forms, because their diagnosis is difficult with the presently available tests, intestinal biopsy would be necessary, and the differential diagnosis must consider all possible causes of diarrhea in small infants (Tables 6.5).

Reactions that are also severe following SPTs with HFs [115, 421] confirm an event occasioned by cutaneous application of small CM doses [246].

No controlled studies documenting the clinical properties of PR formula are known now, yet the published reactions are few [7, 24, 129, 407].

In conclusion, in the cases reported in the literature, the use of HFs provoked 358 reactions to CHFs, many of which were IgE-mediated, in 172 children aged 15 days to 15 years, (1 case of shock, *5 of anaphylaxis,* 7 of generalized urticaria, 1 apparent life-threatening event, as well as 2 localized reactions), and to WHF in 150 children aged 15 days to 15 years, either extensively or partially (2 cases of shock, *10 of anaphylaxis,* 13 systemic reactions, 3 apparently life-threatening events) [90], and 2 cases of hypotension [76], including 36 children allergic to extensively HF [122, 123, 125]. Moreover, there is the case of *acute anaphylaxis* following the ingestion of casein and whey HFs [35], the unspecified number of significant allergic reactions to GS [149, 441], and those ascribed to a CHF [393] at variance with other studies [74, 153]. Two children after long-term CM elimination with ECHF/EWHF following an accidental CM ingestion experienced loss of consciousness and an other 8 dyspnea, angioedema, urticaria, etc. [154].

We deem it necessary to explain why HFs can maintain a striking allergenicity and immunogenicity, either for the presence of peptides with a high MW or the contamination of CM intact proteins.

The allergen physicochemical characteristics are not related to their MW, in that no defined MW exists below which the peptides are not allergenic [4]. Furthermore, currently available methods do not permit precise calculations of MW distribution in HFs [36]. Thus peptides which should not be allergenic become allergenic by aggregation or cross-binding to other molecules, which may turn out to be antigenic or even allergenic. In any case, the non-antigenicity of HFs can be maintained, above all of finished products, as based on the MW of residual peptides [272]. Certainly the methods designed to estimate the MW profile suffer from inaccuracies, especially as regards the limits of sensitivity, which prevent any exact calculation; consequently the MW distribution declared by a manufacturer is approximate, and

cannot assess a 100% non-allergenicity of a given HF [318]. Thus the indiscriminate HA labeling, which literally means "less allergenic" than normal CM formulas, and not *non-allergenic*, is unconvincing because it is not quantifiable, hence open to any evaluation [79]. As methods are refined, more data can reveal the greater gap of such HFs, that is the small but detectable amount of residual and potentially allergizing properties can be demonstrated in HFs even with MW >6,000 D [36] (Table 9.30). However, in CHFs there is 15%–20% peptides with a MW >3,850 D and 35%–42% with a MW between 340 and 3,850 D [443]. After protein enrichment by trichloroacetic acid (TCA) precipitation, the presence of high-MW polypeptides was shown in HFs, such as protein bands visible in SDS-PAGE with a characteristic pattern. Partly HFs (H, NI, PR) show the higher amount of polypeptides with a diffused area ranging from 6,500 D and 71 kD, while high-degree HFs have a lower residue (HR, N, PJ) (Fig. 9.24) [401]. A study of 11 WHFs, 7 of which were HA, one based on hydrolyzed casein, and one ultrafiltrated (unspecified) showed a mean 55.5% content of peptides with a MW of 3 kD, 27% 3–5 kD, 13.5% 5–10 kD and 6.9% >10 kD, including two HA HFs *with a 26.3% and 40.6% content* of >10 kD peptides [480], hence all tested products retain some residual antigenicity of one or more of the individual CM proteins [480]. Previously peptides with a MW >5,000 D were not found in A and N, but in GS (Fig. 9.25) [63]. Yet studies done initially in the animal model [273] suggested that HFs even with peptides <3,400 D were not immunogenic and *peptides with a MW between 3,400 and 6,500 D would induce only weak reactions*. The allergenic and immunogenic epitopes that can be detected in CM proteins by humans are not necessarily the same as those seen in a guinea pig, a rabbit, or a lamb.

Taking into account another area of increasing interest are the immunological data on the processing of native protein molecules (Chap. 1), which suggests that an allergen splits into allergenic peptides of low MW, in association with HLA molecules, will be expressed on the cell membrane. The HLA–peptide–APC (antigen presenting cells) complex is recognized by the T-cell receptor (TcR), an event resulting in T and B cell activation; subsequently specific processes lead to IgE synthesis. Children with CMA may react to the partially hydrolyzed whey and casein formulas which contain components able to be bound by IgE, and to the PWHF showing higher protein content and residual allergenicity than any other HFs [345]. *Such processes are operating already in the neonate and small infant* in prospective. The hydrolysis of native antigenic molecules primes the unmasking of epitopes concealed in folded molecular proteins, thus allowing antibody binding and a sIgE antibody response [494]. In normal subjects, the

Fig. 9.25. Molecular weight distribution of three protein hydrolysates (for details see text)

AA sequences provided with structural characteristics essential to forming complexes with HLA molecules, which often are found inside native protein molecules, become available to bind to HLA molecules after the unfolding of protein structures (Fig. 1.18). Although HFs may contain peptides of lower MW than the native protein source, the peptides still have allergenic potency and can be recognized *by the cell-bound IgE of a child with CMA* [290]. But the MW alone does not suffice to guarantee antigenicity for any given polypeptide [416]. Therefore, a "final product" consisting of two or three AA residues (and one epitope) would be more sufficient to trigger allergic reactions in HR children than 7–8 or 12–17 AA sequences with two epitopes clearly recognized by T cells (Chap. 1).

HFs are obtained by heat denaturation and enzyme hydrolysis to reduce MW of whey proteins: one or more enzymes (trypsin, chymotrypsin, pepsin, carboxypeptidase, etc.) are employed for this purpose. Protein *heat denaturation* may cause undesirable reactions such as protein aggregation or precipitation, thus implying lower solubility and reduced digestibility. It is employed in that normally conformational B epitopes are eliminated, thus facilitating hydrolysis, but not of sequential T epitopes [1]. As a consequence, *enzyme hydrolysis* is preferred, more or less extensive in casein or whey proteins, which in specific conditions acts on both types; the subsequent ultrafiltration removes any residuals of elevated MW [407]. Hydrolysis reached a level of 26% in WHFs, 15% in HA formulas (range, 1.3%–32.5%) and 52% in the sole casein formula [480].

It is difficult to understand why there are differences between the hydrolysis employed at the industrial level and natural hydrolysis with which APCs with appropriate HLA markers on their surface activate T cells, thus priming the antibody response [508]. Paradoxically, the result is overlapping, thus the hydrolysis would *activate the IgE response that should instead be repressed* [479]. It is difficult, if not impossible, to affirm that enzyme hydrolysis in vitro abolishes all the epitopes of original

proteins, unless residual peptides are sufficiently denatured by other procedures [297]. As proof, Isolauri et al have found cells secreting IgM against trypsin- and pepsin-digested βLG, suggesting that some antigenic epitopes may resist such treatments [233], and in children with CMA anti-CM IgE antibodies may recognize CM epitopes of one or more HFs [197].

The Küstner case [395] indicates that epitopes not present in the original food protein can be *neoformed* or made accessible by digestion, unless the segments of peptides that resist enzyme hydrolysis are affected and inactivated by adequate denaturation, or some kind of filtration is used to remove the large residual peptides [297]. *Physicochemical manipulations do not allow the abolition of all the epitopes of native protein source* [290], in that the AA sequence characterizing an epitope may resist heat, enzyme hydrolysis, etc.; immunoreactive epitopes concealed inside tertiary structures may be revealed during formula recomposition or after peptide digestion (Fig. 1.18). Lipids and carbohydrates not concerned by the hydrolysis can bind protein structures, building up the substratum to make new epitopes [479]. Obviously, children RAST+ to CM proteins have circulating IgE antibodies, which recognize peptides common to more than one HF [129] and native proteins by cross-reactivity. Haptens can combine with albumin or other protein carriers, so *a peptide not recognized by the immune system will probably never be available* [459].

Consequently, we are skeptical of the idea of eliminating or neutralizing the epitopes of such a peculiar structure: if allergen enzyme hydrolysis is able to reduce its allergenicity, one so selective to destroy the specific epitopes cannot be conceived [290]. Moreover, starting from the assumption that minute amounts of βLG in BM equal to 0.01 mg/l [451] may result in allergenic processes despite the BM IgA, even more the ingestion of HF declared as HA, containing minute amounts of intact protein fragments but in higher concentrations than that found in BM, may induce severe anaphylactic manifestations in children with IgE-mediated CMA, provoked by peptides cross-reacting with IgE to CM proteins, despite enzyme hydrolysis or even amplified by these manipulations. Some HFs are contaminated by undegraded immunogen CM proteins that have escaped enzyme hydrolysis [79]. Residual allergenic components from CM such as casein-unprocessed components and casein fractions could be identified in both the partial and extensive HFs analyzed [133]. There is an unsatisfactory technological separation of caseins from whey proteins [133, 402, 480], and the difficulty in the elimination of immunoreactive epitopes present in casein aggregates after enzymatic treatment [133]. Data shows that *casein formulas contain whey protein residuals* [401, 402] capable of producing precipitant antibodies against at least three whey proteins and casein as well [443], and *whey protein HFs* (HR, Beba HA = GS) and soy + pork collagen *casein residual epitopes* [302, 480], GS up to

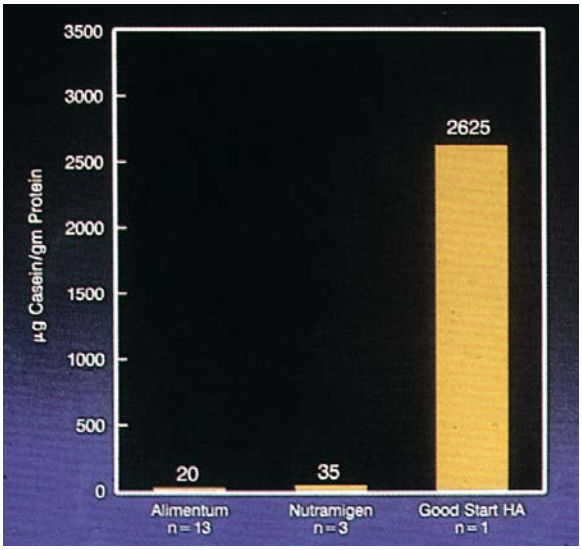

Fig. 9.26. Proportion of immunoreactive casein in a whey partial hydrolysate (Good Start) and in two casein extensive hydrolysates (Alimentum and Nutramigen). (Data from [63])

2,625 µg (Fig. 9.26) of casein/g of protein [63]. An NHA sample has shown bands corresponding to intact whey (ALA and βLG) and casein components (α- and β-casein) [133]. A recent study [220] has shown by inhibition ELISA *that N has a 64.7% whey content and A about 50%, whereas PR has a 36.6% casein content and HR 17.9%*. In a guinea pig model, a PWHF showed a residual sensitizing capacity and a possible casein contamination [388]. An apparent contradiction may be explained because by precipitation methods used to obtain the separation of whey proteins from casein, aliquots of casein may remain in the whey fraction due to casein-derived low-MW peptides, so enzyme hydrolysis is not able to hydrolyze casein completely [297]. Hydrolyzed products may contain 1%–2% or more of nonhydrolyzed molecules; *a single epitope may be sufficient to react with the immune system of highly sensitized children* [455]. Heating casein at a T of 121 °C for 15 min is not enough, and boiling it for 30 min is necessary to reduce its antigenicity and immunogenicity significantly [297]. Casein may resist denaturation, so that fraction α maintains its primary characteristics [23]. Degradation alters in part conformational structures, but IgE binding, almost identical to that of its native form, is preferentially with sequential structures equal to T epitopes, correlated with the elevated allergenicity of fraction κ [402].

Nearly all HFs have significant amounts of βLG detected by ELISA and RAST inhibition (Appendix 9.6) [235, 317, 318, 368], compared to BM [17, 226, 238, 314, 451]. Using ELISA, the immunologically active whey protein levels (IAW) and casein (IAC), either PWHF, or high-degree CHF (in a smaller amount) contain βLG, expressed here in µg/g protein: WHF 1060–1210 IAC

and 140,000–210,000 IAW; CHF, 7.68–12.2 IAC and 19.1–25.6 IAW (compared to intact formulas 400,000–800,000 IAC and 180,000–600,000 IAW) [109]. This study, done using the hyperimmunization method in rabbits [109], demonstrated implicitly the unsoundness of studies done in guinea pigs that previously documented, with no exceptions, only a mild *antigenicity* of whey proteins. Instead, animals sensitized to a WHF after challenge with CM have elicited 8/10 reactions, six of which were fatal [432]. However, if sensitized to an extensively HF, they had no anaphylactic episodes, at variance with 39%–73% of animals sensitized to a partly HF [292].

We have reported that neonates fed HF supplements in the maternity ward in their very first days of life have experienced, at the end of BM feeding, an anaphylactic shock while fed the same formula. Therefore, HFs in that immunogenic category are able to activate sensitization and trigger reactions that are as severe as anaphylactic. So the state of the gut when the allergen challenges the gut and the immune system is probably more important [459].

The bulk of evidence shows essentially that marketed HFs are free of intact proteins, thus guaranteeing their non-immunogenicity (Tables 9.29, 9.30). Great uncertainty on HFs depends on the nebulosity encircling the scientific data related to HFs [129, 136, 292], of no advantage to manufacturers. Not even the documents prepared for physicians contain this information; however, since the technology used differs depending on the manufacturer, at least this information should be delivered to specialists, certainly to the doctor prescribing the formula [427].

In conclusion, HFs *cannot be prescribed for dietetic treatment of children with IgE-mediated CMA* because they are capable of initiating anaphylactic reactions, in that intact or polypeptidic fragments residual from protein hydrolysis are capable of maintaining or precipitating an immunogen activity [402, 480]. Plasma cells-IgE of allergic children may recognize whey proteins in casein [443, 480] and/or casein in whey protein formulas [63, 302, 402], thus explaining the numerical equivalence of reactions provoked by two HFs (Tables 9.31, 9.32). As stated above, the manufacturers of GS had to *remove the HA designation from the label in the US* [149] and based on the data presented here, most manufacturers should submit evidence to document and define their claims of hypoallergenicity. The HA label can also create a false sense of security. Sampson et al [416] recommend that all infant formulas promoted as HA be tested in children with CMA to assess their allergenic potential.

The AAP Committee on Nutrition [4] has stated that *no DBPCCT study has documented the benefits of whey protein hydrolysate, which are not intended to treat children with CM hypersensitivity*. The above-cited AAPSNAD [273] subsequently suggested a definition of the term "hypoallergenic" (accepted by the US FDA), in controlled conditions. A sufficient number of such patients should be enrolled in a prospective study organized in such a way that it can be projected with 95% confidence that 90% of children with CMA will not react to the HF studied [273]. If the 90% level is judged a too low cut-off, using a 95% probability level would require a sample consisting of 120 children with no reaction, but if only one infant reacts to the HF, the group must be enlarged to encompass ≈400 infants (plus 400 controls equally representative), also to avoid the chances of a type II error in the data. However, it seems unethical to increase the number of children only for statistical purposes. In Chap. 24 we will return to such topics and the studies conducted in several countries employing such HFs for atopy prevention in atopic children, also (and above all) from the nutritional point of view.

No HF can offer absolute protection from allergic reactions. HFs have been suggested for children with negative SPTs and RAST, or with GI affections caused by CM intolerance, not IgE-mediated [214, 314], but others disagree since all HFs are not hypoallergenic [419]. We believe that it is more consequential that HFs, if they claim to be effective, be studied in individual children, in vivo in infants with IgE-mediated allergies, and with adequate methods such as RAST inhibition, CRIE, immunoblotting, ELISA, and that studies be organized according to previous procedures [115, 197, 307, 369, 401], or with the patch test that is 3.5- to 7-fold more sensitive than SPTs [235]. Others suggest preferring the lactulose/mannitol test [24], or a FCT with the HF [396], or that the first administrations be under medical control and that during the diet periodic dosages of sIgE anti-CM and anti-hydrolysate are done [322]. The laboratory animal hyperimmunization model proposed to evaluate the immunogenicity of CM protein HFs [109] could reduce costs, risks and the time necessary for DBPCFC studies. Therefore, the task is particularly demanding, because only minimal residual molecular structures are required for antigen recognition by the immune system in previously sensitized children [292]. A recent study stresses that even when infants become sensitized by exclusive breast feeding, there is no justification to change to a HF [352].

A promising base to produce a tolerogenic HF can be found by hydrolyzing a partially whey protein concentrate with both alcalase and papain [518]. A new soybean-whey hydrolysate obtained by the hydrolysis of soybean-whey presented low antigenicity and due to the enzymatic process, an improved digestibility. The combination of high pressure and enzymatic hydrolysis seems to be an efficient tool to reduce or remove the residual antigenicity of soy whey proteins, depending on the protease used. High-pressure technology can supply the ingredients suitable for the HF production [382].

The *meat-based oligoantigenic diets* ensure the reported advantages (Table 9.17) and correspond to established prerequisites for correct and adequate alimen-

tation of children [80] (Table 9.16). The age-related protein/carbohydrate ratio should always be taken into account (Table 9.15). Recently, a rice HF has proven safe when tested by DBPCFC in a study population of 18 children allergic to both CM and soy protein [474]. In 100 children (range 0.18–14.6 years) with a history of immediate reactions to CM and confirmed at DBPCFC, all DBPCFC with a rice-based HF were negative. Therefore a rice-based HF is a possible alternative not only for children with multiple allergies, but also for children with CMA [162], or with clinical reactions to soy and CM HFs. Pediatricians and pediatric allergists are now bombarded with a large variety of information of new special formulas and are confronted with a difficult choice regarding the nutritional adequacy, the immunogenicity and allergenicity of the available CM substitutes. HMMBF may be moderately antigenic, but not immunogenic [80]: therefore homemade formulas may be employed in 99% of cases of CMA, provided that our recommendations are followed [80].

Children with CMA have been reported with good results in the alimentation with *AA formulas* (AAF) [7, 122, 123, 125, 235, 423, 542], with a significant increase in weight and height during follow-up compared to a PWHF [235]. No band corresponding to CM proteins could be detected [133], but in both formulas, unexpected high βLG values were found, in the Nutri-Junior (NJ) formula it was 20-fold that in the Neocate formula [235]. In one batch CM proteins (βLG) were found intact on the same order of magnitude as in the HF used for comparison [235], likely due to residual allergenicity by contamination during the preparation [235]. A 10-month-old girl reacted with urticaria to Neocate [356] and two children with delayed worsening of AD [76]. Recently a new AAF has been marketed, EleCare, that is free of CM and soyprotein.

Although Galen described a case of allergy [305], *goat's milk* has been long employed in infantile alimentation. Even if much more expensive than other formulas [305], recently formulas of goat's milk have been commercialized to feed children with CMA (Table 9.20). Goat's milk, as all animal milks [129], shows a strong cross-reactivity to CM proteins [77, 129, 133, 219] with a risk of 92% in CM-allergic individuals [447]. To RAST inhibition, goat and sheep milk allergenicity is, respectively, 88% and 94% of CM allergenicity [129]. Boiling reduces the allergenicity [23]: this precaution was not recalled by 2/3 parents [513]. Severe reactions to FCTs in 18/20 children aged 3 years (mean) (90%) [305] and in mice with CMA in 100% of cases [219], have confirmed previous data [429]. In 26 children with positive SPTs and CAP results to both CM and goat's milk, DBPCFC was positive to CM, and 24/26 had positive DBPCFCs to goat's milk [27]. In children with CMA or intolerance, 70%–90% showed intolerance to goat's and sheep's milk [97]. Therefore, goat's milk cannot be used to feed genetically predisposed children or those with an IgE-mediated CMA [27, 305]: in a 7-month-old baby in prevention it caused an anaphylactic episode [149] and if children followed by us tolerate goat's milk *this is the proof that they have no CMA*. Therefore, manufacturers should clearly indicate on the label that this is a food not for infants with known or suspected CMA.

Mare's milk can be regarded as a good CM substitute in most children with severe IgE-mediated CMA. It would be prudent, however, to confirm its tolerability by a supervised titrated OFC. Only one child out of 25 had positive DBPCOFC to mare's milk [75].

Ass's milk is intolerant in 10% of children, a 4-month-old girl reacted to this milk with bloody allergy [229].

In conclusion, Tables 9.20, 9.21 and 9.29 summarize the prerequisites of an ideal CM substitute. Apart from the economical factor and the fairly easy availability, its being unpalatable is a cause of frequent refusal in children of >1 year. In two groups of children following a diet supplemented with HFs, the drop-out rates were 38%–56% after 2 weeks and 53%–67% after 6 weeks [308].

Appendix 9.6 shows that a drop of some HFs contains an amount of βLG equal to that found in liters of BM (Chap. 3). As regards maternal levels, is obvious that the studied mothers were not on diets within preventive programs [226, 238, 282, 314, 451]. The more precise data of Sorva et al [451] show that the mean BM level 2 h after a meal of 400 ml of CM is 60- to 420-fold lower than the known levels [226].

Allergy to Single Foods

CM

SPFs are utilized in this age range, also allowing the preparation of CM-free cookies and cakes, thus resolving in older children, when the taste is agreeable, the problem of breakfast and snacks.

The *oligoantigenic HMMBFs* may be utilized with a good index of compliance [309], integrating or varying the diet with an ultimate objective of *personalizing* it as soon as the situation is favorable, amplifying the number of boiled or roasted, or fried foods [80]. Utilizing the food diary and P + P test, the diet can be tailored to the individual child by cautiously adding pleasant foods every 5–7 days such as white potatoes, lettuce, cooked carrots, cabbage, zucchini, cauliflower, Brussels sprouts, rabbit or pork meat, beet, tomato and other greens, legumes, citrus fruit and parsley [80]. While reporting every change on the diary, parents may introduce a new food over a period of 3 days and increase the dose in this time up to amounts normally eaten by their child. Two outcomes are possible: no symptom = food tolerated; the symptoms relapse = return to previous diet up to symptom remission and/or a new directive from the pediatrician. Alternatively a *CM-free diet,* as suggested in Table 9.33, without adding vitamins, whose use is limited in severe cases of AD. For example, the administra-

Table 9.33. Forbidden and allowed foods for weaned children with CMA (see Table 9.25)

Forbidden foods
Bread and pizza made with CM
Candies, cookies, chocolate of all types, ice-creams, whipped cream
CM and dairy products (cheese, butter, yoghurt, etc.)
Cooked ham and sausages in general
Foods containing even minimal amounts of CM (read labels carefully for ingredients)
Lactose-free milk
Margarine (some types)
Meats: beef, calf and young beef
Allowed foods
All raw vegetables, salad, carrots, potato (boiled, baked, fried, etc.)
CM-free cookies
CM-free, home-made soups
Fresh meats: lamb, rabbit, pork (lean parts), horse, ass
Fresh or frozen fish: sole, trout, cod
Fresh or frozen fruit: peeled pears, banana, pineapple; try in different weeks grape, orange, peach, apricots
Pasta of durum wheat (for adults), rice
Raw jam
Rice cream
Soy-milk home-made candies, cakes and cookies (not for soy-intolerant children)
Tea (loose, not in tea bags)
Unrefined sugar
Tap water
Foods may be boiled or baked, or fried
Avoid all foods containing "caseinate"
Ca addition: see Tables 9.23 and 9.24

Diet used in the Division of Pediatric Allergy and Immunology of Rome University La Sapienza.
Chicken and turkey may be added if the child is not allergic to egg.

tion of vitamin E produced proctorrhagia in a girl 37 days old [389]. Appendix 9.8 outlines the nutrient distribution in some special formulas and Appendix 9.9 outlines the Ca content in the main CM substitutes suitable for these children. The *addition of Ca* (Table 9.23) is necessary in all children on a CM-free diet, with the exception of some SPFs.

In all these cases, CM exclusion must follow exclusion of derivatives, extended to all types of cheese, above all goat and sheep cheese [133]. Furthermore, it is necessary to pay attention to *hidden CM sources* and derivatives and/or dairy products also disguised by unintelligible labels: see Table 9.34 [246, 294, 389, 418, 516, 519, 523, 528] *extended to other foods* [516] (Appendix 9.2). Several countries do not require the mention of CM and egg on prepared foods for children which contain either food. CM proteins are always more frequently found in more unexpected cases, such as in old pots [110], gloves (Chap. 8), a diaper rash ointment which has occasioned anaphylaxis a few seconds or minutes after application in two infants with CMA [249, 297], and egg proteins (Appendix 9.1), a substance employed to reduce the lipid content of some foods [418] and therefore able to initiate reactions in allergic children, and in numerous non-food products [389, 516] (Appendix 9.2).

In applying dietetic therapy for allergy to CM and other foods, it is not irrelevant to recall a few important cornerstones, especially the factors capable of affecting the diet's success (Table 9.35) [19], particularly *the compliance of children and their families*: it is often a good idea, also to combat monotony, *to personalize the diet*. Liberalization extensible to allergies to other foods allows restricting the diet only to clearly harmful foods, thus increasing the compliance of young patients and their families [92]. More controls are required by long-term diets.

Egg

To prescribe an egg-free diet, it is indispensable to abolish not only all egg-containing food, but also the meat of animals strictly correlated, and egg shampoo. The albumen, including also OVA and Gal d 1, is the immunodominant and sensitizing allergen, but small amounts of OVA are found in egg-yolk, so both should be eliminated. Tables 9.36 and 9.37 [184, 523] summarize a type of diet for children allergic to egg or egg and CM and suggests how to substitute egg in cooking. Children who are not wheat allergic may eat durum wheat pasta freely (with no CM added) and cookies. See also Appendices 9.1 and 9.2.

The measles vaccination was not recommended to children with IgE-mediated egg allergy based on reports of postvaccination anaphylactoid reactions in two children with egg allergy documented by history. The vaccines employed today are constituted by measles live virus and a cross-reactivity between chick embryo fibroblasts, on which the virus is grown, and egg proteins was suspected, although antigenic diversity was demonstrated [72]. Following studies on surely egg allergic children who have experienced no reactions from the measles vaccine, several authors have vaccinated, without relevant reactions, 1,963 children with manifestations of IgE-mediated egg allergy, while 47 without any contraindication have experienced immediate reactions, virtually independent of egg allergy (Appendix

Table 9.34. Products with potential hidden sources of CM or CM proteins

Bread and breaded foods, including toast bread, bread made with oil, crackers, commercial breads and rolls
Bread, fortified
Breakfast food
Butter substitutes
Candies, especially commercially prepared, also frozen
Candy bars
Canned fish
Canned meat
Canned, dehydrated soups
Caramels
Cereals, fortified
Cheese for vegetarians
Chewing-gums (some types)
Chocolate- or cocoa-containing beverages, also plain chocolate (due to contamination)
Commercially prepared roasted or grilled meat, or *au gratin*
Cottage cheese
Cooked or boiled ham
Dairy foods
Delicatessen meats
Desserts with whipped foods
Doughnuts
Hypoallergenic formulas
Ice creams (also due to contamination)
Instant breakfast, potatoes, etc.
Lactose[a], yoghurt, rennet
Lactulose
Margarine (some types)
Mayonnaise
Meat fillings
Meringue
Muffins
Nougat
Pancakes
Pasta, fortified
Pie crusts
Pizza
Prepared flours
Prepared mixes for cakes
Products for infants and toddlers (soups, pap, biscuits, homogenized foods, etc.)
Puddings
Rarebits
Salad dressings
Sour cream
Sauces and gravies including béchamel, etc.
Sausages (some), Frankfurters (some), and hot dogs
Special nutritive foods: bread, cereals and enriched foods enriched, high-protein beverages, pills or tablets with proteins and/or minerals
Herbal teas (some)
Vegetables, especially creamed and scalloped vegetables
Waffles
Non-foods [389]
Antibiotics
Anti-inflammatory drugs
Drugs containing E and/or P vitamins
Latex gloves (Chap. 8)
Milk-based paints, plasters and wall-paper containing casein (Chap. 24)
Penicillin powder for oral use
Preparations with total pancreas
Products for the hygiene of neonates/infants (ointments, creams, powders, diaper ointments) [246, 294]
Toothpastes for baby teeth

Foods should be home-made if possible, or labeled with all their ingredients, or purchased or eaten only if they are clearly labeled as milk-free. Buy no packaged foods without a complete list of ingredients, and if eating away from home, eat only foods surely free of CM. Furthermore, a D on a product label next to K or circled U indicates CM proteins [516].
Hidden CM may be found even in nondairy creamers, imitation processed cheese, imitation cream cheese, imitation sour cream, and soybean-based ice cream may contain casein [523]. See also Appendix 9.2.
Data from [246, 294, 389, 418, 516, 519, 523, 528].
[a] Lactose-free milk contains CM protein.

9.10 and 9.11) [94, 243, 378]. Sampson and his co-workers asserted that the vaccination is safe, by evaluations based on 95% confidence intervals that 97.5% of vaccinated children are free from adverse reactions [243]. Our calculations on 1,963 children show that systemic reactions occurred only in 0.1% of vaccinations and adverse reactions in 1.7% of cases (p=0.0001) [94]. Recently, the rates were lowered to 0.00035% based on the dos-

Table 9.35. Factors capable of influencing the success of dietary elimination in children with FA

1. Identification of all foods causing FA
2. Achievable elimination of these foods from the diet
3. Elimination of even minimal traces of those allergens in the prepared foods
4. Elimination of possible cross-reactions
5. Exactness and completeness of prepared food labeling
6. Marketing under names generating bewilderment
7. Family factors (compliance, working mother, available funds, etc.)
8. Association with other factors (GI disorders, emotions, exercise, etc.)
9. Concomitant involvement of inhalant allergy
10. Parents' exhaustive information
11. Degree of child's compliance
12. Nature of child's symptoms
13. Variations without physician control
14. Feasible development of malnutrition

Ingestion of fresh food (or frozen at home) is suggested, although industrial deep-freezing is done with more effective methods than household methods.
Modified from [19].

es shipped and 0.00119% on the children studied [189]. No child followed by our division has suffered from immediate reactions to MMR (measles, mumps, and rubella) vaccine and the usual late onset reactions were recorded in sporadic cases [94]. Over 15 years, 18 cases of suspected anaphylaxis were reported in Finland; however, in 10/18 cases the physician treating the vaccinee suspected the reaction to be fainting instead of actual anaphylaxis, so only three of these received epinephrine; therefore the final number of cases was 11, with a 0.0000002% incidence/year [378]. It is therefore likely that the reactions observed by several authors were caused by additional vaccine constituents such as gelatin [189, 266], a component of plasma expanders, which provokes reactions in 0.07%–0.2% of cases and the 0.025 mg of neomycin contained in the MMR vaccine [94]. However, the extremely large amount of gelatin (1.5 to 14.5 mg per shot) [378] in the vaccine is the cause of the reactions, as was definitively proved that 93% of children with anaphylaxis had IgE antibodies against gelatin, and children without adverse reactions all had negative test results for IgE antibodies against gelatin [265]. In 47 children (Appendix 9.11) one case of anaphylactic shock caused by gelatin occurred [265], whereas cutaneous reactions related to neomycin are more frequent, thus explaining the elevated prevalence of urticarious manifestations in vaccinated children: the risk of adverse reactions in children not allergic to egg

Table 9.36. CM-free and egg-free diet

Breakfast
Tea (loose), or SPF, unrefined sugar, CM- and egg-free cookies
Snacks
Banana, bread, raw ham, CM- and egg-free cookies
Dinner and supper
Pasta (normal type)[a], rice dressed with olive oil; try tomato apart
Vegetables[b]: carrot, lettuce, beet, zucchini, green beans, potato in broth or soup (homemade), or dressed with olive oil, or baked, roasted, fried
Meat[b]: rabbit, lamb, horse, pork (lean parts) (boiled, or roasted, or fried)
Fruit[b]: peeled pear, banana, pineapple; try in different weeks orange, peach, apricot
Tap water

Diet in use in the Division of Pediatric Allergy and Immunology of Rome University La Sapienza.
Since egg is necessary as emulsifying in confectionery, an egg substitute may be combined as follows: whole wheat flour 2 tbsp, baking powder 1/2 tsp, oil 1/2 tsp, homemade fruit juice or tap water 2 tbsp.
Data from [184, 523].
[a] Without added powdered CM.
[b] Fresh or frozen only.

Table 9.37. Additional recipes to substitute an egg

Ingredients	Amount
Baking powder	1 tsp
Water	1 tbsp
Vinegar	1 tbsp
Or	
Yeast	1 tsp
to be dissolved in warm water	1/4 cup
Or	
Water	1/2 tbsp
Oil	1 1/2 tbsp
Baking powder	1 tsp
Or	
Gelatin	1 packet
Warm water	2 tbsp

For each recipe, do not mix until ready for use.
A mashed banana may be a substitute for egg in recipes: 2 tbsp for each egg replaced.
Data from [184, 523].

is entirely insignificant: 0.00005% [94]. With modern techniques, it should not be difficult to produce vaccines free of gelatin and neomycin. An egg protein-free vaccine is presently available [378]. Recently two publications [259, 287] have created an *unprecedented confusion and alarmism on MMR vaccination.* Giving MMR vaccinations to all children under controlled conditions in hospital [287] has been suggested, or restricting these precautions to children with cardiorespiratory responses to egg and/or chronic asthma [259]. We stress that cardiorespiratory reactions took place exclusively following SPTs and/or intradermal tests (IDTs) with diluted vaccine [94]. However, extending these recommendations to all children subjected to MMR vaccine appears unmanageable, as it would eliminate all programs in which vaccination is carried out by nurses without doctors in attendance, as occurs in most Third World countries and in almost all public health clinics in industrialized countries. The extreme rarity of severe allergic reactions induced by MMR vaccination supports the view of vaccinating egg-allergic children according to normal vaccination schedules, if necessary with the egg protein-free vaccine [378].

Cereals

A *wheat-free diet* is fraught with difficulties, bread and pasta are widespread foods that children enjoy *throughout the world.* Wheat and cornstarch are found in tisanes, toothpastes, antibiotic products, vitamins, etc. [389]. In specialized shops, biscuits, noodles, bread and other products are found, prepared with rice, soy, and buckwheat flour and starch and leaven for allergic children (all generally reliable) as well as the necessary ingredients for homemade bread and pasta (see Tables 9.38 and 9.39 for suggestions to make bread). As substitutes, tapioca, sweet potatoes, cassava and sago can be employed [531]. Appendix 9.10 lists the hidden wheat sources. *Products for celiac disease* declared as wheat-free may often be contaminated by wheat, even if in very small amounts, as evidenced by immunochemistry and DNA analysis by PCR (polymerase chain reaction) [3], and therefore are not recommended for wheat-allergic children.

Corn allows the preparation of bread and polenta, but is not tolerated by 59% of wheat-allergic children, and thus can be introduced into the diet only after a FCT [379]. Many waxed paper cartons for foods are dusted with cornstarch; therefore all products contained in such cartons, including CM, should be avoided. Corn is used in the preparation of a great deal of processed foods, which may not indicate the term corn (a summary of hidden sources is listed in Appendix 9.10). Instead of cornstarch, tapioca starch and potato starch may be used; check the labels of seed oils to check that no corn is included among the ingredients [379].

Table 9.38. Recipe for bread using wheat-free flour for wheat-allergic children

Ingredients	Amount
Cornflour	1 kg
Olive oil	2 tablespoons
Boiled potatoes (medium size)	3
Lukewarm water	About 200 ml
Salt	1/2 teaspoon
Baking powder	1 tablespoons
Work ingredients together, mixing the baking power with lukewarm water. Let stand for at least 5 h, in a warm place, or all night. Wrap rolls in wax paper and then bake at 220 °C lowering to moderate T after 20 min. Bread will keep for 1 week (or more) in the refrigerator.	

Not indicated for cornallergic individuals.
Diet used in the Division of Pediatric Allergy and Immunology of Rome University La Sapienza.

Table 9.39. Additional recipe with same characteristics

Ingredients	Amount
Rice flour	250 g
Olive oil	2 tablespoons
Sugar	2 tablespoons
Lukewarm water	About 200 ml
Salt	1/2 coffee-spoon
Baking powder	2 teaspoons
Mashed banana or pear	1
Combine all ingredients dry, mixing previously the baking power with lukewarm water. Add oil, banana or pear and lastly water, mixing accurately. Bake the rolls at 220 °C for 15 min, then for additional 45 min at 180 °C. Bread will keep for a week (or more) in the refrigerator	
Wheat substitutions [524]	
Substitutions for 1 cup of wheat flour for wheat-allergic children	
1/2 cup rye flour + 1/2 cup potato flour	
1/2 cup cornstarch + 1/2 cup potato flour	
1/2 cup cornstarch + 1/2 cup rye flour	
1/2 cup cornstarch + 1/2 cup rye flour	
2/3 cup rice + 1/3 cup rye flour	
Substitutions for 1 tablespoon of wheat flour for wheat-allergic children	
1/2 tablespoon cornstarch	
1/2 tablespoon potato starch	
1/2 tablespoon rice flour	
1/2 tablespoon arrowroot	
1/2 tablespoon lima bean flour	

A positive aspect is the reduction in *rice* allergenic activity by genetic engineering that has decreased the allergenic levels of rice grains from 312 to 60 µg/grain, thus creating the basis for hypoallergenic rice. A new variety has also been obtained by hydrolysis of grain globulin fraction, the major allergen; so children who suffer from this allergy may eat rice [511]. The final result was obtained by sequencing the rice genome, thus opening the way to elude rice allergy [525]. We have used rice since 1982 [403] in oligoantigenic diets for allergic children and have never recorded cases of allergy: if the use of rice is widespread as in oriental countries, there should be a high index of sensitization. Similarly to corn, 77% of wheat-allergic children may become allergic to rice [379].

From *barley* is derived malt (often from sorghum), which is employed to flavor some types of bread or breakfast cereals and is also found in powdered drinks to be mixed with CM. Moreover, malt by-products are found in flour for cookies to increase the content of fibers and proteins without altering the taste [531].

Rye is often the first ingredient in commercial cereals; rye flour is frequently utilized in foods for breakfast and if minced, as a component of cosmetics, creams and bath soaps [531].

Several cereals have been transformed by genetic engineering [81] (Table 1.78, 1.79), but we do not know the practical applications.

Fish

Fish often induce IgE-mediated acute manifestations, but also nonimmunological reactions by aspecific mast cell degranulation, not to be confounded with reactions to additives in processed foods. Children with cod allergy (associated with FA in up to 91% of cases) are frequently sIgE positive to several other species, above all caused by notable cross-reactions between Gad c 1 and allergens of these fish [128]. Even if, as previously alluded to, children with cod allergy can eat other types of fish [32], it is a good idea to verify this preventively [289], subjecting children in a specialized center to FCT with the fish to be potentially included in the diet. The fish should be acquired in a well-known shop and never consumed at a restaurant, because of possible contamination with other foods, spices, and additives during the preparation. The consequences of a diet not based on challenge procedures or of involuntary contacts with an often hidden allergen can be potentially harmful, also exposing asymptomatic children to cutaneous, GI, respiratory symptoms and anaphylaxis [289]. If the investigations are not easily feasible, we agree with the colleagues who believe it is prudent to refrain from eating fish, or limiting it as much as possible. Moreover, also for corn-allergic children, oral contact with the glue of some stamps, envelopes, and stickers should be discouraged since the glue may be made up of discards from the preserved fish industry.

Shellfish

A previous anaphylaxis elicited by one species requires an absolute exclusion of every type of shellfish; it is convenient that the block is total when the allergy is IgE-mediated. More common incidents occur with shrimp, *masked allergens* found in cold restaurant, cafeteria, and fast food dishes (Appendix 9.12), often associated with OAS.

Legumes

Allergy to peanuts, soy, and other legumes may be found. Peanuts are sensitizing both fresh and baked, similarly to peanut flour, butter and oil. Numerous are the *hidden sources* of peanuts (Appendix 9.12). Sensitization may be induced by vegetable gums and various flavoring products, but it is unnecessary to exclude several species of legumes from the diet [31]. Peanut allergy may persist over the long term [46]. Since the number of cases is on the rise everywhere, the potential occurrence of incidents from involuntary intake have led us to suggest that these children always be provided with self-injectable epinephrine in case of anaphylactic shock, and if there have been acute reactions in their history, wearing a medical bracelet alert is suggested. The youngest children should be provided with a cellular phone.

In cases of soy allergy, attention should be paid to hidden sources, particularly including prepared foods cooked, baked or fried with soy flour and/or oil, as well as soy lecithin (see the section on chocolate and Appendix 9.12), as with *cocoa* [92]. Lecithin is found in legumes, cereals, nuts and peanuts.

Allergy to Other Foods

In the *potato* family, we found tomatoes rich in histamine positive in 19/80 cases (24%) confirmed by FCT vs only 3/26 of potato (12%), sensitizing only if raw [505]. If cooked potatoes are sometimes not tolerated, this denotes that they were insufficiently cooked, but also cooked potatoes may induce anaphylaxis [99].

The *citrus* family includes oranges (Table 9.12), which usually provokes a PA due to the acids present in these fruits.

Nuts are of numerous types and families (Table 9.12). Cashew was involved in a fatal case, and walnut and Brazil nuts in nonfatal cases [424]. Brazil nuts often provoke reactions by consuming candies, cakes [528] and other foods containing these nuts in a masked form [424] as well as walnuts. These nuts are added to candies and cakes as embellishment, or minced to insert

Table 9.40. CM-, egg- and wheat-free diet (for children with multiple sensitizations not undergoing desensitization)

Breakfast and snacks
Tea (loose) with unrefined sugar – SPF as milk or HMMBF
Rice biscuits or homemade cookies with SPF
Whipped pear/pineapple (homemade) with unrefined sugar
Pear/pineapple jam (homemade) with unrefined sugar
Dinner and supper
Rice, soy, or corn noodles dressed with olive oil
Vegetables (fresh or frozen only): carrot, lettuce, beet, zucchini, green beans dressed with olive oil
Potato in broth or soup (homemade) or dressed with olive oil, or baked, roasted, fried
Meat (fresh or frozen only): rabbit, lamb, horse, pork (lean parts) (boiled, or roasted, or fried)
Fruit (fresh or frozen only): peeled pear, pineapple
Bread made with buckwheat flour, or potato flour or rice flour and cornstarch
Tap water

Add Ca: see Tables 9.23 and 9.24.
Diet used in the Division of Pediatric Allergy and Immunology of Rome University La Sapienza.
Additional data from [184, 523].

Table 9.41. Recommended schedule for monitoring food hypersensitivity in children with FA, not undergoing oral desensitization

Food allergy schedule	Recommended rechallenge
Allergy to CM, egg, wheat	Rechallenge after 12–18 months of food avoidance: if still positive, rechallenge every 2–3 years
Allergy to soy	Rechallenge after 1 year: if still positive, rechallenge every 2 years
Allergy to fish, peanuts, nuts	Rechallenge after 3 years: if still positive, rechallenge every 2–3 years
Other allergies	Rechallenge every 12–18 months

Data from [422].

a tasty ingredient to candies and cakes in general [533]. Hidden sources of nuts and sesame are listed in Appendix 9.12.

Allergics to *hazelnuts,* both raw and toasted (and to rye), are also sensitized to kiwi and poppy and/or sesame seeds [502]. Hazelnuts are widely utilized in nougat dough, an ingredient in candies, ices and pastry [533].

The *mustard* and *parsley* families include celery, anise, cumin and other herbs and spices. Celery cross-reacts with other spices and herbs (see OAS) and cumin is added as a digestive.

Sunflower is found not only in honey, but also in oils, flour (bread, confectionery, etc.), and margarine. As with almonds, the minced seeds are employed as an alternative to peanuts [516].

As discussed earlier, several fruits may induce severe reactions in children. In the case that these fruits are welcome to children, also to provide a satisfactory variation to the diet, the next step is a controlled introduction or personalization.

Appendix 9.12 [25, 27, 207, 276, 301, 390, 478, 516, 523] lists the potential hidden sources of wheat, peanuts, corn, nuts, soy, sesame, coconuts/dates, anise, beef and shellfish.

Multiple Food Sensitizations

Multiple food sensitizations should be suspected when tangible improvements do not follow in adequate time an elimination diet strictly free of CM, egg and wheat. In multiply sensitized children, all the offending foods should be removed from the diet, even if for a limited time. Table 9.40 [184, 523] gives an example of a diet for children intolerant to CM, egg and wheat, which often suffers from poor compliance. In the preparation of meals for sensitized children, use only fresh foods, not processed, or homemade utilizing only unrefined sugar or beet sugar [379]. However, true multiple sensitizations are a rare event, and uselessly subjecting a child to rigid diets eliminating a plethora of foods, often not involved in the pathogenesis, should be avoided [82].

Diet Duration

There are no standardized criteria for the perfect duration of an elimination diet. We have demonstrated that it is unfeasible to pinpoint when the tolerance is acquired. See Table 9.41 [422], for the appropriate moment to do a FCT with the sensitizing food, to verify the potential start of tolerance. CM, egg, fish, shellfish and peanut allergy tend to be the more persistent in FA. To evaluate whether the differentiated reintroduction of the eliminated foods is timely or not, in case of positivity the FCT may be repeated at pre-established terms based on Table 9.41. This scheme is purely indicative, in

that pediatricians caring for these children may decide whether to repeat a FCT after 6 or 12 months, depending on symptom severity. Preliminary data suggest that children with FA symptoms and lower levels of sIgE antibody are more likely to outgrow their reactivity in a few years, so monitoring sIgE levels by CAP System FEIA (Chap. 6) every 1 to 2 years may by helpful in establishing when to rechallenge children [419].

Evaluation of Children on Therapeutic Elimination Diets

Children on prolonged diets should be observed as follows:

- Compliance is obvious to specialists, but the psychological consequences of a restricted diet become more severe the older the children are, while infants up to 1 year of age may accept the monotonous diets without problems. Although initiated despite our suggestions, older children may be deprived of more pleasant foods permitted to their siblings and friends, with the problem becoming aggravated by the unpalatable taste of some popular dietetic alternatives [19].
- Ongoing control of nutritional adequacy of the diet and of the single constituents is important. An inappropriate diet (and even more punitive) may induce diverse disturbances compared with baseline data (Table 9.22). In all cases attention should be paid to the following risks:
  - *Nutritional risks* dependent on a poor caloric supply or of specific nutrients. Based on the data in Table 9.16, pediatricians can check whether the diet prescribed corresponds entirely to ESPGAN prerequisites [151].
  - *Hidden CM sources* and derivatives and/*or of other foods* when country regulations do not require that such foods be mentioned on products for children.
  - *Introduction of sensitizing foods,* both involuntary and voluntary by persons not knowing the effect even of minimal amounts of sensitizing food (see Hamburger et al and Hattevig et al on the problems related to the application of diets, Chap. 24), which may be *cause of anaphylactic shock.*
  - *Small doses* may transform into a cause of immediate hypersensitivity to another allergy that before was asymptomatic [247].
  - Maximal attention should be paid to necessarily integrating Ca and other minerals into exclusion diets.
- Monitor the *hidden sources of penicillin* (Chap. 19);
- Periodically record on growth charts the body weight and height of children based on national standards (calculate the percentiles: Appendices 6.1–6.4), and the parameters of possible signs of malnutrition (Appendix 9.13) [516] (Chap. 21).

Recent data have led us to re-thinking the issue. During an elimination diet without previous problems after CM intake (the last accidental exposure to CM occured *more than a year before the challenge was performed*), 8/11 children developed severe acute allergic reactions to CM after accidental ingestion. During DBPCFCs all 11 children experienced acute allergic reactions to CM. Therefore, there is a considerable chance of developing acute allergic reactions to CM during a CM-free diet in children with AD + FA [164].

Prevention of FA

Even if prevention is discussed in Chap. 24, we comment on issues noted herein and underline the attention required by the hidden sources of CM and dairy products and/or constituents (Table 9.35, Appendix 9.2), and 11 other foods, as shown by Appendix 9.12. In the US, children with CMA had acute and even severe reactions after eating *foods containing unspecified sodium caseinate in products not based on CM*; such traces of CM proteins were not listed on the labels of canned tuna, bologna or hot dog, because according to US regulations sodium caseinate is a natural flavoring [175]. It is therefore necessary to *read product labels carefully* to unmask the hidden CM (Table 9.34). The words on the label depend only on the producers' fairness and not on legal requirements [276]. It is indispensable to remember that:

- Whey proteins or casein (also as caseinate) are important allergenic proteins of CM. Ca caseinate was added to the total parenteral nutrition of the 41 infants with chronic intractable diarrhea [66] (Table 9.6) until they were put on Rezza's diet.
- ALA may be hidden under the words "seasoning" or "flavoring."
- Casein is utilized as an emulsifying agent.
- Whey proteins are added to other proteins as they are considered as fortifying, because these proteins are rich in essential amino acids.

To live with children with FA may therefore be emotionally and materially demanding. The younger ones are not always or almost never able to understand the food restrictions. If they have older siblings, these might be the first to be sensitive to such problems. Practical suggestions include the following:

- Elimination from the home of the incriminated food as such and in all preparations containing it.
- If this elimination is not feasible in practice, warning labels can mark the allergenic foods.
- Pay attention to teasing by older siblings or friends motivated by jealousy.
- Warn all educators in contact with children of this allergy.
- At the restaurant, parents should request precise information on the dish's ingredients,
- Older children should be informed of certain terminology used in food labeling before consuming such foods, but the appropriate sources of this information and the appropriate medical personnel to teach this is currently unknown.

Medical Treatment

In a strict sense, a medical treatment for FA does not exist, also because the dietetic treatment has no substitute. The situation of children with multiple food sensitizations, or in whom compliance with the diet is a major problem, may be ameliorated by disodium chromoglycate (cromolyn), with doses not >40 mg/kg/day, qid 15–20 min before meals (Table 7.19), thus preventing or reducing the symptom flare-ups provoked by sensitizing foods [65]. Cromolyn was administered to 13 children at the dose of 30 mg/kg/day over 7 days: the reactions to foods were efficaciously prevented in six of eight children with CMA and in four of five children allergic to egg [65]. In another double-blind crossover study in 31 children with AD associated with FA, the results were wholly in favor of cromolyn, which was significantly better than placebo in preventing symptom relapses during FCTs [67]. All children had SPT, RAST and elimination-provocation tests positive to sensitizing foods [56, 67, 70]. Otherwise [54] the results were not similar to ours due either to lower doses, or to the short duration of treatment. Among the anti-histamines we use are cetirizine and ketotifen (Table 7.19). The positive effects of *cetirizine* can be of help if the child is invited to a dinner or a party: a preventive prescription will prevent the risk of showing significant allergic reactions in such circumstances. Cetirizine in drops favors the compliance of young children. Allergen avoidance results in some relief; however, we see a dramatic decrease in symptoms after cetirizine is introduced, probably linked to its anti-inflammatory properties [507]. See Table 7.19 also for levotetirizine tablets. *Ketotifen* protects the gastric mucosa after FCT with the responsible allergen [148] and reduces intestinal hyperpermeability and clinical symptoms after FCT with CM and egg (Fig. 9.21) [341]. Administering ketotifen before FCT and measuring the urinary excretion of lactulose/mannitol, the level decreased significantly (Fig. 9.21). *Loratadine* has been demonstrated to reduce significantly the intestinal permeability in children with AD associated with FA [342].

New Therapeutic Perspectives

The most promising aspect is based on oral desensitization in FA, consisting in first diluted, then undiluted foods in progressively increasing doses, which is usually accomplished in 4 months. During treatment, sIgE were significantly decreased, and specific IgA and IgG increased, as well as IL_4 and IFN-γ levels [360]. In a study on 32 children, the success rate was 84.8%: oral desensitization was successful for CM, whole egg, egg-yolk, and fish [375]. See also an oral rush desensitization for CM (Chap. 13). A group of 30 children with recent very severe episodes underwent an original oral desensitization protocol during a 10-day session in the ward. Of these, three children (10%) did not proceed with the protocol because of persistent respiratory symptoms. In a second group of 20 children with less severe allergy, one developed a specific food aversion and two failed to proceed with the protocol (15%). In sum, 87.5% of the children [375] completed this treatment, obviously ensuring a better quality of life for both children and adolescents. An original study on experimental animals, which cannot yet be extrapolated to infantile therapy [171], has demonstrated an effective early hyposensitization to CM by a single intravenous (IV) injection of an IgG-βLG conjugate, abolishing IgE, IgA, IgG immune responses to the protein. The immunosuppression was persistent also after 1 month, and was accompanied by a block of mast cell release. The conjugate thus acted as a tolerogen and the scientific assumption connected with antigen presentation updates the well-known formation of such tolerogen conjugates with IgG, as demonstrated by the hapten mechanism: nucleosides or benzylpenicilloyl bound to IgG prevent in rats IgE formation [171]. We will evaluate the possible practical applications. We recommend tacrolimus and pimecrolimus for children with FA, as reported in Chap. 7.

Acquisition of Oral Tolerance

As pointed out above, standardized and age-related criteria on food tolerance are lacking. It is generally affirmed that tolerance is acquired by 2–3 years of age; however, often IgE-mediated FA tends to persist up to 8–10 years and in some cases up to 14 years. Several data have been reported on the onset age of tolerance to CM or other foods related to 1,286 children (Table 9.42) [26, 40, 66, 83, 92, 93, 98, 106, 122, 212, 213, 224, 227, 230, 234, 241, 281, 439, 454]. Even if 43%–56% of children acquire the FA tolerance within 1–4 years, 53% wait for it up to 5–14 years, and 48.5% and 36.8% develop respiratory allergy and 31% multiple food sensitizations. Although 56% of children acquire tolerance at 3 years of age, many children aged >3 years could benefit from oral desensitization [380]. Even if 16.6% reached tolerance to a limited amount of milk (3.5–45 ml), these children have obtained the primary target: complete freedom from life-threatening reactions caused by the accidental ingestion of offending foods, almost always hidden, or by skin contact [470]. Additional results:

- Tolerance is acquired by children depending on whether they react in an immediate (22%) or delayed manner (59%) [212].
- In 37/41 children with chronic diarrhea with early onset associated with CMA whom we followed up over 4–10 years (Table 9.6), tolerance was achieved in 25/37 cases (67.6%) at a median age of 2 years; 12/37 children (32.4%), at a median age of 6–7 years, were still intolerant to CM; 27/37 children (73%) developed more food sensitizations during the follow-up. Despite a long-last-

A asthma, *AD* atopic dermatitis, *AR* allergic rhinitis

[a] In children with IgE-mediated CMA.
[b] In children with food intolerance.
[c] 9% of children recovered from partial/subtotal villous atrophy by 4.5–5 years.
[d] At the final follow-up (after 5 years), 21% of children suffered from AD.
[e] 67% of CM-allergic, 25 of egg-allergic, and 37% of children with multiple sensitizations.
[f] Only 11% of atopic children.
[g] 80% of children were still affected by AD.
[h] At the 4-year follow-up, the remission was based on the initial IgE level (<or >10 kU/l): the first in 90% of cases, the second in 47% of cases
[i] The first group of children had immediate reactions, the second group delayed reactions (l). The second group had delayed reactions at the age of 27.6±7.1 months.
[k] In the study by Carroccio et al, the first line shows the children intolerant to casein HF, and the second line the children tolerant to the same formula.
[m] 55% of CM-allergic, 31% of egg-allergic, 12% of wheat-allergic and 35% of children with multiple sensitizations 90% of cases in the CN-allergic 47% of cases in the egg-allergic.

ing elimination diet, CM intake was followed by immediate symptoms [66].

- In a prospective study on 88 children with FA and 54.5% of them with FHA+, followed up for 8 years (diagnosis based on positive SPTs and/or RAST and OFCs to the offending foods), the results were not very optimistic (Table 9.43) [83]. The more frequently responsible foods besides CM and egg were wheat and fish, some of which seem to induce more persistent and more severe symptoms, such as fish *(angioedema)* and nuts (Fig. 9.27) [83]. At a median age of 9 years, only 25 children (28%) tolerated these foods (p=0.003). As in other studies, 33 tolerant children (38%) developed additional sensitizations (p=0.035): 10/15 children with CMA (67%) and 4/15 of those with egg allergy (27%) developed asthma (Fisher=0.0326). The children with CMA achieved tolerance significantly later than children with other allergies, while remission implied a greater tendency to develop more sensitizations (Fig. 9.28) [83], with a remarkable incidence of multiple sensitizations (Table 9.44) [83]. The persistent intolerance to offending food was significantly manifested with symptoms such as angioedema and AD separately or variously associated (Fig. 9.29) [83].

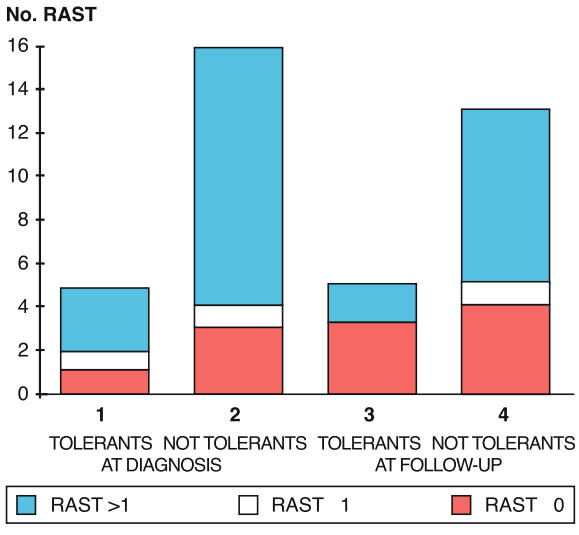

Fig. 9.30. RAST classes to sensitizing foods in 21 children with breast milk allergy at diagnosis (median age, 3 months) and at last follow-up (median age, 13 years), according to tolerance acquisition. *1, 2* NS, *1–3* p<0.0001. (Data from [93])

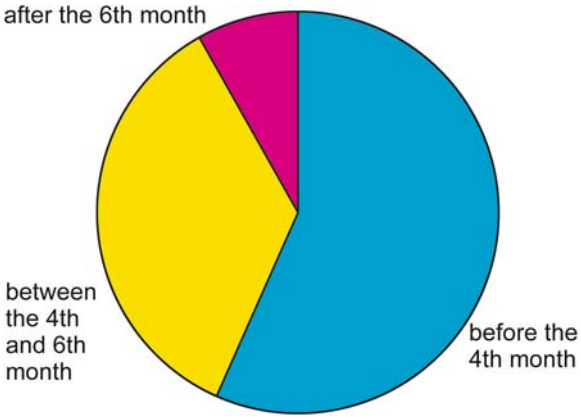

Fig. 9.31. Age at onset of atopic dermatitis in 115 children prospectively followed-up for 14 years; p=0.0001. (Data from [92])

- In 21 exclusively breast-fed children [93] with IgE-mediated FA (follow-up, 10–13 years), 8 of 21 children (38%) developed asthma during the follow-up. Interesting differences between tolerant and intolerant children were shown by RAST classes vs sensitizing foods, particularly indicative for the development of tolerance: at the last check-up, RAST turned negative in 3/5 tolerant children, and in 4/13 intolerant children (p<0.0001) (Fig. 9.30) [93].
- In the 41 children with chronic diarrhea, 2/3 with negative RAST tolerated CM within the 2nd year of life [66], so RAST negativity may be useful for the prognosis of FA;

In 115 children prospectively followed up over 14 years, first examined at a median age of 6 months, the median age for tolerance to CM was 7 years 11 months, to egg 6 years 6 months, and to wheat 7 years 2 months. Only 66 children (57%) acquired food tolerance, but there was the *onset of asthma in 54% of cases*. The median age at *AD onset was very early*, before 4 months of life in 66 babies (57%) (Fig. 9.31), and a large number of both tolerant and intolerant children developed asthma and multiple sensitizations (Fig. 9.32 showing the age-related increase of multiple sensitizations). Table 9.45 [92] shows the correlation between sensitizing food and development of additional food allergies. The study of this correlation (Fig. 9.33) revealed that 58/106 (54.7%) children with CMA developed several sensitizations during the follow-up. Among the improved children, 53 (80%) were <6 months old when AD first appeared, unlike 30 children (61%) with an onset of AD after 6 months (Fig. 9.34) [92]. Table 9.46 [92] shows that a large number of children developed several sensitizations during follow-up. We investigated several factors as predictive of the outcome, including early onset, widespread or untypical (reverse pattern) skin lesions, family history positive for atopy, persistent FA, high levels of total and specific IgE antibodies, association with

CMA and asthma. All these parameters were significantly predictive of a *long-term morbidity of AD children with CMA* (Table 9.47) [92].

- In 54 children whom we prospectively followed (Fig. 9.35), CM and egg sensitization dominated in the first few months, but there was also an early onset of multisensitization, and after the 6th month onset of AD unrelated to FA. During the follow-up (Fig. 9.36) [69], a significant relationship was found between the outcome of AD and the development of food tolerance: 90% of children with healing achieved a complete or partial tolerance to the offending foods, while 60% with persistent AD did not lose the food hypersensitivity and multiple sensitizations were prevalent.
- In a prospective study on CMA, 5 of 21 children (24%) with IgE-mediated allergy were still intolerant at 3 years (Fig. 9.37) [224] vs none of non-IgE-sensitized children. Adverse reactions to other foods were significantly present in 13 of 21 (62%) allergic children vs 8 of 18 of non-IgE-sensitized children (44.4%), and these were still intolerant at age 3: 8 of 21 (38%) vs 1 of 18 (5.5%), with equal differences in the age-related development of inhalant allergy (Fig. 9.38) [224]. These are concrete differences between IgE-mediated and non-

IgE-mediated reactions. *In children with early sensitization to CM, the risk of a persistent allergy is high* (62%), as is the risk of developing *adverse reactions, also persistent, to other foods* (54%) such as egg (38%): high sIgE titers to CM and egg could be predictive of such allergies [224].

- Sampson and McCaskill [421] report that 16 of 40 children (40%) given an appropriate elimination diet and re-evaluated after 1 to 2 years showed food tolerance and improvement of their clinical course, but after 3 years no other child was tolerant.
- Sampson and Scanlon [422] extend to 20 years the negative aspects of natural history with 69% of intolerant children: after 3 years of diet *none of the 20 patients* was tolerant.

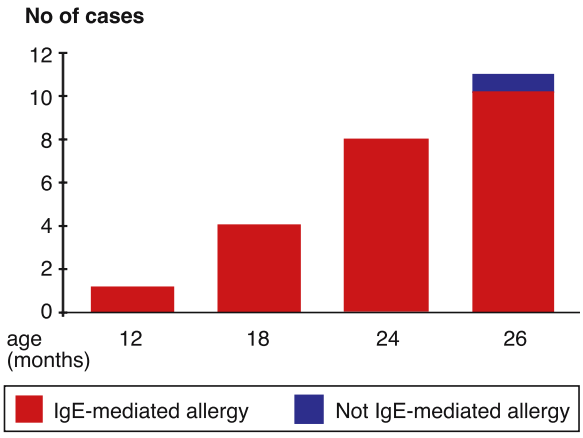

Fig. 9.38. Prospective study of CMA: age of onset of inhalant allergy. (Data from [224])

- James and Sampson [241] confirmed such data, in that only 11/29 children 3–14 years of age (38%) lost their clinical reactivity at the third annual DBPCCT, all affected with AD and FA and/or respiratory allergy; however, they demonstrated a significant decrease in SPT reactivity and had *lower serum IgE antibodies to CM proteins,* both at the initial and final evaluation.
- As seen in Tables 7.23 and 7.24, the tolerance to CM was achieved at the median age of 3 years and 6 months, while the tolerance to egg was achieved at the median age of 4 years and the tolerance to wheat at the median age of 4 years and 6 months. However, 28 children (50%) had respiratory allergy at the last follow-up, 21 children (37%) developed asthma, two (4%) rhinitis, and five children (9%) developed asthma and rhinitis, while 50% with persisting FA did not lose the food hypersensitivity [69].
- A recent study followed 118 children with CMA until recovery and repeatedly measured their sensitization to cow's milk (CM): by age 2.0 years, 60 (51%) children had recovered from CMA. Risk factors for persistent CMA at that age were sensitization to CM at age 1.6 years (OR 6.3), urticaria at diagnostic challenge (OR, 3.3), CM exposure at the maternity hospital (OR, 3.2), and early sensitization to egg (OR, 2.8). By age 5.0 all children with IgE-negative CMA were tolerant compared with 75 (64%) children with IgE-positive CMA. At the final follow-up at a mean age of 8.6 years children in the IgE-poitive group *still had CMA and more frequently had asthma* (31% vs 13%), *rhinoconjunctivitis* (66% vs 21%), *atopic AD* (81% vs 26%), and *sensitization to any allergen* (88% vs 39%) than control subjects ($p \leq 0.001–0.0001$) [408]. In the first 2 years of life 21.5% of 1314 children (MAS study) had early AD, 43.2% of them were in complete remission by age 3 years, 38.3% had an intermittent pattern of disease, and 18.7% had symptoms of AD every year. Severity (OR 5.86) and atopic sensitization (OR 2.76) were major determinants of prognosis. In 33% of these children the onset of wheezing preceded and in 56% followed the AD onset [225].
- Figure 9.39 [26] shows that in 92 children, 62 of whom had FHA+ (67.4%) with AD and allergy to foods and inhalants begun in the first years of life, *54 children (58%) developed asthma, including 25 (27%) with allergy to pollens, 22 (24%) to pets and 39 (43%) with urticaria.* Tolerance was reached to CM in 69% and to egg in 75% of cases vs *0% to fish and dried fruit. At 5 years of age, only 11% of atopic children with AD were tolerant vs 73% of nonatopic children* [26]. The *most dramatic complication is the development of asthma.* A study in 26 children aged 2–9 months at the first visit in our division and at the follow-up at 2–7 years of age showed that ten children tested positive for inhalant allergens (38.5%)

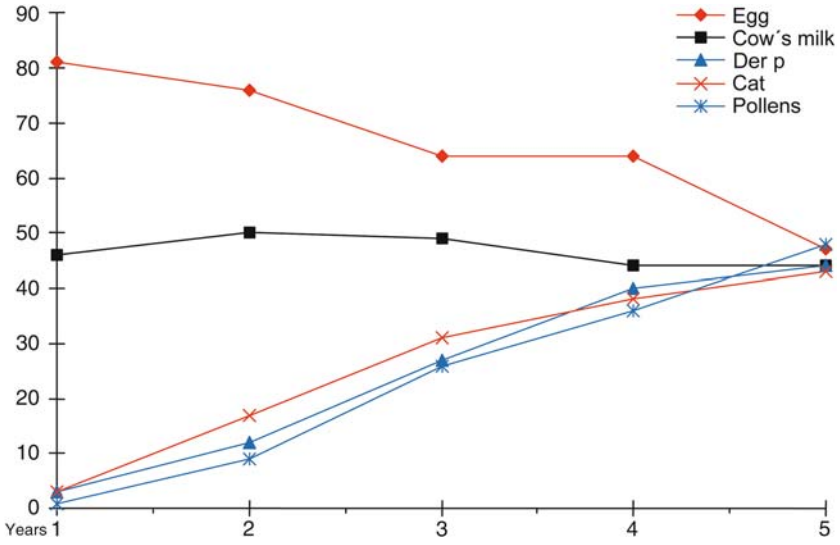

Fig. 9.39. Natural history of food and respiratory allergy in 92 children with atopic dermatitis and allergy to foods and aeroallergens started in the first years of life. (Data from [26])

and had respiratory allergy (asthma and/or perennial rhinitis). All children but two had FHA+ (p=0.0019). Therefore the natural history of IgE-mediated CMA is *less favorable than is usually believed,* especially in atopic children. A 38.5% incidence of asthma at *a median age of 3.1 years* may be explained by the high rate of FHA+ (92.3%).

Egg seems to determine a more persistent allergy:

- In 25 children with allergy verified by DBPCCT, symptoms persisted in 14, in some children from 6–12 years [481].
- Among the children with IgE-mediated CMA, 38% developed IgE-mediated allergy to egg (persistent in 6/8 up to age 3, associated with inhalant allergy), 29% to *citrus* and 19% to *tomato,* with persistent allergy to *citrus* (2/6), *tomato* (2/4) and *nuts* (2/2) [224].
- In 46 children with sIgE to egg within 2 years, 26 (57%) have developed sIgE to inhalants within 4 years, also 19/59 children with allergy to inhalants followed up 12–15 years had sIgE to egg [449].

Persistent sensitization is connected with a significant increase in IgA, IgG, IgM secreting cells after CM challenges [234], or in IgG and IgE antibodies [241], whereas healing is marked by no specific variation, apart from specific IgA antibody-secreting cells [234] and a significant reduction of sIgE to CM [241]. To consider as *favorable markers* the significant reduction of sIgE to CM and the increase in IgA-secreting cells against CM antigens associated with GI mucosal barrier maturation and loss of responsiveness to ingested food allergens, further studies are necessary to confirm such parameters. The maturational process may continue to elicit positive SPTs and sIgE [234, 422], therefore neither can be considered as predictive of tolerance. However, ongoing exposure to allergens may lead to intestinal injury and consequently increased permeability, in turn capable of eliciting more allergic symptoms [234]. Stimulated by CM, PBMCs from infants with CMA released in vitro more TNF-α than those in control infants [208], thus demonstrating that *even during remission CMA may not disappear completely* from the immunological memory of children.

A recent paper provides evidence to contend the prevalent dogma that CMA is a disease of infancy that the infant outgrows after the mucosal immune system matures [278]. Table 9.43 shows that 51.3% of children outgrow CMA between 5 and 8 years of age or that at 8 years have not outgrown CMA [83], yet 48.5% of children have developed asthma and 36.8% AR. In the follow-up of the 39 children [224] at age 10, 21 children with outgrown (86%) OFC-proven CMA developed asthma in 62% of cases and AR in 52% of cases and 18 children with outgrown (100%) CM intolerance developed asthma in 17% of cases and AR in 10% of cases [227]. In 276/1,759 sensitized children (sIgE of ≥ class 2) the rate of current asthma at age 10 was 53% and that of AD 29% [227]. Children with definite CMA had increased densities of IEL CD3, γδ T cells and a higher γδ/CD3 ratio, whereas children with suspected CMA showed a similar trend but without statistically significant differences [278]. However, FA onset has been reported at 10 years of age [270]. Thus, it is confirmed that CMA may exist in school-aged children [270, 278].

Therefore, FA persists for the entire duration of infancy and beyond. The unfavorable markers showing that FA may not be outgrown are as follows (Table 9.47):

- Family history of atopy [26, 83]
- Early onset of sensitization [26, 66, 90, 105, 111, 224]
- Immediate symptoms provoked by food challenge
- Association with persistent allergy to other foods or angioedema or AD, alone or variously associated [83]
- Multiple food sensitization [83]
- High sIgE levels to incriminated foods [64]
- Positive sIgE to egg with high predictive value [203, 449],
- Development of respiratory allergy to inhalants [26, 40, 90, 106, 224, 449]

FA-Caused Death

The cases of fatal anaphylaxis related to CM appeared in the first years of the last century [161, 436] and regained paramount interest after the publication of seven cases of fatal anaphylaxis, four of which occurred *in 11- to 19-year-olds over 16 months* [528], contributing to systematizing this aspect of FA, up to then confined to isolated cases that were difficult to verify. Certainly, the fatal cases by food-caused anaphylaxis are less numerous than those occurring in asthmatics, but are more frequent than those provoked by insect stings [527] and even less foreseeable. Frequently involved are peanuts, a food that is more often sensitizing in Anglo-American children [13, 48, 413], in contrast to what occurs in Europe, where sensitization to peanuts is uncommon: we have elucidated that sensitization takes forms as severe as captious and unexpected [48, 413]. Cod, crab and pecan were also implicated [528] and CM in 50% of cases (Chap. 20). Recently, the medical literature has been enriched by a new chapter: cases of severe anaphylaxis by HFs (Tables 9.31 and 9.32). Sampson et al [424] published six more cases of fatal and seven of nonfatal anaphylaxis in 2- to 17-year-olds, resulting from eating foods prepared with peanuts and Brazil nuts, which are known for their sudden and violent reactions [13, 424]. Neither children nor parents were informed that the allergen triggering anaphylaxis was *hidden in foods and widely diffused candies.* After eating peanuts hidden in a cake, a child was not saved by a quick injection of epinephrine (Chap. 20). Not only children and adolescents and their parents should be informed thoroughly, but also babysitters, day-care and school personnel, as well as restaurant personnel. Allergic children and their families should be warned explicitly but without excessive alarmism about potentially fatal reactions; older children and their parents could venture to the decoding of

symbols, biochemical formulas and labels mostly understandable only to experts. We repeat that children and adolescents at risk should always wear a *medical bracelet* warning of their affection and be provided with a *cellular phone.*

Oral Allergy Syndrome

In 1942 it was observed that pollinotic adults (birch) eating nuts or various types of fresh fruits, especially apples, experienced oral pruritus and other symptoms mostly of the oropharynx [478]. It was subsequently reported that these patients could react to a wide spectrum of vegetables and fruits [135]. This has been named OAS [6]. In this context the first studies on fresh fruits and vegetables with the prick + prick method were done.

The symptoms are disclosed in a polymorphous fashion, mostly within a few minutes of food contact, more frequently with vegetables cross-reacting with pollens [6]. Often the symptoms quickly disappear, but some subjects experience severe manifestations, up to anaphylactic shock. Since these patients have SPTs positive to other foods, OAS is not a syndrome localized to the oropharynx (as stressed by some authors who consider OAS a variety of ACD), but is part of a systemic sensitization.

Epidemiology

Data in children are not available, apart from a substantial trial showing a 1.4% prevalence in children 5–16 years of age (Fig. 5.9) and 3–15 years of age [397] and the *high frequency of SPTs positive to foods as elicited by children with monoallergy to grasses* [126, 343] *and multiple allergy to pollens* [529] compared to adults [6, 39]. Significantly, a girl monosensitized to egg presented OAS symptoms *at age 3 months* [300]; the youngest children had a mean age of 3 [6], 4 [413], or 4.1–4.9 years [126], 11.9±3.8 [529], and 20%–26% of patients were <14 years [6]. In 80 patients, OAS arose in the 1st year of life in 16% of cases, and from 2–12 years in 65% of cases [6].

Pathogenetic Mechanisms

The richness of mast cells and of sensitive fibers of the oropharynx, which has contact with a high concentration of undigested food, could explain the reactivity of this site in allergic subjects: the symptoms occurring within a few minutes indicate that contact with saliva is sufficient to cause food allergen release. An aspecific mechanism has been proposed, based on *lectins* found in raw fruits and vegetables, capable of activating degranulation by an aspecific bridging: by showing a high affinity for carbohydrates the lectins might help food antigens adhere to mucosal cells, in that the consequent increase in permeability would induce a rapid absorption of the antigens released [381]. New knowledge on epitopes common to pollen allergens and vegetables identified in proteins of eucaryote cells shows that the *profilins* [141] induce the presentation of a bivalent epitope to APCs, with ensuing production of IgE antibodies capable of recognizing both pollens and food. Cross-reactive IgE bind to mast cells and a subsequent contact with those particular epitopes surpasses the threshold level and activates mast cells and their degranulation, thus provoking a rapid onset of symptoms [150]. The current mechanism is based on sIgE reacting with profilins, thus explaining the cross-reactivity to common epitopes and between species that are not botanically correlated, including birch, grasses, *Compositae, Corylaceae,* and tree pollens, vegetables (carrot, potato), fruits (apple) analogous to celery and rosacea allergens such as peach [142, 381, 482, 498]. To establish the immunochemical basis of cross-reactions, DNA/RNA technology has recently been used to demonstrate by immunoblotting that patient sera with IgE reacting with Bet v 1 also bind to Mal d 1, Api g 1 (Table 1.74), and proteins of pear and carrot with a MW of 15–18 kD [142]. Using a Bet v 2 DNA clone as a probe, a cross-reaction was shown with the previous allergens, suggesting homology with the pan-allergen profilin, and with cucumber and muskmelon [141]. Therefore, families that are not correlated share common epitopes to which IgE antibodies bind [141, 521]. In certain cases, cross-reactions are caused by IgE contra-glycoprotein epitopes, shared also by pollens and foods, as demonstrated by another major allergen of Lol p IX with glycyl epitopes bound to IgE [482].

Cross-Reactions Between Pollens and Foods and Between Fruits and Vegetables

The pollens of different species within a single family can cross-react with each other and with fruits [482], as frequently occurs between pollens of some families of trees and some vegetables. Several types of cross-reactions are summarized in Table 9.48 [126, 135, 142, 150, 161, 252, 371, 377, 381, 447, 529]. The standardization of fruit and vegetable antigens will facilitate this aspect of OAS.

Clinical Presentation

Onset of symptoms is generally between 2 and 15 min after eating small quantities of the offending food and is characterized by tingling in the lips or mouth, pruritus or lip edema, pharyngeal, palatal and gingival pruritus, facial erythema, a feeling of tightness of the throat, followed after 15–60 min by systemic progression of symp-

Table 9.48. Cross-reactivity between pollens and vegetables

Birch
Apple, apricot, banana, carrot, celery, cherry, fennel, hazelnut, kiwi, medlar, orange, parsley, parsnip, peach, peanut, pear, plum, potato, raspberry, soy, spinach, strawberry, walnut, wheat
Parietaria
Basil cherry, muskmelon
Grasses

Ragweed
Banana, camomile, cantaloupe, cucumber, honey, small pumpkin, watermelon, zucchini
Mugwort
Apple, camomile, carrot, celery, fennel, hazelnut, muskmelon, spices, watermelon
Additional possible cross-reactivity between different fruits and between fruits and vegetables
Apple and pear
Apricot, cherry, peach and plum
Celery and fennel
Celery and parsnip and turnip
Cherry and apple
Kiwi and avocado
Muskmelon, avocado, banana, tomato, and watermelon,
Peach and apple, cherry, pear and plum
Potato and carrot

Data from [126, 135, 142, 150, 160, 252, 377, 381, 447, 529].

toms: urticaria, oculorhinitis, palpebral edema, skin itching, asthma, and less often glottis edema [6]. Cases of anaphylactic shock have been reported: 0.3%–3.7% in adults [6, 413]. After 30–60 min, abdominal pain and vomiting may appear accompanied by nausea and vomiting and more rarely by diarrhea and rhinitis, additional symptoms that usually appear after greater ingestion of food [6]. Tables 9.49 [6, 39, 127, 343, 529] and 9.50 [343] outline the individual foods provoking symptoms in children and the rate of various symptoms. In a pediatric cohort, the symptoms were only oral in 50%, only extra-oral in 16.6% and mixed in 34.4% of cases [529]. The severity of respiratory symptoms may vary remarkably from one child to another, depending on the degree of pollen sensitization.

As Table 7.22 suggests, symptoms may be triggered by a simple indirect contact, more often unnoticed [135]. Oculorhinitic symptoms may appear simply by peeling, or scrubbing, or manipulating raw vegetables or fruits, and be aggravated when itching of the eyes and nose cause patients to rub these organs, thereby rubbing high amounts of allergens from the fingers into the nostrils or conjunctiva [134]. We elucidate that OAS is set off only by raw and not by cooked foods, chemically treated, or long refrigerated, with consequent loss or notable reduction of allergen aggression.

Diagnosis

The clinical history is usually suggestive; the patient's history reveals that the typical symptoms appear in the characteristic chronological order of OAS. Generally these symptoms are seen in young pollen-sensitive subjects with allergic oculorhinitis, who suffer from a simple contact with offending foods. The rapid, typical onset of symptoms and frequent exacerbations allow an immediate diagnosis (see Table 9.51) [126, 135, 150, 160, 377, 381, 529].

For SPTs the prick + prick method is preferred [135] to SPTs with commercial food extracts for all raw fruits and vegetables [413], in 60%–80% of cases positive also to crab, cod, CM, peanuts and nuts [6]. CAP System FEIA (Pharmacia) results when compared with DBPCFCs are most often equivalent to those of SPTs in predicting symptomatic FA (Chap. 6).

For good correlation with history, the FCT is done in an open fashion. A DBPCFC in these patients is technically impracticable: oral contact with a great concentration of foods is crucial and these must be absolutely fresh and without additives of any type, but masking aspect, odor and taste would be unfeasible. It is unknown whether food in capsules after bypassing the oropharynx (which nullifies the goal of the test) still causes symptoms [150].

Treatment

A pediatric study has demonstrated that pollen immunotherapy (IT) is unable to influence OAS symptoms caused by fruits and vegetables; however, 46% of children are improved vs 21% of children treated with oral IT and 15% of those who received placebo [340]. Recently, successful pollen IT was shown to lessen oral symptoms in a small group of patients [265].

Prevention

To prevent the onset of manifestations, often severe, it is necessary that children with OAS avoid every type of contact with the foods triggering such reactions. Bet

v 1- and 2-allergic children may eat apple, pear, carrot and celery cooked >10 min, indicative of their thermolability [141]. Recalling what was discussed in Chap. 6, that pollen-allergic patients may have SPT positive to foods and vegetables and related symptoms by eating such foods during pollination, we stress that this contingency should be taken into account when preparing diets for pollen-allergic individuals.

Bird-Egg Syndrome

A new example of cross-reactions between inhaled and food allergens is based on cases of egg allergy associated with sensitization to avian allergens. Generally these are adults working in the food industries or exposed to household birds, affected with respiratory allergy, with sIgE antibodies against blood serum proteins or antiexcrement of chicken, pigeon and household birds, who acquire a form of FA provoked by the same allergen at the moment of eating egg or chicken meat, even after several years. Six patients with respiratory allergy and sensitization to avian allergens have experienced severe symptoms after eating egg, thus demonstrating cross-reactions between avian proteins and egg, both to egg yolk and egg white [381]. There is therefore a cross-reactivity to egg of birds of diverse species. The case of a feather-egg allergy has also been reported: a child manifested asthma caused by feathers of household birds at the age of 5 and allergy to egg white and chicken 1 year afterwards [11]; the responsible protein of the syndrome seems to have been *α-livetin*, a protein in egg yolk that is the cross-reacting protein responsible for bird-egg syndrome [381].

Pediatricians and FA

Significant progress has been achieved in the understanding of FA. We are a long way from seeing a complete picture and cannot be sure what it will look like when it is all put together. However, the first step is important. The institution of standard definitions for the clinical presentations of FA will render the scientific literature more discernible. Continuing the analysis of doctor–patient relationships, we consider that a large part of the suggestions mentioned at the end of Chap. 7 is pertinent also in this setting, but is extended for a longer time because children with IgE-mediated FA may acquire a food tolerance very late, perhaps beyond childhood, but if tolerance was not reached in adolescence it is very likely that FA will persist even into adulthood. Otherwise pediatricians diagnosing FA in an infant should speculate on the possible onset of future inhalant allergy or multiple sensitizations, with timely initiation of preventative measures, because FA will pave the way to additional and different allergies. We believe that again the doctor plays a prominent part in the early diagnosis of CMA, above all to avoid children being subjected too long to restrictive diets which could negatively influence growth, even psychological. The secret of successful child treatment in FA is: do not only treat the symptoms but try to find the causal factors that are specific to each child! A very promising cure is that of oral desensitization to foods.

Pseudoallergy and Food Immunotoxicology

Allergy and Pseudoallergy

Several reports have pointed out that there is notable confusion between allergy and pseudoallergy (PA), to the point that epidemiological studies carried out in the United States have shown extremely elevated prevalence values for food allergy (FA), justified solely by a wide confusion with PA. According to the Asthma and Allergy Foundation, 5%–10% of Americans affected by allergy (35–40 million) present symptoms of FA, whereas according to the Federal Register of the Department of Agriculture, it is about 15%, while the American College of Allergists reports rates of up to 25%–50%. According to a group of consultants of the American Food Industry [2], in 14% of 3,700 families there was at least one subject affected by FA or who followed a special diet because they thought they were affected, most often by cow's milk (CM) (30%), fish and crustaceans (16.7%), vegetables (20%), fruit (20%), chocolate (9.7%), egg (7%), meat in general (5.7%), nuts (4%), wheat (3.3%), with an unexpectedly low percentage for peanuts (6.4%) [2]. Out of 18,880 adults interviewed by questionnaire, 1.4% reported reactions to alcohol, 1.3% to caffeine, 6.8% to chocolate, and 0.3% to soy [103]. In a German study, among 2,355 children and adolescents (0–17 years) contacted by mailed questionnaire, 739 (31.4%) responses could be fully evaluated. The result was that 455 (61.5%) reported symptoms related to food ingestion, 284 (38.4%) affirmed reproducible symptoms in the standardized telephone interview. But when 184 (24.8%) participants were fully examined, reproducible symptoms to food were found in 31 (4.2%) entrants and only 26 (3.5%) showed symptoms of FA [70]. Therefore the real incidence of FA has been difficult to ascertain: one major contributing issue is an elevated public perception of FA associating the ingestion of certain foods with adverse clinical symptoms. Well-publicized reports have fueled public debate over these results, the mass media have criticized the food industries economic approach and, as a conclusion of the authors (and by us), the public has become familiar with FA existence, in this case of food PA, while the medical profession has condemned the unmotivated publicity [2]. However, the discussion on the part of doctors is sometimes obscured by ideological argumentation, lack of basic principles on FA and PA, and lack of scientific evidence for several proposed dietary regimens. We believe that the existing debate has always divided the experts, perhaps because of the inherent difficulties in the diagnosis of this condition, that not being allergic escapes the usual classifications. As a result, a number of children are hospitalized suffering from a food intolerance due to indefinite causes.

For decades scientists, doctors in general, dietitians and other experts of nutrition have denounced the presence of allergens in packaged food that are not mentioned on the label [46]. Often, active substances from a pharmacological and toxicological point of view are involved such as histamine, tyramine, serotonin, phenylethylamine. Histamine-producing bacteria (*Proteus*, *Klebsiella*) can also contaminate fish that has not been subjected to rigorous preservation processes: for this reason anaphylactic reactions following the ingestion of fish products have occurred [35]. Furthermore, during the physiological digestive processes the presence of β-casomorphine, a derivative of bovine casein, an opioid peptide similar to codeine phosphate (which directly releases histamine, as well as diamines, polyamines and peptones) [56], has been highlighted in the food canal. Apart from foodstuffs, numerous drugs can set off PA reactions, which are discussed in Chap. 19.

Definitions

The general division into toxic and nontoxic reactions, as proposed by an EAACI subcommittee (Fig. 10.1) [12, 62], includes various non-IgE-mediated forms such as enterocolitic or colitic forms, celiac disease, intestinal inflammatory diseases, etc. [37], which we have clinically defined in Chaps. 9 and 18. Non-IgE-mediated and nontoxic adverse reactions to foodstuffs are defined in various ways [3, 29, 38, 62]:

- *Food intolerance* [12], in which a physiologically abnormal response is identified following the ingestion of a foodstuff or additive [38], for which the ability to set off an IgE-mediated reaction is not demonstrated and includes pseudoallergic, pharmacological and enzymatic reactions (Fig. 10.2) [101]. These are grouped by the general term "adverse reactions to foodstuffs" in the USA, or "food PA" in Europe [101].
- *Food idiosyncrasy*, often called PA to food additives or rather a quantitatively abnormal response to additives

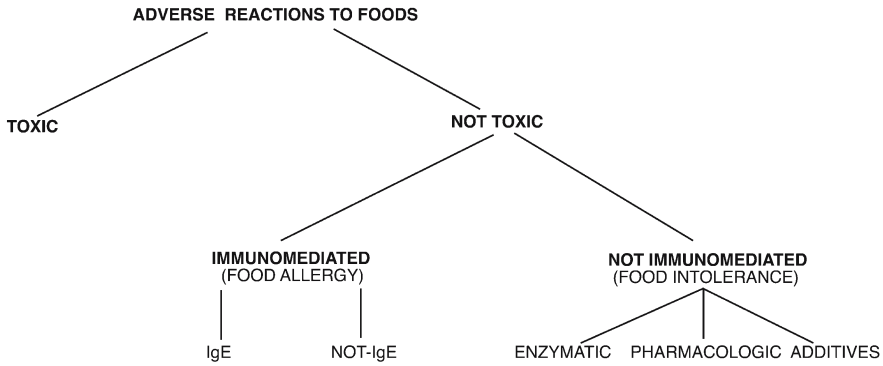

Fig. 10.1. Classification of adverse reactions to foods. (Data from [12, 62])

in particular, which is differentiated depending on its physiological or pharmacological effects: it is similar to hypersensitivity, without, however, involving immunological mechanisms. Notably, the term "PA" is sometimes preferred when referring to reactions to drugs [62]. The EAACI subcommittee includes this PA among the undefined forms in as much as the pathogenic mechanisms are largely unknown [12].

- *Pharmacological reactions,* responsible in the host for a truly pharmacological or similar effect, for example as the result of contact with preformed chemical substances or substances formed spontaneously, which, in subtoxic doses, provoke symptoms in certain intolerant individuals (for example histamine): Moneret-Vautrin proposes the term "false FA" for these reactions [55, 57].
- *Enzymatic reactions* that occur in patients with primitive or secondary enzymatic deficits (for example lactase deficiency) [23].

Separately we discuss:

- *Metabolic reactions* that depend on what effect the substances contained in certain foodstuffs have on the metabolism of certain individuals.
- *Food toxicity* (intoxication), indicating an undesired reaction caused by the direct action of a foodstuff or a food additive without the involvement of immune mechanisms. For this reason, the non-IgE-mediated release of chemical mediators may occur; the toxins may derive from the foodstuff itself or from microorganisms [12, 38].
- *Anaphylactoid reaction,* or rather anaphylactic-like idiosyncratic reactions, with a non-immunomediated release of chemical mediators [3].
- *Immunotoxic reactions* carried out at the immune system's expense by chemical substances foreign to the body, either by accidental exposure as in the case of environmental contaminants, or as a result of their common release into foodstuffs that are then consumed [7]. The role of pesticides (Table 4.21), herbicides and transgenic foods (Table 1.75) has yet to be defined.

For clinical and diagnostic reasons it is useful to consider the non-IgE-mediated, dose-dependent forms in various groups of reactions that often occur in susceptible patients. However, a precise pathogenetic definition is not easy, in as much as various pseudoallergic, enzymatic and pharmacological type mechanisms are often closely intercorrelated [105]. Data available in the literature concern mainly pharmacological reactions and those forms attributable to food additives; enzymatic and toxic reactions are more often considered for a differential diagnosis of IgE-mediated FA. In this environment, the list of substances or harmful foodstuffs is

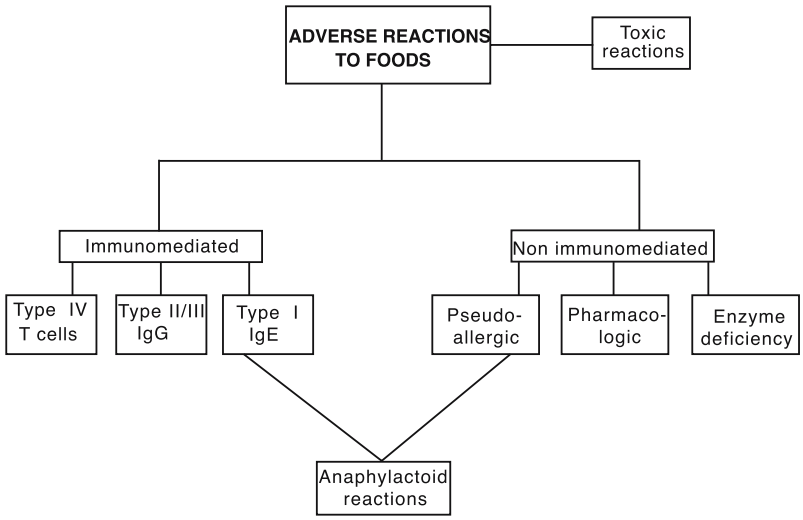

Fig. 10.2. Scheme of adverse reactions to foods. (Modified from [101])

Table 10.1. Prevalence of the reactions to additives. Reported and established prevalence of the reactions to additives (%)

Data and reference	Reported reactions	Established prevalence
18,852 C/A [102]	7.4	0.01–0.02
173 C 5–16 years [33]	18	1.5
333 C 4–15 years [34]	22.7	1.8

A adults, *C* children.
Data from [33, 34, 102].

Table 10.2. Established prevalence of the reactions to additives in two samples of children

Tested additive %	[27]	[80]
Indigo carmine		15.8
Amaranth		10.8
Sunset yellow (E110)	64.2	27.8
Annatt (E160b)	60.7	
Sodium benzoate	57.1	14.8
Sodium metabisulfite		8.3
Monosodium glutamate		8.3
Tartrazine (E102)	50	25.6
Aspartame	48.2	
Erythrosine (E127)	35.7	
ASA	12.5	2.4

Data from [27, 70]

growing daily as new insights are gained, waiting for the authorities to intervene in order to better protect the public, in particular those who are younger and more vulnerable.

Prevalence

The prevalence of positivity for several food additives including ASA is considerable in children [75]. Only for these substances is reliable data available, although studies are characterized by substantial differences between history taking and results, especially when the data are supplied by parents. In Table 10.1 [33, 34, 102], we demonstrate that the prevalence of reactions to preservatives, flavorings, natural and artificial colorings, citric acid, as suggested by parents, was on average 16.3% (up to 22.7%), while with the DBPCFC (double-blind, placebo-controlled food challenge) or the simple blind FPT (food provocation test), it was significantly reduced to 1.1% on average [33]. The values may increase in highly selected pediatric case studies [96]. Botey et al [10] document that 8/82 children (10.9%) had reactions to FPTs as follows: phenylethylamine 4.8%, Na nitrite 3.6%, tyramine 2.4%, while David [25] estimated that 5% of 500 children with severe AD (atopic dermatitis) reacted to the ingestion of tartrazine or benzoic acid. In polysensitive children with severe AD, positive FPT reactions to tartrazine and other food additives have been found [87]. It has already been noted that urticaria-angioedema can be an aggravating factor [80]: 43 children with urticaria, 70% with angioedema, were sensitive to double-blind FPT with various food additives (Table 10.2) [27, 80]; to a lesser extent, out of 120 children tested with seven colorings, 46.4% were positive to DBPCFC [27].

Pseudoallergy to Food Additives

Apicius was famous in ancient Rome for a cook book where he detailed a recipe to preserve the freshness of oysters. It is estimated that 2,000 to 20,000 agents are added to the food (and pharmaceuticals) that we consume. PA to food additives, commercially distinguished into intentional and involuntary, has assumed an ever-growing prevalence in recent years: it is sufficient to consider that they are present in various concentrations in almost all foods and drinks that we typically consume, in order to assure perfect preservation, to inhibit mold growth [94] or to modify the appearance and/or flavor, so as to make the foods more attractive and palatable, especially for children [67]. Others still are used fraudulently: for example, canthaxanthin is added to the diet of farmed salmon to produce a more natural color, or to add up to 400 mg/kg of titanium dioxide (E171) to mozzarella cheese to obtain the same white color as traditional mozzarella made from buffalo milk [26], or to camouflage an incredible number of other foods: even foods for children are not free of such additives [94]. One study found a quantity of aflatoxin, a hepatotoxic furanocumarin derivative produced by *Aspergillus flavus*, to be ten-fold higher than that permitted by current laws (10 µg/kg) in peanut butter sold by 11 of 59 (18.6%) shops specialized in natural foodstuffs vs only 1 of 26 (3.8%) in common shops [26].

Intentionally used food additives are usually permitted by law, which defines a food additive as a substance not normally consumed as itself and not used as a typical ingredient in foods, regardless of whether it has a nutritional value, having been added intentionally to foods for a technological motive, acting as substances which are added at any point during the elaboration to the mass or surface of the foodstuffs in order to preserve the organoleptic characteristics, so as to avoid the spontaneous alteration or to modify smell, taste, appearance, color and consistence, establishing other essential requirements such as:

- Effective necessity
- Short- and long-term absence of toxicity for the laboratory animal
- Absence of suspected carcinogenic phenomena

Table 10.3. Infant foods most frequently containing additives

1. Baby food, powdered or malted milk and other infant food, especially of the ready-to-use type (colorings and preservatives)
2. Bread (whitening additives or to retard oxidation and spoilage: sulfites)
3. Butter and margarine (azo dyes)
4. Potato chips (antioxidants, colorings and preservatives)
5. Fruit juices, beverages, candies (azo dyes, benzoates)
6. Canned, bottled, or frozen foods such as meat, salami, pâté, biscuits, cookies, etc. (preservatives to retard oxidation and spoilage in the prepared foods)

From [67].

- Absence of toxic products deriving from reactions with normal constituents of foodstuffs
- Presence of high purity
- Ease of qualitative and quantitative research in both a purified state and in the foodstuff
- Determination of each recommended daily allowance (RDA) expressed in mg/kg of body weight (b/w)

However, according to EU directives, adopted with the aim of standardizing the international regulations with the adoption of norms valid in all countries, the number of food additives originally allowed has been extended, especially regarding their field of use, in many cases increasing the limit at the maximum allowed dose. Therefore, from a biological point of view the impact of these compounds on the human body, in particular that of a child, cannot be ignored [20], also because the *RDA for babies has not been studied*, especially for neonates, infants and younger children.

The principal uses are aimed at blocking the undesirable activity of microorganisms without affecting the foodstuff's biological value (preservatives or antimicrobials), preventing the spoilage and/or enzymatic browning of some foodstuffs (antioxidants), conferring particular characteristics of appearance and consistency to some foodstuffs (colorings, preservatives, moisturizers, flavoring and emulsifying agents, thickeners), etc. [28]. The foods for children that more frequently contain food additives are summarized in Table 10.3 [67], taking into consideration that the law usually allows the use of a certain number of food additives in infant foods, for example weaning products and in general those for young infants. The foods and drinks commonly containing certain food additives are listed in Table 10.4 [58, 63, 67], and those containing sulfites in Table 10.5 [75, 78, 99]. The hidden sources of sulfites include their use in baked products [63] and in general as antimicrobials and food preservatives, in containers and equipment for fermentation, antioxidants and enzymatic antibrowning [83]; it is hoped that further studies will provide a more complete understanding of this confusion. The hidden sources of thickeners, etc., are shown in Table 10.6 [28] and those of vegetable gums in Appendix 10.1 [91, 106]. The classes of so-called intentional food additives according to the EU are listed in Table 10.7, which includes the division of foodstuffs, specifying in which products they are forbidden. The allowed food additives have been given E numbers, which appear on food labels. Some food additives belong to two categories, for example ascorbic acid, and are divided schematically according to their use into [94]:

- *Acidifiers*

Citric acid (E330), lactic acid (E270), tartaric acid (E334), orthophosphoric acid (E338), to increase acidity by reducing the pH, in order to improve the preservation and the taste, examples: sparkling soft drinks (E338) and nonsparkling soft drinks (E334), sweets, ice creams, fruit juices, cakes (E330), etc.

- *Thickeners*

Carrageenin (E407), cellulose and derivatives (E460–466), Na alginate (E401), alginates (E402–405), Na polyphosphate (E450): in part derivatives of seaweed, they are used to increase viscosity and consequently to prevent separation of food ingredients, examples: cooked ham, meats and tinned meats (E450), puddings, ice creams, mayonnaise, etc. (E401–405).

- *Covering agents*

Bees wax (E901), carnauba wax (E903), to modify the external appearance of the product, for example: citrus fruits, candied fruits, sugared almonds, and dried fruit.

- *Antioxidants*

Disulfites and metadisulfites (E220–224), ascorbic acid and derivatives (E300–304), natural and synthetic tocopherols (E306–309), gallates (E310–312), butylhydroxyanisol (BHA) (E320), butylhydroxytoluene (BHT) (E321), lecithins (E322), to prevent rotting of lipids and the tainting of fruit and vegetables, protecting them from O_2 attack: examples of natural antioxidants are shown in Table 4.22, to which chocolate is added [93].

- *Flavorings*

Amyl acetate, citric acid (E330), benzaldehyde, carvone, citrus fruit essence, menthol, to confer a characteristic aroma to foodstuffs; examples: candied fruit, chocolate, cakes, etc.

- *Colorings*

The principal examples are distinguished here by color:
Yellows: curcumin (E100), lactoflavin (E101), tartrazine (E102), quinolin (E104), sunset yellow (E110).
Reds: carmine (E120), azorubin (E122), lady-bug red (E124), erythrosine (E 127).
Blues: brilliant blue (E131), indigotin or amaranth (E132).
Greens: chlorophyll (E140), cupric complex (E141), brilliant acid green (E142).
Black: brilliant black BB (E151).
Various colors: caramel (E150), carotenoids (E160), annatto (E160b), pigment red (E180), or otherwise distinguished into natural and synthetic, characterized re-

Table 10.4. Foods that may contain the principal additives

Additives	Foods that may contain the additive
Acetylsalicylic acid (preservative)	Alcohols (including beer), aperitifs, cloves, conserve, shellfish, candies, cheese, packaged meat (except seasoned meat), sausages, salami, corn, loaf of bread, potatoes, peaches, tinned or canned foods, grapes; see sodium salicylate
Benzoic acid E210 (preservative)	Soft and fruit drinks, salad dressings, some cheese especially cream cheese, fruit gelatins, low-calorie margarine, industrially produced jams, marmalade and fruit preserves, canned soups, white fish treated with preservatives[a] or refrigerated preserves (anchovies, herrings, sardines, shellfish), drinking chocolate concentrates, ready-made sauces and salads, mustard, ciders
Sodium benzoate E211 (preservative)	Drinks (orange drinks, soda, etc.), caviar and similar products, filled chocolate (not pure chocolate), some cheese especially cream cheese, bananas, fruit gelatins, green peas, licorice, ready-made mayonnaise, gravies and sauces, low-calorie margarine, industrially produced jams and marmalades, canned or bottled fish, fruit juices, common wines
Sodium salicylate (preservative)	Intentional or natural additive present in some foods: apricots, oranges, bananas, blackberry, cabbage, cucumber, cherries, figs, almonds, apples, melons, blueberry, hazelnuts, nuts, green pepper, green peas, tomatoes, plums, raspberry, red currant, strawberry, raisins, zucchini
Methyl para-oxybenzoate E128	Belongs to the same family as benzoate
Erythrosine E127 (coloring)	Red food coloring: candied fruits, canned anchovies, herrings and sardines, ice creams, ice cream bars and popsicles, alcoholic beverages, confectionery cakes, macaroni and vermicelli, mixtures for drinks, medications in lozenges, syrups, tablets
Sunset yellow E110 (coloring)	Yellow food coloring: pickled and salted foods, nonalcoholic beverages, puddings, candy, caviar and surrogates, chewing gum, packed and canned soups, confectionery creams, candied fruit, ice creams, jams and marmalades, salad dressings, ready-made sauces, medications
Tartrazine E102 (coloring)	Foods in oil, soft drinks and sodas, ready-made cakes, industrially made caramel and vanilla custards, fruit candies, sugared almonds, chewing gum, filled chocolate (not pure chocolate), alcoholic beverages, vegetable preserve, cheese-flavored crackers, confectionery creams, potato flakes, cream cheese, ice-creams, ice cream bars and popsicles, fruit gelatins, ketchup, fizzy lemonade (not plain lemonade), industrially made jams and marmalades, pudding and pie fillings, whipped cream, confectionery cakes, orange drinks, concentrated fruit juices, mustard, pickles, nougat, chocolate or vanilla puddings, sandwiches, ready-made hot dogs, filled rolls, sherbets, vanilla, packaged vegetables, fruit yoghurt, meat tenderizers, imitation flavorings and extracts, medications in lozenges, syrups, tablets or inhaled and injected
Sodium glutamate E621 (flavor enhancer)	Processed foods of all kinds (canned, dried, frozen, packaged, etc.), sausages, processed meats of all kinds, seasoned salt, salad dressings, crackers, bouillon cubes, corn pies, dried and toasted fruits, parmesan cheese, meat and fish base, potato chips, canned or frozen fish, dessert salt biscuits, gravies, sauces, toasted seeds, spices, soups: canned and dry mix, tomatoes, tortilla chips
Sulfites (preservatives and contaminants)	Brandy, cornstarch, ready-made or lyophilized crawfish, avocado, other tropical fruits, dried seeds, beer, candied fruits, caramel, sugared almonds, salad dressings, sauerkraut and cauliflower salad, dried cod, fruits and vegetables (frozen, packaged, lyophilized, dried, canned or "dietetic"), seafood, shellfish, shrimps, crabs, etc. (fresh, frozen, packaged, canned, bottled, lyophilized), fresh or dried mushrooms, gelatin, salad including tomatoes especially in restaurants, industrially made marmalades and fruit gelatin, dried cod, cocktail mixture, oysters, spinach pasta, potatoes (raw, peeled whole or cut into slices, frozen, packaged, lyophilized or canned), pectin, fresh fish in general, pie and pizza dough, bakery products, pie fillings (with fruit), common and table salt, gravies, sauces, cider, pickles and relishes based on vegetables, fruit juices, puree and toppings, instant tea, wine, natural and powder sugar, cotton candy, lyophilized and ready-made soups, wine-vinegar; see Table 10.5

Data from [58, 63, 67].

[a] Can be washed off and allowed.

Table 10.5. Common foods that contain or may contain sulfites

Foods	Parts/10^6
Beer	≤10
Canned avocado	
Canned cod	≤10
Canned or dry soups	10
Canned potatoes	≤10
Cider	
Citrus drinks	
Clams, canned and jarred	
Coconut	5
Crackers	≤10
Crawfish	
Dehydrated soup mix	≤10
Dehydrated vegetables	
Domestic jams and jellies	5
Dried fruit (excluding dark raisins, prunes)	1.000–1.200
Dried potatoes	50–99.9
Fresh fruit salad (all types)	≤10
Fresh mushrooms	10–49.9
Frozen potatoes	10–49.9
Fruit juices (not frozen)	≥100
Glucose, syrup and solid	
Grape juice	85
Grapes	1–5
Gravies, sauces	75
Gravies, sauces (canned or dried)	50–99.9
Instant tea	5–10
Lemon juice (nonfrozen)	800
Lime juice (nonfrozen)	100
Molasses	100–150
Malt vinegar	10
Maraschino cherries	50
Mashed potatoes (commercial)	
Pectin	<10–50
Pickled cocktail onions	10–49.9
Pickled peppers	10–49.9
Pickles, relishes	20
Pie dough	7
Pizza dough (frozen)	≤10–20
Salad dressings (restaurants)	
Sauerkraut	10–49.9
Sausage meats	
Shrimp (fresh) and other seafood	10–49.9
Vegetables (fresh, frozen, dried, canned, etc.)	5–30
Wine	100–150
Wine vinegar	50–99.9

Data from [75, 78, 99].

spectively by less or more frequent reactions, and minerals:

Natural: E100, E101, E120, E121, E140, E141, E153, E160–163.

Synthetic: E102–105, E110, E111, E122–127, E130–132, E142, E151, E152, E180, separated into nitrogen-containing (E102, E103, E105, E110, E111, E122–126, E151, E180) and non-nitrogen containing (all others).

- *Minerals*

Ca carbonate (E170), titanium dioxide (E171), Fe oxide and hydroxide (E172), Al (E171), Ag (E174), Au (E175), terra d'ombra (E181) have the unique role of improving the natural color of a foodstuff and of giving it a new color, examples: aperitifs, soft drinks, sweets, etc. Previously only permitted for cakes and ice creams, usually the law allows their use in the majority of products.

- *Preservatives*

Acidic acid (E260) and acetates (E261–263), ASA, ascorbic acid and derivatives (E300–304), benzoic acid (E210) and derivatives, Na benzoate (E211), K benzoate (E212, 213), esters of parahydroxybenzoic acid (parabens) (from E214 to E219), phytic acid, lactic acid (E217), propionic acid (E280) and propionates (E281–282), sorbic acid (E200) and sorbates (E201–205), carbon dioxide (E290), nitrites and nitrates (E249–252), Na nitrite (E250), bromated sesame oil, S dioxide, sulfites and derivatives: sulfurous anhydride (E220), Na sulfite (E221), Na hydrogensulfite (E222), Na disulfite (E223), K disulfite (E224), Ca sulfite (E226), K hydrogensulfite (E227), diphenyl (E230), orthophenol (E231) are used to retard oxidation and spoilage, that is to prevent the oxidative decoloration of fresh and preserved foodstuffs, preventing their deterioration and prolonging the period of preservation. Furthermore, they are used as antimicrobials to disinfect food containers, in as much as they impede or delay the growth of microorganisms. Examples are shown in Table 10.4. Recently the use of E220 and of sulfate in general was extended to foodstuffs in which it was previously forbidden, for example in sausages and salami, and the doses of E249–252 in prepared meats and salami was increased.

Table 10.6. Main hidden forms of thickening, gelling, stabilizing, emulsifying additives

Thickening, gelling, stabilizing additives
Adragant and arabic gums
Agar
Carob seed and guar flour
Carrageenans
Fruit pectins (also modified)
Natural and modified starch
Orthophosphates
Phosphates and polyphosphates
Propylenglycol, alginate
Emulsifying additives
Lactilates
Lecithin
Mono/diglyceride esters of fatty acids
Salts of food fatty acids
Stearoyl
Tartrate

Modified from [28].

- *Sweeteners*

Aspartates, dextrose, fructose, glucose, saccharin, saccharose, sorbitol, and inverted sugars are frequently used substances, some of which are free of nutritional qualities as substitutes for common sugar (saccharose) in various cakes.

- *Emulsifying agents*

Glycerin (E422), lecithins (E322), salts of food fatty acids (E470) make it possible to obtain or maintain for a period of time the uniform dispersion of two phases which cannot normally be mixed such as a fatty substance with an aqueous solution (typical characteristic of emulsifiers). Examples include ice creams, margarines, cooked ham, etc.

- *Flavor enhancers*

Citric acid (E330) is used more as an acidifier, monosodium glutamate (E621) to enhance or improve the flavor and fragrance of foodstuffs, although free of aroma. Examples are given in Table 10.4.

- *Gelling agents*

Agar-agar (E406), carob seeds, locust gum (E410), guar gum (E412), adragant gum (E413), arabic gum, acacia gum (E414), vegetable gums, pectins (E440) are used to confer the consistency of a gel, for example in puddings, canned meats, deserts, jellies, brawn, chewing gum, above all sweet products in which they can constitute 40%–50% of the product, for example sweets or jams, where gelatins and pectins allow a reduction in the quantity of sugars.

Table 10.7. Classification of different additives

Acidifiers
Acidity correctors
Antiagglomerants
Antifoaming agents
Antioxidants
Colorings
Covering agents
Emulsifiers
Flavor enhancers
Flour additives
Fusion salts
Gelling agents
Leavening powders
Modified starch
Preservatives
Stabilizers
Texturing agents
Thickeners
Classification of food products based on additive content
Foods that may contain all additives permitted by law
Foods that may contain only some additives
Foods that should contain no additive: 1. Butter, CM, cream, daily products obtained by living ferments, such as yogurt 2. Honey, nonemulsifying oils and fats of animal or vegetable origin 3. Raw, nonprocessed foods, with exceptions including fresh fish, fruits, vegetables, fresh and chopped meat 4. Dried pasta, sugar 5. Tea and coffee (not instant and aromatized) 6. Mineral water

Source: European Community.

- *Nutrients*

Vitamins A and D, vitamins of the B group (thiamine, niacin, riboflavin), ascorbic acid, Fe, and K iodide are generally added to balance a lack induced by medical treatments.

- *Melting salts*

Na citrate (E331) is used in foodstuff preparation, for examples in cream cheese.

- *Flour food additives*

They are maturing and ripening agents, to whiten flour for bread and complete its maturing process.

- *Rising agents*

Tartaric acid (E334) and $NaHCO_3$ determine the rising of baked goods (except bread).

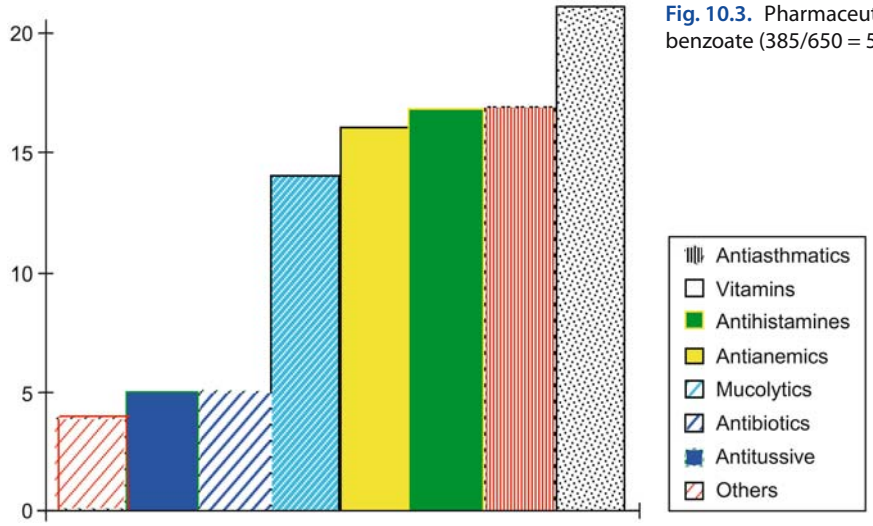

Fig. 10.3. Pharmaceutical preparations containing Na benzoate (385/650 = 59.2%). (Modified from [61])

- *Surfactants*

Methylcellulose, mono- and di-glycerides, and Na phosphate are added to fluids in small quantities to reduce the surface tension, modifying the foaming or wetting qualities.

Regarding colorings, the more restrictive countries seem to be Bulgaria, Russia, Taiwan and Hungary. However, food additives are often used by industries without the necessary guarantees. In one study conducted in Great Britain it was found that 19% of drugs analyzed contain different food additives, 12% of which were colorings and preservatives [68]. In the United States, a wide-spectrum study was conducted on 102 different medicines, sold with or without prescription, including analgesics-antipyretics, antihistamines-decongestants, cough and cold medications, antidiarrheal and theophylline syrups. Although 90% of drug instruction leaflets indicated the presence of food additives, the type was not specified in 35.3% of aroma enhancers, in 24.5% of preservatives, in 10.8% of colorings and in 2% of sweeteners [46]. Such additives, although declared, can be involved in many cases with adverse, pseudoallergic and anaphylactic reactions [61, 68] to fluorescin, sunset yellow, and tartrazine [46], which are also widely used in pharmaceutical products for oral use (Fig. 10.3) [61] (see Chap. 19). Since the triggering dose of Na benzoate is 100–200 mg and the average content of oral drugs examined is 1–2 mg/ml, one can deduce that the use of these drugs should be avoided, at least in asthmatics [61].

Pathogenesis

The mechanism of action of food additives seems to be pharmacological in nature; however, the frequent involvement of histamine would lead to believe that non-IgE-mediated immunoallergic mechanisms are also involved. In patients with symptoms of positive challenge to E102, the levels of histaminemia, methylhistaminuria and urine PGE2 and TXB2 were elevated [60]. Therefore, it cannot be excluded that, like haptens, food additives bind to biological proteins to become allergens and provoke type I, III and IV reactions [100, 101] (Fig. 10.2), as recently observed in an IgE-mediated allergy case [42]. It is, however, very likely that the mechanisms responsible are multiple, including the following which derive from various studies [27, 65, 74]:

- Inhibition of cyclooxygenase, with consequent inhibition of prostaglandin synthesis and unbalancing of the arachidonic acid metabolism toward the production of leukotrienes
- Activation of mast cells and basophils with release of histamine and other mediators, demonstrated in vivo at the gastric level following oral challenge with Na benzoate [74]
- Cellular anoxia determining the inhibition of protective enzymatic activity with a consequent increase in mucosal permeability, which in turn facilitates the passage of allergens
- Alteration of neuronal membrane permeability with interference in their conduction
- Variation in neuropeptide levels [65]

The pathogenic role carried out by ASA [68] is paradigmatic, to which the following actions are related:

- *Virtual inhibition* of cyclooxygenase pathway with a consequent block in the synthesis of prostaglandins (especially PGE), prostacyclins and thromboxanes. This results in the arachidonic acid pathway derailment toward the production of leukotrienes.
- *Direct histamine release* activating mast cells and basophils.
- *Release of substance P* (SP), which orchestrates the vicious circle involving histamine with consequent
- *Release of neuropeptides* by histamine with an increase in serum levels, from which is derived a new impulse to maintain and perpetuate the reaction [7].

Another mechanism involves sulfites, which when orally ingested can determine asthmatic attacks: in the stomach they are transformed into disulfites and sulfurous acids H_2SO_3, which, when they are dehydrated to SO_2, pass from the circulation to the airways [36, 64]. Other pathways include inhalatory, solicited by opening packets of dried fruit or with bronchodilatory aerosols, subcutaneous (adrenaline), and intravenous (corticosteroids) [15]. The pathogenesis is thought to originate from the action of SO_2 on tracheobronchial receptors, which induces a cholinergic reflex, or from the partial deficit of the sulfite-oxidase enzyme, which converts SO_3 into SO_4 [95]. As far as E621 is concerned, glutamic acid is the precursor for the synthesis of acetylcholine, whose level abruptly rises following ingestion of foodstuffs that contain high concentrations, therefore a reduced metabolism of E621 is hypothesized, probably due to a lack of vitamin B_{12} [66]. If this deficit is confirmed, it would be necessary to consider the possible oxidation action of the vitamin, capable of blocking the sulfite-induced bronchospasm in four out of five asthmatic children [4]. Many points relative to PA to food additives require further clarification: for example tartrazine sets off asthmatic crises in 10%–40% of patients with ASA-induced asthma, not inhibiting, as far as can be seen, the cyclooxygenase [58] for which the cross-reactivity with ASA remains difficult to evaluate. Various mechanisms have been highlighted that define a possible role of this food additive as a hapten, which is antigenically efficient following binding to a suitable vector such as a host protein in the presence of a catalyst, whose absence would result in an unstable bond [90].

Clinical Features

Food additives can provoke adverse reactions, or aggravate preexisting illness [64, 65, 67, 89]: anaphylaxis, asthma, chronic or recurrent urticaria-angioedema, perennial rhinitis, behavior disorders such as childhood hyperactivity, Chinese restaurant syndrome and various others highlighted in Tables 10.8 and 10.9 [46]. We stress that 80% of parents blamed food additives and preservatives for the behavior disorders of their children [1].

Sulfites, in particular Na metadisulfite (Table 10.5), used for fresh and preserved foodstuffs, apart from asthma can cause facial erythema, cyanosis, urticaria and/or angioedema, laryngeal edema, lipothymia and potentially fatal anaphylactic shock, especially in asthmatics [66, 99].

Monosodium glutamate, widely used to enhance Chinese and other foodstuffs, at a dose of 3–6 g provokes the Chinese restaurant syndrome, with the features of acute acetylcholine intoxication [66]: severe pulsating migraine, heat flushes, sweating, hypotension, or asthma with alterations in pulmonary functions [94] (≤3 g are sufficient to produce symptoms in sensitive individuals [31].

Table 10.8. Adverse reactions to colorings

Colorings	Adverse reactions
Brilliant blue (E131)	Weak bronchoconstriction
Carmine E120	Allergic cheilitis, asthma
Eosin	Potent photosensitizer
Erythrosine (E127)	Potent photosensitizer
Fluorescin	Urticaria-angioedema, syncope, anaphylactic shock
Ponceau red (E124)	Bronchoconstriction
Quinoline yellow (E104)	Contact dermatitis
Sunset yellow (E110)	Anaphylactoid reactions, anaphylactic shock, retching and vomiting, belching, abdominal pain, angioedema, vasculitis, purpura, cross-reactivity with ASA, sodium benzoate, acetaminophen, and other azo dyes
Tartrazine (E102)	Anaphylactoid reactions, urticaria-angioedema, asthma, contact dermatitis, rhinitis, hyperkinesia in hyperactive patients, eosinophilia, cross-reactivity with ASA, sodium benzoate and indomethacin

Modified from [46].

Table 10.9. Adverse reactions to sweeteners

Sweetener	Adverse reactions
Aspartame	Cross-reactivity with sulfonamides, granulomatous panniculitis, renal tubular acidosis (with large amounts), urticaria-angioedema
Lactose	Diarrhea and malabsorption in lactose-intolerant children, flatulence, vomiting (see also the text)
Saccharin	Cross-reactivity with sulfonamides, diarrhea, gait disturbances, nausea, papular skin eruptions, pruritus, urticaria, wheezing
Sorbitol	Abdominal pain, flatulence, osmotic diarrhea, poor absorption of active drugs
Sucrose	Cariogenicity, increased degradation of active drugs

Modified from [46].

Aspartame (composed of L-aspartic acid and L9-phenylalanine), 180 times sweeter than sugar, used in multivitamin tablets, fruit syrups, fizzy drinks and iced tea, can induce urticaria, gastrointestinal symptoms and

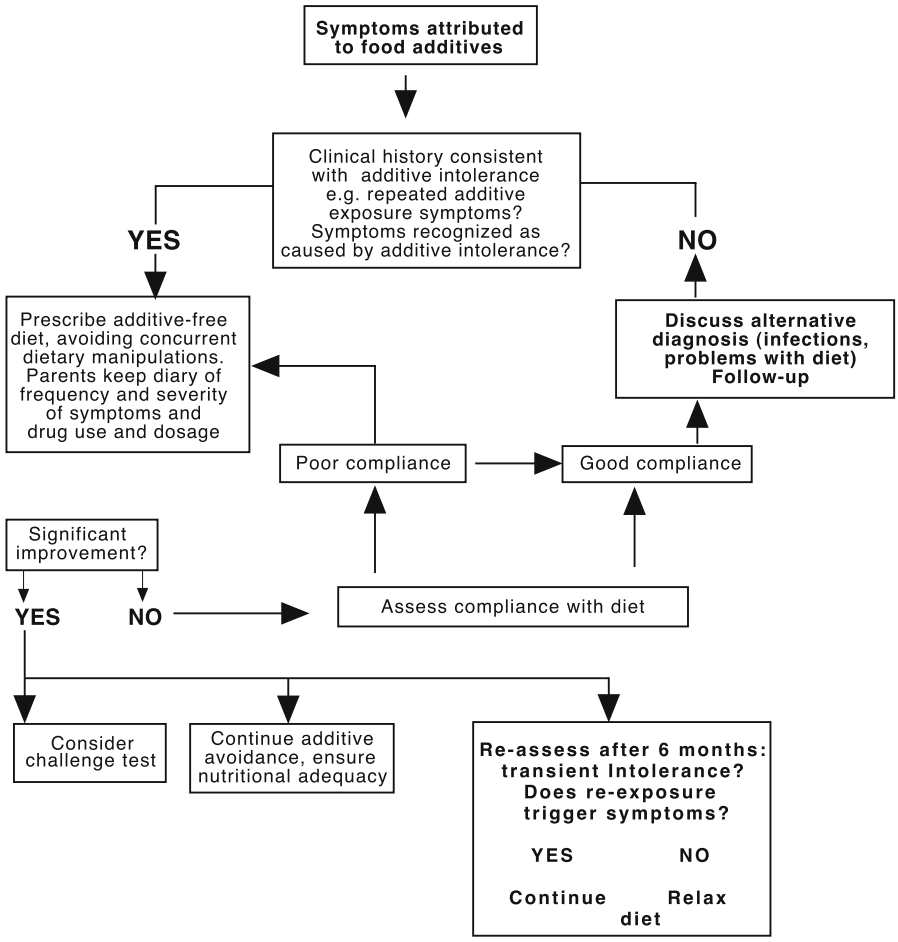

Fig. 10.4. Suggested algorithm of diagnosis and management of suspected food additive intolerance. (Modified from [68])

headaches. However, it does not have side effects as mentioned, neither regarding behavior nor intellectual activity [98] (Chap. 16).

Benzoates (Table 10.4), present as preservatives in commonly used foodstuffs as well as in natural foodstuffs such as many fruits, are responsible for 11%–15% of recurrent chronic urticaria cases [94]. Following challenge, increases in histamine levels in the gastric mucosa have been found [50].

The symptoms induced by *ASA* include shock, asthma-rhinitis and urticaria-angioedema syndrome. Based on pertinent reports, ASA can rightly be considered an important marker for food additive PA.

Gelatins and so-called fruit gums that contain gelatins (Appendix 10.1) [91, 106] also give cross-reactions with IgE-mediated mechanisms, causing symptoms that range from urticaria [91] to anaphylactic shock (Appendix 9.10).

Diagnosis

The diagnosis of PA to foodstuffs and additives is complicated by the great number of incriminated substances and their pathogenic mechanisms; varying the latter from one compound to the next does not favor the availability of a diagnostic test, rendering the certain identification of responsible agents somewhat laborious. Our advice is to act first by exclusion for a possible FA diagnosis.

The first step is composed as always of establishing an accurate personal and family history of atopy (FHA) (Fig. 10.4) [68] based initially on epidemiological data in ≈3- to 8-year-old children who are involved with AD, including symptoms induced by histamine such as urticaria-angioedema, AD exacerbations or sporadic cases of asthma or rhinitis [54]. The history taking will then be focused on highlighting factors that favor digestive alterations such as the use of drugs, dietetic products, laxatives, digestives, irritants, yeasts or a possible infection or infestation.

The compilation of a detailed qualitative and quantitative food diary will enable orientation regarding food habits and preferences for determinate foodstuffs or drinks. It is good practice to advise parents to record the quantity consumed also and above all *when not at home,* noting in detail all foodstuffs eaten with relative amount, the composition, the date of preparation and/or expiry of all prepackaged products, specifying whether boxed, frozen, etc. The responsibility of the

physician is ascertaining whether there has been a high ingestion of foodstuff rich in histamine or agents which release it [10]: if a group of foodstuffs or a single food is suspected, it will be a useful strategy to keep the packaging labels [90].

Specific in vivo or in vitro tests do not exist for PA to foodstuffs or additives; if skin prick tests (SPTs) are positive [52], the diagnosis of a possible FA will follow, if negative, or if clear results for the diagnosis are not obtained (as often happens), an elimination diet rigorously free of food additives and drugs (see "Treatment") will be carried out for 2–4 weeks, or an oligoantigenic diet (Table 9.14], or one followed by a FPT (if necessary double-blinded), also using the food additives presently available, carefully taking into consideration any potential masking [96]. It is good practice to eliminate all food additives and other drugs as indicated [54] (Chap. 6). However, the possible improvement obtained with a restricted diet remains limited, on the clinical side, since it is impossible to establish which eliminated substance causes the hypersensitivity; therefore in children showing improvement, it is necessary to proceed with a follow-up FPT [90]. Since it is difficult to obtain information regarding the upstream pathogenic mechanism, even when these tests allow a cause–effect relationship to be established, the pediatrician must evaluate the opportunity of advising such a test [14].

In particular, in patients aged 3–18 years, free of symptoms, the FPT is performed using a single substance at a time based on the weight of the patient [67]. Some authors administer nonincreasing [41] single doses [27, 80], except for E102 [80]. The doses used in children of 3.3–14 years [27, 80] are 0.1 mg for E110, E122, E123, E132 and 0.1, 0.5, 1 mg for E102, 100 mg for E211, E621 and ASA and 10 mg for E223 [80], or 5–10 mg for E102, E110, E127, E160b, 50–100 mg for E211 and ASA and 20–40 mg for aspartame, with a larger dose used in children weighing ≥20 kg [27], without exceeding 50 mg for E102, 200 mg for sulfites and 5 g for E621 [78]; others use different dosages [21, 41, 78, 94, 96]. In children aged 1.4–14.4 the initial dose was 50 mg of orally administered ASA and subsequent doses were administered at hourly intervals. The maximal cumulative dose was 10 mg/kg b/w [44]. Each substance is given as a gelatin capsule (provided the child is not sensitive), or dissolved in 20 ml of water for the younger children who are unable to swallow the capsule [27]. In asthmatic patients it is necessary to begin with reduced (1/10) doses and spirometric tests are performed at the beginning and then every 30 min until the end. At the first manifestation of reaction, the test is terminated and considered positive. It is necessary to monitor vital signs and check if no clinical signs of a reaction appear [44]. The patient remains under control up to 6 h from the last administered dose to record any possible late reaction [67]. Commercial preparations are available with doses of 5 mg for E102, E127, E160b and E223, 50 mg for E211 and E218 and 100 mg for E621 [40, 101]. Attention must be paid however to the behavior of the parents, some of whom refuse to accept the FPT negative response and continue an elimination diet for their children [25, 68]. A further point to consider is the frequent FPT negativity following a positive result [68]: the possible conclusion is that some transitory reactions are not evidenced, following a delayed FPT response, and can remain underdiagnosed [49]. It has already been reported that late reactions may present only after 24 h, 48–72 h or more.

The most frequent differential diagnosis is with IgE-mediated allergy; PA characteristics are:

- Dose dependency
- SPT negativity
- In vitro test negativity
- Prausnitz-Küstner test negativity (lack of transferability)
- Possible onset of symptoms at first contact with the causal agent [12]: in this case the common allergy tests are sufficiently reliable only when the symptoms are manifested shortly following the ingestion even of small quantities of food additives or of the foodstuff containing them.

Taking into consideration Tables 10.3 to 10.6 it is necessary to differentiate both other food additives as well as numerous gastrointestinal diseases mimicking food intolerance [48].

Treatment

First, the responsible foodstuff or additive and the drugs containing the incriminated additives must be eliminated from the diet (Fig. 10.4). The lack of rigorous diagnosis often renders the diets in these children difficult to follow, above all when the foodstuffs to be excluded are numerous and/or normal constituents of the childs diet. In the younger child, the Achilles' tendon of elimination diets are day-care centers, which cannot always ensure attentive cooperation. In PA to food additives (Table 10.10) [68], we prescribe the diet listed in Table 10.11 [41, 58, 67, 75], specifically free of food additives, to be rigorously followed for a minimum period of 6 months, also excluding drugs containing food additives. Since families have often pointed out the practical impossibility of excluding so many foodstuffs, we add the alternative advice of only using fresh foodstuffs and meals prepared at home and not industrially. Depending the case, elimination diets will be established based on the data in Tables 10.3, 10.4 and 10.10 (food additives), 10.4 and 10.5 (sulfites), 10.6 (thickeners, etc.) and 10.11 (tartrazine, azo dyes, and monosodium gluconate). With correctly predisposed diets that favor the collaboration of the young patient, matchless results are obtained for urticaria, so that after some months the child's diet can be liberalized without inducing acute reactions [43], with positive results varying from 53 % to 89 % of cases [43, 52], even in hyperactivi-

Table 10.10. Suggestions for an additive-free diet (see Table 10.4)

Prefer fresh foods. Check thoroughly the label on the packet of frozen fruits and vegetables. In case of doubt, it is best to avoid these foods.	
Always check the additives listed on the food label.	
Avoid brightly colored soft drinks, sweets, cakes and instant convenience foods.	
Avoid all foods with a label stating "permitted coloring and preservatives" without any specification.	
Avoid non-food products with coloring and preservatives, such as colored toothpaste, throat pastilles and colored lozenges and medicines.	
Whenever possible, avoid the following additives or groups of additives:	
E100–119	Colors
E200–299	Preservatives
E300–321	Antioxidants
E322–494	Emulsifiers and stabilizers
E621	Flavor enhancers
E905–907	Mineral hydrocarbons
Check the diet's nutritional adequacy.	

Modified from [68].

Table 10.11. Foods to be eliminated for a diet without tartrazine, azo dyes, and monosodium glutamate (unless homemade)

Foods that may contain tartrazine
Alcoholic beverages
Cake mixes and icings
Candies, especially orange, butterscotch, lemon, or lime flavored
Canned vegetables
Caramel and vanilla custard
Catsup
Cheese
Cheese-flavored crackers and snack foods
Chewing gum
Concentrated fruit juices
Filled chocolate unless pure chocolate
Fizzy lemonade (except plain lemonade)
Frankfurters
Fruit drinks
Fruit yoghurt
Gelatins
Hot dogs
Ice creams and sherbets
Imitation flavorings and extracts
Jams, marmalades
Jellies
Lemonade
Macaroni and cheese: canned, dry packaged, or frozen
Meat tenderizer
Medications
Orange drinks
Penny candies, caramels and chews, fruit drops
Pickles and relishes
Pie fillings
Puddings and pie fillings
Salad dressings
Seasoning salt
Soft drinks
Stewed fruit sauces, fruit gelatins
Vanilla, butterscotch, or chocolate puddings
Whips and dessert sauces, such as vanilla custard
Foods that may contain azo dyes (unless homemade)
Bakery foods except plain rolls, crackers, cheese puffs, potato chips
Cake and cookie/biscuit mixtures
Candied fruit
Canned anchovies, herrings, sardines, caviar, cleaned shellfish
Caviar and surrogates

Table 10.11. (Continued)

Foods that may contain azo dyes (unless homemade)	Foods that may contain monosodium glutamate
Chewing gum	Accent
Colored toothpaste	Ajinomoto powder
Confectionery cakes and creams	Bouillon cubes
Cream in powder form	Camembert and parmesan cheese
Herrings and sardines	Canned or frozen fish
Ice creams	Chinese restaurant food in general
Jams and marmalades	Fried chicken
Macaroni and vermicelli (certain brands)	Gravy
Mayonnaise, salad dressing/cream; sauces, including ketchup, mustard, ready-made sauces, including béarnaise, hollandaise, curry, fish, tomato, white onion, and parsley sauces	Herbs and spices
Mixtures for drinks	Low-calorie, low-fat diets
Nonalcoholic beverages	Meat and fish base
Packet and canned soups	Potato chips
Pickled and salted foods	Processed foods of all kinds: canned, dry packaged, and frozen
Puddings	Salad dressings
Purees except pure tomato puree	Sauces
Ready-made sauces	Seasoned salts
Red food coloring	Soups: canned and dry mix
Salad dressings	Soy sauce
Waffle and pancake mixes	Spices
Yellow food coloring	Tomatoes
	Tortilla chips
	Wonton soup

In addition, colored toothpaste, medications in lozenges, syrups, tablets.
Data from [41, 58, 67, 75].

ty syndrome (Chap. 16). However, the diet often is in vain because the food additives turn out to be present in many foodstuffs regularly consumed by children, while the label declares simply the presence of *"legally permitted colorings and preservatives,"* followed by a series of names and numbers that give no information to the common consumer, although colorings have been responsible for illness reported for some time [94], or the word "flavorings" is found without specifying *whether they are natural or artificial* [46]. Another imprecision has been introduced: "as necessary" refers to the ascorbic acid added to fresh and minced meat, but the use of ASA has no regulation. An even more serious point is the indication of the expiry date applied to easily decaying foodstuffs such as packaged milk-cheese products, which are therefore not naturally fresh: this simply means that the product is *enriched with food additives to ensure its use without immediate danger* (only for nonallergic individuals) by a given date, but with possible worsening of symptoms, as can be seen sometimes with CM products. We note that it is *not obligatory to mention the packaging date,* which should be necessary. Market research shows that many food-processing industries have complied with the obligation imposed by law [32] and therefore presently produce foodstuffs free of food additives, but in the pharmaceutical preparations a similar compliance is not always found [46, 68]. It is important to answer the fears of parents in a comprehensive and exhaustive way, who are often alarmed by nonscientific publications on the dangers of food additives, also to avoid that the child be unnecessarily subjected to a long series of laboratory examinations or even punitive diets that usually result in malnutrition [49]. We trust that the pertinent Ministry will intervene urgently, also highlighting the specific problem of nonfresh products, in order to protect the at-risk section of the pediatric population, following the example of the Swedish government that has prohibited the use of tartrazine [49].

As such data accumulate, it is likely that adverse reactions to food additives will rival or surpass the importance of adverse reactions to inhalants in clinical immunology and allergy [46].

Pharmacological Reactions

Pharmacological reactions are caused by chemical substances present in foodstuffs, naturally or as food additives, or locally synthesized in the intestine by microorganisms [56].

Pathogenetic Mechanisms

Histamine, one of the best-known and most active mediators of allergic reactions, and other vasoactive amines such as tyramine, dopamine, phenylethylamine, norepinephrine, and serotonin, present in high concentrations in certain commonly used foodstuffs, constitute the predominant substrate of food PA [100]. The amines, produced by bacterial decarboxylation, act directly or indirectly on the intestinal wall by releasing catecholamines; furthermore, they are synthesized by intestinal bacteria [66]. Mast cells in turn can release an abnormal quantity of chemical mediators by aspecific degranulation (non-IgE-mediated), in part due to the effect of substances called histamine releasers. Similarly, interactions between foodstuffs and the autonomous nervous system can take place [56]. Table 10.12 [20, 55, 56] summarizes the foodstuffs rich in histamine (and tyramine) and Table 10.13 some of the more common nonimmunological mast cell activators [21, 65]. Tyramine, a releaser of histamine from mast cells and basophils, has an exogenous origin (namely, foodstuffs) or is endogenously produced by the conversion of casein, serine, globulin into tyrosine, by means of pepsin and proteolytic intestinal enzymes, or it is produced by tyrosine-decarboxylase from intestinal bacteria. The basic oligopeptides and proteolytic enzymes act directly on mast cell membrane, whereas lectins cause degranulation by binding to the carbohydrates present on the Fc and activating specific IgE [66]. The type of diet can influence, either directly or indirectly, the intestinal content of histamine or of other biological amines. However, the fundamental pathogenic role is not only related to eating certain foodstuffs and therefore to the increase in intestinal levels (for example in fermented cheese, tinned fish, tuna, sausages, etc.), but also to the synthesis of excess histamine by the normal flora (for example of the colon) due to the abundant and repeated ingestion of foodstuffs rich in starch or cellulose [66]. A diet rich in carbohydrates indirectly increases intestinal levels, since the endoenteric bacterial degranulation, by eliciting irritating organic acids and gas, causes a disequilibrium in the intestinal flora. Foodstuffs rich in potato flour (potatoes, cakes, biscuits) favor histamine synthesis by fermentation [56, 90]. Some bacteria can trigger reactions similar to those that are IgE-mediated: for example *Proteus morgani* or *Klebsiella pneumoniae* possessing the enzyme histidine-decarboxylase of food or bacterial origin are able to produce histamine by decarboxylating histidine [82]. Normal levels are usually low; however, if these bacteria grow on foodstuffs rich in histidine, the production of histamine may be multiplied, for example when fish is contaminated with histamine-producing bacteria, especially when stored in the refrigerator [82]. With cheese, histamine is formed more slowly, an important requirement is the presence of histamine-producing bacteria [79].

Table 10.12. Main foods rich in histamine and/or tyramine of common use in children

Histamine-rich foods	Content in µg/g when known
1. Bouillon cubes	
2. Fermented cheese[a] (emmenthal, gorgonzola, Roquefort, parmesan, camembert, cheddar, gouda, brie, edam, etc.)	Up to 1330
3. Fermented drinks	20
4. Tinned foods	10–350
5. Vegetables	
Avocado	23
Eggplant	26
Pickled vegetables[a]	
Sauerkraut	160 mg/kg
Spinach[a]	30–60
Tomato (catsup)[a]	22
6. Meat	
Cured pork sausage	225
Meats	10
Pork liver	25
Salami, in general[a]	160–280
7. Fish especially when tinned or smoked	
Anchovy fillets[a]	44
Anchovy, fresh	
Herrings[a]	60
Mackerel[a]	
Salmon	7
Sardine[a]	16
Shellfish, fresh	0.2
Shrimps	
Tinned anchovy fillets[a]	33
Tinned smoke herring's eggs	350
Tinned tuna[a]	20
Tuna, fresh[a]	6

[a] Foods to be eliminated for a histamine-free diet [92].

Table 10.12. (Continued)

Tyramine-rich foods	Content in µg/g when known
1. Chocolate[b]	
2. Fermented cheese	
Boursalt	1116
Brie	0–200
Brick, natural	524
Camembert	20–2000
Cheddar	120–1500
Emmenthal	225–1000
Gouda	20
Gruyère	516
Parmesan	4–290
Provolone	38
Roquefort	27–520
Stilton blue	466–2170
3. Fresh cheese	
Cheese, white	Traces/none
Mozzarella	420
4. Vegetables	
Cabbage	
Cauliflower	
Eggplant	3
Fava bean	
Potato	1
Spinach	1
Tomato	4
5. Meat	
Beef liver (stored)	274
Chicken liver (stored)	100
Meat extracts	95–304
Ripened game	
Salami	
6. Fish	
Salted dried fish	0–470
Pickled herrings	3030
Caviar	
Tuna	
7. Fruit	
Avocado	23
Banana	7
Figs	
Grapes	
Orange	10
8. Miscellaneous	
Brewer's yeast	1500
Soy	1.75
Wine (red Chianti)	25

Data from [20, 55, 56].
[b] Chocolate contains methyltyramine.

Experimental studies in vivo, in healthy volunteers, either by instilling histamine directly into the intestinal lumen by the duodenojejunal tube, or before undergoing cholecystectomy, after instilling 1.75 mg/kg of histamine into the duodenum, resulted only in mild tachycardia and facial flush lasting <5 min. Repeating the test in patients with food PA, 60% noted pruritus, tachycardia, vasomotor migraine, etc., lasting for 10–30 min [57]. On the contrary, in healthy subjects, the ingestion of a large quantity of foodstuffs rich in histamine is not sufficient to evoke ill effects, given that histamine levels >50 g/100 g of food are necessary to elicit adverse reactions [85]. The susceptibility threshold can be reduced in certain patients, who thereby react to small amounts of mediator [105].

Under physiological conditions, several *protective mechanisms* exist in the liver and intestine, which restrain the passage of high concentrations of histamine into the circulation, thus explaining the low levels found in normal individuals (1 mg/ml) [55]. The first protective mechanisms are represented, in the intestine, by the mucins of the gastric juice with an elevated histamine-binding activity, by the glycoproteins of the glycocalyx and by bacteria capable of acting on the imidazole nucleus of histamine to split it; a second line of defense is due to the monoaminoxidase, diaminoxidase and methyltransferase enzymes, distributed throughout the gastrointestinal tract, which inactivate the histamine escaped from the first filter, and to histaminase present in lamina propria eosinophils; when necessary the hepatic filter comes into play whereby hepatic methyltransferase is activated; finally, the barrier formed by serum proteins with histamine-binding activity intervenes [55].

A second pathogenic mechanism could be represented by the local degranulation of intestinal mast cells, which are abundant in the lamina propria, due to the action of nonimmunological activators (Table 10.13) or to autochthonous instability, or finally to an increased threshold for the excitability of the histamine receptors.

Table 10.13. Main nonimmune activators of mast cells

Additives

Foods

1. High content of tyramine (see Table 10.12)
2. High content of histamine-releaser substances
   - Cabbage
   - Egg white
   - Fermented cheese
     - (gruyère, parmesan, camembert, etc.)
   - Fish (especially if canned or smoked)
   - Papaya and other exotic fruits
   - Peaches
   - Pineapple
   - Pork meat
   - Potato starch
   - Seafood in general
   - Shellfish
   - Strawberry
   - Tomato
   - Vegetables with high content of lecithin
     - Legumes (fava beans, lentils, peanuts, peas, etc.)
     - Nuts

Medications

1. Anesthetics, IV

   Antibiotics and chemotherapeutics
   - Chlortetracycline
   - Kinin
   - Neoarsphenamine
   - Neomycin
   - Polymyxin
   - Propamidine
   - Stilbamidine
2. Anti-inflammatory/antirheumatic
   - ASA?
   - NSAIDs?
3. Antihistamines
   - Chlorpheniramine
   - Cimetidine
   - Ranitidine
4. Substances acting on the circulatory system
   - Amphetamine
   - Antazoline
   - Apresoline
   - Atropine
   - Hydralazine
5. Blood derivatives and plasma equivalents
   - Dextran
   - Plasma expanders
6. Enzymes
   - Chymotrypsin
   - Phospholipase A and C
   - Trypsin
7. Iodinized contrast media
8. Muscle relaxants (tubocurarine and derivatives)
   Substances acting on the CNS
   - Apomorphine
   - Codeine[a]
   - Heroin
   - Morphine, etc.
9. Psychopharmaceuticals
10. Vitamins (thiamine)

Activators of the complement systems

Myelomatous proteins
Snake venom

Mucopolysaccharides

Neuropeptides

CGRP, NKA, SP

Animal and insect secretions

Chemical substances

A23187
Basic oligopeptides
Ca-ionophore
Compound 48/80[a]
Detergents
Disinfectants
Peptones

Physical stimuli

Physical exertion
Hypo- and hyperosmolarity
Sunlight
Pressure variations
Optic radiations
Temperature changes (warm, cold)

Venoms

Melittin

Additional substances

Organ extracts
Gammaglobulins
Vaccines

Data from [21, 65].
CGRP calcitonin gene-related peptide, *NKA* neurokinin A, *SP* substance P.
[a] Only at the skin level.

All these phenomena cannot be appreciated in the healthy individual, also because of the a lack of specific studies, and the notion that mast cells are particularly rich in histamine and ready for release brings us back to the previous mechanism. A possible interaction of intracytoplasmatic Mg has come under scrutiny, since a cellular Mg deficiency is observed in 45% of patients. In animals, the defect increased skin mast cell releasability [57]. However, it has been postulated that patients intolerant to histamine containing foodstuffs may have a diamino-oxidase deficit [92].

It is noted that in mast cells various substances can cause axonic reflexes through amyelinic fibers, thus releasing neuropeptides, including SP, capable of inducing histamine release from mast cells. This leads to an increase in epithelial permeability, in particular of the small subepithelial vessels, with increased passage of antigenic macromolecules. Histamine provokes a further SP release, closing the vicious circle orchestrated by neuropeptides and mediators: this mechanism, being also a characteristic of FA, is not specific to PA [55, 56].

Finally, food PA could be provoked by alterations in the regulation of histamine homeostasis dependent upon a deficit of defensive mechanisms; the possible causes can thus be derived from one or more of the following:

- Alterations in the intestinal mucosa, both histological and functional, that would allow an increase and anomalous passage of food macromolecules.
- Functional alterations of one or more of these mechanisms, in which a dysfunction of the monoaminoxidase or methyltransferase enzymes could be involved; a genetic-based anomaly of a mechanism underlying the predisposition to an increased and abnormal release of histamine, or to a hyperactivity to it [56].

As a consequence, each one of these dysfunctions creates the conditions by which, following the excessive introduction of specific categories of foodstuffs, a fertile ground for food PA is determined, with mechanisms which are at times direct, at times indirect. The intraluminal effects of histamine cause an increase in the absorption of histamine-releasing foodstuffs, with a consequent persistence of symptoms.

Clinical Presentation

Methylxanthines, including caffeine, and the vasoactive amines contained in more or less widespread foodstuffs (Table 10.12), above all histamine, which, being thermoresistant, can pass unharmed through the cooking process of the foodstuffs containing it [56, 90], can provoke migraine, palpitations, flush, urticaria, abdominal pains, etc. The methylxanthines, although possessing modest neurobehavioral effects, can stimulate the central nervous system and, by their effects, cause abdominal pains and temporary and/or continuous headaches [88]. Chocolate, which affects even breast-fed infants [81], in addition to tyramine, also contains phenylethylamine, which causes headache and theobromine with its theophylline-like effects. Therefore it must be immediately eliminated from the diet of migraine sufferers [21]. Triggering quantities of methylxanthine contained in common drinks and foodstuffs are summarized in Table 10.14 [35] and the effects of caffeine in Table 10.15 [24]: drinking too many cups of coffee can cause irritability, labeled as behavior disturbances [24]. Significant symptoms are also induced by tyramine: by an overload or an individual susceptibility, the pharmacodynamic properties are manifested in the form of vessel and smooth muscle fiber constriction, as well as release of histamine, provoking urticaria, abdominal cramps and vasomotor headaches [3]. Apart form the foodstuffs shown in Table 10.12, substances naturally contained therein, or derived from cooking or frying, have histamine-releasing activity: certain aliphatic aldehydes such as acrolein (produced from the decomposition of glycerin), formaldehyde, proteases such as bromelin and papain present in pineapple and papaya (cross-reactions), lecithins in legumes, cereals, nuts and peanuts [58].

Table 10.14. Significant amounts of methylxanthines contained in common foods/drinks

Food/drink	Amount	Equivalents (mg)	
		Of caffeine	Of theobromine
Cola can	350 ml	55	
Espresso coffee	75 ml	70[a]	
Cup of tea	200 ml	40[b]	
Chocolate bar	100 g		200

Modified from [35].

[a] Depends on whether it is a weak or black coffee.

[b] Depends on the time of infusion, after 20 min equals the caffeine content of a cup of coffee.

Table 10.15. Main effects of both coffee and caffeine

Increased vigilance to both simple visual and auditory stimuli
Decreased motor reaction time to both simple visual and auditory stimuli
Caffeine may slightly affect more complex tasks and fine motor coordination
Significant effects on the EEG spectrum and on visual and auditory evoked potentials
Coffee ingestion 30–60 min before going to bed often increases sleep latency, reduces total sleep time and significantly worsens subjective evaluations of sleep quality
Increase of stage 2 sleep and decrease of stages 3 and 4 sleep
The number of involuntary awakenings by a loud tone at stage 2 sleep is frequently increased after caffeine consumption
Pronounced effect on mood exercised by caffeine
Caffeine may lead to effects possibly misdiagnosed as an anxiety disorder

Data from [24].

A wide variety of symptoms can ensue systemic: shock, quite rare (>2% of cases); skin and mucosal: urticaria-angioedema syndrome (50% of cases), skin rashes; respiratory: asthma, rhinitis; gastrointestinal: dyspepsia, nausea, vomiting, diarrhea, abdominal pain; hyperactivity.

These disorders are usually observed in 3- to 8-year-old children, in particular when there is FHA+. Apart from typical histamine-dependent symptoms (urticaria-angioedema), there may also be exacerbations of an aphthous stomatitis or AD, in this case not due to FA. Since the eczematous skin is rich in mast cells (Chap. 7), histamine is released from this site in greater amounts than elsewhere and consequently itching will induce the child to scratch, thus aggravating the lesions. If histamine effects are not too pronounced, the child, once healed of the AD, will be able to eat the pertinent foods without provoking any cutaneous reactions. Instead the older child (>8 years) becomes progressively less sensitive to histamine, therefore incriminating foods can be ingested in normal amounts without causing adverse reactions. The patient will, however, maintain the (false) notion of being allergic to some foods that, if tested appropriately, will turn out to be negative [55]. Although adolescents and young adults who are monosensitized to pollens complained of urticaria, abdominal pains and itching in 20%–30% of cases, the symptoms were confirmed upon challenge in 5%, 2.5% and 0% of cases, respectively [9].

Diagnosis

Diagnosis is difficult because of the several foodstuffs rich in histamine, tyrosine, histamine releasers, frequently contained in snacks, orange drinks, ice creams, fish sticks, salamis, tinned foods, etc.

Treatment

Diets free of histamine and/or tyramine can be prepared according to Table 10.12; if the diet is followed regularly, the positive results are more frequent in children than in adults [68].

Enzymatic Reactions

Enzymatic reactions can also reproduce FA after ingesting particular foodstuffs [38]. They are typically seen in individuals with congenital or secondary enzyme deficits [3, 35, 53]. The most common is primary lactase deficiency, frequently seen in Afro-Asian children, while European children can develop a secondary deficit [40]. Apart from this deficit, all other congenital errors of metabolism are rare in this field [23]:

Table 10.16. Types of lactase deficiency

Types	Characteristics
Congenital	Present from birth, probably autosomal recessive, very rare
Acquired, late onset	Hypolactasia of various degrees, autosomal recessive, manifested in adolescents or young adults, marked racial predilection
Secondary	Transient hypolactasia secondary to small intestinal disease: celiac disease, malnutrition, immune defects, inflammatory disease, enteritis, etc.

Modified from [6].

- *Lactase,* an enzyme necessary for the metabolism of lactose found in CM, the only carbohydrate present in mammals' milk and absent in all other foodstuffs, *lactase deficiency* is rare in its congenital form, transient in premature neonates and more frequent as an acquired form in adulthood [13, 72] (Table 10.16) [6]. In infants it can result in gastrointestinal symptoms such as meteorism, flatulence, cramps and diarrhea, mistakenly attributed to FA in carriers of a *transient deficit* of the enzyme caused by an acute episode of infectious diarrhea [14], or in individuals with low levels of lactase (from the 3rd year of life to puberty), who present overlapping symptoms following the ingestion of modest quantities of lactose [3]. Diarrhea can occur in individuals lacking lactase or saccharase who abuse so-called dietetic foods [50]. By anticipating breast feeding of the premature child to the 4th day of life increases lactase [76]. The lactose breath H test may help to differentiate between symptoms caused by CMA and a lactase deficiency [35].
- The neonate affected by *galactosemia* may present vomiting and diarrhea from CM: early diagnosis is imperative [31].
- In breast-fed babies with *phenylketonuria,* occasional vomiting and irritability may be observed following meals [31].
- Malabsorption of carbohydrates can be identified by clinical symptoms such as watery diarrhea, abdominal distension, cramping pains and excessive flatulence because of the increased osmotic charge of the unabsorbed carbohydrates and gas production from colonic bacteria. Distension of the colon therefore ensues, with a consequent increase in motility and reduction of the transit time, a pattern often observed in *irritable bowel syndrome* [23]. Similar symptoms can be provoked by formulas enriched with modified starch [47].
- *Malabsorption of saccharose-isomaltose* and of glucose-galactose, both objectively rare, can also result in the outline of symptoms characteristic of disaccharidase deficiency [23, 48].

Table 10.17. Malabsorption presenting as food intolerance

Malabsorbed carbohydrate	Foods containing the malabsorbed carbohydrate	Clinical manifestations
Lactose	CM and dairy products	Lactase deficiency
Fructose	Fruits, soft drinks, berries	Malabsorption
Sorbitol	Peach, apple, pear, plum, diet foods, sugarless gum	Malabsorption

Modified from [48].
CM cow's milk.

- Comparable symptoms are also provoked by deficits in the metabolism of *fructose* and *sorbitol* (Table 10.17) [48].
- The increased use of both sugars as artificial sweeteners in infant formulas [47], packaged foodstuffs, especially low-calorie foods [22], and drinks and fruit juices [39] has multiplied the cases of intolerance and malabsorption.

Metabolic Reactions

Metabolic reactions are prevalently reactions in hypersensitive individuals; however, normal individuals who consume or chew excessive quantities of a given food or vegetable are also at risk [53]. On the other hand, food metabolic reactions are also observed after the ingestion of completely normal quantities of habitual, harmless foodstuffs in individuals who become sensitive following drug intake (monoamino-oxidase inhibitors, isoniazid) [31], to malnutrition, aspecific intolerance, or congenital enzyme deficits, as mentioned in the previous section [35]. In contrast, symptoms can manifest in well-circumscribed territories and in certain cases also in the general population [35]:

- *Avidin,* a vitamin agonist contained in raw egg white, can cause a dermatitis in individuals lacking biotin, but also a normal and balanced diet can sensitize these individuals [35] and the reactions can be mistakenly diagnosed as allergic.
- The presence of *amines* following an excessive ingestion of bananas, green tomatoes, avocados, or pineapple can cause sporadic headache and hypertension, while cheeses and chocolate can have a more serious effect [54].
- In areas with an endemic *lack of iodine* (I) the excessive ingestion of cabbage, turnips, radishes and mustard, containing goitre-producing substances (thiocyanates, goitrin, β-5vinylthiooxazolidone) can cause thyroid hypertrophy [37].
- *Elementary diets,* especially if rich in methionine, isoleucine or threonine, can cause nausea and/or headache [31].
- *Tryptophan,* an essential amino acid naturally present in many foodstuffs and a vasoactive mediator of serotonin, if taken in large doses as a therapy for insomnia, premenstrual pain, depression or weight loss, causes a syndrome which in an early phase presents myalgia, arthralgia, edema and eosinophilia of more than 1000 cells/ml and in the chronic phase scleroderma-like cutaneous involvement, peripheral neuropathy and diffused paresthesia [8, 77].
- Eating *spinach and carrots* and other vegetables, or drinking water and cured meats, in which nitrites are formed by the action of nitrate-reductase caused by high-nitrate-content fertilizers, long life at room temperature, especially if cut, may cause methemoglobinemia, as well as cyanosis. For higher levels anemic anoxia is seen [86].

Among the more metabolic aspects, serious effects on behavior (aggression, hyperkinesia, also severely antisocial behavior) and on the intelligence of children have been attributed to an excessive intake of carbohydrates [51], suggesting the existence of a possible allergy to sugar [51]. On one hand, studies conducted according to the DBPC methodology have cast doubts on the existence of such disorders [98] (Chap. 16); on the other hand, it has been demonstrated that these postulated effects of carbohydrates can be balanced by a normal diet of proteins [58]. Similarly, it has not been confirmed that hypoglycemia may cause states of delinquency [5].

Toxic Reactions

Toxic reactions (see "Immunotoxicology") are defined as such if recognized as harmful universally or limited to certain genetically predisposed individuals, but also healthy individuals, *especially children* [38], who present a particular intolerance. These reactions recognize an extraimmunological pathogenesis since the release of mediators is caused by a direct action on mast cells. They depend on natural toxic substances or contaminants (bacterial and chemical) present in foodstuffs and are classified into [53]:

- Natural substances distinguished into naturally produced endogenous substances and exogenous substances deriving from the earth, water, microorganisms, etc.
- Contaminants of foodstuffs, or otherwise toxic or infectious agents, or industrial agents (see "Immunotoxicology").

Toxic Endogenous Substances [35, 37]

- *Amanita phalloides*, whose ingestion, even in tiny quantities, causes potentially lethal effects.
- Digitalis (*Digitalis purpurea*), a plant with leaves and seeds with well-known effects.
- The ingestion of calderine grass (*Senecia vulgaris*) and of the heliotrope (*Heliotropium*) in fields and uncultivated earth, rich in pyrrolidine alkaloids (dihydropyrrols): indirect exposure derives from honey when bees collect pollen from such plants or the milk of cows that graze on toxic weeds, or for an involuntary substitution of herbs for infusions with *Senecio longilobus*; the target is the respiratory apparatus [86].
- Fruits and leaves of the *wild apple tree* (*Datura stramonium*) causing hallucinations [53].
- The ingestion of *rhubarb leaves* (rather than the stems) causes a serious corrosive gastritis due to high oxalates and glycoside content [26].
- *Peas and parsley* contain photosensitizing psoralens and nutmeg and carrots contain myristicin, which are perhaps hallucinogenic [21].
- We point out for tourists under 15 years of age that there is a possibility of an intoxication (toxic hypoglycemic syndrome) caused by the ingestion of unripe fruits of the widespread *akee tree, Blighia sapida*, in Jamaica and western Africa. The fruits contain hypoglycin A, a hepatic toxin with hypoglycemic activity and an inhibitor of hepatic gluconeogenesis, and with an effect that limits cofactors for the oxidation of long-chain fatty acids. Symptoms consist of hypoglycemia, profuse vomiting, convulsions and coma with an occasionally fatal outcome.
- Children's hand-to-mouth behavior can turn out to be negative only if they suck or chew even tiny amounts of *leaves, fruits or berries* present at home, in the garden or in the countryside, such as holly, azaleas, hawthorn, eucalyptus, ficus, lily of the valley, oleander, hydrangea, poppy, potus, and rhododendron, with clinical characteristics (diarrhea, vomiting, edema of the glottis, hypotension, arrhythmias, apnea, convulsions, coma, etc.) that require *clinical observation.* Other rarely toxic plants include cyclamen, ivy, philodendron, geranium, mimosa, Christmas star, tulip, mistletoe (but with analogous clinical manifestations and need for clinical observation) [11, 30]. Just touching several plants can cause itching, intense pain, localized or diffused dermatitis, while the ingestion of a yew berry can cause the child to die [11].

Furthermore, the general public ignores the duplicity of the foodstuff, harmless for some, poisonous for others [16]: that the very same natural foodstuffs contain toxins [26] or, if eaten daily, can become toxic if cooked in a different way, or also if abused [35, 37].

- Following ingestion of large quantities of cabbage, turnip and other vegetables of the same family, even when not living in regions lacking I, goitrogenic compounds are ingested, such as thioglycosides [37].
- Foodstuffs containing *cyanogenic glycosides* (lima beans, cassava roots, millet sprouts, the pits found

Table 10.18. Toxic substances present in vegetable foodstuffs

Substances	Chemical origin	Food sources	Main effects and symptoms
Agaritrin	4-hypoximethylphenylhydrazine der	*Agaricus bisporus*	Mutagenic effects
Alkaloids	N,N,-dimethyltryptamine	*Mucana pruriens*	Hallucinations
Cycasin	Methylazoxymethanol β-glycoside	*Cycas revoluta*	Carcinogenic
Favism factors	Pyrimidine-β-glycoside	*Vicia faba*	Hemolytic anemia in G6PD deficients
Furocoumarins	Benzofurans (psoralens)	Celery, citrus fruits, figs, parsley	Photosensitization
Gossypol pigments	Gossypol	Cotton seeds	Hepatic damage, hemorrhages
Hemoagglutinins	Proteins (MW 10,000–124,000 D)	Legumes	In vitro erythrocyte agglutination, reduced nutrient absorption
Protease inhibitors	Proteins (MW 4,000–24,000 D)	Cereals, legumes, potatoes	Inhibit protein utilization, pancreas hypertrophy, growth retardation
Lathyrogens	β-Aminopropionitrile, diamino-propionic acid derivative	Chickling (*Latyrus sativus*) (legumes)	Skeletal deformities, myalgias, paralysis of the lower limbs
Saponin	Glycosides	Asparagus, beans, peanuts, soy, spinach	Hemolysis

Data from [37].
der Derivative, *G6PD* glucose-6-phosphate dehydrogenase, *MW* molecular weight.

in some edible fruits such as apricot, cherry, bitter almond, apple, pear, peach, plum, perhaps also chick peas, maize, sweet potato, etc.), nontoxic *per se* but when, on contact with digestive enzymes and the β-glycosidase of the bacterial flora, they are metabolized and release cyanuric acid in the stomach in variable amounts, from 0.003% to 3.6% depending on origin. With *chronic ingestion,* cytochrome oxidation is inhibited with suppression of cell respiration, resulting in ataxic neuropathy, blindness and death. As far as fruit seeds are concerned, it is sufficient for a child to ingest two to five seeds to put his life at risk and ten bitter almonds to cause death [11, 30]. The toxic effects can be eliminated by thorough cooking, avoidance of eating large quantities, or cultivating varieties with lower content of these toxins [50].

Commonly eaten foods may be toxic if excessive quantities are consumed [35, 37]:

- *Green potatoes* have high concentrations of glycoalcaloids, including solanine, with an algicide part, considered very toxic (symptoms: headache, incoherence, hallucinations, vertigo) [95].
- Substances that are considered harmless such as *licorice* can cause hypertension, water and Na retention if abused.
- Foodstuffs consumed in uncommon ways: insufficiently cooked *raw red beans* can result in gastroenteritis [35].

In Table 10.18 [37] other naturally toxic substances present in foods are listed.

Exogenous Toxic Substances

Exogenous toxic substances (see the immunologic effects in Table 4.17) are produced during the phases of storage and preservation of foodstuffs, during which mycotic contamination is almost unavoidable. They include the mycotoxins [37]:

- The *aflatoxins,* toxic products of foodstuffs with an elevated sugar and grease content, contaminated with mycetes of the *Aspergillus* species, even for fraudulent reasons [26] such as badly preserved dried fruit and cereals, as well as peanuts, figs, wheat, corn, almonds, millet, hazel nuts, walnuts, Brazil nuts, pecans, filberts, coconut and pistachio nuts [35]. Symptoms of intoxication are anorexia, weight loss, jaundice, encephalopathy (Reye's syndrome), hallucinations, etc. [53].
- *Patulin,* produced in particular by *Aspergillus* and *Penicillium*, is found in fruit and fruit juices. It produces acute and chronic toxic reactions.
- *Metabolic products* of the mycetes *Fusarium*, *Trichoderma*, *Cephalosporium*, etc., contaminate millet, barley and wheat, the pathological effects are headache, vertigo, shivers, nausea, vomiting, diarrhea and visual disturbances.
- If *mycotoxins* contaminate cereals, residues can pass into meats and the milk of the animals that consume them [37].

Toxic-Infectious Contaminants

The following are considered as pathogenic agents: microbial toxins, or organisms that, contaminating foodstuffs, cause symptoms of poisoning, often confused with those of FA:

- *Bacteria and their toxins: Clostridium botulinum, Staphylococcus aureus, Vibrio cholerae, Campylobacter jejuni* [35];
- *Scombroid fish poisoning* caused by the ingestion of tuna, mackerel and similar fish that is not fresh or is poorly conserved, or even tinned, with rapid symptoms (15–60 min) of giant angioedema urticaria, tachycardia and anaphylactic shock, absolutely indistinguishable from IgE-mediated reactions but with rapid improvement after therapy, in which high concentrations of histamine are seen from histidine decarboxylation, caused by aerobic and anaerobic microorganisms [59]. It has been challenged that histamine is not involved with the active scombroid fish toxin [19]; however, it is clear that the toxin is involved in increasing the toxic power of histamine [85]. Other symptoms involve the gastrointestinal apparatus: nausea, vomiting, and diarrhea. Sometimes disturbances of the cardiovascular system are present, hepatic toxicity, neuropsychic disturbances, etc. [59].
- Eating other fish products can also turn out to be toxic [37, 86]:
- *Lamellibranchs* such as oysters, mussels, clams and similar molluscs acquire toxicity from marine algae [31].
- *Tetrodotoxin,* contained in the liver and ovaries of certain species (among which the puffer fish, *Arothron hispidum*), causes oral, lingual and pharyngeal paresthesia, nausea, vomiting and diarrhea, in certain cases complicated by ataxia, and respiratory paralysis, which results in death in approximately 60% of cases.
- Poisoning by eating *crustaceans contaminated with dinoflagellates,* producers of a powerful neurotoxin, saxitoxin, produce muscular paralysis (the toxin binds to Na channels in nerve cell membranes and blocks neurotransmission).
- *Red seaweeds* contain carrageenan, which may be used in low-fat hamburgers: it is toxic in experimental animals, and especially immuno-suppressive, accumulating in macrophages [86].

It should be pointed out that only 1% of sea creatures have been studied for their chemical properties and potential harmfulness.

Finally, vitamin excesses can cause the following [35]:

- *Vitamin A:* irritability, vomiting, endocranial hypertension and death.

- *Vitamin D:* anorexia, nausea, vomiting, diarrhea, migraine, polyuria and polydipsia in acute form; edema, pallor, weight loss, fever and constipation in chronic form.
- *Vitamin K:* in pregnancy, hyperbilirubinemia in premature neonates. Other food sources of this vitamin are represented by turnip, lettuce, cabbage and spinach.

Diagnosis

It is necessary to stress the past history (if the child is old enough) as well as the present history, in as much as the harmful action of toxins, even in minimal quantities, often lasts a long time. It is necessary to examine the possible correlation between food habits (with preference to choice as much as cooking methods), the purchase from usual or occasional suppliers, whether there has been refrigerated storage, possible exposure in restaurants or school meals, the exposure to environmental chemical substances and the development of symptoms. Certain foodstuffs such as plums and other fruit, onions, cucumbers, beans, etc., can induce gastroenteric symptoms, often diarrhea, by irritation rather than pharmacological action and they are to be considered in a differential diagnosis with FA [54], in the same way as scombroid fish poisoning [59]. Lactose intolerance, apart from occasionally being a confusing factor in the diagnosis of FA, can mimic irritable bowel syndrome; even when the two disorders coexist in the same patient, it is appropriate to treat the primitive disorder of motility [14]. Laboratory examinations are chosen based on symptoms, if necessary using the FPT and investigating organs and function also from an immunological point of view [53]. Such investigations also become significant for the *differential diagnosis,* which should aim to identify the mechanism in action and the exact background of cutaneous and gastrointestinal symptoms, so as to make the evaluation of the only possible cause possible [29]. The distinction is also based on time courses: while anaphylactic reactions explode only a few minutes after ingesting the foodstuff, the urticarial reactions manifest within a few minutes to a few hours and the toxic reactions within minutes to several hours. As a comparison, gastrointestinal disorders require several hours to manifest and an infection 8 h to several days [57].

Anaphylactoid Reactions

Anaphylactoid reactions are reactions clinically similar to anaphylaxis [104], caused by the excessive ingestion of foods and/or food additives. Basically they are non-IgE-mediated mechanisms: they can also be caused by pharmacological, metabolic and toxic reactions to foods [101]. They are dealt with in Chap. 20. For the differential diagnosis, see Table 10.19 [35].

Table 10.19. Diagnostic clues for food-related anaphylactoid reactions

IgE-mediated food allergy
IgE-mediated allergy to a given food
IgE-mediated allergy to a food contaminant (such as, penicillin)
Food pseudoallergy
High histamine levels in the food
Scombroid fish (tuna, mackerel)
Raw or canned fish contaminated by *Proteus* or *Klebsiella*
Cheese contaminated by *Proteus* or *Klebsiella*
Sulfites
Monosodium-L-glutamate
Idiopathic anaphylaxis

Modified from [35].

Immunotoxicology

By the term "immunotoxicology" we mean the study of the immunotoxic potential of chemical substances that are foreign to the body (xenobiotics) on the immune system (Chap. 4): this is the discipline that organizes the toxic effects of environmental agents to different components of the immune system [7]. Such agents include all components of the environment external to the human body, from the most simple chemical compound to the most sophisticated microbial agent. Immunotoxins are included among substances consumed, *even in low doses,* for long periods of time, such as those considered as foodstuffs, either intentionally (food additives) or involuntarily (contaminants), with potential risks to the immune system [18]. In fact, the most important characteristics of xenobiotics cannot be imagined: immunotoxic substances exercise their effects at doses notably lower than those normally expected [7].

Various actions and other mechanisms are present, often with toxic consequences: accidental contaminants of foodstuff may also include heavy metals (Hg, Cu, etc.) or others such as Al, As, Cd, Co, Mn, Mo, Pb, Se, etc.; symptoms of poisoning are caused when foodstuffs or acid drinks are prepared in containers made of Cu, Sn or galvanized [7]. Refer to Table 4.12 for the probable effects of xenobiotic immunotoxins on the immune system and Table 4.18 for the environmental agents that compromise the immune system of experimental animals [73].

We briefly review the effects of *industrial contaminants* or rather toxins produced during production processes [53]:

- *Heat:* carcinogenic substances
- *Decolorants:* methionine sulfoxime (produced by proteins containing methionine treated with NCl)

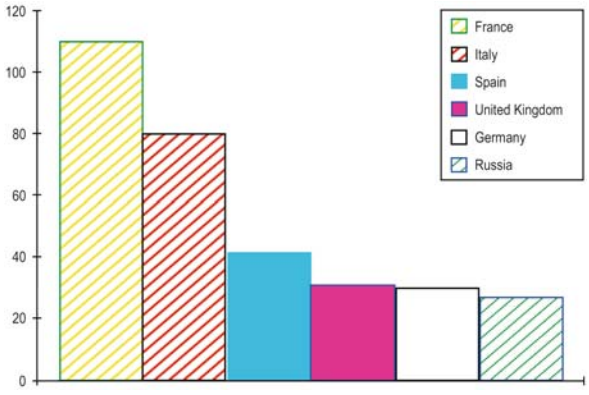

Fig. 10.5. Pesticide use in some European countries ($t \times 10^3$). (Data from FAO)

- *Industrial solvents:* trichloroethylene
- *Sterilizers:* ethylene oxide

A particular case concerns polychlorinated dibenzofurans and diphenyls [86], once used widely as electric insulators and for resistance to heat: only several years later was the toxic potential of *dioxin* to man and the environment realized, also for the prolonged existence *in loco* and the incorrect incineration of home and industrial products; less known is that *smoking is a third source,* for the whitened paper of the cigarette, or for the pesticide used to treat the tobacco. The accidental contamination of rice oil with a commercial diphenyl has caused an epidemic in Japan know as *"oil disease"*, with skin alterations, blepharo-conjunctivitis and, in the lungs, asthma-like symptoms [86].

- Toxic contaminants [53, 73] (Tables 4.7, 4.8, 4.17)

Pesticides (organic phosphates), especially persistent organic pollutants (POPs) (Table 4.21), also used as herbicides and insecticides, may be responsible for liver and central nervous system symptoms, as well as alterations in immunoglobulin levels. Pesticides, with Italy the second largest user in Europe (Fig. 10.5), are found on fruits and vegetables, especially on those without a smooth surface, such as strawberries, or with thick skin such as citrus fruit, *Cucurbitaceae,* etc. We point out the notable toxicity of diphenyl and orthophenol, used as preservatives on the external surface of citrus fruits, bananas and cheeses, even though they should not penetrate into the pulp of the fruit. However, the peel of citrus fruits cannot be used without checking prior to the production of cakes, jams, ice creams and various other foods.

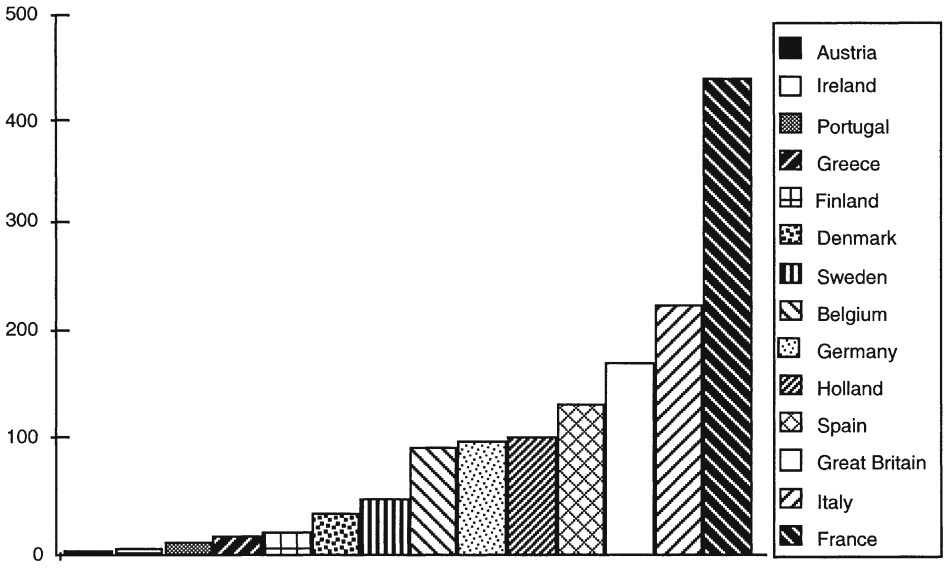
Herbicides (compounds with a chlorophenothane base) can induce neuropathy, and fungicides (pentachlorophenol) can induce hepatopathy. As far as paraquat is concerned, the risk of ingesting contaminated foodstuffs is remote as long as the edible plants are disinfested with truly nontoxic products [86]. A further molecule, lindane, caused an alarm when foodstuffs were found that contained quadruple levels of it: this is to be ascribed to the uncommon persistence of the polluting agent and it is strange that its use has not already been banned by the authorities.

Animal-based drugs (penicillin) are present in traces in meats, CM and cheese products.

Minerals such as Ni, frequently found in foodstuffs (Chap. 8), yeasts and molds that contaminate fruit, vegetables and cereals [28].

In Tables 1.78 and 1.79 it is noted that *genetically modified foods* (GMFs) are obtained from plants modified for protection from insects and tolerance to herbicides, as well as from plants and substances defined as nontoxic to man that deactivate the herbicides. Long-term studies are necessary on humans to evaluate the safety of such foods. Figure 10.6 illustrates how widespread GMFs are.

Fig. 10.6. Number of fields where transgenic cultivations are experimented. To be noted the second place of Italian fields. (From Legambiente, personal communication)



Food Immunotoxicology

In the intestine, the ingested immunotoxins theoretically have the capacity of harming the GALT, in particular in the mucosa, which, for more or less prolonged chronological periods, can come into contact with potentially high levels of xenobiotics during the processes of absorption, altering the local immune response and thereby favoring the setting off of allergic reactions, as well as increasing susceptibility to infection [18]. It should be noted that these products are capable of polluting and, in the case of environmental accidents, affecting the mother's milk, with understandably serious consequences [70]. *Four out of 14 neonates* have presented hemorrhagic forms in the first 4 weeks of life: the *breast milk had levels of dioxin* (TCDD) that were significantly higher than those in the other ten children [45]. In addition to the TCDD, there were also several halogenated pesticides and industrial chemical products [71]. Food safety is threatened by TCDD derived from animal feeds, formed from fats of dubious origin (perhaps even *residues of car oil*) and from ground *animal carcasses;* the permitted levels are unknown. Table 10.20 [70] shows the relationship between concentrations of certain xenobiotics in maternal milk and blood measured in certain Italian areas (see also Chap. 21). In general, the levels that pass into breast milk are reassuringly lower than the concentrations present in the maternal plasma; however, atopic breast-fed children can have immunotoxin levels that are four times higher than those of nonatopic subjects [97]. The levels present are usually very low and somewhat far from the doses considered dangerous, and depend on various factors, including the dose of xenobiotics received by the mother, the absorption, the distribution, the metabolism and the elimination of the single compounds, both regarding the mother and the breast-fed neonate [69]. Therefore, although sometimes there have also been *prenatal exposures,* there is little evidence to suggest that toxic effects are seen in infants [71]. The negative effects of the POPs are represented by their wide distribution, for which they can be found in areas distant from the place of release (Chap. 4). Let us re-examine, under an immunotoxicological profile, a few xenobiotics for which we have listed the clinical effects in Table 4.3, while in Tables 10.21 and 10.22 the immunotoxic effects of some food components are listed [18]. In this context, even more harmful effects are experienced by those individuals weakened by malnutrition (Chap. 21).

Table 10.20. Xenobiotics in breast milk above detection limits

Caffeine	0.8
Chloramphenicol	0.55
Ethanol	0.9–0.95
Iodum^{131}	65
Nicotine	0.17
Streptomycin	0.5–1.0
Theobromine	0.7
Theophylline	0.7

The high iodum^{131} value in milk/plasma rate means that iodum, due to its specific properties, tends to accumulate in breast milk.
Data from [70].

Diagnosis

From the patient's history, particular activities can be revealed, or places frequented may be discovered, or particular experiences, restaurant meals, etc. This may be the beginning of a careful investigation.

The immunological investigations to be carried out include in general:

- SPTs

Table 10.21. Immunotoxic effects of some food components

Substance	Examples[a]	General effects
Additives	BHA, BMT	Reduced T-dependent humoral response
	Carrageenins	Increased IgE response
	Na benzoate	Reduced aspecific defense (phagocytosis, intracellular killing)
Contaminants	PBB	Numeric reduction of B and T lymphocytes
	DES	Reduced macrophage function
	Dioxin	CMI reduction (neonatal exposure)
	Malathion	Immune response suppression
Artifacts	Benzopyrene	Altered immune response
	DMB	Reduced T-dependent humoral response

[a] *BHA* Butylated hydroxyanisole, *BMT* Butylated hydroxytoluene, *DES* Diethylstilbestrol, *DMN* Dimethylnitrosamine, *PBB* Polychlorinated biphenyl compounds
Modified from [18]

- Lymphocyte counts and their subpopulation (Tables 1.33–1.34)
- Lymphocyte stimulation
- Immunoglobulins (Table 1.15)
- Specific antibodies (tetanus, pneumococcus, etc.)
- Bactericidal activity
- T lymphocyte-mediated cytotoxicity
- Macrophage functionality
- Complement

Treatment

Apart from the interventions for pathological forms, which are dealt with according to the organ or apparatus involved, the best kind of therapy is *prevention,* based on one hand on the strict control by the governing organisms involved [32] and on the other on the renunciation of "foodstuffs that man invented departing evermore from the natural state simplicity" [17], prophetic words even more significant today.

Pediatricians, Pseudoallergy, and Immunotoxicology

Nonallergic adverse reactions to foods may account for the majority of food-related reactions, and children may be more vulnerable than adults. Children face risks that were neither known nor imagined decades ago. Although recognition of PA dates back to several years ago, a wealth of clinical data suggests that the constellation of food additive intolerance represents an emergent PA manifestation, and a relevant pathogenetic factor, commonly affecting children and adolescents. Considering the harmful effects of food additives on health benefits, one intriguing challenge should be to interpret the medical consequences of a directive of the European Union that has liberalized the use of additives even in foods for neonates, infants and toddlers. However, governments should critically and regularly update food labeling legislation, inducing producers to specify the food additives employed, abolishing the general wording "permitted by law." Pediatricians and primary-care physicians are a front-line source of information and guidance for families, and are thus in a unique position to suggest that the parents of children affected with atopic disease exercise meticulous control on foods and beverages for their children, referring children and adolescents in whom PA is suspected to specialized hospital departments, to ensure an exact diagnosis and appropriate treatment. Several pharmacological, enzymatic, metabolic and toxic reactions may be misleadingly labeled and therefore they need an accurate setting. Moreover, immunotoxicology is concerned about an emerging issue, the potential hazards of transgenic foods while it cares for breast milk, the most natural of all foods.

Asthma

Pediatric Asthma

Asthma has been recognized as a disease since the earliest times. In the *Corpus Hippocraticum,* Hippocrates used the term "ασθμα" to indicate any form of breathing difficulty manifesting itself by panting. Aretaeus of Cappadocia, a well-known Greek physician (second century A.D.), is credited with providing the first detailed description of an asthma attack [13], and to Celsus it was a disease with wheezing and noisy, violent breathing. In the history of Rome, we find many members of the Julio-Claudian family affected with probable atopic respiratory disorders: Caesar Augustus suffered from bronchoconstriction, seasonal rhinitis as well as a highly pruritic skin disease. Claudius suffered from rhinoconjunctivitis and Britannicus was allergic to horse dander [529]. Maimonides (1136–1204) warned that to neglect treatment of asthma could prove fatal, whereas until the 19th century, European scholars defined it as "nervous asthma," a term that was given to mean a defect of conductivity of the ninth pair of cranial nerves.

If, from a clinical point of view, asthma can be defined with a fair degree of precision, much doubt still surrounds its etiopathogenesis, although the important role played by inflammation has been largely clarified. To this day, asthma still retains the characteristics of frequency and unexpected severity that can negatively affect a child, leading to considerable concern in the family. Asthma begins early in life [305] within the 1st year of life (Table 5.5) with the developing immune system interacting with environmental influence [305]. Moreover, cases of pediatric asthma are increasing, as can be seen from epidemiological figures (Tables 5.10, 5.12), even though cases may be differently labeled, especially when symptoms are mild or moderate, and subsequently often *underdiagnosed* [446]. A large body of epidemiological evidence shows that allergic disorders in the pediatric population represent a current major therapeutic and preventive challenge for pediatricians. The surprising upsurge of severe asthma is occurring mainly in infants and children (Figs. 5.1, 5.3, 5.8). Until recently, asthma was defined as a disease fundamentally characterized by a state of bronchial hyperreactivity (BHR). In the last few years, it has been concluded that BHR and bronchoconstriction could be the result of the inflammation primed by Th2 T cells [340]. This change in our understanding has stimulated new lines of research and led to a new therapeutic approach [340]. Progress has derived from information gained by new investigative methods such as the study of bronchoalveolar lavage fluid (BALF) cells, using immunohistochemical and molecular biology techniques, and widespread use of more precise fiberoptic bronchoscopy, especially in children [501]. Asthma is a disorder *involving all bronchial structures* and depends on a complex interaction between the respiratory tract and inflammatory cells, mediators and adhesion molecules. Release of mediators by metachromatic cells primes both activation and migration of inflammatory cells that cause various degrees of airway obstruction over relatively short periods of time, alterations in the mucociliary system and hyperreactivity of the bronchial smooth muscles. It follows that both inflammatory cells and their products play a key role in provoking an airway inflammation, capable of triggering severe symptoms in predisposed children when specific and aspecific stimuli are present. *Pediatric asthma differs from adult asthma by its etiopathogenesis, treatment and prognosis.* Studies reporting that the future prospects for treating asthmatic babies and children are optimistic [604] have not taken into account the severity of childhood symptoms [264]. The understanding that events during both fetal and postnatal life may be the major determining factors of chronic asthma is also making progress [589].

The classic concept of asthma is that of a chronic inflammatory disease with a multifactorial pathogenesis, characterized by a state of hyperresponsiveness to various stimuli and a level and intensity that for the most part do not cause disturbances in healthy subjects, which consequently leads to a diffuse airway obstruction, either partially or fully reversible, either spontaneously or following treatment. The confusion still existing in terminology (Chap. 5), the reluctance of doctors to use the term "asthma" and of parents to accept it, *serve only to delay the diagnosis and treatment*. It has long been debated whether two forms of asthma exist: allergic, or extrinsic, and infection-induced, or intrinsic. Some [61] have not confirmed the existence of the latter and others [552] have not found any difference between the IgE values in normal subjects and in subjects with so-called intrinsic asthma. Probably many patients thus classified may be sensitized to unknown

allergens and/or are not included in the usual allergen battery of tests. For example, patients from Catalonia showed 8.5% of sensitization to an unusual pollen of the profilin family, perhaps an emerging pollen (Chap. 6). This chapter also includes bronchiolitis, extrinsic allergic alveolitis (EAA), and allergic bronchopulmonary aspergillosis (ABA).

Definitions

Asthma. To date asthma is a *severe pediatric disease,* affecting a great number of infants during their very first years of life (Table 5.5), which requires early and specific cures. Pediatric asthma should be viewed as a syndrome of lung dysfunction with an imbalance between the forces that maintain airway patency and those forces that operate to narrow or close the pediatric airway [274]. Apart from symptomatic management, pediatric asthma can be cured by anti-IgE, antileukotriene drugs (anti-LT) (see "Leukotriene Modifiers") and SIT (specific immunotherapy) or respiratory desensitization.

Canny and Levison have suggested that any child, in any age group, who has ≥3 episodes of afebrile bronchospasm should be considered as suffering from asthma until the contrary can be proven [79]. This is the definition we and others also prefer [574]. However, the number of asthmatic episodes is not always a helpful guide: 50% of children suffering ≥4 attacks at age 4–5 years had no symptoms by the time they reached the age of 10 [471]. Asthma is a chronic lung inflammation, whose characteristics may be summarized as an acute onset of symptoms with bronchoconstriction (clinical data), reversible either spontaneously or with appropriate treatment (pharmacological data) [465, 594], accompanied by BHR to diverse stimuli (functional data) and by an inflammation of varying degree, which conditions its persistence, duration and severity (biological data) [465, 739]. Asthma can be clinically defined as an *airway response to different stimuli, with paroxysmal dyspnea, wheezing and coughing, variable in form from mild to severe,* or ultimately status asthmaticus [594]. Asthma is characterized by lymphocytes and eosinophils infiltrating in the submucosa. chronic airway inflammation leading to BHR, mucous gland hyperplasia, microvascular leakage, mucus hypersecretion, thickening of the subepithelial collagen layer, epithelial desquamation, mast cell degranulation, airway tissue hyperplasia and hypertrophy, causing variable airflow obstruction [31, 739] that requires long-term recovery.

Wheezing. Wheezing is an onomatopoeic word reproducing the sound made by air rushing through narrowed airways in a flow that is no longer laminar but turbulent, which may also be defined as wheezing and/or dyspnea.

BHR. BHR is the particular ease with which the bronchi constrict in response to stimuli [154]: specific stimuli, the allergens, which provoke bronchospasm in a restricted number of subjects defined, therefore, as allergic; aspecific stimuli cause wheezing even in nonallergic children [603] suffering from bronchial disorders of various types [722] and even in healthy children, if the intensity is at least fivefold stronger than in asthmatic children [335]. BHR is therefore dependent on a markedly lowered threshold of the bronchial response to causative factors, which results in exaggerated bronchoconstriction, following which the bronchi constrict too readily and excessively [154]. Bronchoconstriction depends partly on inflammation, partly on smooth muscle spasm, on the mucosal edema and on the modification of the secretions, with formation of viscous plugs that often fill the bronchioles [255]. Some authors, in consideration of the fact that BHR occurs in the presence of nonallergic stimuli [636], propose the synonym "aspecific bronchoreactivity," which, however, ignores the specific forms [179, 481]. In fact, nonallergic stimuli work through specific, though different, mechanisms, so it seems imprecise to apply such terminology. We believe that it seems clearer to define BHR by the agent that provokes it [238].

Prevalence

Asthma is the most prevalent chronic breathing disease that affects subjects of all pediatric ages, but begins in the first few years. In 85% of cases, it begins in children by the age of 1 year, 80%–85% by 5 years of age (when statistics begin) and 94%–97% within 10 years. This is confirmed by 10.8% of new cases in the 2nd decade of life (Table 5.5); therefore, 90% of cases occur in infancy, considering that sensitization to inhalants is established very early [98] and that cases of sensitization from the 1st year of life onward occur very frequently. During 1991, there were approximately 1.6 million visits for pediatric asthma care. Asthma accounted for 16.9%±9.0% of all pediatric emergency department (ED) visits [121]. During 2000, a nationwide survey among 437,873 Chinese children aged 0–14 found a 1.69% prevalence in children aged ≥3 years and of 0.23% in those aged ≤3 years [100]. Among these children are those with AD (atopic dermatitis) who in 21%–79% of cases, subsequently develop asthma (Table 5.8). The prevalence is also increasing as in our study in 592 children compared to controls (Chap. 5), documenting an 88.8% increase in severe pediatric asthma. In 411 children (220 males and 191 females) ranging in age from 7 to 13 years, we have found asthma in 31.5% and AR in 25.8% of them. Respiratory allergy affects children even more than food allergy (21.7%). Moreover, pollutants represent an adjuvant factor in the onset of respiratory allergy [521] (Figs. 4.26, 4.27) and we wonder whether similar interactions increase its prevalence.

Defense Mechanisms in the Airways

BALT (*Bronchus-associated lymphoid issue*) and Specific Defenses

The respiratory apparatus's first and qualitatively most notable line of defense against excessive local immune responses is the defensive barriers, both physical and immunological, that range from safeguarding the tight junctions among epithelial cells to IgA secretion in the bronchial lumen. The respiratory epithelium is subjected to a virtually uninterrupted exposure to environmental antigens present in the 8,000–12,000 l of air inhaled daily by an average person [520]. The key factor in the maintenance of airway immunological homeostasis is the immune system's ability to discriminate between intrinsically inoffensive antigens and/or those associated with pathogenic microorganisms, and the exclusion of the latter from the respiratory apparatus by the mucociliary system censoring mechanism, before they reach the underlying immune system. The defenses are not always well equipped and penetration of small quantities of allergens can be viewed as a normal occurrence [533].

Parallel to that which has been described in Chap. 9, a *common mucosal immune system* (MALT) exists, to which BALT is connected, located in the respiratory mucosa [40]. It has been hypothesized that in newborn babies and healthy children BALT is absent, or at least reduced [54] and that it could be an inducible system that develops in the airways of infants and children, especially in concomitance with exposure to antigens and pathogenic agents [193]. Several studies on humans [40] have, however, confirmed the existence of BALT. Anatomically, it consists of a well-developed lymphatic system originating from the NALT (*nasal-associated lymphoid tissue*) at the airway entrance, and continues with follicles and submucosal lymphoid aggregations distributed along the whole respiratory tract up to the bronchoalveolar junction [40] (Fig. 11.1). The tissue is covered by a layer of flat epithelial cells, with few B lymphocytes, but essentially with T lymphocytes ($CD3^+$, $CD4^+$ or $CD8^+$), grouped in clumps of lymphoid and follicles distributed in a seemingly homogeneous manner over the entire epithelial layer in the main bronchi of the pulmonary lobes, principally at the bifurcation with the bronchioles [193]. The most common lymphocytes are *intraepithelial* (IEL), situated close to the basement membrane (BM), generally not affected by pathological changes typical of epithelial structures and, as with GALT, CD4 T cells dominate over CD8 T cells [193]. Even in the lymphocytes distributed under the BM of the epithelial layer, T subsets are more numerous than B cells [193]. Specific to IEL is CD103, widely expressed on T cells, of which up to 80% are CD45RO. As in the intestine CD7 expression is frequent; expression of CD25 is lower [520]. The TcR with γ/δ chains plays a prominent

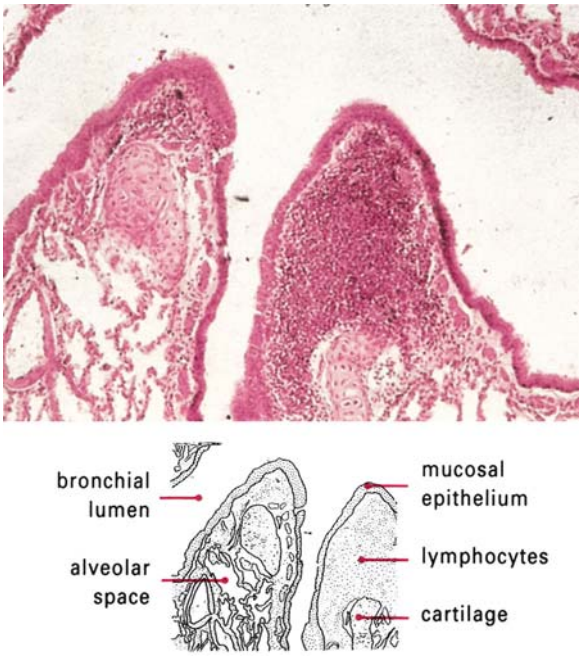

Fig. 11.1. BALT. Section of lung showing a diffuse accumulation of lymphocytes in the bronchial wall

role in the pulmonary *first line of defense* [250], and there is greater evidence, on the other hand, of TcR αβ, which display a large number of Vβ genes [520]. Seen in this light, it is important that in asthmatics the γδ are reduced in the circulation parallel to eosinophil increase, even if the two phenomena seem to be unrelated: nevertheless, low γδ levels in the airways could be detrimental (see Chap. 1 for further details).

The lymphocytes passing from blood flow to the airways reach BALT, devoid of afferent lymphatics adhering to the HEV (high endothelial postcapillary venules), which in BALT function similarly to the mesenteric lymph nodes where B and T cell numbers are similar [40]. BALT follicles contain small and medium lymphocytes but lack capsules and germinal centers characteristic of true lymph nodes [40]; T and B cell rates are similar to those of GALT: 20% of T and 40%–80% of B cells. This rate is reversed in both lymph nodes and circulation: 70% of T and 15%–20% of B cells [533]. Mast cells and macrophages with APC (antigen-presenting cells) activity are present in BALT; therefore antigens can be directly presented to lymphocytes in this location [520]. Additionally BALT might function as a repository for immunoglobulin (Ig)-bearing cells, but because it is poorly provided with plasma cells, further B-cell differentiation should occur outside the BALT; therefore, B_{IgA} migrate directly to the lamina propria along the respiratory tract to produce antibodies for the mucosal surface [533], that is in the NALT, which appears to be the principal supplier of B precursors in the upper airways [54]. All Igs are diffused along the airways: plasma

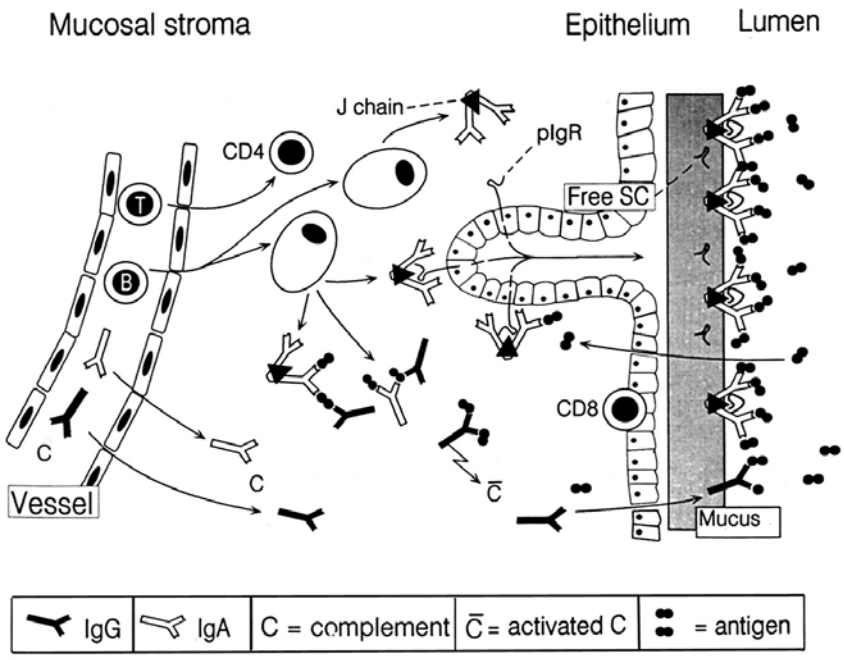

Fig. 11.2. Schematic representation of immune homeostasis in the airway mucosa. Mucosal sIgA antibodies act as a first-line defense by performing antigen immune exclusion. Antigens circumventing this barrier meet mucosal IgG antibodies. The resulting immune complexes activate complement, and inflammatory mediators most likely formed locally. However, the adverse inflammatory development is usually inhibited by serum IgA and by locally produced polymeric and monomeric IgA. Antigens may be returned in a noninflammatory way to the vasal lumen by pIgR-mediated transport mechanisms. The final homeostasis depends on the profile of adhesion molecules expressed by vascular endothelium, normally facilitating preferential extravasation of B and T cells belonging to the MALT (for details see text). *pIgR* Polymeric Ig receptor, *sIgA* secretory IgA

cells of the lamina propria pass into the lumen across the BM and epithelium. In the upper airways, IgA antibodies predominate, with the capacity of neutralizing the RSV (respiratory syncytial virus) *Rhinovirus* and influenza virus and of agglutinating microorganisms, increasing the mucociliary clearance. In the trachea and bronchial tree secretory IgA (sIgA) are 10% of the total proteins; progressing to the alveoli, IgA decrease as low as 5%, while IgG increase up to 10%–15% [533]. Under normal conditions, the respiratory immune system is able to suppress immune responses triggered by allergens circumventing the barrier, in that a successful sIgA defensive system is ready [54]. As seen in Fig. 11.2 [54], sIgA are generated from locally produced polymeric IgA (pIgA), armed with J chain, which is transported by the pIgR (polymeric Ig receptor) to the lumen along with the SC (secretory component) [54]. Consequently, immune tolerance is established after the first contact with non-self agents with a two-phase mechanism related to genetic factors, but, mainly because of environmental factors capable of negatively affecting the immune system, a sensitization with the same mechanisms that we have seen play a part in food allergy (FA) can occur [54].

Nonspecific Defenses

Nonspecific defenses are essentially represented by *bronchial secretions* that block and neutralize soluble toxic substances and by the activity of the mucociliary system that propels them upward. Bronchial secretion emitted by the submucosal glands and/or by the goblet cells, and enriched by transudation fluids or exudation of blood origin, is made up of glycoproteins originating in the mucosa, arranged in a type of fibrillar network and of a component, more precisely a fluid, containing anti-infective substances (Ig, lysozyme, lactoferrin) and C3 [648]. Additionally, the bronchial secretion performs a major role by hydrating the inhaled air and maintaining the ionic balance. The *mucociliary system,* already in place in the first days of life, is made up of ciliated cells, each possessing, on average, 200 cilia, 5–7 µm long and 0.25 µm wide. Each *cilium* is formed structurally of nine pairs of contractile longitudinal microtubules [648], connected two by two by means of nexin links, and arranged in circles around a central pair. All the tubules converge toward the tip of the *cilium,* forming a hood connected to the ciliary membrane. Two dynein bridges catalyze hydrolysis of ATPase and transduce the energy into a mechanical force in the form of ciliary bending. The cilia act on the mucus blanket shed from the mucosal glands and especially that from goblet cells. At the moment of the active phase of the beat (15/s), the mucus is driven by the ciliary tip toward the oropharynx at increasing speed from the periphery toward the trachea, accelerating from 2–4 µm/min. At the alveolar level, the alveolocapillary membrane is covered with surfactant, produced by type II epithelial cells and nonciliated Clara cells, situated on the branching border between bronchial ducts and bronchioles, which synthesize the surfactant A-C proteins. This substance, having surface-active properties, changes the surface-charge properties, making foreign particles less viscid and therefore more easily cleared [648]; in addition, it promotes the intervention of the phagocytes. Ciliary clear-

ance is substituted in the distal airways by that of macrophages and by cough reflexes [648].

The *alveolar macrophages,* in the presence of antigens, pollutants, or chronic irritants, pass from a state of quiescence to one of activation and, if the stimulus persists, to one of intense phagocytic activity, with IL (interleukins) production. In particular, inorganic substances are taken up and transported mechanically to the mucociliary system, while organic substances are decayed by cytoplasmic and lysosomal enzymes, and microorganisms are phagocytized and subjected within the phagosomes to the action of free radicals and cationic proteins [330]. Macrophages can also have a deleterious effect on the airways, by releasing enzymes with lytic activity, oxidants and proteases normally neutralized by anti-proteases and by ILs produced by macrophages. Free radicals, ozone (O_3) and nitrogen dioxide (NO_2) can, in turn, alter the local protease/anti-protease equilibrium. Lastly, the macrophages have the role of controlling T-mediated activation of the immune system: in subjects with BHR, but without symptoms of inflammation and asthma, macrophage hyperactivity may result in the suppression of local T cells, while a reduced activity could be fundamental in triggering T lymphocyte hyperactivation and up-regulating chronic inflammation, which could further exacerbate BHR up to a pattern of full-blown disease [503].

Alterations of the Defense Mechanisms

- *Immaturity.* At birth not all the mechanisms contributing to the protection of the airways have reached their full functional potential. The mucociliary system develops very early during intrauterine life and proves to be fully suited to the mechanical purification of the particles *inhaled from the very first hours of life.* The alveolar macrophages, on the other hand, are late in reaching the airways. This is because they are immature cells endowed with phagocytic activity, but without an oxidizing metabolism or cationic proteins able to ensure efficient bactericidal action. In addition, the factors of acquired immunity have not yet been stimulated and therefore, the appropriate protection is temporarily taken care of by the maternal antibodies.
- *Constitutional disease.* Diverse genetically transmitted diseases share the same characteristic of appearing in the first years of life with recurrent respiratory infections (RRI), for example, cystic fibrosis (CF), primary ciliary dyskinesia, etc.
- *Immunodeficiencies (IDs),* which reduce the airway resistance (Raw) to infections, including primary IgA deficiency, chronic granulomatosis, etc. (Chap. 22).
- *Deficiency of α1-antitrypsin.* The primary deficiency lies in an insufficiency of the anti-protease defense, corresponding to phenotype ZZ, which favors the development of emphysematous lesions.

Genetic Factors

Asthma can be considered a multifactorial disease in that different genetic and environmental factors contribute to influencing its phenotypic expression [340]. The pathogenesis is consistently related to genetic factors, family history (FH), and the particular role of atopy, intimately interrelated.

Four sets of data have emerged recently: a clear-cut genetic component *of 125 genes related* to the causation and progression of asthma symptoms (Table 4.2), *IL_{13}* overexpression [321], *IL_{12}* deficient expression [415], *and Th1 phenotype* downregulation due to reduced expression of T-bet (Th1 transcription factor) [188] while GATA-3 is overexpressed [328], which is implicated in the Th2 development [430].

Several studies on the genetics of asthma confirmed the linkage between asthma and genetic markers on 13 chromosome regions including *5q* and *11q*. Recently, the *ADAM33* gene encoded on chromosome *20p13* (Table 4.2) was found to be associated with small-airway remodeling in patients with asthma. *ADAM-33* polymorphisms may accelerate the proliferation of smooth-muscle cells and fibroblasts, leading to BHR and subepithelial fibrosis [582]. IL_{13} is thought to be especially critical in asthma (Table 1.5): normal signal transducer and activator of transcription 6 (STAT6) expression in epithelial cells is both necessary and sufficient to IL_{13} to induce BHR, eosinophil inflammation, mucus production, lung emphysema, and other central features of asthma in the absence of inflammation. However, mice lacking STAT6 were protected from all pulmonary effects of IL_{13} [321]. Two new ILs are more destructive. The IL_{17} family resulted in bronchoalveolar lavage neutrophilia and inflammatory gene expression in the lung. In addition, intranasal administration of IL_{25} protein resulted in the production of IL_4, IL_5, IL_{13}, and eotaxin mRNA in the lung, marked eosinophilia in the BALF and lung tissue, eosinophil chemotaxis and activation mast cell stimulation, epithelial cell hyperplasia, increased mucus secretion, and BHR [269]. In CRH (corticotropin-releasing hormone) deficiency, such as in CRH knockout mice, increased levels of IL_4, IL_5, IL_{13}, IFN-γ, RANTES and eotaxin in BALF were observed, thus increasing asthma severity [588]. FP in vitro impairs IL_{13} production by PHA (phytohemagglutinin)-stimulated PBMCs (peripheral blood mononuclear cells) from asthmatic and control subjects [150].

Thus the pathogenesis is associated with ILs, namely IL_{12} (down) and IL_{13} (up). Children heterozygous (HET) for IL_{12}B promoter polymorphism (associated with reduced IL_{12} gene transcription) have a greater risk for progression to severe asthma, irrespective of disease cause, but with no difference between nonatopic and atopic children with asthma [415]. As a consequence,

everything is ready to up-regulate aberrant Th2 responses in atopic children, probably leading to a class switch to IgE antibody formation.

Outcomes in adult asthma may be determined primarily in early childhood. In an unselected birth cohor, >25% children had wheezing that persisted from childhood to adulthood or that relapsed after remission. At age 21, 26.9% had continuing symptoms of asthma; 14.5% had persistent wheezing from onset with no remission, and 12.4% had relapsed after remission. The factors predicting persistence or relapse were sensitization to Der p, BHR, female sex, smoking, and early age at onset [554]. It was previously found that at 25 years 88% of symptomatic subjects had BHR, a proportion statistically higher in the asthmatics than in the group of controls (12.8%) [218]. The reason is that a very early presence of eosinophilic inflammation and even remodeling of airway wall occur early in the natural history of pediatric asthma and are present well before asthma would be diagnosed based on clinical symptoms [501]. That the pattern of asthma during childhood predicts outcome is confirmed by the Melbourne study in the original children followed-up at age 42. Most children with persistent asthma (70%), frequent asthma (69%), and infrequent asthma (69%) had severe asthma into adult life and reduced PFTs [264].

Stimulating findings have opened up an unexpected facet of asthma pathogenesis. Studies suggest that TNF-α, a proinflammatory IL that participates in the inflammatory reaction in asthmatic patients, or nearby genes, including those in the HLA region, may contribute to the development of asthma in the Japanese population [449]. Platelet-activating factor (PAF), also implicated in the pathophysiology of inflammation in asthma, is degraded and inactivated by PAF acetylhydrolase: its deficiency is found more frequently in children with atopic asthma [275]. Polymorphism in the activation-induced cytidine deaminase gene might be associated with the pathogenesis of atopic asthma and the regulation of *total serum IgE levels in children aged <3.* The related deficiency leads to a complete defect in class-switching, resulting in a hyper-IgM phenotype and lack of IgG, IgA, and IgE. An area requiring further study is on the role of CC16 (Clara cells), which is secreted in the airway epithelium and plays a key role in inhibiting airway inflammation, but CC16 levels are reduced in patients with current asthma due to increased levels of its *A38G* allele [325]. This allele was associated with increased BHR *at age 1 month* and increased risk of asthma at age 6 [324]. It might be an intriguing candidate gene determining asthma severity in children with the CC16*38A phenotype by increasing Th2 IL production in their airways [242].

Even if the existence of a *genetic predisposition* to asthma has been proved (Table 4.2), the precise mode of hereditary transmission is not yet clear; according to several investigators it could appear to be of the autosomal dominant type. The same model has been attributed to BHR, because of the significant difference between parents of asthmatic children (50%) and those of healthy children (10%) and, based on hyperreactivity to histamine, between nonasthmatic atopics, nonasthmatics (33%), and the general population (6%) [179]. In twins, the concordance rate of asthma (about 50%) is 14.7%–19% in monozygotes (MZ) and 4.8%–8.7% in dizygotic (DZ) twins [174]; 44.5% of asthmatic children have positive skin prick tests (SPT^+) vs 20.7% of healthy children [209]; also, total IgE and sIgE (specific) to inhalants are significantly high in asthmatic children, but normal in controls [433], indicating that genetic predisposition is an essential prerequisite, that increased BHR risk is associated with atopy and that severity is correlated to that of atopic manifestations. Although total serum IgE tracks with age, children who are predisposed to persistent wheezing and early sensitization to local aeroallergens already have high levels of IgE at age 6 [305] and 9 months [572].

Martinez et al [383] clearly indicate that a FH of asthma imposes an increased risk for childhood asthma and that elevated serum IgE levels measured during the first year of life are associated with subsequent asthma [383]. Total serum IgE levels were high at age 6 months in a cohort of 150 children at risk for developing asthma as offspring of mothers with asthma; IgE levels were still significantly higher for the asthmatic children at age 6–8 years with a GM (geometric mean) = 38.32 as compared with nonasthmatic ones (GM = 12.28). IgE levels were higher when the infants were 6 months of age [305]. Within the same family group, some members can have BHR and elevated IgE, others only high levels of IgE [229]. As mentioned in Chap. 5, the risk factor is significant in relation to positive FH (FH+): the prevalence of asthma has increased from four- to tenfold compared to subjects with negative FH [174]; if it is specifically related to asthma, children have an increased risk of becoming asthmatic within the 2nd year of life [746], with a BHR-atopy association correlated to age and to FH [122]. In our everyday work, we see that almost all asthmatic children have a positive FH, and in those with severe asthma, such as the above-cited 592 children, the rate surpasses 95%. A prospective cohort study has shown that even in the absence of respiratory symptoms FH+ children and those with personal atopy could have impaired PFT (pulmonary function tests) early in life [360]. Asthma in adults is usually associated with an elevated PRIST (paper radio immunosorbent test) and with SPT+ to allergens, and therefore *with an IgE-mediated mechanism.* The concept that IgE was central in allergic asthma [305] was stressed by data from a population-based study, which showed a close and highly significant relationship between asthma and serum IgE levels [63]. Conversely, the existence of the two forms of asthma has not been confirmed because, once IgE levels have been standardized according to sex and age, the intrinsic forms were brought back to an IgE-mediated mechanism [63]. Even in children [65, 572] *asthma and*

BHR are associated with elevated concentrations of IgE and atopic sensitization. Additionally, *BHR is already present in newborns and in 2- to 10-week-old infants*, before acquired factors can come into play [745], *in 6-month-old at-risk babies* [553], but also in 8% of apparently normal babies [746]. In early life, children of atopic parents and those with personal atopy have impaired PFTs even in the absence of respiratory symptoms, but with a significant interaction between history of maternal asthma and the child's atopic status [360]. These findings have up to now been observed only in adults and children with significant respiratory disease. The importance of serum IgE in determining BHR is decisive in the pediatric field [64]. If the association of BHR with the FEV_1/VC (vital capacity) rate is operative only in asthmatic young people with at least moderate levels of IgE, then IgE influences the given relationship by interacting with BHR. Asthma associated with BHR increase is independent of all other factors considered. Introducing IgE levels and PFT results into this calculation, all other diagnostic and/or clinical parameters play a substantially secondary role [64]. Therefore, *in infancy, BHR appears to be associated with atopy,* with FH+ of atopy (FHA) and asthma (indicating that it is hereditary) and *with wheezing beginning very early* or after 2 years of age.

In additional studies on pediatric cohorts, a significant correlation between BRH, asthma and atopy was found in 90%–100% of cases [574] and the degree of atopic sensitization was assessed by SPT+ to several allergens and BHR in asthmatic children [65]. Agreement on a positive correspondence between BHR and atopy is not unanimous [574]: this was confirmed in two longitudinal studies [4, 107]. Moreover, BHR is significantly more often found in atopic children with wheezing than in nonatopic children [108]. The correlation is absent in other children [108] and in adults followed up from age 7 [289]; infants at risk aged 6.5 months have reacted to the histamine test with BHR independently of wheezing [106]. Atopy can nonetheless be considered the main independent determining factor that contributes to BHR and even acquires a predictive character when accompanied by altered PFTs [574], in that subjects atopic from birth are those affected with more severe BHR in childhood [666]. Certainly, in childhood an airway inflammatory reaction manifests itself early, strictly related to atopy, which underlies on the one hand BHR and on the other – whether directly or not – PFT reduction [574]. The even greater relationship between atopy, elevated IgE levels, infant asthma and BHR seems to us especially significant [16]. Another possible pathogenic factor is the finding of IgG subclass deficiency, with or without associated IgA deficiency, in children with chronic and/or severe asthma, especially if accompanied by RRI. Table 11.1 summarizes the intimate links between infant asthma and atopy.

Table 11.1. Pediatric asthma and atopy

Asthma is present in a high rate of parents of asthmatic children
In the parents and relatives, atopic disease and SPT positivity to allergens are increased
Up to 90% of asthmatic children have one or two atopic parents
If children suffer from atopic asthma, asthma is even more frequent in their family
The risk of asthma is related to the atopy degree
Asthma severity is correlated to severity of atopy
Early onset of atopic asthma is predictive of subsequent BHR severity
Allergic rhinitis is present in 28%–61% and atopic dermatitis in 50% of asthmatic children
More than 80% of asthmatic children have IgE specific to one or more allergens
Even in the absence of specific IgE, the challenge test with allergens may be positive in some children
Asthma frequency was the exception in developing countries before the arrival of an industrialized society

BHR bronchial hyperreactivity, *SPT* skin prick test.

The pathogenic role of allergens as propitiatory of asthmatic attacks is expressed not so much in immediate reactions as in being the cause of long-term inflammation. Instead, symptom worsening over a short period is more easily released by irritants such as O_3, physical exertion, variations in T (temperature), etc. [333]. However, none of these factors has been formally identified as the cause of airway inflammation [499]. Often, intercurrent respiratory infections are able to amplify not only the clinical features, but also the chronic inflammation, because of the increase in the airways of eosinophils and cationic proteins, including MBP (major basic protein) [158, 341, 477]. This is significant, given the positive interaction between Rhinovirus infection and childs response to allergen exposure [341].

Other details regarding the child:

1. BHR can be present in children with AD, with greater probability in those displaying an early onset of AD.
2. BHR associated with an increase of total IgE levels can be present in children who have never suffered from asthma.
3. Altered PFT can constitute a factor of asthma risk in the first 3 years of life.
4. The onset of atopic asthma in infancy is liable to continue into adulthood if not diagnosed in time and treated appropriately.

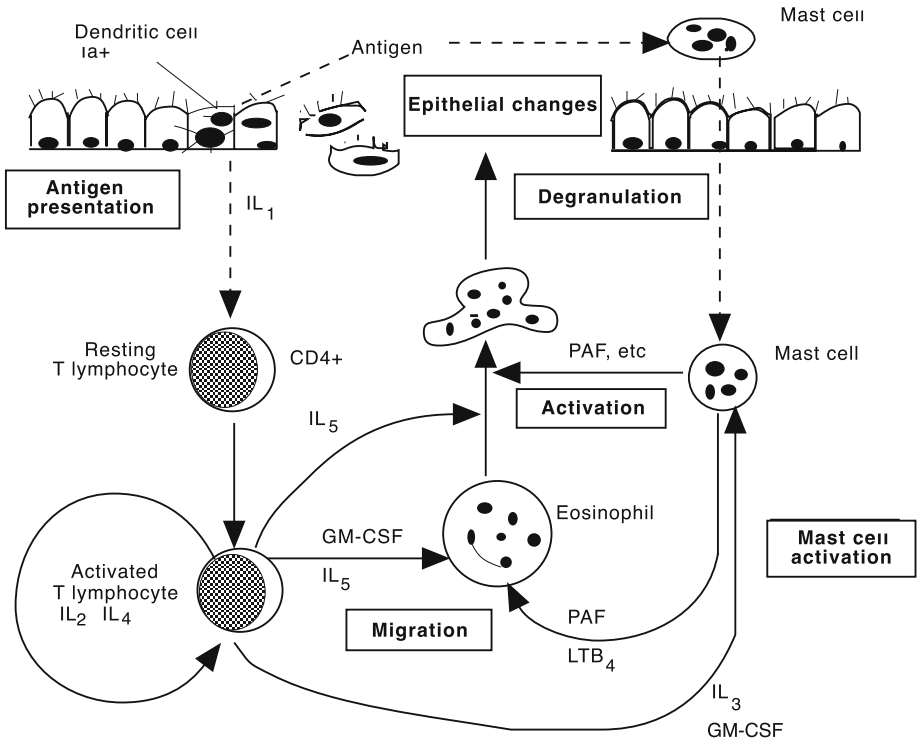

Fig. 11.3. Subsequent phases of the asthmatic immune inflammation, showing the interactions between T lymphocytes, mast cells and eosinophils, and the consequent changes involving the epithelial cells. (Modified from [194])

Pathogenesis

Role of Immune Inflammation

Airway inflammation is a characteristic feature of asthma and contributes significantly to many features of this disease. No doubts remain regarding the pathogenic role of airway inflammation (Fig. 11.3) [194], either in severe, prolonged attacks of asthma or in children with chronic disease. Since 1906 [173], *anatomopathological studies* of patients who died after an asthmatic attack have highlighted the presence of numerous changes in the bronchial mucosa [255, 516, 600] (Figs. 11.4, 11.5):

- *Clear inflammatory response* with subepithelial infiltration of inflammatory cells, eosinophils and activated lymphocytes, with class II antigens, mast cells and macrophages more numerous than in controls.
- *Desquamation* of the bronchial epithelium with shedding of epithelial cells from basal cells and swollen ciliated cells.
- *Hypertrophy and hyperplasia* of smooth muscle.
- *Edema* of the mucosa and the submucosa as a consequence of increased permeability of the microvasculature and plasma leakage.

The lumen of the bronchiole is completely occluded with mucus, eosinophils and cellular debris. **b** Pathological changes in asthma: diagram of cross-section on an airway in severe asthma showing the characteristic hypertrophy of smooth muscles

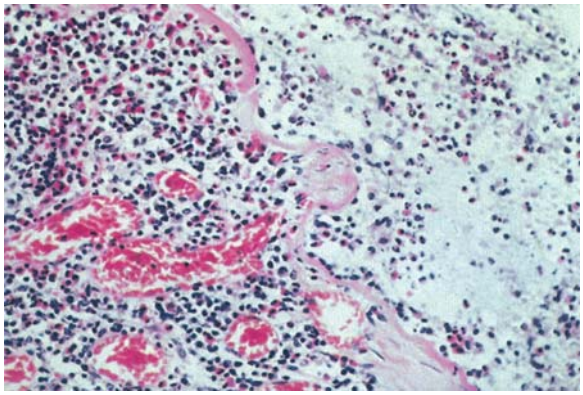

Fig. 11.5. Denudation of the epithelium in an asthma death. Epithelial cells are absent; only the thickened basement membrane remains, with hyperemia and eosinophil infiltration

- *Mucus hypersecretion* with mucus plugging in the airways (also containing desquamated epithelia, lymphocytes, Charcot-Leyden crystals (CLC) and Curschmann's spirals) up to the segmental bronchi and bronchioles.
- Numerical increase of *epithelial goblet cells.*
- *Mucosal gland hyperplasia.*
- *Fibrotic pseudo-thickening* of the BM by deposits of interstitial collagen under the epithelium.

The end result is a further compromise of the airway lumen [340].

In these studies, however, a greater number of neutrophils and a lesser number of eosinophils may be present, while fibroscopy has made it possible to demonstrate that asthma is prevalently a chronic airway inflammation in which eosinophils and metachromatic cells play a primary role in provoking tissue damage: the bronchial surface *is left naked by epithelial desquamation,* from which the remodeling processes originate, regenerative of the epithelium with squamous and calyciform metaplasia [53]. If adults with mild forms of asthma show a severe pathological picture, and deceased subjects suffering from asthma during life are found to have relatively normal bronchi [287], the damage found in specimens from lung biopsies in children with asthma in remission were similar to pathological specimens of others of the same age who died from status asthmaticus and even of patients who died of causes unrelated to asthma [255]. Figures 11.6 and 11.7 [50] show the differences between the bronchial state of a healthy subject and that of an asthmatic one during the pollen season. It should be emphasized that consistent damage of a chronic airway inflammatory process caused by more than one cell type is observed in subjects with newly diagnosed asthma, having asthma for <1 year (Fig. 11.8) [327], even after 2–3 months of asthma duration, showing a greatly decreased number of ciliated cells in the airway epithelium as compared with those in the control subjects [328].

If anatomopathologists underline the inflammatory aspects, clinicians favor that of spontaneously reversible bronchoconstriction, or reversible following specific treatment, whereas physiologists consider the increased BHR as the dominant factor. Even if the concepts of reversibility and of hyperactivity have long attracted a great deal of attention, the idea that asthma should be regarded as a pulmonary inflammation has only recently been given its due attention. Based on recent research, BHR is related to the degree of airway inflammation: as such, both tissue damage and BHR can find a unifying pathogenetic mechanism in the interaction of the different mediators discharged by different cells [255]. It does not, however, seem to be caused by the basic inflammation, since it does not regress with corticosteroid (CS) therapy [94].

Figure 11.9 [499] illustrates the etiology of asthma, BHR and bronchoconstriction. Figure 11.10 [287] shows the relationships between T and B lymphocytes and eosinophils in acute and chronic asthma [274]. Figure 11.11 [513] illustrates the physiopathological correlation and Table 11.2 [162, 538] the main differences between immediate asthmatic reactions (IAR) and

BHR bronchial hyperreactivity.

late asthmatic reactions (LAR), whose characteristics are summarized in Fig. 1.9. The immediate phase is summed up in IgE production in response to allergenic stimulus (Fig. 1.40). On the next encounter, in the atopic child, the interaction between allergens and sIgE linked to receptors on effector cell surface initiates a complex chain of biochemical events leading to cellular activation, culminating in mediator release within a few minutes of the allergenic stimulation, and, at the same time, to the appearance of clinical manifestations [207] (Fig. 11.11). Parallel with this, in the airways, 3–12 h after allergenic exposure, recruitment of eosinophils, neutrophils, basophils and PBMCs, which constitute the primary histopathological infiltrate in status asthmaticus, starts the delayed reaction ultimately resolving in chronicization. A close relationship between basophil number and histamine serum level, and between eosinophil number and MBP concentration [283] is evident. Eosinophil number, 30 min at most after antigen challenge, reaches its peak after 4–6 h and, in individuals without LAR, after 24 h [538], so it is assumed that their transition occurs from the mucosa to the secretions. The pathogenesis of this second phase no longer focuses on mast cells, which, nevertheless, participate in releasing ILs and chemotactic factors, but rather on ef-

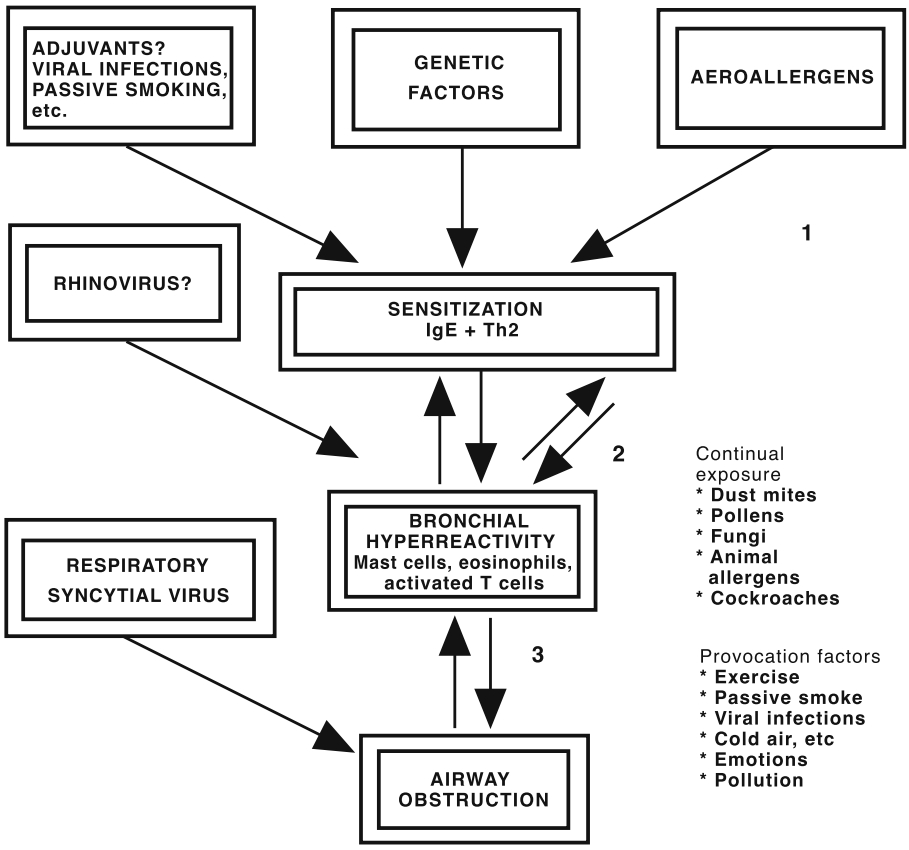

Fig. 11.9. Pathogenesis of asthma and bronchial hyperreactivity (BHR) and interactions with bronchial obstruction. *1* The first phase is asymptomatic and several children with serum IgE levels do not experience disturbances, but persistent exposure may cause bronchial inflammation with BHR. *2* The second phase is symptomatic; however, children may have normal lung function. *3* The precipitant factors are the allergens and aspecific stimuli, including passive smoke, exercise, etc. The susceptibility to viral infections is a challenge for pediatricians. (Modified from [499])

fector cells such as basophils, neutrophils, and, above all, eosinophils, as is demonstrated by cationic protein concentrations [442], ECA (eosinophil chemotactic activity) and NCA (neutrophil chemotactic activity) [240] during a BPT (bronchial provocation test) with allergens [240] up to 24 h later [442]. This role is a prerogative of specific Th2 lymphocytes, ILs, and factors they secrete, that is LTB_4, PAF, IL_3–IL_6 and the chemotactic factor of CD8 T cells [258]. On the other hand, a relative absence of IL_{10} characterizes the airways of asthmatic

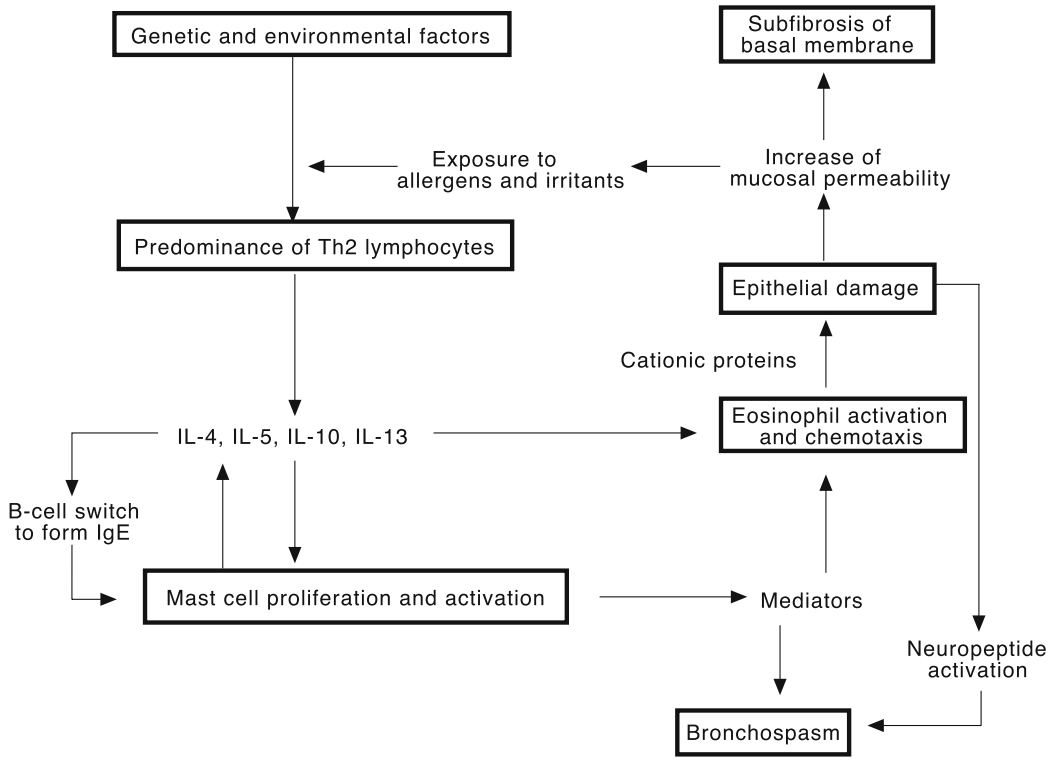

Fig. 11.11. Asthma physiopathology and pathogenesis. (Modified from [513])

sufferers, potentially increasing the severity of allergic inflammation [384]. The role of platelets still remains to be elucidated. On the basis of the latest information available, this reaction appears to be suited for further studies of the physiopathology of asthma and to assess the therapeutic potential of new drugs [162]. Both in asthmatic adults [435] and in children [255], inflammation is usually present. Moreover, a pediatric study has revealed an intimate correlation between activation of both eosinophils and mast cells and BHR [187].

A single pathogenic mechanism does not exist at the basis of the inflammation and consequential BHR; rather, it is likely that the orchestrated action of mediators, their products and cells attracted in this process can play a salient role in provoking BHR [340]. From a histopathological point of view, interesting progress has been made possible by the study of BALF cells via fiberoptic bronchoscopy, which can be performed even in nurslings, using models as small as 1.8–2.3 mm in diameter [737], and which can also be achieved, in severe cases, using a noninvasive method such as a neonatal catheter [182]. Using these techniques, immune cytochemical research has demonstrated that, in asthmatic children, neither the discriminatory presence of cell types nor their quantitative increase as compared to nonasthmatic atopic controls (Tables 1.40, 1.41) have been found. Studies of BALF cells and lung biopsies have revealed that a great number of $CD4^+$ [15, 236] are activated by the expression of CD25 and of class II HLA molecules [691]. In atopic asthma sufferers, these T cells have a Th2 phenotype, which is notably relevant in the pathogenesis of allergic disease, especially of the airways, so a great deal of asthma is associated with the activation in the bronchi of IL_3-IL_6 and GM-CSF (granulocyte-macrophage colony-stimulating factor), a pattern compatible with Th2 activation [524–526]. IL_{13} hyperproduction [321] could also bias the differentiation of T cells toward a Th2 phenotype through its ability to modulate IL_{12} production from APCs. Whether as a result of exaggerated Th2 cytokine production or as a primary defect, lack of IL_{12} can clearly influence immune responses toward a skewed Th2 response [676]. Furthermore, alveolar macrophages, bronchial epithelium, eosinophils and mast cells express these and other ILs, whose secretions lead to the pathological findings observed in asthma [15, 236, 691]. Some CXCL and CCL chemokines (Tables 1.54–1.57) act on both basophils and eosinophils; the former could represent the key mediators of immune inflammation. In immune inflammation, it is not easy to draw a balance of the importance of the different cell types or of the mediators involved. It seems more evident that they act together, each armed either with its own weapons or those shared with others, releasing a complex cascade of harmful events [73]. Of no minor importance are the notable alterations experienced by the *postcapillary microvasculature:* it is known that, in addition to the explicit damaging action carried out by powerful mediators, even vagal nerve stimulation, through neuropeptide release, secreted by neuroendocrine tissues of the airways, including substance

P (SP), can contribute to the vasodilation in the microvasculature. In turn, edema contributes to different worsening changes, including the inhibition of mucociliary clearance. In addition, proteins become available that form the substrate for anaphylotoxins of complement derivation and kinins [287].

Role of the Inflammatory Cells

Different cells are involved in immune inflammation.

T Lymphocytes

Characteristics [537]:

- *The tissues of atopic sufferers* show an accumulation of Th2 capable of orchestrating immune inflammation; consequently, Th2 predominate in the BALF of atopic asthmatics.
- *Activated Th2 cells* are found in blood and airways of asthmatics and their expansion is preferentially allergen-induced.
- *Th2 produce proinflammatory ILs* and, in particular, IL_3 and IL_4, with a major role in the synthesis of IgE, IL_5 and GM-CSF, whereas IL_2 and IFN-γ are absent.
- *Th2 are involved* in the enrollment of eosinophils, the primary effector cells of inflammation [537].
- *During asthmatic attacks,* there occurs in children an expansion of allergen-specific Th2 clones, accompanied by very high production of IL_4, as demonstrated by an increase in CD23 on B cells and on $CD4^+HLA\text{-}DR^+$ [200] (Fig. 11.12) [513].
- *In BALF of nonasthmatic children,* CD8 T cells are more numerous than CD4 T cells (Tables 1.40, 1.41), while in atopic pollen-allergic subjects the proportions are more than reversed: CD4 85% (Th2 48%, Th0 39.5% and Th1 12.5%), CD8 15%, allergen-specific T clones 27% [141].

Thus an imbalance between Th1 and Th2 lymphocytes primes the Th2 or allergic phenotype, whereas the Th1 phenotype may be underexpressed. A reduced expression of T-bet, in T cells from airways of asthmatic patients compared with that in T cells from airways of nonasthmatic patients, suggests that loss of T-bet might be associated with asthma pathogenesis [188].

In a normal lung, T cells, on the order of 1.5×10^8, are in direct contact with aeroallergens [263]. However, in moderate asthma, their number may not be increased (Fig. 11.13). In the mucosa of lower and upper airways, *dendritic cells* (DCs) have been found, whose percentage in BALF cells is 1% [693] and whose number is greatly increased in atopic sufferers [412] and in asthmatic smokers [533]. DCs form a continuous intraepithelial reticulum interdigiting with epithelial cells, similar to the skin process [619]. They do not protrude through the epithelium, being confined by the tight junctions; consequently the allergens that are not removed from the mucociliary clearance must cross the mucosal layer and penetrate via the junctions to encounter immunocompetent cells [533]. DCs send the start signal to T cells during the sensitization phase and can also act as synergistic agents of their activation process in the airway walls during IAR. They are equipped with FcεRI-α that can facilitate allergen uptake and internalization, enhancing their potential role in the induction and amplification of chronic airway inflammation [660]. Having elevated levels of class II HLA, in vivo they efficiently trap aeroallergens and in vitro are skillful APC for

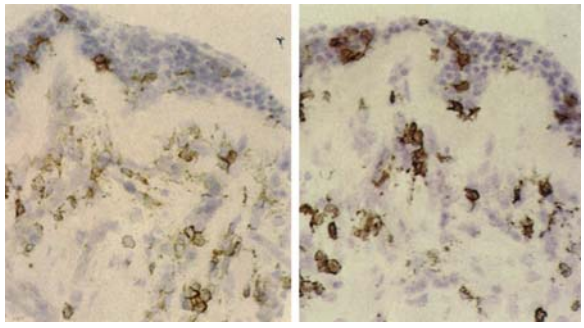

Fig. 11.13. Epithelial and subepithelial T-cell subpopulations (**left**) and CD4 and CD8 (**right**) in a bronchial biopsy specimen of an mild asthmatic subject: in mild to moderate asthma T cells are activated, but their total number is unchanged

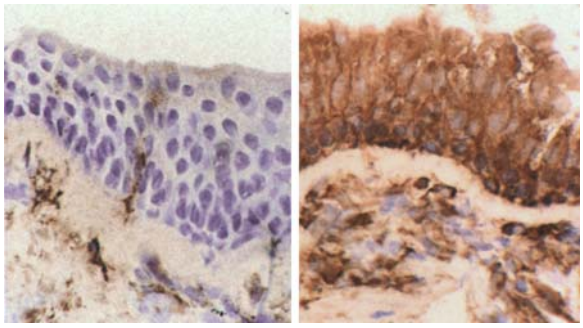

Fig. 11.14. HLA-DR (immunoperoxidase demonstration) in the bronchial epithelium of normal (**left**) and asthmatic subjects (**right**)

IELs [263], where they are CD1α-positive only for 30% [693]. They also are able to transport antigens, by migrating from the respiratory epithelium to the regional lymph nodes, where they undergo a maturing process, acquiring a greater immunostimulating activity [263]. In this way, they provide for antigen processing and presenting to T lymphocytes, thereby involving HLA-DR molecules, up-regulated in asthmatic subjects (Fig. 11.14), which, by linking to allergenic peptides, form bimolecular complexes easily recognized by TcR-CD3 [258]. Even in the bronchial mucosa in correspondence with lymphatic structures, *M cells* similar to those found in the intestinal epithelium situated over Peyer's patches have been described. In the airways, they could perform a similar function, transferring antigens from the bronchial lumen to lymphatic structures, even if they do not play a primary role in mucosal immunoregulation [537]. CD8 T cells induced by antigen encounter are in turn activated in the regional lymph nodes that drain the upper respiratory tract [262].

Lymphocytes accumulate in the respiratory tissues *during the 1st hour* of allergic reaction: in LAR they are attracted by specific receptors located on T cells, as well as on mucosal capillaries and epithelial venules, and activated in sites of immune inflammation, they induce phenotypic alterations in endothelial cells [524]. The predominant clones of allergen-specific T lymphocytes of atopic asthmatics, which are Th2-like, are able to produce elevated levels of IL_4 [535]. Recently, GATA-3 overexpression was found to be implicated in Th2 development in human T cells and IL_5 promoter activity in $CD4^+$ T cells of asthmatic patients was enhanced by GATA-3 [286]. In asthmatic patients, more cells from BALF contain mRNA for IL_3–IL_5 and GM-CSF (whose genes are associated in a gene cluster of chromosome 5), and reduced IFN-γ levels compared to controls [530]. More precisely, using *in situ* hybridization, and the immunofluorescence technique on BALF cells from asthmatic subjects, there is an evident imbalance between the reciprocal proportions of IL_4 and IFN-γ in tissue infiltrates of allergic inflammation [530], with a significantly larger number ($p<0.01$–$p<0.001$), in comparison with controls, of cells showing elevated mRNA concentrations for IL_4 and IL_3, CD3-positive (that is T lymphocytes, predominantly CD45RO), and no difference for IFN-γ [530]. IL_3–IL_5 and GM-CSF are associated with Th2, eosinophil accumulation [531], bronchoconstriction and Aas score [532]. This picture is compatible with the predominant activation of the Th2-like subset, the promotion of an IgE response and generation of pro-inflammatory mediators [524].

In asthmatics, a predominance of Th2 and Th2-like T-cell ILs are reported. T lymphocytes are therefore capable, even supported by the four classes of chemokines, of directly coordinating the accumulation and activation of specific effector cells at the mucosal surface. In particular IL_3, GM-CSF and IL_5 (with the aid of CD54, = ICAM-1) appear to be very active in attracting and activating eosinophils; GM-CSF and other T-like ILs are active in the differentiation of monocyte-macrophages, IL_3 and GM-CSF and metachromatic cells [524]. In this context, the presence of mast cells and basophils assumes great relevance, given that their precursors are able to produce IL_4 for Fcε receptor cross-linking. IL_4 synthesis modulates that of IgE antibodies, by acting directly on B lymphocytes, or by activating Th2-like $CD4^+$ cells. The latter produce on the one hand IL_4 (and therefore IgE) and on the other IL_5, finally closing the inflammatory cycle [535]. Since 24 h after BPT with allergens the majority of ILs originate from T cells [531], we may conclude that expanding allergen-specific Th2 lymphocytes directly orchestrates both the development of bronchial inflammation by producing specific IL and the *continuous synthesis of IgE*, able to elicit decisive influxes on inflammatory cells [525]. Titers of B cells, CD19 and CD23 markers are found to be increased compared to controls [552].

Examination of lymphocyte subsets in asthmatic individuals shows that $CD3^+$, $CD4^+$, $CD8^+$ and $CD45^+$ are present in notably greater numbers than in nonasthmatic atopic subjects and in nonatopic controls [15]. The marker CD25 (receptor of IL_2, IL_2R) [15, 119] and of HLA-DR and CD49a/CD29 (VLA-1) in greater numbers than in normal controls denotes that such activated cells are able to contribute to the pathogenesis [119]. Soluble IL_2R (sIL_2R) is a marker of their activation, with particularly elevated levels in asthmatic children compared to healthy controls and adults [408]. Even in the pediatric age group, high percentages of both CD4 and CD8 peripheral blood T cells express activation markers: thus T-cell activation as compared to controls is found [153, 207, 252, 590], with significantly higher differences regarding the increase in absolute numbers of CD4/$CD25^+$, CD4/$HLA\text{-}DR^+$ and CD8/$CD25^+$ [207], of T-cell specific markers CD23 and CD25 [252], HLA-DR antigen [590] and PEF-correlated CD25 [153]. Associations between eosinophil activation, $CD4^+$ cell numbers, and a high correlation between CD4-Th2 and eosinophils and severity of asthma [691], are totally *confirmed by the evidence in children of CD4-Th2 and CD8 displaying*

CD25 and HLA-DR positively correlated with disease severity (p=0.03) and with a significant increase in total eosinophilia (p=0.01) as compared with the controls [207]. Remarkably, the proportion of CD4 T cells expressing the *memory cell marker CD45RO* was significantly elevated in both atopic and nonatopic asthmatics compared with controls, whereas the naive marker CD45RA was expressed by a high proportion of CD8 T cells only in the nonatopic asthmatics compared with controls. Moreover, high rates of these CD4 and CD8 T cells express mRNA encoding IL_5, but only CD4 expressed mRNA encoding IL_4 in asthmatic children compared with the controls [208]. The relationship between cells displaying IL_5 and activated eosinophils in bronchial biopsies in asthmatics [236, 340] (Fig. 11.10) indicates that high levels of IL_5 distinguish between severe asthma [119] and moderate asthma, where they cannot be measured [153], considering that CSs reduce their transcription, together with several others, being capable of inhibiting in atopic asthmatics T-cell activation markers in BALF and in peripheral sites [723] and DC as well [412]. For these reasons, *T lymphocytes,* with all the cells and factors they stimulate, above all eosinophils, can be considered as the key cells that *bring into effect, sustain and perpetuate the immune inflammation,* the catalyst element that induces BHR in relation with endogenous and exogenous factors, and triggers the series of events that lead almost inexorably to asthma [287]. This is especially evident when the impossibility of establishing a state of tolerance through Th1 T cells results in the sensitization to environmental allergens [262], guided by the Th2 in the critical phase of developing the immune system in infants. Tables 1.40 and 1.41 summarize normal data on lymphocytes and other cells in BALF in nonasthmatic children.

Mast Cells

Characteristics [537]:

- Are present in airways of asthmatics in increased numbers and in various stages of degranulation, but are absent in normal subjects
- Respond to allergens in an IgE-dependent manner with high-affinity IgE receptors (FcεRI)
- Have a key role in driving the IgE-mediated reaction
- Directly express CD154 as basophils do, with the immediate implication that *synthesis of IgE occurs even in peripheral tissues, other than in germinal centers of lymph nodes*
- Produce short-lived mediators and inflammatory ILs

Mast cells derive from bone marrow precursors as regulated by the same ILs that are important contributors to the allergen-specific airway inflammation [537]. Their greater concentration is in more peripheral airways, where they localize prevalently in the sub- and intraepithelial layers, and in the bronchial lumen [258]. A striking increase in the number of mast cells was in the bundles of smooth muscle, and in patients with asthma this number was correlated with the hallmark of asthma, BHR [55]. In asthmatics there is no *instability of mast cell membrane,* which could facilitate degranulation, an event that can be mediated not only by encountering sIgE, but also by sIgG (specific) and anaphylotoxins. Similarly, there is no *functional heterogeneity,* since mast cells of the human airways belong mainly to the T type, even if both phenotypes can coexist in the same site with different levels (Table 1.27). Mast cells participate in the *immediate phase of allergic reactions:* they are found in the BALF of atopic asthmatics taken 15 min after allergen challenge in the *degranulation stage* [258], often in proximity to the small vessels and nerve endings and intimately correlated with smooth muscles, with spontaneous *release of histamine* and eicosanoids [73]. Once the degranulation has started, it is possible that allergen encounter with superficial mast cells provokes an initial mediator release that increases tissue permeability, with consequent enlargement of the intraepithelial tight junction network, thus allowing a greater number of allergens to reach the layers below, where a strong group of mast cells are to be found [283]. The array of primary and secondary mediators further increase the permeability of the epithelial barrier, permitting the entrance of plasma proteins and blood platelets [283]. This is how the true asthma allergy explosion is set off. Consequently histamine, PG, thromboxanes (type A_2), LTs (leukotrienes), PAF, bradykinins (BKs), granule derivatives and chemotactic factors are crucial for developing an inflammatory stage of immediate reaction [287]. As well as inducing adhesion, diapedesis, directional migration and activation of eosinophils and neutrophils, they also recruit other cells that are fundamental for the establishment and self-maintenance of inflammation, such as monocyte-macrophages, blood platelets, more eosinophils, and neutrophils to the injured site [283]. Mediators participating in the triggering of asthma affect the infiltration of leukocytes, probably aided by afferent vagal stimulations, affecting the bronchospasm as well as mucosal gland secretions, which are unrelated to symptom severity [283]. ILs, whose secretion is associated with histamine release and mast cell proliferation (probably associated with IL_3 and IL_4 generation), are in turn able to amplify the vasoactive phase of immune inflammation [73]. Mast cells, as well as sharing with basophils the CD154 production with a direct effect on IgE synthesis, express mRNA for IL_4 and for IL_5, whose release, together with IL_3 and IL_6, is triggered by an IgE-mediated mechanism [287]. Mast cells, however, appear to be *the only cells producing IL_4 in the airways of asthmatics:* this could indicate their possible intervention in LARs, which, however, has not been fully confirmed. On the other hand, the mediators seem to be correlated to IARs, as demonstrated by the increase in histamine levels in circulation and the increase in histamine and tryptase in BALF of atopic subjects a few minutes after allergen

stimulation, and by increased urinary methylhistamine in the ensuing hour [283]. Tryptase in BALF is correlated to PC_{20} (concentration of methacholine inducing a 20% fall in FEV_1), but not in serum after TPB with allergens [240], which could suggest that mast cells, along with their mediators, represent the key cells in a child's BHR, given the possibility of a tryptase-induced up-regulation of bronchial smooth muscle tone [187]. Mast cells could also have the function of controlling the immune inflammation by releasing repair mediators such as heparin [467] and LTB_4, which is highly chemotactic for both eosinophils and neutrophils [54].

Basophils

The characteristics of basophils are as follows [376]:
- They produce MBP.
- They express CD154 as do mast cells.
- Anti-IgE modulate their allergen-induced activation [581].
- PAF selectively induces them to release histamine.
- They have an important relationship with the CCL, lesser with CXCL chemokines.
- IL_3 induction produces IL_4 and activates MCP-1 (monocyte chemotactic protein-1), stimulating their degranulation.

Basophils share with mast cells the IgE-mediated degranulation process, with histamine and LTC_4 release that makes them powerful inflammatory cells; however, they do not release PGD_2 and are unique since they contain MBP along with eosinophils (Table 1.25). Together with mast cells they are high histamine producers, which release after stimulation by PAF, C5a and anti-IgE IgG [581]. Basophils release a greater quantity of histamine in asthmatics than in allergic rhinitis (AR) sufferers [376], even if anti-IgE IgG could down-regulate histamine release [581]. IgE-mediated *basophil releasability* has a clinical relevance in the pathogenesis of airway reactivity, since they are increased in atopic asthmatics: symptom severity is correlated with basophil responsiveness in vitro [376]. Lymphocytes and other cells promote their maturation and differentiation as well as mediator secretion, favored by various ILs such as IL_1–IL_3 and GM-CSF. In particular, IL_3 and GM-CSF induce their migration in vitro in picomolar doses and increase their chemokinetic activity and adhesion [742]. Basophils express, together with eosinophils but not with neutrophils, the integrin CD49d/CD29, equal to VLA-4, counter-receptor of VCAM-1, equal to CD106, which allows adhesion to the endothelia [561]. The parallel with eosinophils is strengthened by the community of receptors for IL_5 that become active in picomolar doses also on basophils [249]. Recently, it has been established that the *basophil role seems to be decisive in LAR,* coinciding with that carried out in the pathogenesis of AD: 19 h after the challenge, an increase in mediators released by these cells has been noted [73]. Of equal importance is the link with CCL chemokines and with MCP-1, MCP-2 and RANTES (now CCL2, CCL8, and CCL5, respectively), which stimulate basophil migration (Tables 1.54–1.57), while the CXCL with a function identical to IL_8 and CCL5, promote their adhesion, to which several integrins contribute (Tables 1.45–1.49).

Eosinophils (Figs. 11.3, 11.4, 11.8, 11.10, 11.11)

The characteristics of eosinophils are as follows (see Table 1.24):
- They are *markedly increased in number* in blood and airways, with statistically significant differences in asthmatic children compared to healthy controls [254, 639].
- They are *equipped with numerous integrins,* CD45, CD59 and HLA-DR among the inducible molecules.
- Dependent on IL_3, IL_5 and GM-CSF, as well as on TNF, PAF and IL_1, for development, activation and survival [460] (Table 11.3) [22, 284, 466].
- An *increase in the bronchial mucosa* of mRNA for IL_5 (eosinophilopoietic) [236] associated with GM-CSF (IL para-eosinophilia) [59] indicates its presence and activity [59, 236], and also the significant connection with a number of activated T cells [236].
- They are *laden with cationic proteins,* which once released may be highly toxic to airway tissues.
- Better than any other cell, they represent the common factor *able to correlate IgE hyperproduction* and involvement of metachromatic cells, macrophages and of themselves in the immune inflammation [526].
- Some studies, but not all, show the *hypodense phenotype* and the correlation of ECP (eosinophil cationic protein) levels with clinical manifestations.

Eosinophils also are *heterogeneous,* as far as density and activity are concerned. Their growth from eosinophil precursors is highly dependent on a set of ILs. IL_5 and PAF not only activate eosinophils but transform the normally dense cells into a hypodense phenotype (Fig. 1.35 c) that responds equally to chemotactic signals [354, 460]. Numerous studies have evaluated the possible role played by such cells, more cytotoxic [73], with more receptors for IgE and IgG, that produce more LTC_4 and more active, from a metabolic point of view, in patients with delayed responses to inhalants [538]. Such data is suggestive, but it is not yet possible to transfer them automatically to the pediatric field since it could more simply be related to immature forms [408], scarcely increased in number [254, 408], an effect inhibited by nedocromil sodium [578]. Moreover, the increase in hypodense cells can depend on artifacts resulting from techniques that use dextran or gelatin, or on the significant increase in eosinophilia in asthmatic children, therefore an epiphenomenon [254]. Thus, notwithstanding recurring indications, density appears to be an overly imprecise sign to be useful to recognize a pathogenic role in the pediatric field as an index of cellular activation.

Table 11.3. Functional correlations between eosinophils and interleukins (*IL*)

Function	ILs	Effects
Leukotriene production	GM-CSF, IL_3-IL_5	Increase
Phagocytosis	GM-CSF	Increase
Proteoglycan synthesis	GM-CSF, IL_3-IL_5	Increase
Superoxide production	GM-CSF, TNF	Increase
ADCC	GM-CSF, IL_3-IL_5	Optimal increase
	TNF	Modest increase
	IFN	Delayed increase
Adhesion	GM-CSF	CD54 increase
	TNF, IL_1	EAEC increase
Degranulation	GM-CSF, $IL_1\beta$	Increase
Density	GM-CSF, IL_3-IL_5	Reduction
Survival	IL_5	Optimal increase
	IL_3	Modest increase
	GM-CSF, TNF, IFN	Low increase

Data from [22, 284, 466].
ADCC antibody-dependent cell-mediated cytotoxicity, *EAEC* eosinophil adhesion to endothelial cells.

Eosinophils have, equal to mast cells, a great number of FcεRI and FcεRIIb (CD23), which demonstrates their *crucial role in atopic IgE-mediated disease*. In fact atopy contributes to infantile asthma by the mobilization and activation of such cells [408]. As can be seen from the data in Table 1.24, eosinophils can be primed to express HLA-DR in vivo, implying the presence of HLA class II molecules: therefore they are APCs able to present antigens to CD4 T cells. The modulating and regulating role carried out at the level of the immediate hypersensitivity reactions is also demonstrated by the increased presence in the IAR sites and by the ability of some of their cellular proteins to inhibit or degrade the mediators of the immune reaction [679]. Especially EPO (eosinophil peroxidase) can degrade LT, and PGE_1 combined with PGE_2 have been credited with being able to inhibit histamine release [679]. Additionally, eosinophils contain great quantities of VIP (vasoactive intestinal peptide) and produce SP. The mature cells synthesize PAF, which causes an increase in cytotoxicity and superoxide generation [758].

Immunohistochemical studies on BALF cells have shown that *eosinophils are in motion 30 min after the antigen encounter* [15, 217] and that their relative percentage, along with that of ECP in BALF, in the majority of patients, is correlated with the severity of asthma (Fig. 11.15) [51]. In fact they predominate over other cells in BALF, together with MBP, ECP and neurotoxins produced by them [531], data significantly documented in histological specimens of patients who died from asthma [255]. Other studies done to evaluate the differences between asthmatics and healthy controls have made it possible to ascertain that in asthmatic subjects, eosinophils appeared in the degranulation stage under the BM and among the basal cells, with a *significant parallel between the presence of eosinophils in a degranulation phase and epithelial damage*, whereas they were not activated in controls [51]. The asserted verifications of such alterations even in normal subjects can be explained by the potential damage provoked by the biopsy per se and in the preparation of the microscopic specimens [15]. As at the peak of cutaneous reaction, eosinophils are markedly reduced during exacerbations in asthmatic children [605].

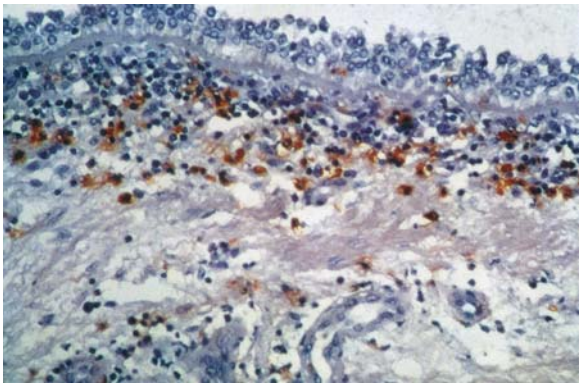

Fig. 11.15. Eosinophilic inflammation in asthma

Numerous lines of research have given further evidence that activated cells and granule products are *implicated in the tissue destruction* that accompanies and

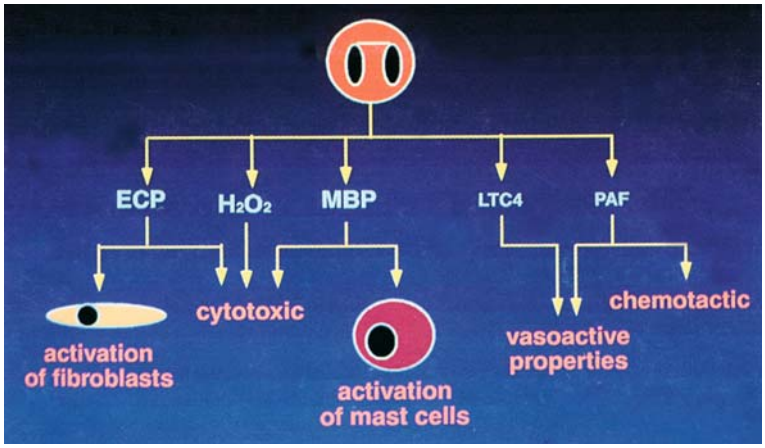

Fig. 11.16. Deleterious role of eosinophils in asthma. *ECP* eosinophil cationic protein, *LTC* leukotriene, *MBP* major basic protein, *PAF* platelet-activating factor

amplifies immune inflammatory changes (Fig. 11.16) [52]. Moreover, as a result of the change in volume and composition of the secretions of the airways that follows, *the mucociliary clearance is compromised* (by the parallel effects of LTC_4). In particular, MBP has a cytotoxic effect on airway epithelium, up to the point of dys-epithelialization [217]. The protein in concentrations of 100 µg/ml provokes in vitro ciliostasis and cell exfoliation within 12–48 h, and, if the dose is increased fivefold, the *denudation of the superficial epithelium* and of the nerve endings appears, whereas with a level of 700 µg/ml, within 30 min, the ciliary beat frequency is inhibited by 20% and the zone of activity reduced by 40% (Fig. 11.17) [217]. Experimental research has proven that EPO, in the presence of H_2O_2 and halide, tangibly damages the tracheal epithelium [51], while MBP stimulates the tracheal smooth muscles into producing PGE_2 and in secreting chlorides [217]; additionally it increases its reactivity to acetylcholine and to histamine, if the epithelium above is normal. If this is not the case, its action is negated [57]. MBP can neutralize the heparin anticoagulant activity [217]. Other highly toxic products derived from the granules play a significant role in determining the epithelial lesions during inflammation, such as ECP, ten times more cytotoxic than MBP, EDN (eosinophil-derived neurotoxin), free O_2 radicals, eosinophil-activating factor (EAF) and eosinophil cytotoxicity enhancing factor (ECEF), two factors empowering the eosinophils and their cytotoxicity [679]. An aggravating role is played by complement components, first C5a, which, like PAF, stimulates ECP and EPO release and the production *de novo* of toxic O_2 radicals. Given that components and deposits of the complement components are present in the bronchial secretions and in airway mucosa, it is likely that C5a not only stimulates eosinophils, but also contributes to their activation in tissues close to the inflammatory foci [749].

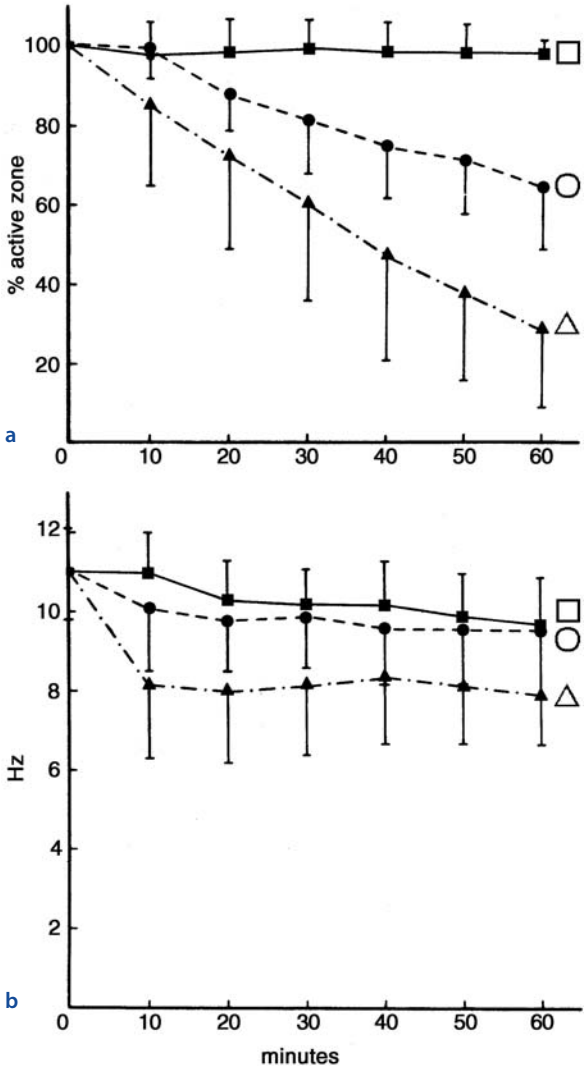

Fig. 11.17 a,b. MBP effect on ciliary activity (**a**) and on ciliary-beat frequency (**b**) in rabbit tracheal explants treated with 1.0 mg/ml of lysozyme control solution (*squares*), MBP 100 µg/ml (*circles*) and 700 µg/ml (*triangles*). The decline in percent active zone in **a**, after addition of MBP 0.1 mg/ml and 0.7 mg/ml became significantly different from control at 20 and 10 min; in **b** the decrease in ciliary-beat frequency is significantly different from the control at 10, 20, 40 min for MBP 0.1 mg/ml and from 10 min onward for MBP 0.7 mg/ml

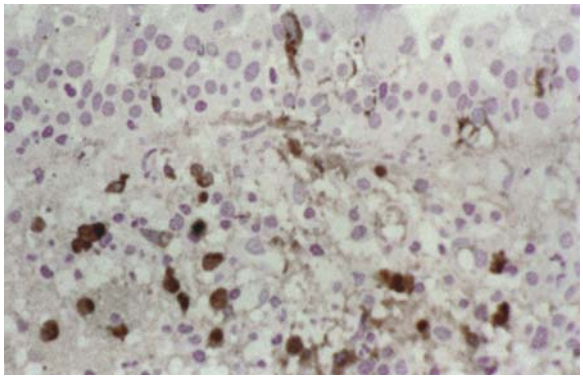

Fig. 11.18. Immunohistochemical demonstration in an asthmatic patient of migrating eosinophils stained for ECP (*in brown*)

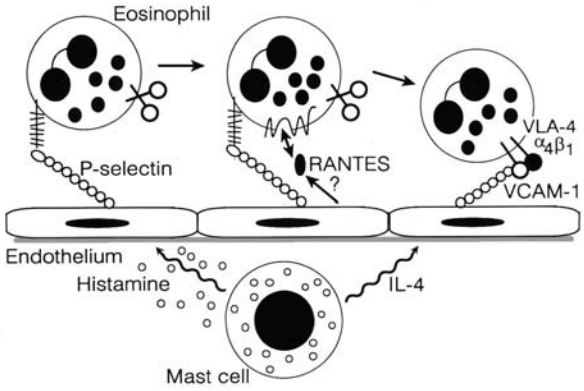

Fig. 11.19. Mast cell putative role on eosinophil transendothelial extravasation. Histamine released by degranulation mediates translocation of preformed CD62P to the endothelial surface and CD62P is involved in eosinophil adhesion. IL_4, another mast cell product, induces CD106 expression that binds to $\alpha_4\beta_1$ on eosinophils

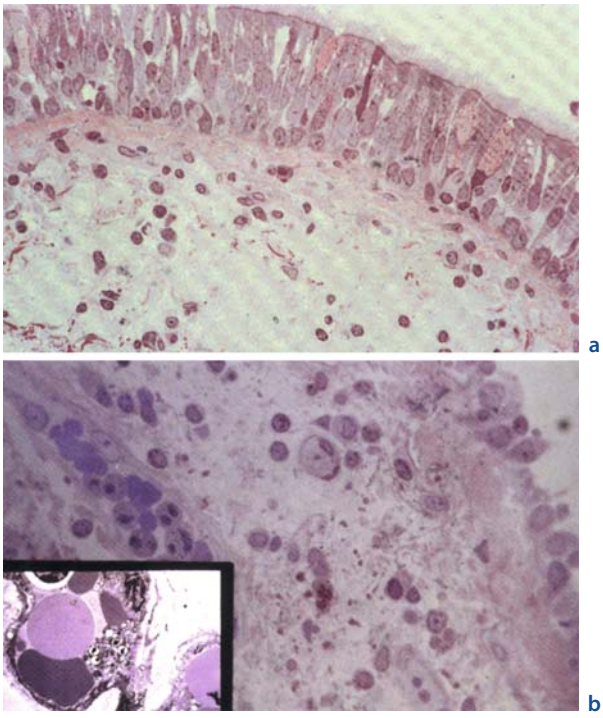

Fig. 11.20. Characteristic aspect of the bronchial mucosa achieved by fiberoptic bronchoscopy from normal (**a**) and asthmatic individuals (**b**): the comparison amplifies the extensive inflammatory infiltrate of the asthmatic biopsy and highlights the eosinophil-endothelial interactions (*inset*)

The role exercised by eosinophils in causing inflammation therefore appears dominant, as demonstrated by a significant increase in asthmatic adults in both number and ECP levels (Fig. 11.18) and in the correlation between the two concentrations, with statistically significant differences compared to controls [442, 678]. In this regard, data is controversial in atopic children [240, 442, 627, 639, 756], making asthma monitoring problematic given that *the rates decrease with treatment* [756], but not when asthma is stable [756], or in asymptomatic children [240]. More convincing seems to be the significant increase in FEV_1 after treatment, correlated with an ECP decrease, whose levels could be predictive of the results of treatment and of eventual relapses [755]. Such discrepancies are only apparent when one recalls that ECP levels depend on those of active eosinophils when inflammation is present and not on total eosinophilia. *BHR is therefore secondary to the epithelial damage caused by eosinophils and their cationic proteins*. In fact, at BHR resolution, eosinophils remain unvaried numerically, but with a reduced activation, as proved by the normalization of EPO levels, which is accompanied by the transitory increase in neutrophils and in the levels of MPO (myeloperoxidase) [229].

There exist *ample interactions with ILs* (Table 11.3) *and adhesion molecules* (Tables 1.44–1.49 and Fig. 1.59). There are three highly selective phases: expression of CD62E, CD62P and CD62L ligands (Table 1.50); activation of CD11a/CD18, CD11b/CD18, and CD49d/CD29 (VLA-4=$\alpha_4\beta_1$); and transendothelial transmigration through adhesion molecules of the Ig superfamily (CD106=VCAM-1, CD54 and CD102= ICAM-1 and -2) (Table 1.4), with a putative mast cell role in binding them to eosinophils through CD62 P and IL_4 (Fig. 11.19) [54]. Like eotaxin-1 and -2, RANTES and MIP-1α induce eosinophil chemotaxis during transendothelial transmigration [563]. The adhesion of only eosinophils and basophils to small-vessel endothelium is mediated by the interaction of CD106/CD49d/29, which therefore plays a primary role by recruiting cells to be sent toward inflammatory sites in vivo [561]. Let us remember that on a cutaneous level the CD62E selectin facilitates eosinophil and/or neutrophil adhesion, allowing them to migrate through epithelial layers, suggesting that endothelial activation, in the late stage, and due to ILs, covers a primary role in the directional migration of inflammatory cells [258] (Fig. 11.20). The glycoprotein

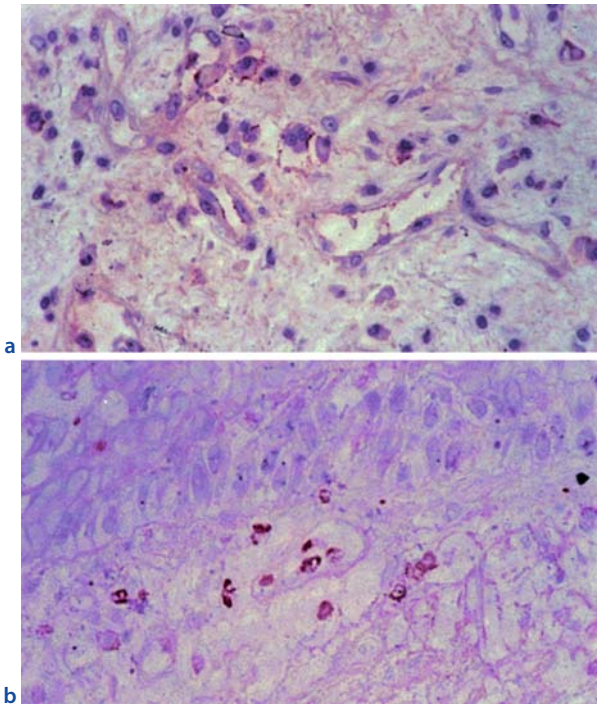

Fig. 11.21. Basal CD54 expression on endothelium of subepithelial blood vessels in a patient with symptomatic asthma (**a**) and of CD11a/CD18 receptor on T lymphocytes and eosinophils in an asthmatic bronchial biopsy specimen (**b**)

membrane of the eosinophils interacts with CD62E; thereafter eosinophils are linked via β1 and β2 integrins to endothelial cell membrane and activated under the influence of IL_3, IL_5 and GM-CSF produced by lymphocytes and mast cells [561]. Eosinophils adhere to endothelium in vitro, IL_5 induces them to express on membrane CD11a/CD18 CD54, they express their ligand on HEVs, and eosinophils are also bound to CD102, CD62E and CD106, which can contribute to their migration to the inflamed tissue in vivo [233]. They adhere to epithelium activated by IL_1 or IL_4; IL_4 can synergize with IL_1 or TNF in promoting the eosinophil link and successive transmigration [563]. Linking to CD102, CD62E and CD106 is crucial in encouraging their accumulation in the airways of asthmatics, and is so characteristic as to be able to consider the levels of CD54 and CD106 as activation indexes that are more sensitive than those based on ECP [233].

Activated eosinophils *migrate to mucosal sites* and through the action of IL_5 and PAF progress to the bronchial epithelium [460]. Elegant data indicate that only IL_5 is correlated with eosinophil enrollment and degranulation. IL_5 promotes the differentiation of mature eosinophils from precursor cells and a current hypothesis suggests that along with GM-CSF and IL_1, it can stimulate their degranulation, even in pollen-allergic subjects during the pollen season [87]. IL_5 is also able to prolong their survival for 24–48 h, with a lesser role compared to other ILs, and to activate them in successive phases, along with elaboration of lipid mediators and PAF activation [460]. In particular [563], it carries out a chemotactic action on eosinophils. Moreover, since it is a growth factor inducing pro-inflammatory modifications in these cells and acting on B lymphocytes, it increases IL_4-induced IgE synthesis, making it possible to conclude that IL_4, after its release from IgE-activated mast cells, can foster eosinophil recruitment and differentiation, both in blood and in the airways. As pointed out previously, the comment that IL_5 regulates eosinophil adhesion, an event underlying a fundamental role in their persistence in airway tissue, is relevant [460].

Studies on animals have widened the field of experimental knowledge, indicating that CD54 expression is induced on *endothelial and epithelial cells of the airways* in the hours following an inflammatory stimulus [81] (Fig. 11.21), that repeated antigen inhalations concretely increase CD54 manifestation on tracheal vascular epithelium and endothelium with a consequent rise in BHR and eosinophils in the airways, and also that anti-CD54 monoclonal antibodies reduce neutrophil adhesion and migration and inhibits (partial) in vitro eosinophil adhesion to endothelial cells [230]. Anti-CD54 delivered in vivo lessens or eliminates eosinophil infiltration and aspecific BHR induced by methacholine [230]. These experimental data clearly indicate that CD54 can play a substantial role in BHR pathogenesis [705], while blocking it by a monoclonal antibody can provide a therapeutic approach for the treatment.

Monocyte-Macrophages

Pluripotent monocyte-macrophage cells are implicated in the pathogenesis of asthma, performing important functions in chronic inflammation, due also to their long life-span (about 180 days). Similarly to mast cells, they are divided into two subpopulations: low-density cells that appear in a state of activation, and high-density cells that are in a state of quiescence.

Immunohistochemical studies on cells taken from BALF have shown evidence that:

- Their numbers are higher in atopic asthmatics than in healthy controls.
- Many cells carry monocyte markers, suggesting that they are of recent derivation from blood monocytes.
- They are provided with receptors for IgE (FcεRIIb) and therefore are activated [330, 693].

Monocytes

The characteristics of monocytes are the following [330]:

- They produce ILs stimulated by endothelin-1 (ET-1) and endothelin-4 (ET-4) [129].
- They liberate thermostable factors.

• They express HLA class II antigens and activation molecules CD11a and CD11b.

Such expression is suppressed by hydrocortisone in sensitive subjects, but not in those who are resistant [330]. They migrate in the alveolar cavities as a consequence of a series of factors related to endothelial microvasculature and chemotaxis phenomena [537]. In the airways, they actively participate in inflammation, secreting numerous ILs with pro-inflammatory activity such as IL_1, TNF, M-CSF, chemokines as well as thermostable factors that stimulate eosinophils and neutrophils to release LT and ECEF. Monocytes in asthmatics are activated, as demonstrated by IL_5 production in atopics with peripheral eosinophilia; they produce GM-CSF in vivo that, on its own or in concert with other ILs, can induce bone marrow progenitors to generate new colonies [330]. Monocytes show a striking ability to produce $O_2^{\cdot -}$ and, when they are linked by FcεRIIb to the receptors, can activate NADPH oxidase, thereby playing a significant role in chronic inflammation by their ability to release toxic products, in part through their linking to CD23-IgE [144]. Co-expression of $CD14^+/CD23^+$ is significantly increased, while the specific CD14 marker shows no change [552]. ET-1 and ET-4 are potent stimuli for monocyte production of TNF-α, $IL_{1\beta}$, IL_6, IL_8 and CM-CSF [129].

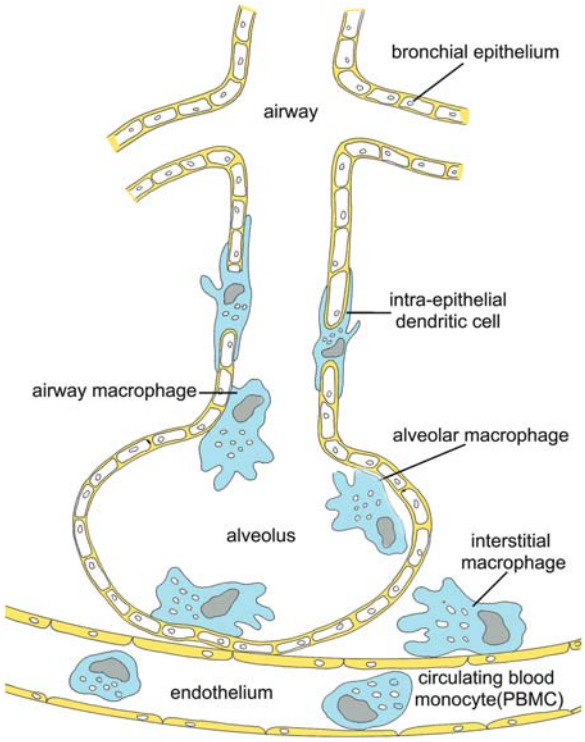

Fig. 11.22. Airway macrophages are significantly increased in asthmatic subjects

Macrophages

The characteristics of macrophages are [537]:

• They are increased in number in asthmatic airways and BALF.

• They can produce proinflammatory ILs such as IL_1, IL_6, IL_8, TNF, and also PGs, LTs, PAF, NO (N oxide) and O_2 free radicals.

• They express FcεRIIb.

It is hypothesized that the majority of active macrophages derive from circulating monocytes [97] (Fig. 11.22). The lung alveolar macrophage is the primary phagocytic cell in the alveolar space [533]. Although their numbers are significantly increased in asthmatics [503], their proliferation in the airways is generally negligible, leading to underestimating their contribution to asthmatic inflammation [330]. On the contrary, they are equipped with HLA class II molecules, becoming, in this association, the predominant cell type in the airways [537], and they are able to process and present antigens to histocompatible CD4 T cells, even though alveolar macrophages are APCs of little effect [287]. After interacting with CD4 T cells, active macrophages pass to a quiescent stage, which precludes the perpetuation of the inflammation [97]. They synthesize a *wide range of mediators*: eicosanoids of both metabolic cycles, including LTC_4, LTD_4 and LTE_4, PAF, and β-glucuronidase. Moreover, they produce O_2 free radicals, pro-inflammatory ILs of toxic effect on the bronchi, various proteins and peptides, C5a, PDGF (platelet-derived growth factor) with consequent release of other mediators (Fig. 11.22) and, if Ca is present, HRF, and they also participate in LARs [564]. In contrast to their ability to release factors impairing ciliary function, macrophages also express a potent capacity to synthesize ILs that may up-regulate ciliary beats [648]. In 75% of cases, macrophages react with GM-CSF [330], which activates them, stimulating their response to IgE via CD23, so IgE occupying the CD23 molecule on macrophages leads to a potential loop for allergens to activate macrophages [537].

As effector cells they are charged with clearance of cellular debris ingestion and killing of microorganisms. They have the ability to migrate to sites of inflammatory reactions where they produce growth factors, bioactive lipids, free O_2 radicals, NO and nitrites [537]. In particular, the marked production of NO [443] may have important effects on vascular and bronchial smooth muscle tone and on bronchial epithelial cells: therefore, the role played by macrophages in airway inflammation [212] is significant. Alveolar cells synthesize elastase and metalloproteins, capable of breaking down macromolecules of the extracellular matrix (ECM), among which elastin is an element in connection with the elastolysis found in asthmatics [53]. As regards the relationship with other cellular types, they contribute to the recruitment and immunological activation of granulocytes, attracted by LTB_4 and IL_8/NAP-1 (neutrophil activating peptide-1), of eosinophils by PAF, GM-CSF and IL_5, of neutrophils by IL_8/NAP-1 and of mast cells [287].

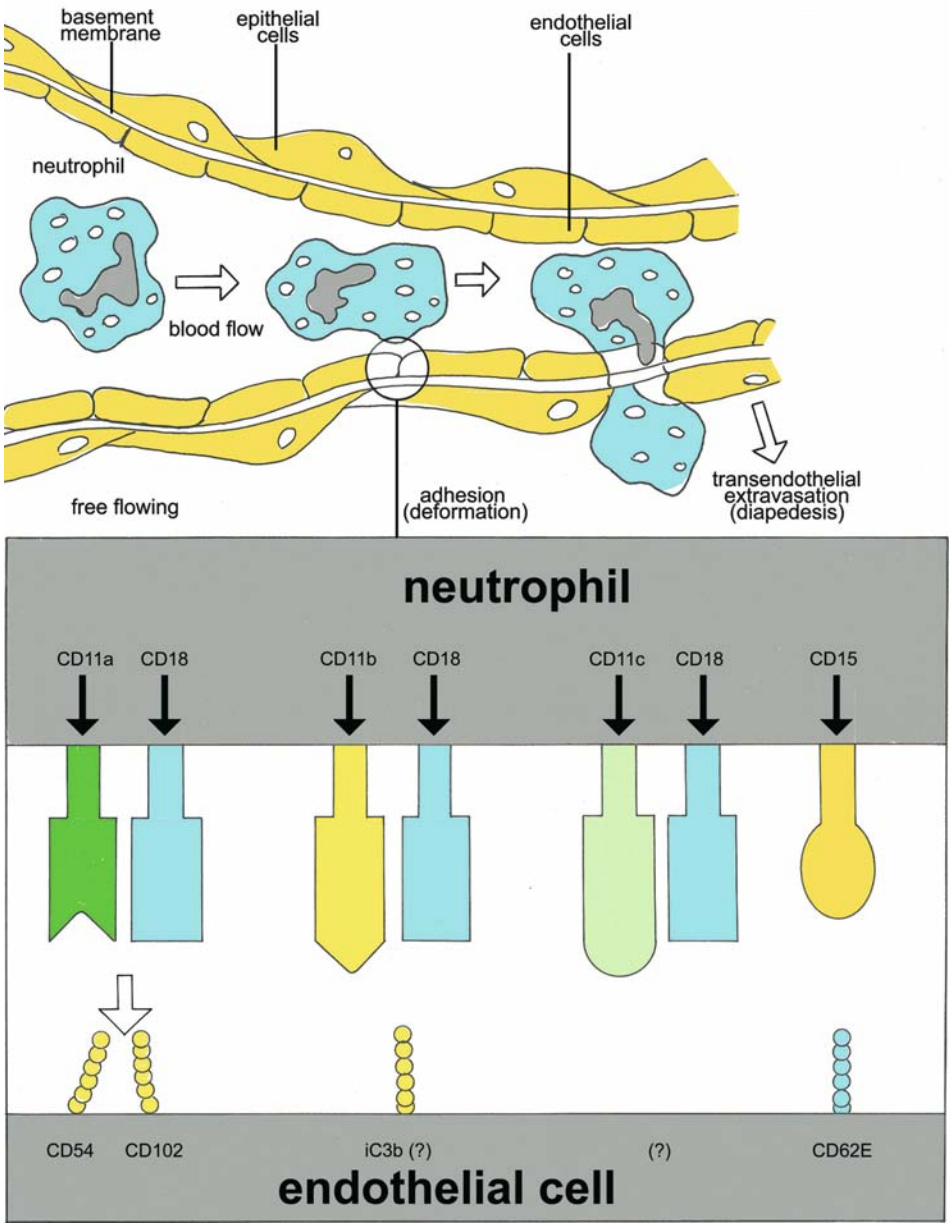

Fig. 11.24. Neutrophil extravasation

To summarize, macrophages participate in regulating the inflammation by releasing ILs and growth factors, and in the growth and activation of mast cells and eosinophils. All these effects stimulate the release of vasoactive mediators capable of provoking bronchoconstriction and mucus secretion. Recently, it has been reported that macrophages produce CCL chemokines such as MIP-1 and -2, MCP-1–3, and that alveolar cells are activated by MCP-1, with increased levels in asthmatics [330]. It follows that even *macrophages could play the role of key cells in immune inflammation* [52], as depicted in Fig. 11.23. Moreover, the virtual involvement in the fibrosis process in the reparative stage [53] demonstrates their wide powers. Finally, they constitute the only cell line that does not undergo the positive effects of therapy [212].

Neutrophils

The characteristics of neutrophils are:

- They can have *cytotoxic enzymes* and toxic radicals of O_2.
- They appear to be *more active in LARs.*
- They enter into close contact with *selectins and integrins.*
- They secrete numerous *ciliostatic substances.*

Neutrophils are active in acute asthma in both IARs and LARs, as shown by the presence in both phases of *neutrophil chemotactic factor* (NCF). Neutrophils accumulate in the sites of IgE-mediated acute allergic reactions within a time that varies from 30 min to a few hours. Therefore, these effects are carried out after the initial action, when NAP-1 and NCF come into play, promoting an accumulation of inflammatory cells that prolongs the inflammatory effects of allergen challenge. Their primary role seems to be that undertaken in LAR, depending on the time needed to produce NCF. Neutrophils are found at the center of inflammatory lesions because of two specific cell sites: the cytoplasmic membrane and the intracellular granules, which contain a vast array of digestive enzymes (Table 1.23). Elastase, collagenase and gelatinase, which attack the vasal endothelium of the respiratory apparatus, are particularly cytotoxic. Not all authors are in agreement regarding the attribution of a specific role to neutrophils [53, 600], even if IL_{17} secreted by T cells could involve them in the airways (Table 1.5).

Recently, however, a better understanding has been gained of the role they play in immune inflammation, which is summed up in the stages described above and which require the recruitment of CD11a/CD18, CD11b/CD18, β2 integrins of neutrophils, which link to their counterparts on endothelial cells, CD54 and CD102 [420] (Fig. 11.24). Furthermore, in vitro studies have shown that the duo NAP-1/IL_8 [266], stimulated by CD62E, directs neutrophils to transmigrate through the endothelium [420], and that SP directs them toward inflammatory sites, joining with VIP and somatostatin in modulating their functions, in concert with various ILs [88]. As underlined in Chap. 1, PAF and SP favor neutrophil adhesion to the walls of vascular endothelium and their successive migration in the interstice of respiratory airways of asthmatics, where they can produce several negative effects on both structure and function [88]. In a mouse model, the link between allergen-induced T cell activation and neutrophil influx induced early IL_{17} mRNA expression in inflamed lung tissue, concomitant with a prominent bronchial neutrophil influx [243]. In asthmatic children, the manifestation of CD11b, localized in specific granules, is also increased in the neutrophils, thus carrying out an important role in their migration together with eosinophils: the induction of complement receptors, in particular of CD35, could constitute the first step in the inflammation [37]. The *negative effect of neutrophils on ciliated cells* caused by proteases such as elastase, by oxidants that impair their motility, as well as by bioactive lipids such as PAF that up-regulate mucociliary clearance [413, 648], has now been confirmed.

Epithelial Cells

The role of epithelial cells is to provide passive support to sensorial receptors, which are opportunely protected by tight junctions and regulate the hydroelectrolytic perireceptor environment, also ensuring, by means of mucus and *cilia,* the clearance of abnormal substances and performing antimicrobial, antioxidant and antiprotease activities [648]. According to recent information, they also play an immune role as APCs, as they are equipped with FcεRII and class II antigens that they can present to CD4 T cells (Fig. 11.13), and express enzyme pathways for cyclooxygenase and lipoxygenase. Oxygenated metabolites have robust effects on smooth muscles, nerves and glands, as well as on inflammatory cells and epithelial cells [52] (Fig. 11.25). Due to specific phospholipases, these cells release eicosanoids, NCF and endopeptidase, able to degrade neuropeptides and fibronectin that mediate cell adhesion together with integrins, and *participate in epithelium regeneration* [525]. Epithelial cells contribute, therefore, by means of these mechanisms, to the pathogenesis of asthma, promoting both infiltration and local activation of granulocytes and T lymphocytes [374].

The epithelial cells also produce:

- *IL_1,* an IL_6 synergistic component of T lymphocyte, IL_8 growth and activation [374], IL_{10}, IL_{11}, and IL_{16} [189]
- *NAP-1/IL_8,* chemotactic for T cells, neutrophils and above all eosinophils, in contrast with normal subjects [33]
- *Growth factors:* TNFR-1 (CD120a), endothelins, lipids, NO, PDGF [189]
- *Adhesion molecules* such as CD54, CD102, CD62E and CD62P, ligands of the counterparts on T lymphocytes (CD11a, b/CD18, CD49d/CD29) and CD62L

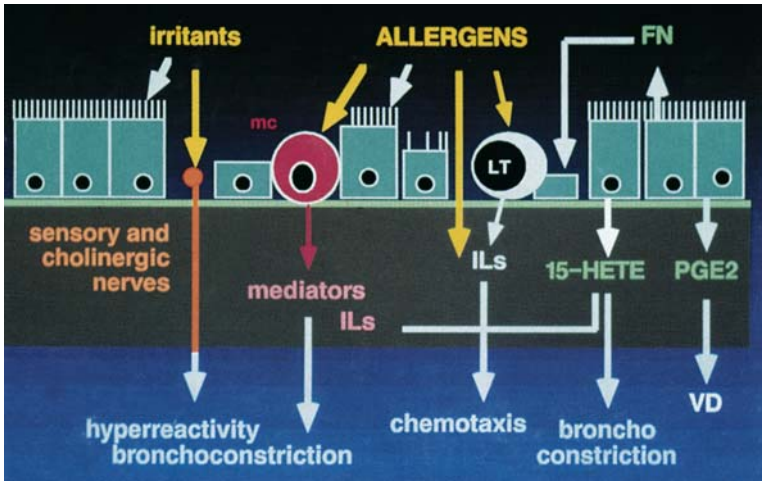

Fig. 11.25. Putative role of epithelium in asthma. *FN* fibronectin, *IL* interleukin, *LT* T-cell, *MC* mast cell, *VD* peripheral vasodilation

- *Chemokines:* MCP-1 and GM-CSF specific for monocytes, MCP-4, GRO-α and GRO-ɣ [189]

The report that $IL_{1\beta}$ produced by monocytes induces an increased synthesis of IL brought about by epithelial cells denotes the possible existence of an amplifying network among epithelial cells and monocytes/macrophages.

Recently the effects in the airways of ET-1, provided with a powerful bronchoconstriction action – less so in endothelin-2 and -3, whose synthesis is codified by an equivalent number of genes identified in the human genome – have been defined [431]. Bronchial epithelium of symptomatic patients produces larger quantities of it compared to asymptomatic patients. ET-1 binding sites are present in bronchial and bronchiolar muscles [4]. Additionally, such peptide stimulates the lipoxygenase activity with an increase of LTs, with both chemotactic and constriction effect on smooth muscle [4]: in a pediatric cohort it reflected the degree of effort required by asthma [12]. In confirmation of its autochthonous production, ET-1 levels in BALF are high; the output is regulated by TNF-α, IL_1, lipopolysaccharides (LPs) (endotoxin) [431] and histamine [4]. Consequently, the airway epithelium, like vascular endothelium, plays an important, double role in regulating the muscular tone of the area of interest, releasing both constriction factors, such as ET-1, as well as the epithelium-derived relaxing factor (EDRF) [431], identified with NO [10].

The potentially harmful activity of epithelial cells also comes about through 15-HETE, a biological mediator that stimulates the infiltration of inflammatory cells by inducing the release of mucosal glycoproteins, influencing in leukocytes 5-lipoxygenase activity and stimulating in asthmatics a premature bronchoconstriction in response to inhaled allergens. They are therefore activated cells, which, with their products, can play a deleterious role in the genesis and persistence of bronchial inflammation and BHR (Fig. 11.25), while their changes are the heart of remodeling [491].

Endothelial Cells

The vascular endothelium, in addition to contributing to the passive barrier and also *taking part in airway remodeling* [490], seems to be involved in asthma pathogenesis and in inflammatory processes associated with its severe forms. It is considered a true endocrine gland, with a surface made up of about 10^3 cells corresponding, in an adult, to about 1.5 kg of tissue [112]. Its cells locally regulate the inflammatory cells that, to reach inflammation sites, must cross endothelial walls. This process is articulated in two phases: first adherence and then passage through endothelial cells. The regulatory activity consists of impeding the adhesion and aggregation of blood platelets and other blood cells, maintaining bloodstream regularity by endothelium-released NO, with an action that is both vasodilatory, especially at the arteriolar level, and antiaggregating along with PGI_2 [10]. Once activated, endothelial cells induce:

- An increased expression of *adhesion molecules*
- Production of *GM-CSF, IL_8 and RANTES,* potentially reduced by inhalation of beclomethasone dipropionate (BDP)
- Production of *chemotactic factors* for neutrophils and T lymphocytes, and of PAF and IL_5 [654]

Basophils adhere to endothelia by means of CD49d/CD29 [561], and TNF-α and IL_1 induce CD54 on endothelium (a prerogative also shared by macrophages) and CD62E for leukocyte adhesion. Activated endothelium could be capable of self-protection against TNF-α negative effects, which exposes the barrier to O_2 toxicity, thus increasing its permeability [654]. Nor should one forget the complex interactions between subsets of lymphocytes and endothelial tissues in the control of lymphocyte recirculation (Fig. 1.5). Hence, it is not out of the question to also attribute to these cells a participation in the inflammatory process.

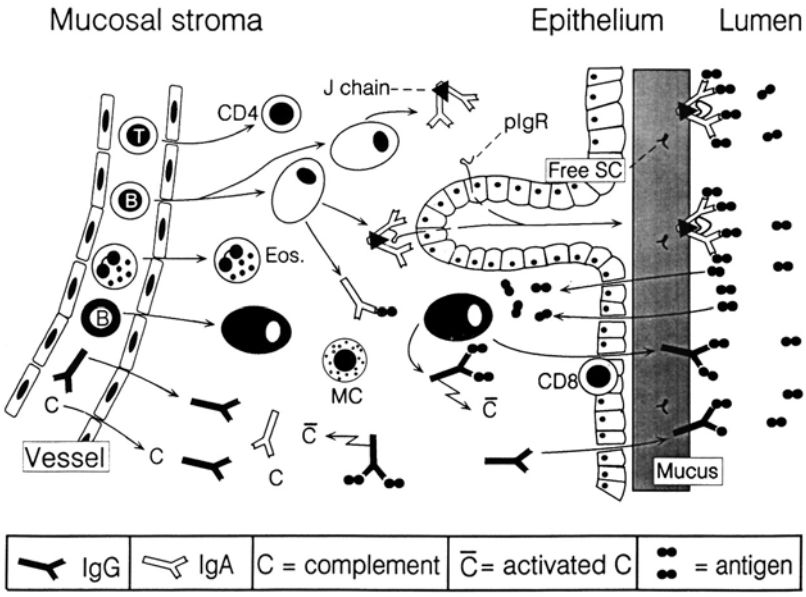

Fig. 11.26. Altered immunological homeostasis in respiratory mucosa. The altered mucosal homeostasis is reflected by distorted B lymphocyte accumulation because of aberrant lymphocyte extravasation, and emigration of mast cells (*MC*) armed with IgE and partly primed eosinophils (*Eos*) is facilitated by cytokines modulating the profile of endothelial adhesion molecules. A second line of defense is set up in the mucosa to perform immune elimination, including local IgG production to limit dissemination of foreign antigens. Due to the proinflammatory IgG properties, a vicious circle may develop with further increase in epithelial antigen penetration, complement hyperactivation, massive phagocyte recruitment and inflammatory mediator release (for details see text)

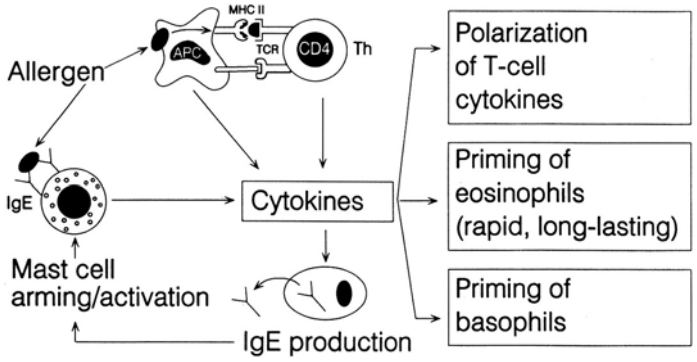

Fig. 11.27. Central role played by IgE and mast cells in development of late-phase allergic reaction. Processed peptide is exposed by APC to T lymphocytes in the context of HLA class II molecules, while intact allergen cross-bridges IgE antibodies on the surface of mast cells. Cytokines generated by CD4 and mast cells enhance preferential IgE production triggering mast cells, thus polarizing T-cell cytokines to a Th2 pattern (for details see text)

Blood Platelets

Blood platelets provided with FcεRII migrate by diapedesis to inflamed tissues, acting as effector cells in the immune inflammation. An inappropriate activation leads to eosinophil recruitment by the expression, either singularly or in combination, of PF4, PAF, PGE_2, and thereby to BHR and asthma. In asthmatics, thrombocytopenia, an increase in associated circulating blood platelets in the microvasculature, of blood platelets in BALF, of PF4 levels and thromboxane B_2 (TXB_2), as well as the prolonged bleeding time and a reduction in the time needed for blood platelet regeneration and survival have been identified. These cells liberate TGF-β and PDGF, the former being able to stimulate fibroblast proliferation, the latter smooth muscle hypertrophy. βTG (β-thromboglobulin) generates NAP-2 and PF4, chemotactic for neutrophils and monocytes/macrophages, respectively (Table 1.57), suggesting platelet involvement in infiltrating and perpetuating structural alterations which, in the long run, lead to subepithelial fibrosis and smooth muscle proliferation at the basis of BHR [743]. The hypothesis that βTG and PF4 perform the role of platelet-activation markers has not been confirmed [743].

The Role of IgE

As already noted, the production of IgE is slight in the respiratory mucosa which, instead, is populated by mast cells armed with IgE in the epithelium and connective tissue, which, along with basophils, produce CD154, whereas eosinophils have the CD40–CD154 duo (Chap. 1). In making a comparison with Fig. 11.2, in the mucosa a contrast with the alteration of immune homeostasis can be noted (Fig. 11.26) [54], provoked by an excessive local accumulation of B lymphocytes following a combination of an aberrant extravasation of lymphocytes, an increase in vascular permeability and an excessive exposure to antigens by the local immune system. All this is transformed into a worsening and perpetuation of the inflammation, laying the foundations for a chronic disease of the mucosa [54]. The increased production of IgE and mast cell positive regulation play a role in the outcome of the late reaction which cannot take place without T cell cooperation (see "Role of the Inflammatory Cells") (Fig. 11.27) [54].

Parallel to the suggestion of interpreting to interpret AD as a failed attempt by Th2 T cells to inhibit Th1 T cells to restore local homeostasis, asthma could be the

result of *a failure of the normal defense of the organism to control IgE-mediated immune responses* [263].

Role of the Mediators

A host of mediators, some preformed such as *histamine* (Fig. 1.56) and others generated *ex novo,* participate, directly and indirectly, in inflammation and bronchoconstriction [162, 538]. Many of those initially released are widespread, far from the discharge site to go toward metabolization or inactivation. Histamine, BK and PAF are at the basis of IAR (Table 11.2); others such as PGs, thromboxanes (TXs) and LTs provoke both IAR and LAR. Other *inflammatory factors* are PGD_2 and TXA_2, which produce vasodilation, LTs, which induce mucus secretion and increase vascular permeability, and factors released by neutrophils, basophils and eosinophils, discarded by mast cells after allergen/IgE-FcεRI interaction and drawn back to the site of immune inflammation by chemoattractant factors (BCF, NCF, ECF, LTB_4). The peptide LTs such as LTB_4, discarded by stimulated neutrophils, monocytes and macrophages, LTC_4 by mast cells and eosinophils, are *powerful mediators of asthma attacks.*

Lipid Mediators

PAF is a vasoactive mediator released by a range of cells that carries out a bronchoconstriction activity after exposure to a specific allergen. It has chemotactic and activating action on neutrophils and, above all, on eosinophils. Additionally, it increases eosinophil cytotoxicity, provoking the release of granule content; it stimulates $O_2^{\cdot-}$ generation (less in neutrophils), promoting the release of MBP and ECP cationic proteins and, in blood platelets, the flow of Ca ions and aggregation [758]. PAF linked to specific receptors can stimulate complex mechanisms of intercellular transduction, by which it induces G proteins and C protein kinase activation, and inositol phosphate and intracellular Ca turnover increase, the result being the secondary activation of phospholipase A_2 with subsequent discharge of arachidonate by membrane phospholipids, with subsequent production of a mediator cascade, including TXA [607]. For eosinophils, it is the most potent chemotactic factor which causes, in vivo, their accumulation in the airways, amplifying their activity both in IAR and LAR. Additionally, TXA promotes their adhesion to human vascular endothelium, stimulating eosinophils to synthesize LTC_4, an effect amplified by the fact that, when eosinophils come into contact with PAF, they release further quantities [607]. Eosinophils can attract other cells through PAF, with an increase in vascular permeability and bronchoconstriction, to the point *of destroying the bronchial epithelium of asthmatic children* [558]. Exudation of serum proteins in tissues – also due to a combined action with LTC_4 – is at the forefront in contributing to the amplification and maintenance of long-term immune inflammation [607]. The selective attraction-activation eosinophil ratio as also documented by the orchestration of cationic proteins, and powerful mediators, makes PAF the *leading player in eosinophil inflammation,* able to reproduce the entire sequence of typical asthma events. PAF plays a notable regulatory role in pediatric asthma re-exacerbations, as demonstrated by its marked increase during acute asthmatic attacks and by the parallel decrease after SIT [265], and by higher levels in asthmatic children, as compared to asymptomatic children and controls [558].

Eicosanoids

Eicosanoids are secreted in the airways by mast cells, alveolar macrophages, neutrophils, eosinophils and epithelial cells [362]. Among those derived from mast cell membrane, via the arachidonic acid metabolism, the second class of cysteine derivatives in particular possess a spasmogenic action, while LTB_4 carries out a chemotactic action. Lipoxygenase leads to the formation of various PGs, which, together with TXA_2, cause bronchoconstriction, milder if induced by PGE_2.

LTs are assuming an ever more important role in the pathogenesis of asthma as based on new experimental data (Fig. 1.57). Inhalation of cysteine derivatives provokes an acute bronchoconstriction that is prolonged and stronger than that caused by histamine in asthmatic sufferers, whose upper air tract is particularly sensitive to LT bronchospastic actions [387]. Higher levels in BALF and urine of asthmatics during a severe, acute crisis can always be noted. LTs also exert a sensitizing action on the airways, making them vulnerable and susceptible to BHR to triggering agents such as allergens, intense physical activity or cold air [387]. Additionally, LTs increase vascular permeability, mucus hypersecretion and the production of IL_1 by monocytes [362]. LTE_4, in particular, recruits eosinophils and neutrophils in the ratio of 10:1, able to increase their numbers in only 4 h [329], while LTC_4 reduces the activity of respiratory cilia in vitro [709], a negative effect confirmed by the report that pretreatment with cromones inhibits LTs [578]. LTB_4, on the other hand, possesses striking chemotactic activities for neutrophils, eosinophils and monocytes, also regulating the expression of membrane receptors and of IgE-FcεRII. Recent data show that concentrations of exhaled LT and 8-isoprostane (a marker of oxidative stress) are increased in atopic asthmatic but not in atopic nonasthmatic children. Exhaled LTE_4 concentrations are reduced by 18% by inhaled CS treatment whereas LTB_4 and 8-isoprostane are not reduced [588].

Prostaglandins PGF_{2a} and PGD_2 are powerful bronchoconstrictors. PGE produces bronchodilation in healthy subjects and bronchoconstriction in asthmatics. PGI_2 has little effect on smooth muscle but, since it

Table 11.5. Effects of mediators in the airways

Effects	Mediators
BHR	ECFs, NCF, HETEs, LTB_4
Bronchospasm	Histamine (H_1 receptor), LTC_4, LTD_4, LTE_4, PGD_2, PGF_2, TXA_2, BK, PAF
Epithelial desquamation	H_2O_2, OH^-, $O_2^{\bullet-}$, proteolytic enzymes
Mucosal edema	Histamine (H_1 receptor), LTC_4, LTD_4, LTE_4, PGE, BK, PAF
Mucus secretion	Histamine (H_2 receptor), LTC_4, LTD_4, LTE_4, PGE, acetylcholine, C3a, C5a

Modified from [283].

has a striking vasodilatory activity, can cause, in concert with other mediators, edema and therefore BHR [362].

Tables 11.4 and 11.5 [22, 283] summarize the mediator activities and the pathological events for which they are responsible.

Role of Cytokines

These immunotransmitters, able to induce their own release besides that of other mediators and of regulating the expression of the receptors, have specific effects on immune inflammation acting on both growth and differentiation of the progenitors of hematopoietic cells, which are released at the sites of immune inflammation. ILs (Table 1.5), many of which can be found in BALF, are released [58, 334]:

- many that can be found in BALF are released by [58, 334]: IL_3–IL_5, IL_9, IL_{11}, IL_{13}, IL_{17}, IL_{25}, and GM-CSF by Th2 lymphocytes and mast cells
- IL_2, IL_9 and IFN-γ by Th1 lymphocytes
- IL_1, IL_6 and TNF-α by macrophages
- GM-CSF, IL_3, BaDF, NGF by epithelial cells
- GM-CSF, IL_6 by fibroblasts and endothelial cells (see the complete list in Table 1.5, also including IL_{16} and IL_{17})

Allergic airway disease is associated with skewed Th2 cytokine production, although the underlying cause of this aberrant immune response is not well understood. GM-CSF, IL_3 and IL_5 prolong eosinophil survival and stimulate their degranulation. GM-CSF stimulates granulocytes to generate LT and PAF, basophils to release histamine and neutrophils and macrophages to secrete more cytokines, among which are found IL_1, TNF, G-CSF and M-CSF [58]. All ILs act according to what is summarized in Table 1.5, in concert with the newly released and activated factors (Fig. 1.56), perpetuating the allergic inflammation and forming the molecular basis of its becoming chronic. IL_4 plays a highly important role in promoting the isotypic switching of B_{IgG} cells into B_{IgE} cells and, as a consequence, increases the concentrations of total IgE and sIgE recorded in allergic asthma. IL_6 en-

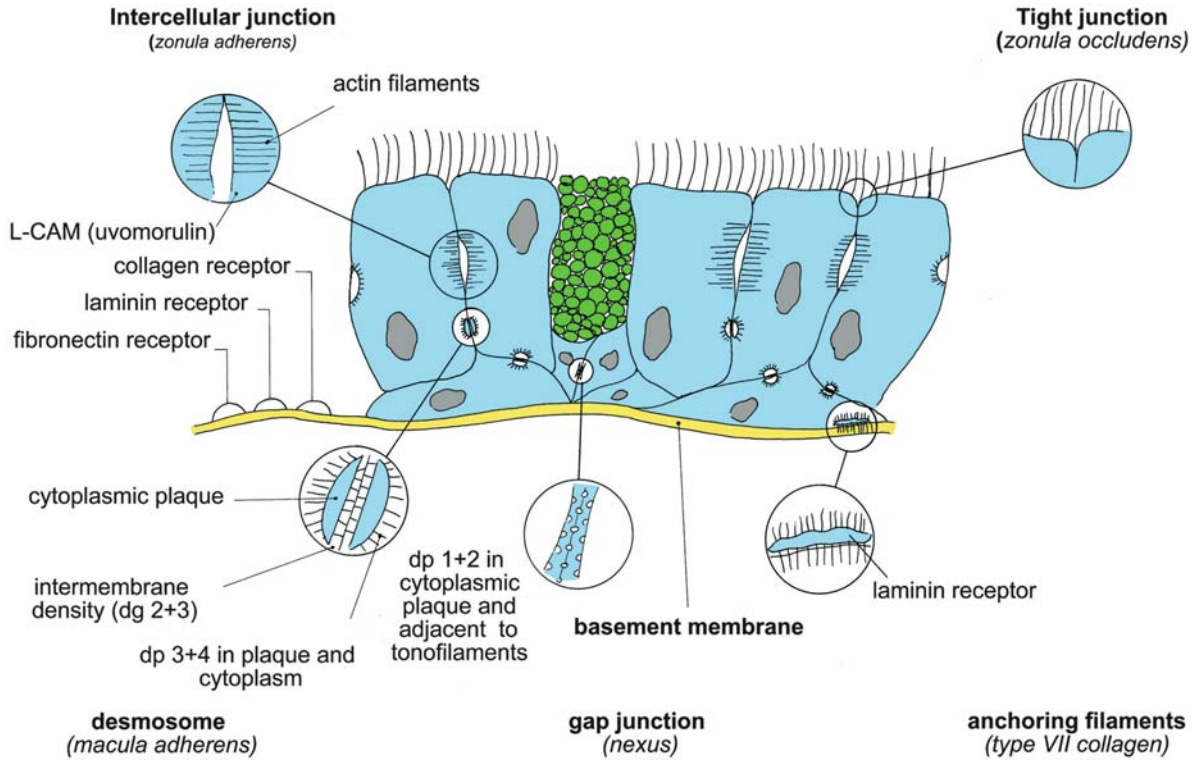

Fig. 11.28. Intercellular adhesion molecules responsible for maintaining bronchial epithelium integrity

hances in B lymphocytes IL_4-induced production of IgE antibodies. All these data reinforce the opinion that ILs perform a leading role in propitiating in the airways the conditions that trigger asthmatic manifestations. Wild et al [721] found that the administration of IL_{18} increased the production of ragweed-specific IgE and IgG_1 in serum in a mouse model of allergic asthma, effects consistent with the support of a Th2 phenotype. Furthermore, intranasal application of IL_{18} together with ragweed increased the production of BALF eosinophilia, suggesting the stimulation of an allergic sensitization when coadministered with an allergen [721]. On the contrary, IL_{11} has a profound inhibitory effect on antigen-induced inflammatory responses in the lung. This inhibitory response is associated with marked diminution in eosinophil recruitment, Th2 cell accumulation, Th2-like T cell IL production, and antigen-induced endothelial cell CD106 expression.[692]. Thus, IL_{11} is an important mediator of the remodeling response in the asthmatic airway and its elaboration reflects, at least in part, an attempt at healing and repair in this setting [752].

Airway Remodeling

In all inflammatory diseases the processes of recovery begin early in the course of asthma (premodeling). They start in the first stages of cell denudation and lead either to restitution to a former state (*restitutio ad integrum*), which does not leave a residue, or leaves changes in connective tissue deposition and to permanently altered airway structure which, in its permanent state, constitutes cicatrization [681]. Epithelial BM collagen deposition and thickening is already apparent in asthmatic children before the age of 3 years, compared to symptom-free children [501]. Normally, healthy epithelium is in contact with cylindrical cells, contact which is characterized by tight junctions in such a way that the adjacent cells oppose an impermeable barrier to the intercellular passage of macromolecules, inhaled pollutants, infectious agents, and other particulate matter. The mucosa generally absorbs small molecules as well as proteins by paracellular means, but when exposed to foreign agents it responds with plasma protein leakage. However, persistent allergic airway inflammation in asthma is accompanied by airway remodeling changes, including hyperplasia of airway mucus glands, myofibroblasts, smooth muscle and vasculature, and the thickening of the airway wall with subepithelial fibrosis [261]. The prospect of developing irreversible airway obstruction should prompt early treatment decisions [189]. IL_{11} induces an airway remodeling response in the asthmatic airways characterized by tissue fibrosis, deposition of types I and III collagen, and myocyte and myofibroblast hyperplasia [752].

It follows therefore that the remodeling process can also involve other cells such as leukocytes and ECM [491].

Fibroblasts

Their biological activity is regulated by a range of cytokines and growth factors:

- IL_1, PDGF and TGF-β stimulate their proliferation and collagen synthesis. Furthermore, IL_1 can activate T lymphocytes that respond with TNF.
- GM-CSF induces the formation of CD106, CD54 or CD62E and is able to stimulate the eosinophils either directly or through the induction of IL_5R (CD125].
- IL_1, TNF, TGF-α, histamine and heparin regulate mast cell number and function, modulating their content of proteoglycans and enhancing the filling of mast cell granules in the bronchial mucosa.
- IL_8 has an important role in directing inflammatory cells in the bronchial mucosa [534].

The fibroblastic activation may be responsible for the deposit of interstitial connective tissue under the epithelial BM [534]. During the initial processes of recovery, fibroblasts proliferate actively, secreting proteoglycans and collagen. These cells, which perform a vital role in the secretion of ECM components, can change phenotype in response to environmental signals and differentiate in myofibroblasts [534]. Macrophages, lymphocytes, mast cells and eosinophils, cells which probably participate in various ways in ECM fibrosis and/or remodeling [53], are always almost present in the granulation tissue. As the recovery process progresses, tenascin, a glycoprotein, qualitatively increases, while fibroblasts and the newly formed vessels diminish [189]. Myofibroblasts, deposits of fibronectin and laminin, and collagen hyperplasia are also found. Even in case of restitution to a former state, the regeneration of the submucosa is always, in part, abnormal [53].

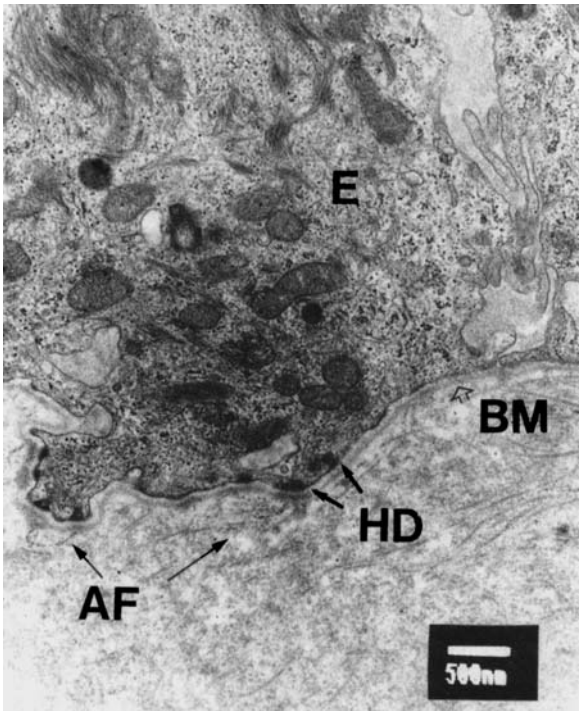

Fig. 11.29. Electron micrograph of thickened subepithelial basement membrane (*BM*). Basal cells possess hemidesmosomes (*HD*), by which they adhere to the superficial part of BM. Anchoring filaments (*AF*) are part of adhesion complex. (*E*) Airway epithelium

Epithelial Cells

Epithelial cells release a wide spectrum of molecules participating in airway repair including:

- Fibronectin, growth factors
- Cytokines including IL_9, IL_{11}, IL_{16} and IL_{18}
- Chemokines such as GM-CSF and eotaxin
- Adhesion molecules such as CD40 and CD54 [681]

The bronchial epithelium is actively engaged in defense of the airways by secreting mucus and many specific and nonspecific cytoprotective molecules that trap and inactivate inhaled components. If the asthmatic immune inflammation is protracted over time, the adhesion mechanisms are compromised, which should ensure the maintenance of epithelial integrity, represented by desmosomes, hemidesmosomes and tight junctions (*zonula occludens*) and *zonula adherens,* which is located immediately below the intercellular joints (Fig. 11.28) [327], as well as adhesion molecules such as β_1-integrins and CD62E [413]. In some cases, a pseudostratified epithelium can be observed with increased goblet cells and vacuolized ciliated cells, often devoid of *cilia* [51]. This tissue often exfoliates, with separation of mucosal cells, leaving the basal layer exposed but intact, though weakening the connection system between columnar and basal cells. It is clear, therefore, that to induce the effects described, destructive activities must take place, concentrated in both space and time (Figs. 11.30, 11.31) [52, 53]. Epithelial damage could depend not only on the cytotoxic effects of eosinophil-derived basic proteins and oxidants, but also on neutrophil intervention which, in vitro [413] and in vivo [677], have the ability of producing similar effects, as well as the exfoliation and detachment of the epithelium from the BM [413, 677]. In addition, epithelial injury is mediated by exogenous factors such as air pollutants, viruses and allergens as well as by endogenous factors including the release of proteolytic enzymes from mast cells [260]. It has been suggested that such changes could also originate from an abnormal response of epithelial cells, stimulated by leukocytes [413]. Moreover, IL_{13} hyperproduction promotes subepithelial fibrosis and thickening of smooth muscle layer [321]. The epithelial response to these stimuli in asthma may be impaired despite up-regulation of CD44 capable of enhancing presentation of EGF (epidermal growth factor) ligands to EGF receptors (EGFR) [260].

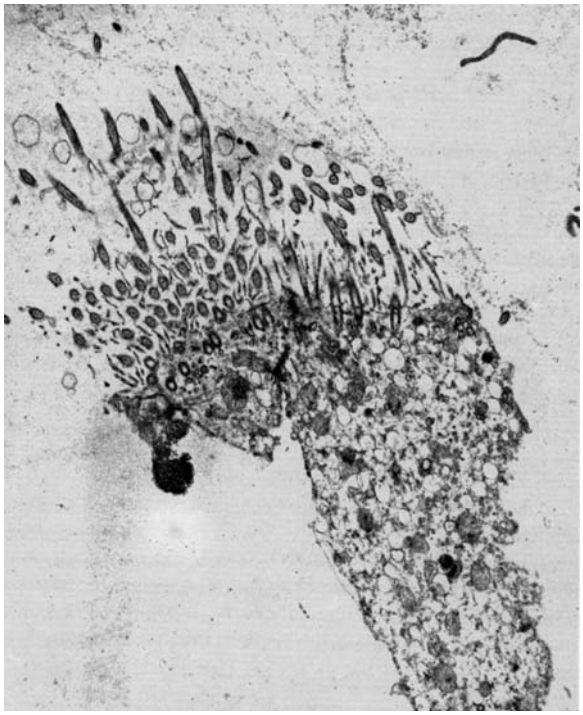

Fig. 11.30. Desquamated epithelial cells undergoing necrosis recovered by BALF from the airways of an asthmatic patient after an exacerbation

However, *regenerative activities* begin with the *re-epithelialization of the denuded surface,* as demonstrated by various stages of ciliogenesis related to nonciliated superficial epithelium, and by a quantitative increase in goblet cells in the ciliated epithelium. The speed and rapidity with which restitution to a former state begins and continues is surprising. Vascular endothelial cells proliferate, forming granulation tissue, the newly formed vessels have open junctions that permit the release of proteins and erythrocytes, the microvasculature also responds by recruiting neutrophils [490]. It is likely that bronchial epithelial cells originally involved with the lesion are able to initiate these reparatory activities, producing chemotactic factors for intact epithelial cells and for PMNs [600]. Facilitated by an adequate hydraulic pressure, the plasma proteins enter the lumen of the tight junctions of the intact cylindrical cells that circumscribe the denuded area [491]. These cells respond immediately, leading to a supposed intervention of specific factors in vivo: substitute secretory cells, both ciliated and basal cells, undifferentiate, become flattened and migrate beyond the membrane – *a process which takes place rapidly in the 1st min following denudation (about 3 µm/min)* [490]. A fibrin and fibronectin gel, also rich in neutrophils, contributes in covering up the stripped areas where it is continually enriched with plasma until the epithelium has been regenerated with the tight junctions [491] (Fig. 11.32). The *fibronectin,* present in the ECM with a great number of binding sites for the cells and other molecules, appears to participate in epithelium regeneration since it is responsible for cell adhesion, a mediator role that is shared, via different receptors, with collagen and laminin [600]. However, the simple restitution of epithelial cells has the potential of being involved in many aspects of structural alterations, present in human airways, that are at the base of symptoms similar to asthma (Table 11.6) [491].

Extracellular Matrix

ECM is a complex and dynamic meshwork influencing many cell biological functions such as development, migration, and proliferation. ECM plays an essential supporting structural role, which differs somewhat in the three physiological zones of the lung: the proximal conducting airways and vasculature, the distal gas-exchanging respiratory zone (alveoli), and the intervening transitional zone (respiratory bronchioles). In the conducting airways, the ECM of the rigid cartilage (composed largely of proteoglycans and collagen) and the more flexible interstitial tissue support the adjacent epithelial and smooth muscle cells. ECM allows some mobility to

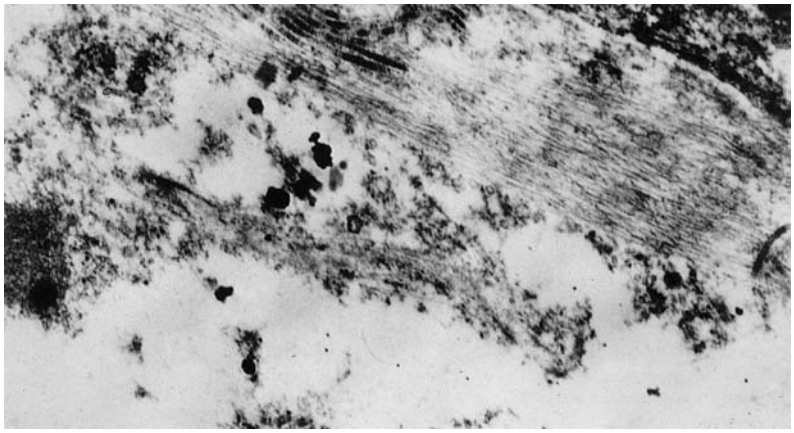

Fig. 11.31. Elastolysis in asthmatic airways: electron microscopic study

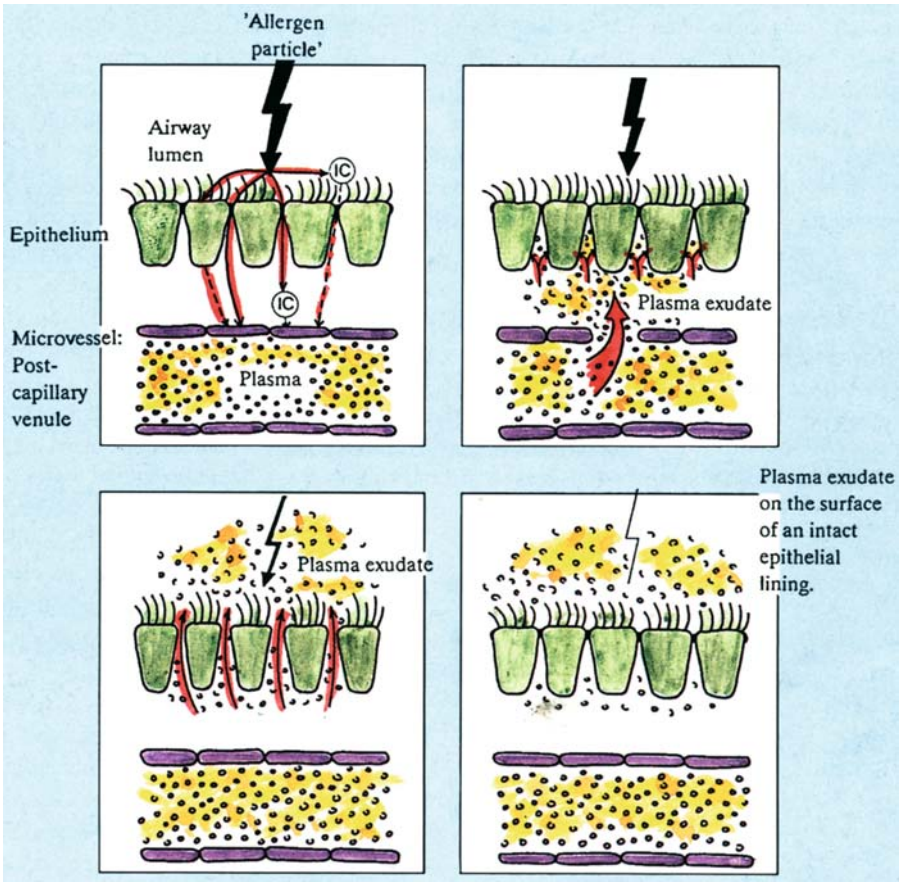

Fig. 11.32. Plasma exuded through barriers in the airway microvasculature and mucosa. Plasma leakage from subepithelial microcirculation multiplies its solutes and expands in volume. It surrounds the basolateral aspects of the epithelial cells; by increasing the hydrostatic pressure the exudate may compress the sides of these cells. At a certain pressure, the tight junctions at the apical pole of epithelial cells would separate due to the increased pressure load. Plasma leakage through the ensuing holes in the venular wall. Tight junctions are reestablished as soon as the interstitial pressure returns to normal levels

Secretion	Neutrophil accumulation and activation	Adhesion molecules of plasma origin
		(Pseudo) thickening of basal membrane
		Proliferation of fibroblasts and/or smooth muscle cells

Modified from [491].

regulate airway and vascular diameter and acts as an essential stabilizer for preventing airway collapse during expiration. In the respiratory and transitional zones, the ECM is more dynamic to accommodate the constant fluctuations in alveolar volume that accompany inspiration and expiration. Macromolecules constituting ECM are secreted locally and consist of fibrous proteins (fibronectin and laminin) embedded in a hydrated polysaccharide gel containing several glycosaminoglycans including hyaluronic acid. *ECM is a dynamic structure,* and an equilibrium between ECM synthesis and degradation components is required to maintain its homeostasis [681].

Basement Membrane

The BM of surface epithelium is composed of two layers: the basal lamina (referred to as the true BM) and the *lamina reticularis.* The basal lamina is of normal thickness in asthma. However, thickening of the lamina reticularis is a characteristic feature of the asthmatic bronchus, occurring early in the disease process [681]. Studies of postmortem reports initially led to the conclusion that in asthmatics the BM becomes thicker as a result of edematous collagen deposits, with fibrils of a plexiform appearance. Electron microscopy (EM) and immunohistochemical investigations subsequently made it clear that BM is normal. Airway thickening be-

neath the BM occurs with collagen deposition and other ECM proteins, including fibronectin and tenascin in the connective tissue layer surrounding the blood vessels, and alveolar interstitium [261]. The degree of collagen deposition into the BM lamina reticularis in children who underwent fiberoptic bronchoscopy is such that airway fibrosis evolves in parallel with eosinophilic inflammation before a clear clinical diagnosis of bronchial asthma could be made [501]. Instead, reticular BM thickness or inflammatory cell number determined in ultrathin sections of endobronchial biopsies were not present in 53 infants aged 3.4–26 months with severe wheeze and/or cough, with reversible airflow obstruction [548]. In healthy subjects, BM, independent of asthma etiology, gravity and duration, shows a *pseudothickening* [51] caused by a deposit of collagen III, V and I (to a lesser extent) and of fibronectin in the *lamina reticularis* situated below the BM [534], confirming that at the basis of this process, is the *activation of contractile myofibroblasts* in the subepithelial site, rather than an epithelial dysfunction [53]. Since BM appears to be the main structure appointed to the regeneration organized by connective tissue, forming a sort of framework for parenchymal cell replication, its structural alterations, in the airways of asthmatics, can result in an ECM deficiency of the submucosa that could be at the basis of airway remodeling.

Elastic Fibers

Most patients with asthma have an abnormal superficial elastic fiber network with fibers appearing fragmented. The deeper layer of elastic fibers is also abnormal in most patients with asthma: fibers are often patchy, tangled, and thickened. EM studies show that a severe elastolytic process occurs in patients with asthma, and in some patients, disruption of fibers has been observed.

Role of Bronchial Hyperreactivity

The pathogenesis of asthma (Fig. 11.11) is in large part identified with BHR which, together with epithelial alterations, secondary to immune inflammation, constitutes the causative element in triggering the chain of events that result in an asthmatic attack. On the whole, BHR measurement could represent a useful means of identifying in advance subjects at risk of PFT worsening, well correlated with severe manifestations and treatment implications. Nevertheless, in children a noticeable variation in clinical symptoms is found, which is why, in practice, the usefulness of measuring BHR is somewhat reduced. Furthermore, the uncertainty of a certain correlation of this parameter with the clinical state and its diversity over time renders BHR not very reliable as a diagnostic test for selecting an adequate treatment and for determining a prognosis [108]. Other authors have demonstrated that reduction of activated T cells and CD25 is correlated with that of BHR [119] but with an improvement of FEV_1, the number of eosinophils and probably of IL_5 [665] decreases.

With the aim of prospecting the nosological picture, it should be clear that [110, 603, 722]:

- BHR is not synonymous with asthma, neither is it systematically predictive of an asthmatic state. Rather it is one of the factors that suggest asthma presence, without possessing the characteristics of a diagnostic symptom *in se* and *per se*.
- BHR is not, therefore, the only component of the physiopathological mosaic of asthma. The etiopathogenic mechanisms of mucus hypersecretion and of bronchial edema are equally noteworthy factors not to be ignored in the overall picture [238].
- BHR does not lessen with age [344] as previously suggested [414] because a small child is more susceptible to BHR also because of airway caliber reduction [584]. BHR is present even in chronic airway disease such as CF [186].

Virtually all asthmatic children have BHR, but not all children with BHR suffer from asthma [108, 476]: more precisely it can be present in apparently healthy children and absent in others who are asthmatic, while nonasthmatic subjects can manifest signs of BHR – for example if faced with a cold air challenge [238]. It is also possible that BHR is present without any ongoing symptoms, which can be ascribed to patients unable to describe correctly the symptoms during initial history [496]. On the other hand, transitory BHR can be present in children with viral infections; therefore exogenous events increase BHR in both healthy and asthmatic subjects [753]. Even exposure to small allergen doses can trigger BHR, without, however, altering airway caliber [722], whereas in asthmatic children the opposite occurs: *continuous or repeated exposure to aeroallergens induces a BHR increase,* causing an almost unnoticeable progressive increase, persisting for weeks or even months. This gives rise to the premises of a vicious cycle, consequently subsequent exposures, even to nonallergic or banal stimuli easily provoke BHR. Even if inflammatory injuries caused *in loco* are numerous and severe, when administering histamine parenterally bronchoconstriction is likely to occur [167]; therefore what results is the product of a series of joint causes.

At present, the contribution of environmental factors is considered important in eliciting BHR, as demonstrated by a greater asthma prevalence in southern countries, where SPT+ to aeroallergens is less [287]. The pathogenic links between damage provoked by pollutants, mediators, inflammation and BHR are harder to characterize [238]. Strongly suggestive in this regard is that BHR may be possibly generated by O_3 with a potent inflammatory action on airways. Injected in test animals, it induces NCA and of LTB_4 formation in epithelial tissues, provoking in the respiratory mucosa a PMN in-

filtration from the microvasculature which, once activated, release TXA_2 able to sensitize the smooth muscles or the nerve terminals, thereby causing BHR [287, 317] (Fig. 4.22). O_3 induces BHR, be it through oxidizing damage [317], in concentrations of 0.12–0.15 ppm [606], or through indirectly stimulating the tachykinins to induce BHR [315]. As a result of BHR, the threshold of bronchial response to various stimuli that unleash factors with bronchoconstriction effects, is noticeably lowered. Among these, the role of mediators should be considered. As seen in Tables 11.4 and 11.5, those capable of inducing BHR are many: PAF and PG, and, to a lesser extent, TXA and LT, even if it is clear that there is not only one but a *combined interaction at work* [283]. These factors are therefore capable of causing a clinical response, increasing and/or maintaining BHR, as a result of which vicious cycles are born between clinical response, immune inflammation, triggering factors and symptoms. BHR degree is often correlated with disease severity with important clinical implications, when these are clearly the important correlation in children between BHR to histamine and the increase in mast cell tryptase and of the number of eosinophils/mm of BALF [187]. As opposed to other children, serum tryptase levels did not increase after BPT with allergens [240]. Recent studies suggest that depletion of IL_{12} [415] and overexpression of IL_{13} [321] increase susceptibility to development of BHR, even in the absence of inflammation [308].

To better explain the pathogenesis, various theories have been put forward based on the intervention of endogenous and exogenous factors.

Endogenous Factors

Among the endogenous factors, the following may be enumerated [154]:

1. Autonomic nervous system (ANS) alterations
- Deficit of adrenergic receptors
- Vagal hyperactivity
- Altered neuropeptide release at the sensory terminals
2. Anomalies of smooth bronchial muscles
3. Anomalies in airway epithelium
- Desquamation of the epithelium
- Loss of EDRF
4. Changes in the biochemical homeostasis
5. Effects of NO

ANS Alterations

Several inflammatory mediators effecting neurotransmitter release by airway nerve endings, or able to act upon ANS receptors, have been identified. Conversely, neuromechanisms could contribute to the inflammatory reaction at the bronchial level. It is therefore possible that some BHR mechanisms are linked to an imbalance of the lower airway nervous control mechanism, entrusted either to the sympathetic (adrenergic system) or parasympathetic system (cholinergic system). These systems are usually in balance: the cholinergic system promotes bronchoconstriction; the adrenergic system, in contrast, modulates bronchial smooth muscle relaxation. At the present time, the ANS airway innervation is considered to be far more complex. Given that sympathetic fibers do not directly innervate smooth muscles, in addition to the usual adrenergic and cholinergic fibers, fibers belonging to a third system called NANC (nonadrenergic and noncholinergic) have been reported, which include both e-NANC (excitatory noncholinergic/nonparasympathomimetic structures) and i-NANC (nonadrenergic/nonsympathomimetic inhibitory structures) [21].

Cholinergic Systems

The fibers of cholinergic nerves travel along the tenth pair with synapse in the airway parasympathetic ganglia, spreading to smooth muscles and submucosal glands. Stimulation of vagal receptors present in the airways provokes one of the most powerful bronchoconstriction reflexes, besides mucus secretion. In particular, mechanical or pharmacological stimulation of vagal terminals occasion, by reflex action, characteristic asthma symptoms and signs such as coughing and rapid, shallow breathing. Cholinergic innervation of upper airways is most dense, thinning out in the periphery. Animal studies have shown that stimulation produces little effect in the lower airways [21]. Given that in humans the muscarinic (M) receptors are equal to parasympathomimetic, which are diffused even in the lower airways, investigations to ascertain whether in asthma there was an increase in their activity [719] were made. This view point is supported by a study showing that many stimuli having a bronchospastic action, such as S dioxide (SO_2), histamine, PG and BK, also affect afferent receptors, therefore inducing reflex bronchoconstriction inhibited by anticholinergics. There could also be an increase in neurotransmitter activity in cholinergic ganglia, either as a result of other neurotransmitter or mediator release, or because postganglion nerve terminals carry out an action favoring acetylcholine release [18]. Given that adrenergic nerves are able to inhibit this production via receptors β or α_2, it is likely that a deficiency in adrenergic responses is reflected in cholinergic tone increase by an increase in muscarinic receptors or others related to them. Asthmatics have an exaggerated bronchospastic response to cholinergic action, but an analogous effect can also be brought about by other spasmogens; therefore an isolated deficit of muscarinic receptors with inhibitor action is unlikely.[21].

The presence in vivo in humans of five muscarinic receptors (only the first three are found in the human lung), each encoded by different genes, has been

reported. Stimulation of such receptors results in bronchial secretions and in smooth muscle contractions, and correlated G proteins have also been identified and cloned [318]. Specific studies have clarified the functionally active types [77, 719]:

- M_1, located in the parasympathetic ganglia, submucosal glands and in alveolar walls, regulating both vagal tone and mucus secretion. They are inhibited by pirenzepine.
- M_2, located on the postganglion nerves in the presynaptic position, with autoreceptor functions, inhibit acetylcholine release and, consequently, the reflex vagal bronchoconstriction actions. They are blocked by gallamine.
- M_3, located in the bronchial and bronchiolar smooth muscles in the postsynaptic position and in submucosal glands promote muscular contraction and mucus secretion. They are inhibited by hexahydroxyl-diphenidol.
- M_4, located in the postganglionic cholinergic nerves, airway smooth muscle and alveolar walls, inhibits acetylcholine release.
- Human skin fibroblasts also express M_2, M_4, and M_5.

In particular, M_1, like α_1 adrenoreceptors, are linked to Gq, and activate phospholipase C (PLC), from which results the turnover of phosphatidylinositol-bisphosphate (PIP2) and Ca^{++} release, whereas M_2 are connected to Gi containing Gi_2 to bind to GTP; the stimulation of the receptor inhibits adenylcyclase and modulates the ionic channels for K^+ and Ca^{++} [21].

The inhibiting activity is not operative in asthmatics, probably due to a *functional deficiency of the M_2 receptors*, which could be expressed by an exaggerated cholinergic activity because of the loss of a normal acetylcholine release retroinhibition, thereby explaining the sometimes dramatic bronchoconstriction action of β-blockers in asthmatics. In fact, a block of β-receptors could abrogate the antagonistic actions of cholinergic nerve activation, thus achieving an excessive acetylcholine release, which is not autoregulatory in asthmatics [21]. Therefore, nonselective antagonists of muscarinic receptors, for example, atropine or ipratropium bromide (IB), are able to mediate both bronchodilation (M_1 and M_3 receptors) and bronchoconstriction (M_2 receptor) [525].

The potential deficits of the parasympathetic cholinergic system affecting BHR are the following:

- Increased cholinergic reflex activity
- Stimulation of the efferent nerve terminals, exposed as a result of inflammation
- Vagal hyperreactivity
- Increased acetylcholine release via ganglionic or postganglionic effects
- Smooth muscle hyperresponsiveness or hypersensitivity to acetylcholine-mediated cholinergic activity
- Possible decrease or dysfunction of protective M_2, which turns into exaggerated cholinergic activity

The M_2 deficit is confirmed by the simple observation that pilocarpine, their antagonist, blocks SO_2-induced bronchoconstriction by limiting the acetylcholine, whereas in asthmatics such a block does not occur. It is significant that influenza virus selectively damages M_2 receptors rather than M_1, probably by an effect of neuraminidase action on M_2 sialic acid residues, providing a valid mechanism to explain increased BHR in subjects after viral infection [77].

Adrenergic Systems

The bronchodilator effect of adrenergic stimulation seems to depend on the basal vagal tone. The adrenergic receptors are of the α type, divided into three α1, subdivided in A, B and C, four α2 further divided into A, B, C and D, and type β, with β1, β2 (present in the lungs with a relationship of about 1:3) and β3 with a more limited diffusion. Also G proteins have been cloned for these receptors, α_1 to Gαq, α_2 to Gαi and β to Gαs (which, together with G_{i2} form the four subfamilies of the α subunit) [318]. Under normal conditions, the sympathetic tone (specifically the β receptors), represents the main balance unit by antagonizing the vagal tone and diminishing vagus-induced bronchoconstriction. The β-receptor antagonists have no effect on the cholinergic tone of a healthy subject; on the contrary, they cause bronchospasm in asthmatics with a greater efficacy the more the vagal tone is raised, α stimulation produces mucus secretion and, above all, mast cell mediators are discharged. β2 receptors are widely distributed over the bronchial area: they can be found on smooth muscle fibers and in epithelial and glandular cells. In asthmatics, due to a poor reactivity of the adrenergic system, it is likely that the main role in regulating the bronchomotor tone is played by circulating catecholamines. Epinephrine inhibits the bronchoconstriction action of histamine, acting as a true circulating hormone, and could play a protective role with regard to bronchoconstriction agents. In asthmatics and other atopic subjects, a *deficit of β-adrenergic receptors* and a parallel *α-receptor hyperresponsiveness,* which could be expressed into blocking the balance of vagal action, has been demonstrated. A supposed *genetic deficit of β-receptors in asthma* has remained an enigma since the beginning [636], even if this anomaly can be hypothesized in a few patients [502]. The postulated interconversion between β and α receptors has been negated by studies with monoclonal antibodies on receptor structures [90]. Generally, potential deficits of the adrenergic system can be summarized as follows:

- An increase in α receptors in the airways
- A decrease in α-receptor antagonists
- A quantitative and/or qualitative decrease in β receptors
- Anomalies in receptor splitting, with α, M_1 and M_3 increase causing a reduction in the number of β and M_2 receptors

Table 11.7. NANC system and potential functions

Action	Innervation	Site of action	Neuropeptides
Bronchoconstriction	Sensory C-fiber axon	Smooth muscle	NKA/SP
	Microganglia	Smooth muscle	SP
Bronchodilation	Parasympathetic	Smooth muscle	VIP/PHM
	Microganglia	Smooth muscle	VIP
Gland secretion	Parasympathetic	Glands	VIP/PHM
	Sensory C-fiber axon	Glands, microganglia	SP
	Microganglia	Glands	SP+VIP, GRP
Vasoconstriction	Sympathetic	Arterioles	NPY
		AV anastomoses	NPY
Vasodilation	Parasympathetic	Arterioles	VIP/PHM
		AV anastomoses	VIP/PHM
	Sensory C-fiber axon	Arterioles	NKA/SP
		AV anastomoses	CGRP

Modified from [18].
AV Arteriovenous; see Table 11.8 for other abbreviations.

Thus it appears that the postulated β-receptor deficiency is secondary to asthma, probably as a result of the inflammation. Additionally, if the increased α receptors were of any significance, the α blockers could have a therapeutic effect, which, however, does not happen; consequently these possible anomalies have few clinical implications. Finally, given that treatment with β-blocking drugs can yield bronchoconstriction in asthmatics (but not in normal subjects), a deficit of this system is excluded [77].

Given the existence of a certain amount of polymorphism related to some β_1 loci, for example at codon 16 (Gly 16), which is more evident in subjects with nocturnal asthma [661], it has been hypothesized that this phenotype predisposes to the nocturnal reduction of the β_2-adrenergic function and therefore to the scant effect of β2-adrenergics on the clinical symptoms. It has also been suggested that substituting glutamic acid with Glu 27 (glutamine at codon 27), which has a receptor with reduced suppression, is associated with a bronchoconstriction reduction [234]. In conclusion, G protein studies are justified by a possibly better understanding of the action mechanism of related drugs.

NANC and Neuropeptides

The functions of NANC, composed of naked nerve fibers that are found free in the submucosa, are summed up in Table 11.7 [18]. NANC was originally described in the gastrointestinal tract. Given that the respiratory system also derives from the cephalic portion of the archenteron, it is logical that NANC and related peptides can be found in both systems; they are, however, present in all organs and can be produced by cells other than CNS cells [21]. It has been suggested that anomalies of the NANC system, in its two components (e-NANC and i-NANC), *represent another important component in asthma pathogenesis.* Numerous stimuli release neuropeptides [18, 90] or tachykinins in the respiratory tract, neurotransmitters that send signals not only to nerve cells, but also to other cells or systems. So-called *neurogenic inflammation* is based on the contribution of numerous neuropeptides to the pathogenesis of a major part of the anatomopathological lesions thus far reported, thereby determining a series of biological responses during the recurrences of acute asthmatic attacks such as vasodilation, plasma extravasation into postcapillary venules, an increase in vascular permeability, exudation of capillaries in the bronchial lumen and edema development, contraction of bronchial smooth muscle cells, mucus hypersecretion, coughing, activation of inflammatory cells and their adhesion to endothelial cells [426] (Fig. 11.33).

Bronchoconstrictors (e-NANC System)

As seen in Table 11.8 [18], several tachykinins released by sensitive nerve endings belong to e-NANC: SP, NKA, NKB (neurokinin A and B), CPS (capsaicin), NPY (neuropeptide Y) and CGRP (calcitonin gene-related peptide) [21].

SP is released by afferent nerves to sensitive amyelinated terminations known as C-fibers. SP binding sites are diffused throughout the smooth muscles of the whole tracheobronchial tree. Injected intravenously, in humans SP provokes an evident vasodilation, probably

Table 11.8. Neuropeptides in human airway mucosa

Trigeminal and dorsal root ganglion cell sensory-motor neurons	
CGRP:	calcitonin gene-related peptide
GRP:	gastrin-releasing peptide
Tachykinins	
NKA:	neurokinin A
NKB:	neurokinin B
SP:	substance P
Postganglionic parasympathetic neurons	
ACh:	acetylcholine
PHI:	peptide histidine-isoleucine
PHM:	peptide histidine-methionine
PHV:	peptide histidine-valine
VIP:	vasoactive intestinal peptide
Postganglionic sympathetic neurons	
NE:	norepinephrine
NPY:	neuropeptide Y (tyrosine)
Neurons of undetermined origin	
ANP:	atrial natriuretic peptide
CALC:	calcitonin
DYN:	dynorphin
ET-1:	endothelin-1
ET-2:	endothelin-2
ET-3:	endothelin-3
ET-4:	endothelin-4
ENK:	enkephalin
GAL:	galanin
NT:	neurotensin
SOM:	somatostatin

Data from [18, 76].

because of the antidromic activation of local axon reflexes that affect the sensitive C-fibers and also other tachykinins, while PFT alterations result from smooth muscle constriction. SP could, therefore, be the e-NANC neurotransmitter [18]. The presumed mechanism of axon reflexes is that, in response to harmful stimuli in the airway lumen, nerve fibers in the epithelium layer release SP, while other fibers of the same axon, by supplying different targets, release SP by antidromic activation. In this manner, stimulation of epithelial nerve fibers can provoke bronchoconstriction and extravasation of plasma proteins with an axon reflex by SP release near airway smooth muscles and postcapillary bronchial veins [333]. In particular, SP bronchoconstriction activity, at least in vitro, is fulfilled antidromically when reflex cholinergic bronchoconstriction is present, as a result of exposed afferent nerve endings situated under desquamated epithelium, especially those of C-fibers [426]. As well as affecting the muscle, SP also affects bronchial mucus production, stimulating both the submucosal glands to an increased secretion, as well as the myofibrils surrounding glandular ducts to increase their secretion. Furthermore, SP increases mucociliary clearance in the airways [362]. Other evidence suggests that SP induces aspecific degranulation of cutaneous and peritoneal mast cells, but not those of the airways, and causes T-lymphocyte proliferation, neutrophil and alveolar macrophage phagocytosis [90], and enhances neutrophil [88] and eosinophil chemotaxis [90]. Thus, we understand how *BHR to SP in asthmatic children is correlated with asthma severity* [429].

NKA-induced bronchoconstriction, which in the airways travels in the same fibers containing SP, is dose-dependent [126] and stronger than that provoked by SP, which, in turn, is more powerful as a vasodilator and vasopermeabilizer. Therefore, in the present state of our knowledge, NKA and SP exercise a bronchoconstriction

action (e-NANC) that can clash with i-NANC, which has a bronchodilator effect, as well as with EDRF, with an effect on bronchial smooth muscle equal to NO [10]. Epithelial denudation can involve the loss of these factors, thereby increasing reflex bronchoconstriction – an effect also mediated by tachykinins contained in microganglia [90].

CPS stimulates SP release from sensory terminals and, to the same degree as SP, provokes bronchoconstriction and an increase in vascular permeability. Furthermore, it suppresses not only the inflammatory effects of airway vagal stimulation but also the effects provoked by tobacco smoke and chemical irritants [90].

CGRP is a peptide codified by the same gene as the thyroid C-cells which, in turn, codifies calcitonin. It is located in the sensory nerves where SP is also present. It performs a notable vasodilator action on smooth muscle, strong and persistent, associated with eosinophil infiltration, potently contracting in vitro human airway smooth muscle [96], acting in synergy with immune inflammation mediators, including PAF, BKs and LTB_4. It has been credited with a role in blood flow regulation in tracheobronchial small vessels [18] and in APC inhibition [525].

NPY has no direct effect on tracheobronchial smooth muscle contraction, while it stimulates bronchial gland secretion and is a long-acting constrictor of vascular smooth muscles.

The effects of tachykinins are mediated by specific receptors in such a way that each of them activates, by preference, a distinctly separate receptor: NK-1 are activated by SP, and NK-2 by NKA [90].

Possible deficits of the e-NANC system comprise the following mechanisms:

- Enhanced noncholinergic excitatory activity
- Diminished degradation of tachykinins
- Stimulation of the afferent nerve endings in which travel neuropeptides, exposed as a result of inflammation
- Smooth muscle hyperresponsiveness or hypersensitivity to neuropeptide bronchoconstriction activity [96]

Bronchodilators (i-NANC System)

Human PHM (peptide histidine-methionine), its homologous PHI (peptide histidine-isoleucine), the equivalent in many mammals and VIP, have the same localizations and analogous functions (they are codified by the VIP gene in the same pro-hormone and they have in common >50% amino acid structure) [90]. They have a bronchodilator activity, more pronounced with VIP, with an effect 50 times greater than isoproterenol [21]. i-NANC works via parasympathetic nerves containing VIP and/or PHM, these being the only neuropeptides with a bronchodilator action.

VIP, most probably an i-NANC neurotransmitter, is found in parasympathetic ganglia (efferent ways), localized in the cholinergic motor nerve endings in smooth muscle bundles, submucosal glands and bronchial blood vessels. In test animals, VIP has been shown to modulate histamine-induced tracheal smooth muscle contractions, kallikrein, PGF_{2a}, LTB_4 and NKA, an effect not inhibited by adrenergic or cholinergic receptor activation nor by cyclooxygenase blocking activity [90]. Also characteristic of VIP is an abundant distribution in both upper airways and nasal mucosa, but not in bronchioles, which is why its bronchodilator action is greater in regulating the caliber of large airways, and is practically wholly ineffective in small airways. In consequence, the therapeutic effect in the asthmatic patient is deceptive, either because specific VIP receptors are scarce in this location, as has been said, or because of the effect of peptidases (for example tryptase) capable of degrading VIP which are released by inflammatory cells present in asthmatic airways [333]. It is characteristic that tryptase degrades VIP with bronchodilator effect, but not so SP, thus promoting bronchial reactivity, causing in prospective BHR and bronchospasm [96]. The prevalent conclusion is therefore that i-NANC exercises a modulator activity of cholinergic effect rather than a direct bronchodilator action [96].

Potential alterations of the i-NANC system foresee the following mechanisms:

- Shortage of nonadrenergic neurons with inhibitor activity
- Increased degradation of VIP/PHM
- Reversible blockage of nerve ganglia or nerve endings with nonadrenergic inhibitor activity
- Numerical reduction of VIP/PHM receptors [96]

What, then, is the role of neuropeptides? In a healthy individual at rest, the adrenergic, cholinergic and NANC effects are balanced for a perfect bronchopulmonary homeostasis and there is a balance between the bronchodilator mechanisms (β-adrenergic system + VIP/PHM) and bronchoconstrictors (α-adrenergic/cholinergic + SP/NK/CGRP) [90]. As shown in Table 11.7, NANC displays opposing functions: broncho- and vasoconstriction, and broncho- and vasodilation. Confronting the neuropeptide multiform actions, the host generates numerous defense mechanisms. If, on the one hand, VIP reduction/inactivation could contribute to asthma pathogenesis, on the other, the neutral endopeptidase 24.11 (NEP, CD10) is capable of inactivating neuropeptides in bronchial epithelial cells. The contrasting effects of NKA and SP on the one hand and PHM and VIP on the other have already been mentioned. There could be present anomalies of the intrinsic microganglia, the efferent parasympathetic fibers containing VIP, and the VIP receptor system [18]. On the other hand, the effects of bronchoconstriction NANC hyperactivity could, in some patients, play a negative role, such as a hypersensitivity of sensitive nerves and of axon reflexes, amplifying inflammatory responses by releasing factors stimulating such sensitive endings, or an increased smooth muscle sensitivity to bronchoconstriction tachykinins [426]. Its sensitivity to O_3 or to

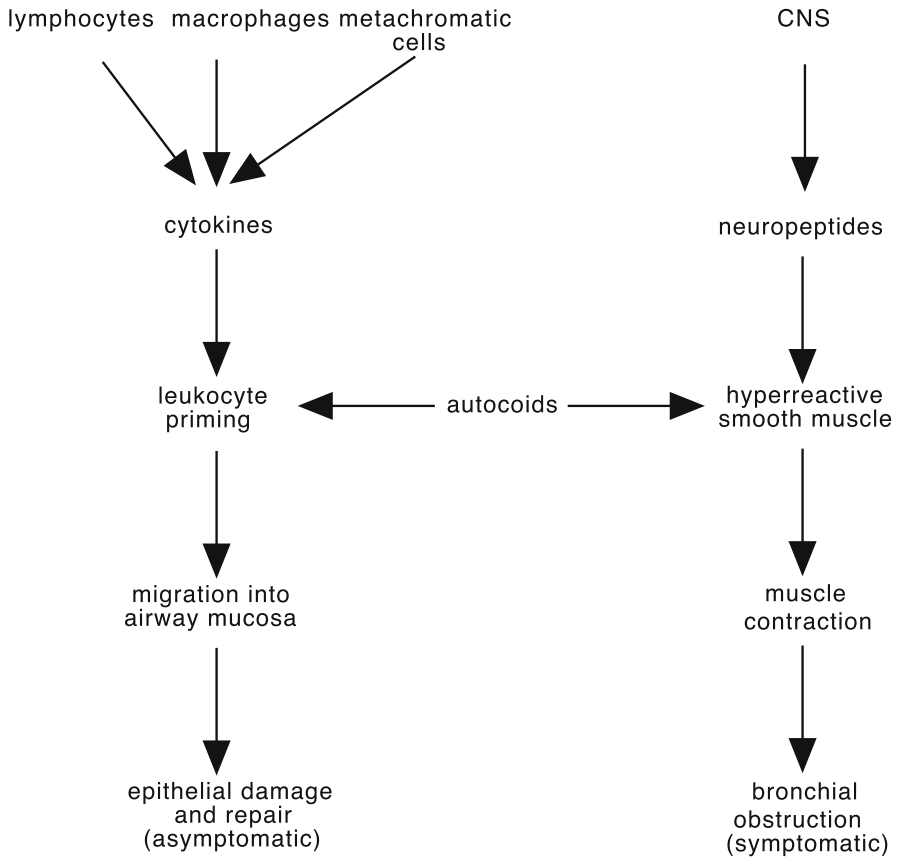

Fig. 11.34. Pathological processes linking inflammatory events to airway hyperreactivity without a causal interrelationship. The autocoids provide the second signal to start both processes, either separately or more frequently conjointly, so that their signal becomes effective. (Modified from [418])

cigarette smoke [315, 337] has recently been defined. Furthermore, the afferent sensitive fibers, even terminating normally in the brain, can branch out and, by antidromic stimulation, be induced to release tachykinins and other mediators in peripheral areas via an axon reflex [426]. The final result therefore is that in the asthmatic, unlike in a healthy individual, *the balance tends toward bronchoconstriction effects* [90]. Neuropeptide action can be linked to that of ILs, with a point of unification represented by the joint action of autacoids, substances physiologically active such as histamine, serotonin, PG, etc. Thus, on the one hand ILs contribute to asymptomatic epithelial damage, while, on the other, neurotransmitters contribute to bronchoconstriction (Fig. 11.34) [418].

Other ANS Dysfunctions

Another factor can be represented by dysfunctions in the stimuli–response relationship. As is known, Szentivanyi [636] advanced the theory that a β-receptor anomaly was at the basis of BHR and other related disturbances. However, there is an interesting paradox worth mentioning: β-adrenergic receptors are quantitatively normal, but cell response to β-adrenergic stimulation is reduced, as can be noted in atopic patients who have not received treatment. Further, administering β-adrenergic drugs causes a rapid receptor desensitization [318]: what conclusion can finally be deduced from this? β-adrenergic receptors are made up of peptides from the cellular membrane which bind either to epinephrine or to norepinephrine. The link to one of these hormones activates Gs – a G-protein – which in turn stimulates adenylyl cyclase to produce cyclic adenosine monophosphate (cAMP), while the Gi inhibit this process. A chain of Gs is deactivated by pertussis toxin. This activity was studied in the murine model in which it reproduces both the immunological anomalies of atopy and hyperreactivity in diverse organs [516]. An experimental model of this type has made possible the definitive demonstration that *G-protein deficit is at the basis of signal transduction anomalies* [318], or of *stimulus–response relationship common to both AD and asthma.*

Anomalies of Bronchial Smooth Muscles

Hyperplasia and hypertrophy of bronchial smooth muscles have been observed, though insufficiently to provide an explanation of BHR pathogenesis, since it is improbable that they are already present in asthmatic children. The reduction of bronchial caliber, especially of bronchioles, which are unique in being surrounded by smooth muscle [255], caused by the joint action of

mucosal edema, smooth muscle constriction and intraluminal secretion increase, cannot, in itself, constitute the *primum movens* of the pathology under examination [722]. Mast cells and eosinophils are both able to contribute in a more significant manner – by means of tryptase action on smooth muscle tone [154]. In the asthmatic, smooth muscles could evolve under the effect of certain stimuli from a multiple-unit to a single-unit system. These changes in the contractile properties of smooth muscle in human lungs may be associated with changes in myosin H chain isoforms, thus contributing to BHR [138].

It has also been suggested that in asthmatics there is a reduction of an epithelium-derived inhibitory factor (EDIF) of the muscle contractility, or of NEP, a factor with a relaxing effect on smooth muscle [675], where it is located. In any event, the result is the loss of the barrier mechanism and therefore of bronchoconstrictor control. A noteworthy impulse has also been given to cAMP study, which that is entrusted with muscle relaxant effects and inhibits mast cell degranulation and consequently histamine discharge, unlike cGMP (cyclic guanosine monophosphate). Normally there is a balance between cAMP and cGMP, which can be broken in either one direction or the other. Maintaining the cAMP level within normal limits is useful to bring adrenergic receptors back to a functional stage in which they can again be activated. Recent research shows that cAMP production induced by adrenergic β receptors is not deficient in the PBMCs of asthmatics compared to healthy subjects [155], as was suggested previously. However, PBMCs of patients even with stable asthma do not have the ability to make adenylyl cyclase more powerful [155], so the lack in increase of cAMP concentrations is correlated with a transduction defect. There are two possible pathogenic mechanisms: the existence of a generalized deficit involving bronchial smooth muscles, no longer relaxed under the effect of cAMP metabolism, and therefore the impossibility of potentiating cAMP when facing a bronchoconstriction stimulus, which could result in an equilibrium upset between cAMP and cGMP; or, alternatively, the adenylyl cyclase deficit could reflect negatively on IL production by PBMCs, the tissue inflammation being at the basis of an increased BHR [155]. In vitro, in biopsy specimens of airway smooth muscle of asthmat sufferers, there is a correlation between muscle functions and BHR level, indicating that BHR, which is observed in the presence of a great variety of stimuli, is a demonstration of the noteworthy contribution given to bronchoconstriction by the bronchial smooth muscle spasm. The differences between asthmatics and nonasthmatics have not yet been fully elucidated, nor have the variations induced by different types of stimuli. It is believed that there are other exogenous factors at the basis of this anomaly. Probably, the airway infiltration of inflammatory cells contributes to smooth muscle tone by the action, on a local level, of various mediators such as histamine, PAF and eicosanoids [138].

Anomalies in Airway Epithelium

The effect on the mucosal epithelium by toxic products of eosinophil origin has been analyzed, together with changes that range from loss of ciliated cells to complete epithelial denudation:

- As previously said, the *epithelial barrier permeability* is increased by histamine, LTs, BKs, CPS, SP, TNF-α, reactive oxygen metabolites, viruses, etc. Consequently, access to the mucosa and submucosa by inhaled molecules such as allergens, microorganisms, dusts, environmental pollutants and inflammatory mediators is made easier. Among those last named, superoxide anion has a particularly harmful effect on the airways with its highly destructive radicals [726]. The epithelial damage exposes intraepithelial mast cells, afferent nerve endings and, in particular, irritating vagal receptors to the combined action of various stimuli. These lie in the upper and lower tract mucosa immediately below the epithelial tight junctions [722], which, though physiologically impermeable, allow a greater absorption of allergenic and irritating substances to take place if altered. In addition, the mucociliary clearance reduces its filtering action of inflammatory substances and airway secretions.
- Experimental studies have highlighted the role played by epithelial denudation, which could lead to NEP loss, usually found not only on smooth muscle, but also on target cell membranes such as epithelial, endothelial and alveolar type II cells, submucosal glands, postcapillary venules and nerves, all of which are sites of tachykinin activity [126]. NEP selectivity makes it possible to degrade SP and NKA, blocking their bronchoconstriction activity while the inhibition, especially if associated with O_3-induced BHR [406], potentiates NKA [126] and SP effects [421]. Exfoliation of epithelial cells and other serious cytopathic effects – caused by viruses harmful to cells [20, 72, 130], chemical substances, pollutants, etc. – points first to a NEP deficiency, thereby preventing both the destruction of bronchoconstriction neuropeptides as well as the synthesis of those with bronchodilator action, also amplifying the inflammatory action of tachykinins and reflex bronchoconstriction [18]. If, as a result of epithelial damage, the sensitive nerve endings of bronchial mucosa remain exposed to the bronchial lumen, having a much lower threshold of stimulation, they are stimulated continually by inflammatory metabolic products [21]. In this way, as a result of antidromic stimulation of these nerve endings, an exaggerated neuropeptide release with a highly rapid and diffuse action on bronchial airway occurs [21]. BK could play a part in allergic asthma since, administered either inhaled or IV, it provokes bronchospasm in asthmatics, but not in healthy subjects. It works indirectly, probably via the stimulation of sensitive nerve terminals, with consequent retrograde release of SP no longer degraded by NEP, NKs and CGRP by an axon reflex [421, 429]. BK antagonist therapy is based on these premises [18]. Following these phenomena of

neurogenic inflammation affecting target cells, cholinergic reflex bronchoconstriction, hyperemia, edema and mucus hypersecretion, with an increase in vasal permeability will follow. This axon reflex, amplifying the immune inflammation, could therefore represent an important pathogenic element in provoking asthma and BHR [21].

- Moreover, there is *a receptor loss:* if they belong to the β type, there are no disturbances of note; if they are H_2, production of PGE_2, which acts by inhibiting, at least in part, the smooth muscle responses to histamine and NKA ceases. The receptor loss by numerous epithelial ILs involves mainly IL_1, with a possible amplification of the inflammatory response and consequential jeopardizing of lesion repair [22].
- Other studies have shown the *loss of NO production,* catalyzed by iNOS (inducible NO synthase) and induced into the epithelium by TNF-α, $IL_{1β}$ and IFN-γ, also compromising both vascular muscle regulation and harmful chemical substance clearance [10].
- Another pathogenic hypothesis cites the *inhalation of endotoxins* present in Gram-negative germs, identified with the somatic antigen, which are located in the cell walls as LPS as a possible culprit. Such toxins, brought into homes by environmental germs, could provoke bronchoconstriction in asthmatics in doses of 20–40 μg, and in healthy subjects as well in doses of 200 μg [433].
- BHR persistence, also produced by MBP-induced discharge of factors of epithelial origin stimulating muscarinic reactivity [57], could be explained by the thickening of the *lamina reticularis* below the BM [600]. A crucial point is played by *myofibroblasts,* capable of producing subepithelial fibrosis, whereas in asthmatics an excess in their numbers below the bronchial epithelium, with a close correlation between the number of myofibroblasts and the collagen layer thickness, has been reported. It is therefore evident that fibrosis jeopardizes the respiratory function and that a network of contractile myofibroblasts underneath the BM markedly contributes to BHR persistence. Moreover, activated eosinophils present in these locations, as well as deposits of ECP, stimulate the synthesis of hyaluronate and proteoglycans in human fibroblasts [600].

Alterations of Biochemical Homeostasis

The main cause of asthma inflammation, which, apart from smooth muscls spasms, also depends on mucosal edema and on secretion changes, with formation of mucus plugs in the smaller bronchi.

Bronchial Edema

Bronchial edema is attributable to the increase in capillary permeability with exocytosis of serum proteins in interstitial areas with an array of mediators among which are histamine, BKs, PAF, PGE and LTs, potentiating each other in turn. For example, PAF-produced edema resulting from the harmful action exercised on microvasculature is increased by the coincident action of LTC_4 [283]. There are several other edema factors such as cigarette smoke, viral infection, pollutants, neuropeptides and proteases, all capable of altering epithelial integrity and mucosal permeability: thus allergens may penetrate *across the junctions that are no longer tight,* for their encounter with APCs [619]. Even if the pathophysiological contribution of this process is little known, it has been seen that following an airway effect of local BPT, an extensive edema is formed and that both edema and inflammation increase the thickness of airway walls, thus contributing to bronchospasm in children [619]. Therefore, pharmacological prevention of the increase in vascular permeability requires the inhibition of histamine receptors and of arachidonic acid metabolism through cyclooxygenase and lipoxygenase, with the aim of simultaneously blocking PGs and LTs, respectively. The role of bronchial edema has been the object of few studies and merits a closer examination [283].

Mucus Hypersecretion with Formation of Plugs in the Smaller Bronchi

The formation of tenacious mucus plugs in the airways is one of the characteristics of asthma [255]. Mucus hypersecretion, a possible consequence of hyperplasia and metaplasia of submucosal glands and goblet cells that cover the respiratory tree, contributes to an exaggerated insufflation and focal atelectasis. The pathogenesis is complex: various mediators and cells of inflammation are able to contribute – along with C-fiber activation also stimulated by BK and inhalants – leading to mucus-producing cell quantitative increase and exocytosis, as well as to myoepithelial cell contraction [362]. The mediators (Tables 11.4, 11.5) that are principally responsible are, in order: LTD_4 >LTC_4 (active in picomolar concentrations) >HETE (nanomolar) >PGF_{2a} = PGD_2 = PGI_2 = PGE_1 = PGA_2 >histamine H_2 (μmolar) [283]. Mucus hypersecretion may be produced by IL_{13} even in the absence of inflammation [321].

Increase in Permeability

We summarize the numerous mechanisms that lead to vasodilation and hyperpermeability evidenced so far, with consequent bronchoconstriction amplification. Plasma proteins release from tracheobronchial microvasculature and the forcible fluid passage deriving from it are important inflammation components and, consequently, a basic characteristic of pathogenesis [177]. They occur gradually within 10–20 min after an allergenic BPT in the airways: the stronger the stimulus, the greater the exudation [490] (Fig. 11.32). The continuous

vascular extravasation can give rise to the production of mediators of inflammation facilitating the intraluminal transmigration of inflammatory proteins. Since the absorption of solutes is directed above all by mediators, the mechanisms that reduce or abolish their activity cause the regression of protein accumulation in the lumen, an effect which can be achieved following treatment with CSs in moderate doses (400 µg/day) [669]. Nonetheless, measurements in controlled asthma have shown little or no increase in airway permeability and no correlation with BHR degree [722].

Surfactant Dysfunctions

The loss of pulmonary tissue elastic properties can cause bronchoconstriction. Testing immunized animals to BPT with ovalbumin, the resulting protein transudation in the airways inhibits the surfactant, with a consequent Raw increase [356].

Effects of NO

Until 10 years ago, NO was known only as one of the components of the harmful gases discharged by vehicles and cigarette smoke, also held to be jointly responsible for acid rain and the O_3 hole. Recently NO equal to EDRF has been localized at the airway epithelium, where it could act as a mediator of bronchodilation under the nervous control to counterbalance the bronchoconstriction caused by mast cell degranulation (or by ET). Moreover, NO, produced in large quantities, provokes an increase in vascular permeability and cytotoxic effects, contributing to epithelial denudation [10]. In this cytotoxic activity, it also mediates O_3 effects – a significant fact given the increased incidence/prevalence of asthma [759]. From a pathogenetic point of view, NO deriving from airway epithelium (as well as from macrophages, mast cells and Th1 cells) could play an important role in amplifying and perpetuating the Th2-mediated inflammation (Chap. 4). iNOS can be induced in the epithelium by pro-inflammatory ILs such as TNF-α and $IL_{1β}$, secreted by macrophages, and IFN-ɣ derived from Th1 cells [759]. It is also feasible that even viral infections induce iNOS production by the epithelium, thus increasing NO secretion during asthmatic attacks [443]. Elevated concentrations of NO thus generated in the airways carry out a suppressive action on Th1 cells and a reductive action on IFN-ɣ, resulting in a net proliferation of Th2 cells. CSs inhibit iNOS both directly and by blocking pertinent IL synthesis by macrophages [443]: in fact, in asthmatics treated with oral or inhaled CS (ICS), NO levels are reduced, in contrast to untreated patients [293]. Exhaled NO levels are increased in atopic non-asthmatic children and, all the more, in atopic asthmatic children, but were reduced by 53% by ICS treatment [587]. Therefore, ICSs inhibit NO production by epithelial cells, stimulating the proliferation of Th1 at the expense of Th2 cells [443]. Further improvements in techniques will permit monitoring inflammatory events, by measuring exhaled NO (eNO) levels and providing a noninvasive marker for the early diagnosis (Chap. 6) and a more precisely aimed treatment of pediatric asthma [759].

Main Exogenous Factors [333]

- Pharmacological stimuli, histamine, methacholine, acetylcholine, hypotonic aerosols [154], all medications may provoke adverse responses (see "Treatment"). In a cross-sectional study on 1,881 children aged 6–7 years, the use of antibiotics during the 1st year of life was significantly associated with wheezing. This increased risk was a prerogative of children genetically predisposed to atopic immune responses [156].
- Physical stimuli: fresh and dry air [206], ultrasonic mist, smog, inert dust, atmospheric pollutants, physical exercise [606].
- Chemical and pollutant stimuli: oxidant, harmful and irritating gases, tobacco smoke [167, 195, 621] (Table 2.26)
- Allergens, especially aeroallergens
- Viral infections [167]

Predisposing Factors

Anatomical and Physiological Predisposing Factors

Anatomical and physiological factors, specific to the pediatric age, can predispose to the airway obstruction, as can extrinsic factors more readily predisposing, some of which are even etiological factors.

Strictly Anatomical Dynamic Factors

Anatomical dynamic factors are represented by an evident reduction, more or less to scale, according to age, of anatomical parameters.

The following [174, 204, 274, 589, 648] show that the child's airways are not to be viewed as a miniature replica of the adult's airways:

- At birth, the lungs weigh ≈48 g; at 1 year 130 g; at 12 years 390 g; in the adult ≈1,200 g.
- The estimated gas-exchange area at birth is almost 27-fold lower than that of an adult: 2.8 m^2, 32 m^2 at 8 years and 75 m^2 in the adult.
- The total pulmonary capacity of a newborn child is 180 ml; at the age of 16 it is 5,100 ml.
- Bronchi and bronchioles have reduced caliber and length. The diameter increases by 200%–300% from birth to adulthood.

- The alveoli are reduced in number. The number of alveolar structures increases exponentially from 30–32 weeks of intrauterine life until birth, the newborn has only 8%–11% of the alveoli of an adult and with a less differentiated structure, and by the age of 8 the alveoli increase tenfold, and proceeding to adulthood, the airways triple in diameter.
- The cartilaginous tissue, the submucosal glands and the smooth muscle of lower airways complete their development at 8 months; the smooth muscle of proximal airways in adulthood.
- Formed *cilia* and mucus are found in the airways at 13 weeks of life.
- The thorax is extraordinarily flexible in infancy and it stiffens with age.

Within this anatomical framework, the neonatal epithelium develops structurally and provides important functions in the normal airway development.

Anatomical and Physiological Factors Predisposing Children to Airway Obstruction [584]

The younger a child, the more evident the anatomical details facilitating the onset of bronchospasm, therefore provoked by trivial causes such as a mucosal edema and/or a catarrhal secretion. The relevant infantile characteristic of the respiratory mechanism in this context is the resistance to air flow. A reduction in bronchioles and/or bronchi caliber translates into a hindrance of air flow so that, in young babies and children, an obstruction, even a limited one, requires great exhaling pressure during exhalation, from which derives a dynamic compression of the peripheral tracts which worsens the obstruction itself. Among the principle causes of this, some of which have been better defined by new methods of investigation (Chap. 6), are the following.

Reduction of the Caliber of the Peripheral Airways

The relationship between the caliber and upper and lower airways is physiologically reduced as compared to that observed in adults. This condition exposes an infant, often male, to severe bronchoconstriction because the edema, the secretions and the cellular debris cause stenosis more easily in bronchioles of a smaller diameter. We must also consider that Raw varies inversely with the fourth power of the radius of bronchioles. Therefore, it is sufficient that the radius is halved, for example caused by a viral infection, for the Raw to be increased 16-fold. An increase in caliber occurs only towards 5–6 years of age.

Decreased Lung Elastic Recoil

The infant chest wall is less rigid, so that the thoracic wall and airways have a greater propensity to deformability. The decreased static elastic recoil properties predispose to an early airway closure even during tidal breathing. On the other hand, greater elasticity means that the airways of babies are more easily susceptible to vibratory movements, which are at the basis of wheezing. The cartilaginous substances of the trachea and segmental bronchi also are less rigid, so that airway collapse is facilitated during expiration. The early airway closure at elevated pulmonary volumes determines an alteration of the ventilation/perfusion rate, potentially complicated by hypoxemia.

Decreased Smooth Muscle in Peripheral Airways

Decreased smooth muscle in peripheral airways facilitates obstruction especially following an edema, mucous hypersecretion and infiltrations by inflammatory cells. Infants and children are therefore more vulnerable to small airway pathologies. Smooth muscle reduction compared to that of an adult also contributes in many cases to a poorer response to bronchodilators (the younger the baby, the more this is the case).

Mucous Gland Hyperplasia

Compared to an adult, an increased percentage of mucosal glands in walls of the larger bronchi contributes to intraluminal mucous secretions and in turn to airway obstruction.

Diaphragmatic Disadvantage

Another anatomical disadvantage from a mechanical point of view is the position of the diaphragm since the angle of insertion on the ribs is horizontal, in contrast to an oblique insertion in adults, which, combined with the compliance of the bronchial wall devoid of cartilaginous support and that of the thorax with low skeletal or muscular support, cause retraction of the rib cage during inhalation, therefore requiring greater effort, whereas in adults the diaphragm tends to elevate the rib cage, thus increasing its diameter.

Functional Insufficiency of the Diaphragm

Functional insufficiency of the diaphragm occurs because the increased effort cannot be sustained efficiently, caused by relative reduction of muscle fibers. The diaphragm must ensure >70% of respiratory excursions, given that a child up to the age of 6–7 years con-

tributes only in part to thoracic cage expansion, either because of increased compliance (see "Decreased Lung Elastic Recoil"), or because the movements of lifting and lowering the rib cage are conditioned by their almost horizontal position, and by the almost cylindrical form of the thorax, so that diaphragmatic contraction during inhalation can cause subcostal retraction rather than rib elevation.

Decreased Alveolar Pores and Decreased Collateral Ventilation

The alveolar openings that permit ventilation between alveoli (pores of Khon) and the bronchoalveolar communications (canals of Lambert) are decreased in number and size in the infant lung, thus impeding a normal collateral ventilation. For this reason, young babies and young children are more easily susceptible to atelectasis distal to obstructed airways.

Role of Pulmonary Volume

The reduced caliber of peripheral airways can be a risk factor for relapsing wheezing. The functional residual capacity (FRC), airway conductance (Gaw) and V_{max} were found to be significantly lower in young babies suffering from bronchiolitis before the age of 1 year and related relapses [375].

In conclusion, the fact that the airways of the very young face obstructions more easily and more rapidly than older children is not surprising. Therefore the lung is more vulnerable to inflammation in this early age and this may result in *persistent airflow limitation* [274]. We have so far outlined some of the principal causes for which the particular predisposition needed to develop not only *reversible wheezing* in the very first period of life, but also bronchoconstriction and respiratory insufficiency, which is at the basis of the high number of hospital admissions and assisted breathing that is recorded in this age group.

Predisposing or Etiological Factors

Several factors can modulate the onset and severity of asthmatic clinical symptoms in a child [174]. With advancements in research, knowledge regarding the way in which these factors provoke alterations at the airway has been perfected, even if still far from achieving a univocal pathogenetic mechanism. It is certain, however, that asthmatic children display BHR, an abnormal marked sensitivity to most varied stimuli, which in healthy subjects usually do not induce responses of any particular clinical relevance. In asthmatic children, these and other stimuli can provoke smooth muscle spasms of the lower airways, bronchial edema, dense mucous secretions and respiratory dynamic alterations as well [307].

Aeroallergens

Sensitization to inhalants is rare in very early infancy, but clearly prevalent from 3 years onward (Fig. 9.39), with high successive sensitization to pollens and to Der p 1 (Fig. 5.22), and an unusual and elevated prevalence of positive SPTs to cat derivatives in children >9 years (Fig. 7.17) and of sIgE in 17-month-old infants (Fig. 5.21). Multiple sensitization to inhalants (Fig. 5.20, Tables 5.18, 5.19) may be very prevalent among children suffering from multiple FA (Chap. 9).

Other Atopic Disease

Of children affected with AD, 44%–53% are at risk of developing other atopic disease, namely RA or asthma (Table 5.8), and 47% of these children have asthma with or without BHR (Table 7.10). Additionally, some foods can be responsible for asthma in allergic children, more frequently than in adults (Tables 9.18, 9.19). M cells transport allergens to subepithelium where they facilitate allergen access to lymphoid tissues, then interacting with allergen-specific T cells or with B_{IgE} lymphocytes, finally reaching the airways via blood vessels and causing BHR and asthma [537] even in children <2 years of age (Fig. 11.35) [450]. In our division, it is not infrequent that children react positively to food provocation testing manifesting wheezing.

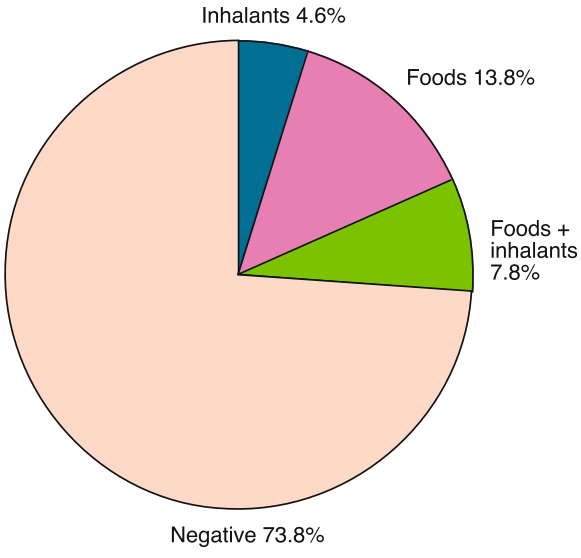

Fig. 11.35. PTC results in 65 <2-years old asthmatic children. (Data from [450])

Physical Exercise

Aretaeus reported cases of *exercise-induced asthma* (EIA) at the first Olympic games recorded in history [13]. Twenty-four centuries later, approximately 3%–10% of athletes taking part in international competitions are affected by asthma. Physical activity regularly leads to a decline in PFT in children and adolescents with asthma. This decline is a consequence of what is known as EIA, a theme of much research in recent years [542]. EIA is found in up to 63% of asthmatic children (Table 5.11), in 30%–40% with RA [307, 584], in nearly 3%–8% of schoolchildren and in 13% of child athletes [542]. The main cause is BHR that typically appears after 3–8 h of vigorous exercise, so that in diagnosing EIA, the subject is required to run on an equipped treadmill under controlled environmental conditions [39]. After 5–15 min, bronchoconstriction, ranging from moderate to severe and lasting 15–30 min can occur, followed by a refractory period of 2 h during which no exertion can provoke EIA. Delayed reactions can occur even 8–12 h later, and this two-phase reaction is not uncommon [39].

Free-running tests and treadmill tests (Fig. 6.24) induce EIA [542] more easily. Objectively, arduous exercise – for example: running, bicycle riding or cross-country skiing, but not long-distance skiing [335] – provokes bronchoconstriction in at least 70%–80% of asthmatics, which is neither intense nor prolonged [394]. Running provokes EIA more easily than jogging and this, in turn, more frequently than walking. In evaluating the triggering factors, a variety of issues come into play including cold, dry air, environmental pollutants, a recent allergic exposure or inflammatory mediators. The pathophysiology and cause of EIA remain controversial, but two theories have been offered: 1) the hyperosmolar theory and 2) the airway rewarming theory. Warm air and humidity can accelerate bronchospasm, exacerbated by cold air inhaled during exercise, especially if open-mouth breathing results from increased need for O_2 [606]. Hyperpnea induced by physical exertion causes water release via evaporation of mucosal periciliary fluid with consequent local hyperosmolarity [606], which could provoke bronchospasm via direct vagal action, or by induction of mast and other cells to produce mediators, thus activating the successive cascade of immunological events [464]. Other authors, however, place emphasis on heat loss caused by hyperpnea, which could have consequences on subsequent rebreathing, with vasodilation of peribronchial vascular plexus, hyperemia, edema and, finally, bronchoconstriction [66]. Therefore, thermal shock could occur [394]. Since asthmatics have a hyperplastic vascular bed possessing greater permeability, the initial cooling down and subsequent warming up could cause bronchospasm via a true vascular blockage, with the onset of reactive hyperemia and edema involving the bronchial walls [394]. At the moment, however, there is insufficient data to clarify which of the two theories (warming up and hyperosmolarity) is pre-eminent. In studying BALF before and after exercise, no significant differences were found in histamine and tryptase levels. This could make doubtful a possible intervention by the airway mast cells accompanied by liberation of histamine and other mediators [278]. However, Kikawa et al have shown that in children with severe asthma, following physical exercise, LTE_4 urinary levels were clearly higher than those of controls, thus concluding that airway reactivity seems to be a salient factor in EIA development [294, 295]. The analyses of histaminemia have revealed elevated levels of histamine 10 min after BPT, returning to normal after 20 min and significant subsequent reduction of T lymphocytes 2 and 4 h after the test [66].

Drugs and Additives

Certain drugs such as ASA and food additives can induce bronchospasm in asthmatic and nonasthmatic subjects, by means of a nonallergic mechanism probably linked to the interference on mediator regulation (Chap. 10).

Irritant Factors

Irritant factors [584] like smoke, gases, dusts, vapors and immunotoxic substances, in addition to being harmful to the cells, have a more negative clinical impact on asthmatics compared to the general population, being able to provoke or aggravate asthma in subjects with BHR. Irritants, formaldehyde, fine wood dusts, etc. must be avoided in the home of asthmatic children (Chap. 24). Other factors involve meteorological, hygrometric and/or barometric variations. *Fog,* in addition to its specific effect (larger drops deposit in smaller bronchi and trigger bronchoconstriction, smaller drops stratify on bronchial walls increasing mucous fluidity), can also transport harmful dusts and fungi.

Environmental Pollutants

Tables 4.15–4.17 and Fig. 4.22 illustrate the agents that compromise the immune system in test animals and, prospectively, in human beings. The *immunotoxic substances* include: exhaust gas, atmospheric dust, industrial smog – notably SO_2, O_3, NO, NO_2 – as well as anion superoxide, from which H_2O_2, OH^-, O_2 "singlet" ($^1O_2$) and other O_2 radicals are derived, with directly damaging effects on human cells [262]. Small doses induce BHR and high and/or persistent doses induce lasting toxic effects [262]. TNF-α and $IL_{1\beta}$ are able to elicit a rapid and temporary increase in ciliary beat frequency following release of NO and, consequently, of iNOS [648]. Experimental data show how in children the in-

crease of respiratory symptoms and asthma are proportional to that of pollutants [694], *even acting in newborn babies* (Table 2.26). As yet, no studies have quantified the relationship between atmospheric pollution and BHR [694]. In communities with high O_3 concentrations, the RR (relative risk) of developing asthma in children playing three or more sports was 3.3 (95% CI, 1.9–5.8), compared with children playing no sports; thus, air pollution and outdoor exercise could contribute to pediatric asthma development [390]. Patients exposed to particulate air pollution and gaseous pollutants such as NO_2 concentrations can present with an increased prevalence of asthma symptoms and medication use [687]. Children are more at risk both because of the *smaller caliber of their airways,* and because of the increased RR with a resulting increase in inhaled pollutants per kilogram of body weight [521]; therefore an irritation provoked in an adult may turn into a significant bronchoconstriction in a very young child.

Cigarette Smoke

Passive smoke could constitute the most important environmental factor in the etiology of early infantile asthma (Tables 4.21–4.23), being involved in 38%–65% of cases (Fig. 4.23 and Table 5.11).

Viral Respiratory Infections

Viral respiratory infections (VRIs) have been related to the onset of recurrent wheezing illness and asthma in infants and are probably the most frequent cause of exacerbations of established disease in children. Studies discussed in Chap. 4 have shown that children with siblings have a lower prevalence of allergies and asthma than do children without siblings, an association attributed to a preventive effect of early infections, according to which early-life infections up-regulate Th1 lymphocytes that may inhibit the expansion of allergen-specific Th2 lymphocytes, thus limiting the development of allergic diseases. The action of respiratory viruses on the airways is modulated by several factors, including atopy, male sex, age, type of virus, possible BHR and development of correlated symptoms [545]. Infection by respiratory viruses can induce in children (even nonatopic children) [72] airway obstruction even though limited to the upper tract, BHR, functional changes in the airways, and PFT changes, which can persist for weeks after recovery (Table 11.9) [20, 72, 130].

Infections, especially if contracted in the early stages of life, can damage the mechanisms underlying the mucosal barrier, thereby allowing a massive allergen penetration. As seen in Table 11.9, the necrotizing action that various influenza and parainfluenza viruses can have on the bronchial mucosa has been demonstrated: *denuding it of its epithelial covering, they allow a greater penetration of inhaled viral allergens* and their absorption [20]. Clinical studies confirm that VRIs markedly aggravate or even directly trigger asthmatic symptoms in a high rate of cases, most especially *in very young children* [20, 167, 611] (Table 6.1). A re-examination of studies done in pediatric cohorts (0–>17 years old), with respiratory infections of both upper and lower airways and asthmatic symptoms, found a link with viruses in 25.2% of general cases and in 35.6% of asthmatics [69]. In the follow-up of 11- to 17-year-old students with asymptomatic BHR, 45% developed a symptomatic form and 80% had suffered from past respiratory infections [753]. More recently, early respiratory infections indicated an increased, rather than a decreased, risk of developing bronchial obstruction during the first 2 years of life and of having asthma at 4 years of age [427]. Two cohort studies indicate that RSV lower respiratory tract infections (LRTIs) during infancy are associated with increased risk of asthma in the following years [585, 597]. Respiratory inflammation (RSV) during the 1st year of life seems to predispose, possibly via IL_{13}-mediated mechanisms, to augmented allergic airway responses [361]. Moreover, both pneumonia and RSV LRTI during the first 3 years of life are associated with an increased risk of asthma or asthma-like symptoms up to 11 years of age [88, 616], or up to 5 years in Gambian children [670].

In infants and toddlers, RSV plays an especially important role and can induce respiratory disturbances with variable degrees of severity, culminating in hypoxia [714] and even death [271]. In particular, the course of bronchiolitis in a baby can prove very severe, sufficient to warrant RSV classification as *the greatest agent of morbidity and morbility in the 1st year of life* [477]. As with other respiratory viruses, RSV causes an increase in IgE [428], altering their immune regulation, and of eosinophils, which show a greater ability to participate in the immune inflammation [130]. It is highly probable that during infections, virus-specific IgE linked to mast cells react with an RSV antigen, by releasing vasoactive and inflammatory mediators, and start the whole cascade of events leading to BHR already described [72]. The increased airway permeability opens the door to allergens triggering allergic asthma, with an increase in cholinergic responsiveness and a decrease in the β-adrenergic responsiveness, thereby increasing BHR and airway inflammation.

RSV has an additional specific influence on PMNs producing $O_2^{\cdot-}$ and TXB_2, with a significant chemiluminescence when incubated with RSV, and cytotoxicity for target cells [298]. They are the dominant inflammatory cells in the nasal secretions of babies with RSV-induced bronchiolitis, and in BALF of infants who have undergone ventilation for severe VRI [182]. It appears that PMN-deficient motility (Table 2.10) protects very young babies from RSV. RSV pathogenicity is shown by its ability to activate eosinophils notably producing cationic proteins in greater quantities, and obviously causing persistent BHR and damaging the respiratory

Table 11.9. Mechanisms of virus-induced wheezing and/or asthma exacerbation

Direct effect on the airway epithelium
A. Damage to the airway epithelium
Epithelial denudation
Disrupted epithelial integrity
Enhanced allergen penetration
Reduced mucociliary clearance
Loss of neutral endopeptidase, cyclooxygenase
Enhanced contractility to substance P
Up-regulation of adhesion molecule expression
Loss of protective mediators, including the endothelium-derived relaxing factor (EDRF)
Altered airway surface fluid osmolarity
Disruption of tight epithelial junctions
Exposure to irritant and cough receptors
B. Effect on vascular endothelium
Increased permeability
Fluid and plasma protein efflux
Production of inflammatory mediators
C. Increased mediator release
Histamine release
Increased arachidonic acid-derived lipoxins
Kinin generation
Enhanced activity of lipid mediators and superoxide
D. Enhanced leukocyte inflammatory function
Activation of basophils, mast cells, macrophages, eosinophils and neutrophils
T-lymphocyte-mediated cytokine release
Activation of cell-mediated immunity
E. Altered neural system function
β-adrenergic blockade
Cholinergic stimulation
Enhanced neuropeptide release
Defective NANC responses
F. Antibody-dependent enhancement of inflammation and cytotoxicity
G. Generation of virus-specific IgE antibody
Allergic sensitization
Mediator release
H. Effect on metachromatic cells
Direct activation
Activation via virus-specific IgE antibodies
Anaphylotoxin activation of complement cascade
Chemokine-mediated activation
IFN-γ amplified activation
I. Effect on lymphocytes
Stimulation of IFN-γ production
Activation of cell-mediated immunity
$CD8^+$ deficiency
L. Effect on cellular adhesion molecules
Stimulation of interleukin generation
Up-regulation of adhesion molecule expression
Increased eosinophil and neutrophil migration and adhesion
M. Neutrophil activation
Neutrophil respiratory burst up-regulation
Consequences
1. Mouth breathing
Reduced nasal filtering of inhaled allergens → increased penetration to lower airway
Reduced conditioning of inspired air → low temperature/humidity → bronchospasm
Reduced lower airway temperature → increase of viral replication
2. Increased circulating mediators and/or cytokines
Enhanced bone marrow production and subsequent activation of inflammatory cells
3. Increased serum IgE levels
In conclusion:
a) Epithelial changes and mucociliary clearance alteration favor a deeper penetration of viral inhaled allergens
b) Increased histamine release and IFN-γ-induced greater mucosal permeability may prime allergen absorption
c) Respiratory virus produce airway inflammation, and by increasing cholinergic receptor sensitivity promote a vagus-mediated reflex bronchoconstriction
d) Respiratory virus, directly or via metabolites produced by infected cells (including IFN-γ), impair airway β-adrenergic tone, thus perpetuating the inflammatory changes
e) Respiratory viruses, alter small airway geometry thus leading to bronchiolar wall narrowing and plugging with mucus, a mechanism of virus-induced airway obstruction
f) Virus-specific IgE antibodies trigger mast cells and basophils with subsequent mediator release, which may contribute to airway sensitization

These studies, as a whole, disprove that respiratory infections may be protective toward asthma.
Data from [20, 72, 130].

Table 11.10. Potential capacity of Rhinovirus to cause asthma in sensitized subjects

Pathophysiology						
Sublminal exposure in sensitized subjects	→	CD54 induction on respiratory epithelium Peristence of inflammation	→ →	Increases susceptibility to Rhinovirus infection Rhinovirus infection	→	**Asthmatic attack**
Clinical manifestations

Modified from [81].

epithelium with subsequent airway exposure of vagal receptors [298]. Studies [201, 298] indicate that *RSV triggers eosinophil degranulation by directly activating them* [299], a plausible and stimulating link between VRI and asthma exacerbations. Attention has been drawn to the role of alveolar macrophages in RSV infections: once infected, they acquire the ability to replicate RSV, also expressing HLA-DR and immunoregulatory ILs such as $IL_{1\beta}$ and TNF-α, capable of stimulating phagocyte cytotoxic responses. Consequently macrophages, by regulating local immune responses, perform an antiviral activity conditioning both viral replication and disease severity [401]. Lymphocyte studies have shown that the CD4/CD8 ratio in the lower tract is 22.5:1, and in the upper tract 15:1: thus diminishing the CTL importance, residing, however, in intraparenchymal locations, not intraluminal or bronchiolar [182].

Even influenza and parainfluenza viruses, *Rhinovirus*, *Mycoplasma* and *Adenovirus* often trigger respiratory infections, which can be found in very young babies as copathogenic factors [514], becoming recurrent in older children (Chap. 22). In 70% of nasal lavages in children <2 years with respiratory wheezing, RSV has been identified in 35% and *Rhinovirus* in 15% of cases [161], whereas in the >2-year-age group, only 31% of the cultures proved positive, with *Rhinovirus* predominant and an almost total lack of RSV [161]. Therefore, in older children, *Rhinovirus* influenza virus, *Mycoplasma pneumoniae*, etc. are the most frequent cause of wheezing. In a group of children aged 1–6 years, the viral origin of 45% out of 115 infection episodes of the airways has been ascertained, underlining, in the following order, the causative role of: *Coronavirus*, *Rhinovirus*, influenza virus A, and parainfluenza 1–3 viruses, *Adenovirus,* and *Mycoplasma*. The study revealed an RSV absence [400] and a total agreement with the identification process carried out in three other pediatric cohorts [477]. As well as *Chlamydia trachomatis* active in bronchiolitis, *Chlamydia pneumoniae* can induce in asthmatic children, especially <4 years [428], asthmatic crises whose onset is linked to sIgE production with consequent triggering of symptoms, which can wholly overlap what is known properly asthma. Indeed, the more protracted and pronounced sIgE production, the longer the disease duration [175].

Infection by *Rhinovirus* is by far the most common cause of wheezing disease in older children [280, 547] (Table 11.10) [81], in that it significantly stimulates mast cell mediator release, contributing to BHR development and possible late reactions [341]. In ten patients with AR and BHR, their responses to BPT to both histamine and allergen (*ragweed*) were evaluated during an experimental infection from *Rhinovirus.* Four weeks later, BHR had increased in both tests; specifically, only one patient reacted prior to infection with a late response to the allergen, while 8/10 manifested it during observation, 5/7 persistently (Fisher, 0.0027) [341]. *Rhinoviruses* are able to increase BHR and promote the appearance of *late reactions* to the specific allergen. Even if the virus does not usually have a direct effect on the airways, the infection heightens the eosinophil response to challenge [341]. The major risk of causing asthma in children aged >2 years was that of the association of *Rhinovirus* infection with the sensitization to domestic allergens and exposure to passive smoke [161]. In asthmatic children the triggering element of the exacerbations was represented in 66% of cases by *Rhinovirus,* compared to 13% in controls. Furthermore, the relapses and PEF reductions were numerically equal to hospital admission [281]. It is hypothesized that even a subliminal inflammation induces in endothelial cells CD54 expression, CD11a/CD18 receptor, which plays the role of the linking site for the virus. Linking to CD54, the virus can interfere with CD11a/CD18 and the host's natural defenses, thus inflammatory reactions to viral infection can stimulate *Rhinovirus* receptors to induce new ones, thereby spreading viral infection [280].

To summarize these reports, a unifying mechanism has been proposed [72], suggesting that *virus action has a major implication in triggering asthma.* From Table 11.10, it can be deduced that the epithelial damage and persistent inflammation that follows have an effect on sensitive nerve endings, provoking the onset of bronchoconstriction reflexes. Above all, respiratory viruses, in addition to provoking airway inflammation and prolonging its effects – either directly or through cellular products infected by them (such as IFN-γ) – promote the formation of virus-specific IgE and the release of mediators.

Emotional Factors

The influence of emotions on asthmatic attacks has been widely documented; therefore any emotional conflict being experienced by the child must always be taken into consideration (Table 5.11), even if for parents such occurrences are rare (Table 6.1). It is known that in 12%–13% of wheezing increase can be triggered by worries regarding school [307], a forthcoming trip, the birth of a sibling, etc. – all events that carry great emotional weight. *Often the child uses the disease* as a means of attracting parental attention, or to obtain privileges which might not otherwise be granted, or to divert existing tensions within the family nucleus, thereby avoiding subsequent conflicts. Studies carried out using BPT have confirmed the asthmogenic role of physiological factors: it has been noted that blind placebo (BP) inhalation prior to the test significantly reduced the onset of asthma, while open BPT with placebo, which the children believed to be the specific allergen, provoked an obvious bronchospasm [363].

Crying and Laughter

Sometimes, a child has bronchospasm following laughter or crying, in the latter case with a frequency of 40% [339]: this can be explained by the mechanical airway irritations caused by intense and rapid exhalations, as well as by hyperpnea, which, as previously mentioned, plays its part in EIA and can trigger bronchospasm even in healthy subjects. We have observed numerous cases of parents of asthmatic children who literally *forbade them to laugh,* for fear of setting off an asthmatic attack, and, conversely, other *children tried blackmail* by threatening to cry [68]. Pediatricians should clarify all these issues both to parents and children, especially explaining that these forms of attack recede spontaneously within a few minutes and should not be viewed as a cause for alarm; but should not be underestimated [68]: a child belonging to a small group of asthmatics under observation over a period of 10 years *died following a fit of laughter* [339].

Collateral Pathologies

AR, frequently complicated by sinusitis, can aggravate asthma (Table 11.1). The presence of such conditions should therefore be ascertained in all asthmatic children and, especially, in those affected with chronic asthma who also presented Rx evidence of sinusitis [179].

GER (gastroesophageal reflux) may be a severe disease and is often neglected in the etiopathogenesis of asthma [702]. GER is a pathology more commonly found in younger infants who have not yet learned to sit up and is determined by functional immaturity of the lower esophageal sphincter. GER is caused by the retrograde movement of gastric contents across this sphincter into the esophagus [702]. The estimated incidence of GER in asthmatic children reaches 50%–60% and can be an aggravating factor of the disease, higher than in the general population [702]. The reflux of acid material provokes bronchospasm, very probably through a vagal reflex. Exposed receptors could be activated with stimulation of the X afferent fibers situated in the esophageal mucosa. This could provoke a vagus-mediated increase of BHR with amplification of the bronchoconstriction effects of other exogenous stimuli [221]. The activation of this reflex between the esophagus and the airways is also related to the fact that embryologically both derive from the anterior archenteron and that they have a common autonomous innervation (Chap. 9). Based on this pathogenetic mechanism, the cough-producing clinical symptoms that have no other etiologies [170] such as in the child with asthma who is difficult to control, or who shows symptoms 1–2 h after having gone to bed, etc. [584], can be assessed. In 40 children aged a median of 14 months with persistent respiratory symptoms, a significant decrease was noticed in the number of further GER-related episodes of recurrent bronchopneumonia, reactive airway disease, nocturnal symptoms and in their nutritional status after starting antireflux therapy [277]. An esophageal scintiscanning was used to detect GER in 126 asthmatic children with a mean age of 2.31 years who were refractory to routine antiasthmatic medication [647].

Drugs to Be Used and Routes of Administration

The treatment of the asthmatic child, summarized in Table 11.11 [26, 360, 476, 508], is determined according to age and according to the severity of the symptoms.

Routes of Administration

There are four routes of administration:

The *parenteral route* is recommended for more severe cases, to achieve elevated concentrations of a drug in a short period and to obtain a good bronchodilatory effect. This method does not produce selective effects in that the drug spreads more or less at the same rate to all areas; it is most often used in EDs or in intensive care units (ICU) and, in any event, under medical supervision for *asthmatics in severe conditions* (in a state of unconsciousness, requiring intubation).

The *oral route,* having a latency time of 1–2 h linked to the rate of gastric absorption, has neither rapid nor selective effects, but certainly finds higher compliance. Higher dosages are needed than for the inhalation route to reach effective levels in the bronchial area, possibly with a higher rate of incidence of undesirable effects as a result of β_2 and β_1 receptor stimulation in extrapul-

Table 11.11. Features of four delivery systems to be used with children

MDI	MDI + spacer and face mask	Dry-powder inhalers	Nebulizers
Requirements			
Shake the canister thoroughly	Rinse the mouth	Elevated inspiratory flow after 6 years of age	Selection and maintenance of a well-functioning device
Hold the canister upright	Shake the canister + spacer	Both Turbohaler and Rotohaler should be held vertically	Preparation of drug solutions to be nebulized in the correct proportions
Place the inhaler between the lips	Actuate the MDI and fill the large volume spacer	Inhale as quickly as possible	Rinse the mouth after each inhalation
Breathe out steadily	Inhale from the spacer by five tidal breaths		When a close fitting mask is used, babies should breathe by their mouth and with no gap between mask and face
Release the dose and take a slow, deep breath	Synchronize dose release with inspiration	Gargle/mouth rinse after steroid administration	
Assessment of correct dose (delivered to the lungs)			
High (80%)	**Very low (<5%)**	**High (60%)[a]**	**Very low (5%)**
Advantages (rate of inhaled drug)			
Delivery efficiency	Rapid onset of action	Delivery efficiency	Adaptable to doses
Rapid onset of action	Rapid onset of action	Minimal child coordination required	
	High effectiveness and low adverse effects	Absence of dispersing propellants	Utilizable in noncollaborating babies
(7%–14%)	(15%–25%)	(30%)[a]	(10%–15%)
Mean age (years)			
6 or more	**1–5**	**5–6**	**1–3**
Therapeutic issues			
None	In acute and chronic asthma these are effective, cheaper, less time-consuming	Only with medications with no adverse effects	Severe bronchoconstriction In absolute absence of cooperation

Face mask devices should be applied firmly to the face, especially if a valved spacer is used; with nebulizers the mask should be held as close to the face as practicable without undue disturbance. Any gap reduces the dose dramatically.
Data from [26, 359, 476, 508].
MDI metered-dose inhaler.
[a] By Turbohaler.

monary sites. In any event, it is recommended for the *very young who are not able to tolerate aerosols* and in cases of nonsevere asthma [79].

Inhalation is the preferred route, in that it reaches the tracheobronchial tree immediately and requires lower doses, with a parallel decrease in adverse effects compared to other routes of administration.

The *subcutaneous (SC) route* is reserved for epinephrine and terbutaline.

To obtain the desired therapeutic effects using inhalatory routes of administration, the following must be considered:

- The size of the inhaled particles
- The appropriateness of the apparatus used
- The child's compliance
- The child's age, strictly linked to the above (Table 11.11), because MDIs (metered-dose inhales) developed for use in adults may be difficult for young children to

use, because they may have difficulty coordinating actuation with inhalation [28].

Regarding the first point, only particles with a diameter of 1–5 µm efficiently reach the lower airways. If they are larger, they will stop in the upper airways and, if smaller, they will reach the alveoli, or be exhaled.

In asthma, there are 4 routes to administer drugs by inhalators:

1. Predosed MDI or pressurized MDI spray can (with spacer)
2. Dry-powder inhaler (DPI)
3. Pneumatic nebulizer with compressor
4. Traditional aerosols

Predosed Pressurized Sprays

These are predosed spray cans or MDIs that manually release fixed predosed drug doses (puffs). These MDIs, if not used properly, deposit up to 90% of the drug in the oropharynx with the same effect of a drug administered *per os;* moreover, steroids may cause dysphonia and predispose the child to oropharyngeal candidiasis [517]. Therefore, the instructions for use should be carefully followed [78]:

- Shake the inhaler.
- Hold it upright and exhale deeply.
- Close the lips around the mouthpiece.
- Press the inhaler while inhaling slowly and as deeply as possible.
- Hold the breath for at least 10 s (in such way that the drops are deposited on the airways as a result of gravity and not of impact).
- Exhale slowly and wait 1–2 min, if the dose is to be repeated.

MDIs are suitable for children at 10 years (Table 11.11) and 7–8 years of age if properly instructed [273]. The main difficulty arises as a result of poor coordination at the moment of discharge, mostly due to:

- Rapid inhalation
- Blocking the inhalation at the moment when the aerosol discharges its content
- Breathing though the nose
- Premature or delayed breathing (lack of hand-lung coordination) [78]

The major problems can be obviated by keeping the mouthpiece 3–5 cm away from the lips, an expedient that overcomes the instinctive defense of small children using their tongue to impede any further drug entry to the lower airways: the effect becomes noticeably increased, also allowing for confirmation of its proper use, but it is not always a recommended method for this age group [78]. It should be noted that MDIs contain chlorofluorocarbons (CFCs) 11, 12 and 114, which provoke cough and reduce ventilatory function in one-third of patients [128]. New hydrofluorocarbon inhalers (HFIs) deliver albuterol, BDP, and various other medications.

Spacers or Holding Chambers

To overcome the difficulty caused by the lack of synchronization between discharge and act of inhaling, *spacer devices* are available. These are adapters consisting of an expansion chamber placed between the MDI and the patient's mouth, facilitating use in preschool children [273]. It consists of a container in which drug particles are held in suspension, that is held inside the apparatus until the moment of inhalation, discharging the required amount even in situations of noncompliance. Consequently, *a minimum deposit in the oropharynx* is assured and *a higher percentage of inhaled drug, as well as a decreased incidence of side effects* resulting from systemic absorption [25, 220, 359]. After the puff, the majority of finer small drops remain suspended inside the spacer for at least 30 s, thereby allowing even *the youngest children* to undergo treatment. The larger aerosolized particles, on the other hand, are withheld, thus obtaining a more rapid administration of the drug and a more efficient supply and an unquestionably adequate cost-effectiveness ratio [436]. In addition to being helpful to children unable to use MDIs correctly, such adapters become indispensable for those undergoing an ICS treatment, to reduce the pharyngeal drug impact and prevent the side effects listed above [80] (Fig. 11.36).

Another innovation has been the introduction of a valved holding chamber (VHC) at the mouthpiece of large-volume spacers to aid the inhalation by very young babies. The principal MDI models with valve spacers are as follows: with the Aerochamber (150 ml volume), also available with a mask for infants and young children, the rate of swallowed medication is barely 2%–3% compared to 60% and 80%, respectively, with the spray or MDI; inhalation is also correct [357], while the rate reaching the airways is 17% compared to 14% of an adequate MDI inhalation [357]. Also available are Babyhaler (Fig. 11.37) and Volumatic, more suited for older children, with volumes of 350 ml and 750 ml, respectively, Fisonair, Nebuhaler and Turbohaler for DPI budesonide (BUD) (Oxis) Turbuhaler for formoterol and Diskus for salmeterol. In addition, there is the pocket-size spacer-discharger of predosed aerosol (Jet) for BDP (Fig. 11.38), which avoids the synchronization problem mentioned and has an inhalation quota of 30% and a swallowed one of 10% [359]; and the *breath-actuated* Autohaler, a dispenser of albuterol. Therefore these last two are useful in acute attacks and for children who have difficulty in using MDIs [128, 485] – not for everyone. Patients aged 5 years have difficulty with the Autohaler since it requires quick inhalation, as with MDIs [128].

For nurslings and very young children, a well-designed mask must be placed on the dispenser (Fig. 11.37), or alternatively, an Aerochamber can be used for nurslings with a closely fitting anatomically designed mask [180], to avoid an empty space between the mask and the face,

Fig. 11.36. A child about to use a pressurized MDI with incorporated PEF meter

Fig. 11.37. A girl using a valved large-volume spacer with face mask

Fig. 11.38. A girl using a pocket MDI with spacer

eventually changing the type of mask if necessary. The choice between large or small chambers has been resolved in favor of the latter, which are easier to manage if the child rejects the treatment, and are also less frightening. They release at least the same amount of medication as the larger ones, if not more, at a low tidal volume (TV) rate [180]. If the spacers are not equipped with valves suitable for nurslings, during inhalation the air can be contained within a nonanatomical mask, thus reducing the dosage inhaled [44]. For children unable to tolerate a face mask, a MDI with a polystyrene cup can be used, especially in case of emergency [508]. In conclusion, face mask devices should be applied firmly to the face, especially if a valved spacer is used. With nebulizers the mask should be held as close to the face as practicable without undue disturbance. Any gap reduces the dose dramatically; therefore in very young children high doses of ICS are not effective because a lot of the spray is lost and does not reach the lesser airways, because of the small TV in these babies.

Another characteristic of critical importance is the volume. The right size is a matter of balance. Using a small, low-resistance, two-way chamber with nurslings and children, 38% of the dose is received, whereas with larger chambers, only 20% is received [44], obviously depending on details: it is larger, more cumbersome and inconvenient to use.

An alternative to the MDI is the small-volume nebulizer (SVN). Advantages to SVNs include use at any age, or administration while asleep [102]. A recent meta-analysis has found the efficacy of MDI-VHC superior to that of SVNs, particularly in regard to onset of action and reduction of hospitalization [86]. In 123 children <2 years of age with moderate-severe exacerbations of wheezing seen in the ED, the response to salbutamol delivered by MDI-VHC and facial mask was faster than to salbutamol delivered by SVN [540].

Dry-Powder Inhalers

DPIs are ecological since they do not contain CFCs: the micronized powder is contained in capsules, is inhaled by special dosers such as Spinhaler for DSCG (cromolyn); Diskhaler, Rotahaler, and Easyhaler for albuterol, and Turbohaler for BUD and formoterol. They do not require coordination of inhalation techniques since the patient inhales directly from the mouthpiece, the inhalator being breath-actuated. Multi-dose apparatuses, in addition to their convenience, ensure greater compliance, especially from preschool children [232]. Even with this system, difficulties arise. The very young should be taught to rapidly inhale without holding his (her) breath and told not to lean their head backwards [508]. In fact, the micronized particles of the medicine tend to agglutinate in clumps of excessive size. For effective use, children should inhale rapidly with high peaks of inspiratory flow (PIF) of at least 30–60 l/min, to create

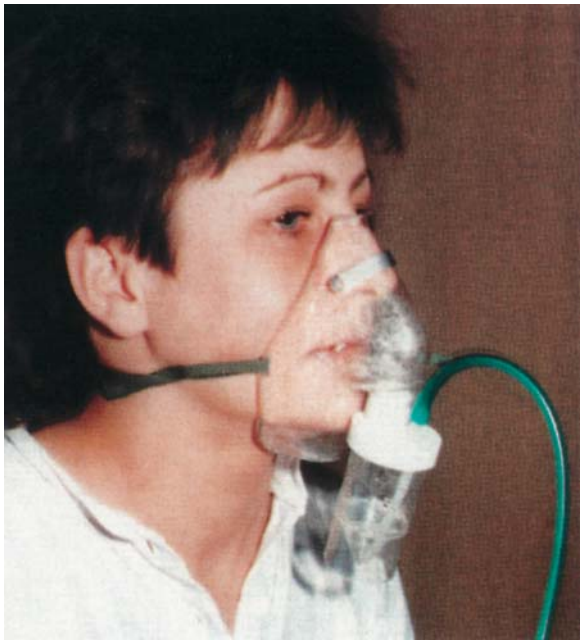

Fig. 11.39. Nebulizer system

Fig. 11.40. Nebulized β_2-agonist therapy is primary in the management of severe asthma also with toys

sufficient turbulence to break them up: at a lower rate the functionality, for example of the Rotohaler, drops to 10% [128]. Since large amounts of medication may remain in the mouth, it is advisable to have the child rinse it thoroughly after inhalation [508]. These models are not suited for children suffering from acute asthmatic attacks [44]; they are advisable for use with children aged 5–6 who can use them [44].

Nebulizers

Jet nebulizers can be used with a mask or directly from the mouthpiece, to avoid the frequent problem of small infants and young children unable to use MDIs, or suffering from acute attacks or persistent bronchoconstriction (Fig. 11.39). The advantages are obvious: even superficial breathing over several minutes can effectively deliver the medication deep into the airways. Compared to traditional MDIs, they produce a larger number of particles in a given time and particles that are also smaller in size (0.5–5 µm instead of >5 µm), thereby distributing the drug more quickly. However, if children are not cooperating during the brief time of discharge, this technique will be inadequate. During nebulization, if the mask is distanced even 1 or 2 cm from the face, the delivered medication is reduced by 85%. Given that even the most tranquil child cannot stay still for more than 5 min, a means of reducing this time frame could be studied [181]. Ultrasonic nebulizers (for example, Fisoneb) ensure rapid nebulization, but are commonly less efficient for drug delivery, especially with suspensions, have a poor cost-benefit ratio and are difficult to handle [26]. Some nebulizers (for example, Nebula and Soffio) can also be used at home (Fig. 11.40). With nebulizers equipped with electric compressors, the need for good coordination from the moment of discharge and the act of inhalation is eliminated, thereby facilitating a sustained administration [476]. Newer types of hand-held nebulizers are small enough to be safely carried in a briefcase, a purse, or a backpack.

Even with nebulizers some rules should be followed:

- Regular checks of the proper functioning of the machine.
- The drug must be diluted in saline, 4 ml.
- Time of nebulization about 10 min.
- Careful rinsing of the oral cavity, especially after using CSs.
- Washing under running water of the flask, mouthpiece and mask after use.

Traditional Aerosols

The traditional models are suitable for all children who will accept them. Usually, they produce too large particles (>5 µm) to reach the airways effectively but, unlike cromolyn and BDP, they are suited to β_2-adrenergics, which are characteristically effective even in low doses, since they are easily absorbed by the oral/nasal mucosa. Even in this case, wheezy infants or toddlers should inhale with an open mouth, otherwise 75% of the aerosol is blocked, with the nose acting as a filter [549]; nor should the mask be distanced from their mouth [192].

Table 11.12. Starting and subsequent drug doses recommended in children <5 years in severe conditions (maximum doses and minimum do intervals for domiciliary use in parentheses)

Age (years)	Device	Symptomatic	Prevention
0–2	MDI spacer and face mask[a]	Albuterol 200 µg q 6 h (1 mg q 3 h) Terbutaline 250 µg q 6 h (2.5 mg q 3 h) Ipratropium bromide (IB) 1.25 µg q 6 h (250 µg q 6 h)[b]	Cromolyn 5–10 mg q 6–8 h BDP 50–200 µg (600 µg) q 12 h FP 25–100 µg (250 µg) q 12 h BUD 50–200 µg (600 µg) q 12 h
	Nebulizer	Albuterol 2.5 mg q 6 h (q 3 h) Terbutaline 5 mg q 6 h (q 3 h)	Cromolyn 20 mg q 6–8 h[c] BUD up to 800 µg q 12 h
>2–5	MDI+spacer	Albuterol 200 µg q 6 h (1 mg q 3 h) Terbutaline 500 µg q 6 h (2.5 mg q 3 h)	Cromolyn 10 mg q 6–8 h BDP 50–200 µg (600 µg) q 12 h FP 25–100 µg (250 µg) q 12 h BUD 50–200 µg (600 µg) q 12 h
	Nebulizer	Albuterol 2.5–5 mg q 6 h (q 3 h) Terbutaline 5–10 mg q 6 h (q 3 h)	BUD up to 800 µg q 12 h

[a] Doses of inhaled corticosteroids are recommended for children in such severe condition that they are no longer controlled by nonsteroidal anti-inflammatory drugs. However, higher doses and concentrations may be required for younger children because of the relative inefficiency of delivery devices (see Table 11.13).

[b] IB should not be administered at intervals less than 6 h to avoid atropine-like toxicity.

[c] Cromolyn is more effective if administered at age 9 months by nebulizer [479].

When prescribing steroids, pediatricians should always prescribe the lowest dose required for symptom control; when symptoms remit, steroids may be stepped down and started up again when symptoms return.

Data from [56, 604].

BDP beclomethasone dipropionate, *BUD* budesonide, cromolyn, *FP* fluticasone propionate.

Age Ranges for Inhalant Therapy

To summarize [476, 508, 699] (Tables 11.10, 11.12) [56, 604]:

- *Children 1–2 years of age*

Nebulizers are useful for acute attacks not requiring the child's total cooperation [272]. The more economical MDIs with valve expanders are also recommended. Both are provided with face masks suitable for use even with nurslings and toddlers if the problem of keeping the appliance in position on the face can be overcome, adapting the expansion chamber volume to the specific needs listed in the previous section [180, 181]. Only 0.3%–1.5% of the nominal dose inhaled by children, even 9–16 months old, reaches the lungs, significantly more if nebulized [549]. A recent trial has established that MDIs with spacers may be as efficacious as nebulizers for the ED treatment of wheezing in children aged ≤2 years [143]. For decades we have used in children aged 6 months and older with wheezing a BDP or flunisolide suspension for nebulization dosed in drops (1 drop/kg) plus albuterol solution for inhalations (half dose), 3–4 doses/day as needed. The symptoms are improved in 90%–95% of cases.

- *Children 3–5 years of age*

MDIs with VHC spacer plus face mask [44, 56] are preferred; however, many children probably use nebulizers because that is the route they began [78]. New cases should first try MDIs with spacers [56]. Devices have been created that allow the child to breathe while receiving the medication, and placebo spray cans produce excellent preventive training. Breath-actuated MDIs are not recommended for this age group [57].

- *Children 6–8 years of age*

At this age children spend a great deal of time outdoors, and they need a portable model that is easy to use and efficient. The aerochamber fulfills all these requirements well. The DPI is useful for subjects who have not yet become accustomed to MDIs. Both systems avoid the problems associated with CFCs.

- *Children aged >10 and adolescents*

Young people of this age are able to use MDIs, which are economical and fulfill the requirements needed [476].

The instructions provided with the device are unsuitable for younger children (Table 11.13) [476, 486], and even adults have found difficulty in using the equipment [103, 350], to the point that manufacturers were invited to change the mouthpiece [350]. Additionally, there are problems related to the dosage absorbed and to be delivered [112]. In the first instance, a pharmacokinetic analysis revealed that nurslings and toddlers absorb only 0.13%–0.33% of the dose being delivered by MDI or nebulizers, respectively [549], and on average only 14% of nebulized medication is deposited in the airways, increasing from 9% to 19% in older children [357]. Reports have shown nebulizer reactions including tachyphylaxis or increased BHR due to β-agonist overuse

Table 11.13. Frequency of the most common problems encountered by 217 children using an inhaler (%)

Problems	MDI inhaler (no. 132)	Tube spacer (no. 85)
Forgetting to shake the canister	49	34
Forgetting to exhale before inhaling	45	51
Neck flexed during inhalation	12	14
Coordination problems	55	17
Too rapid inhalation	67	28
Breath holding for 7 s	42	39
Stopping inspiration when firing aerosol	38	6
Nasal inspiration	24	32
Submaximal inspiration	23	19
Help from the parents	5	6
Possible explanations of the poor compliance:		
Misunderstanding		
Poor reliance on drug effectiveness		
Fear of adverse effects		
Rebellion		
Coordination problems with administration technique		
Coordination problems with administration timing

or allergic reactions to the medication or the excipient. Recently two asthmatic children experienced a life-threatening exacerbation of their symptoms after nebulizer use. Cockroaches were detected in the reservoir of the nebulizers used [48].

Dosages for the Very Young

The point of departure is the anatomical differences found in the very young. Nurslings inhale with a relatively rapid TV and in so doing retain the therapeutically useful particles for a shorter time [436]. Nonetheless it should be noted that TV and PIF are reduced, compared to older babies and preschool children, so that infants <6 months inhale the aerosol directly, thereby receiving a greater dosage of the undiluted medication, whereas an older infant or preschool child inhaling with normal TV, but at ambient air, receives a comparatively smaller dose, underscoring the dosage/kg problem [112]. Taking into consideration that the reduction in caliber of the lower airway tracts reduces the penetration drug in the peripheral areas [584], and that newborn infants tend to breathe through their nose, in the best hypothesis the amount of the drug that is deposited in the airways is only 33%–50% of that inhaled *per os* [344]. Also, the correlation between the drug concentration in the aerosolized or nebulized solution (Cs) and that per inhaled volume unit of gas (Ci) appears to be inconstant, since for a given Cs the Ci can be five times greater in a young infant compared to an older child, in whom the inhaled dosage is independent of weight [112]. Therefore, doses for children aged 6 months to 5 years have to be regulated according to weight in kg, to balance the discrepancies that arise from a dosage based on a single measure for all [112]. If no correction is made, children aged 1–5 might receive a larger dosage than those aged 5–10 [344, 488]. However, based on studies conducted related to the plasmatic concentrations of albuterol, it has been noted that doses calculated on the basis of weight can prove to be less in children aged 6 months to 5 years. Therefore in cases of severe asthma, the dose can be increased – even up to 25%–50% [488] or more – with no risks, whether it be the result of greater drug clearance in the airways or of an insufficient inhalation coordination between the method of discharge and the technique [488]; and finally – we should add – whether it also be because of the great differences among individuals. One could settle for a fixed dose for all patients, given that the results produced are similar [459]. Further research will ascertain which dosage is *the most suitable in early infancy,* based also on pharmacokinetic studies of each drug.

Drugs to Be Used

The drugs to be used are the following:
- Adrenergics
- Anticholinergics
- Theophylline
- Corticosteroids

Table 11.14 [124, 617, 634, 635] sets forth the action mechanisms whereby drugs that can be used to treat acute asthma work; Table 11.15 [174] those of β_2-adrenergics; Table 11.16 [35, 56, 406, 437, 552, 582] specifies the dosage for each method of administration.

Adrenergic Drugs

Adrenergic or sympathomimetic agonists can be classified, according to their respective actions on the receptors, as follows:
Drugs acting on receptors α, β_1 and β_2: epinephrine
Drugs acting on receptors β_1 and β_2: isoprenaline, orciprenaline
Drugs with selective action on receptors β_2 (β_2-adrenergics, β_2-agonists), further divided into:
- Catecholics: isoprenaline
- Resorcinolic: fenoterol, orciprenaline, reproterol, terbutaline

Table 11.15. Role of β_2-adrenergic function in asthma

1. Bronchodilator effect acts on bronchial smooth muscles
2. Functional antagonism opposes bronchoconstrictor agents on bronchial smooth muscles
3. Inhibition of microvascular permeability, especially of tight junctions
4. Inhibition of mast cell degranulation and mediator release
5. Direct action on irritative receptors
6. Stimulation of mucociliary clearance
7. Increased water flow to the secretions
8. Inhibition of leukocyte lysosomal enzyme release

Modified from [174].

- Saligenins: albuterol (salbutamol), salmeterol, carbuterol
- Others: clenbuterol, procaterol, formoterol, bambuterol

Epinephrine (adrenaline) is a catecholamine that becomes active within 5–6 s and has an effect that lasts 30 min. For SC administration of terbutaline, 0.5 mg vials are available. Symptoms of epinephrine overdose (Chap. 20) may be frequent (47%) in children treated with SC epinephrine compared to those given terbutaline inhalation (11%). In Chap. 20, b/w based doses of inhaled epinephrine are detailed. In case of a severe attack, epinephrine remains the preferred drug [352].

β_2-Adrenergics for predosed MDIs or nebulizers (Fig. 11.40) offer the best results because of rapidity of action, good efficacy and limited adverse effects on the cardiovascular apparatus. Given the recognized benefits of short-acting β_2-adrenergics, attention was directed to extending the duration of effect of β_2-adrenergic agonists. As a result, long-acting β_2-adrenergics with a 12-h duration of action were introduced: salmeterol and formoterol. For an immediate effect, lasting 4–6 h, albuterol is recommended: to limit the adverse effects of short-acting β-agonists, the stereoisomer of albuterol, levalbuterol, compared to racemic albuterol significantly reduced the number of hospitalizations in the ED management of acute asthma in children aged 1–18, but the hospitalization length of stay was not significantly shorter between the two groups [84]. For an effect with 5 min of latency, but with long-term effect (12 h), salmeterol 25 µg is recommended. A dose of 50 µg has induced a significant HR increase in the first 5 min [19] in children of 13.4±2.5 years. Formoterol has the same latency and lasts 12 h [441], while systemic administration of formoterol (via the oral route) displays a short duration of action (4 h). Salmeterol is a long-acting β_2-agonist with a long side chain, diffuses quickly from

Table 11.16. Pediatric doses and routes of administration of epinephrine and main β_2-adrenergic (quick-relief) medications

Medication	Route	Dosage form	Dose
Adrenaline (epinephrine)	SC	1 ml vial of a 1:1,000 dilution	0.01 ml/kg repeated q 15 min for 3–4 doses[a] as needed. Up to a maximum of 0.3–0.5 ml per dose or inhaled (Chap. 20)
Racemic	Nebulizer solution (2.25%)		0.1 ml/kg diluted to a total of 2 ml in 0.9% NaCl, or ″ 2 years: 0.3 ml in 1.5 ml of saline <2 years: 0.5 ml in 2.0 ml of saline
Albuterol (salbutamol)	Oral	Tablets 2–4 mg Syrup (10 ml = 4 mg)	Children <6 years 0.1–0.2 mg/kg × 3–4 daily Children 6–12 years 2 mg/kg × 3–4 daily Children >12 years 2–4 mg × 3–4 daily
	Rotocap DPI	(200 µg/capsule)	200 µg × 3–4 daily prn or q 4–6 h
	Nebulizer solution (0.6%)		2.6 mg (0–2 years) to 5 mg (2–5 years) prn or q 4–6 h
	MDI	(100 µg/puff)	100–200 µg (1–2 puffs prn or 3–4 puffs daily)
	IM/IV vials	100/500 µg	2–6 µg/kg × 3–4 daily
	Levalbuterol	Unit dose vials of 0.31 mg, 0.63 mg, 1.25 mg	Pediatric 1.25 mg qid, or q 20 min (max 6 doses)
	Racemic	Solution of 5 mg/ml or unit dose vials	Pediatric 2.5 mg qid, or q 20 min (max 6 doses)
Bambuterol	Oral	Solution in 2- to 5-year-old children	10 mg in the evening
		Tablets in 6- to 12-year-old children	10–20 mg in the evening
Bitolterol	MDI solution 0.2%	(1 puff = 0.5 mg)	Children 4–12 years 1–2 puff q 4–6 h prn
	Nebulizer solution (0.1%)		1 mg (range 0.5–1.5 mg) q 4–6 h prn
Fenoterol[b]	Oral	Syrup 0.05% (10 ml = 5 mg)	0.1–0.2 mg/kg × 3–4 daily
	Nebulizer solution 0.1%	(20 drops = 1 mg)	Children <6 years 50 µg/kg Children >6 years 100 µg/kg × 1–3 daily
	MDI	(100 µg/puff)	100–200 µg (1–2 puffs) x 3–4 daily
Formoterol	MDI	(9–12 µg/puff)	Children >6 years 1–2 puffs × 2 daily or × 3–4 daily prn
	DPI Turbohaler	(9–12 µg/capsule)	Children 5–12 years 12–24 µg × 2 daily
Pirbuterol	MDI 250 µg/dose		>12 years 2 puffs × 3–4 daily or prn
Procaterol	Oral	Tablets 5 µg	1 µg/kg × 2 daily
		Syrup 5 µg/ml (10 ml = 50 µg)	1 µg/kg × 2 daily
	MDI	(10–25 µg/puff)	10–25 µg (1–2 puffs) × 2 daily
Salmeterol	MDI	(25 µg/puff)	25–50 µg (1–2 puffs) × 2 daily[c]
Terbutaline	Oral	Tablets 2.5–5 mg	Children <12 years 0.05–0.1 mg/kg (max 5 mg) q 6–8 h, Children ≥12 years 2.5–5 mg q 6–8 h
		Solution (0.1%)	0.01 ml/kg up to 0.3 ml SC
	1 mg/ml		q 2–6 h prn
	MDI	(250 µg/puff)	0.25 mg dose (1 puff) q 6–8 h prn

Two dosages (10–25 µg/puff) means that two different preparations are available, or that two different doses are suggested. The rate of inhaled drug may be lower than 30% (Table 11.11). In small children, spacers with a mask are imperative. Epinephrine is suggested for babies with bronchiolitis and children with status asthmaticus.
MDI metered-dose inhaler, *DPI* dry-powder inhaler.
Data from [35, 56, 158, 406, 437, 552, 583, C Kercsmar, pers. comm. Nov 30, 2005] and Aucoin RG. Respiratory pharmacotherapy (Accessed at http://search.yahoo.com/search?fr=fp-pull-web-t&p; http://picuBOOK.net/1999/04-001(e1).htm).

[a] Acts within 5–6 s, duration is of 30 min; more data on epinephrine and terbutaline are in Chap. 20.
[b] Decreased doses have been suggested, see text for details.
[c] Adult dosage, the 25- to 50-µg dose should be the highest in children aged 6–12 years [582].

the aqueous phase into cell membranes of the lung with maximal bronchodilation ≈1 h after administration. Formoterol has a medium-sized side chain and diffuses both into the aqueous phase and cell membranes of the lung with an onset of action within minutes. Two recent articles have reported that formoterol provided superior bronchodilator efficacy over 12 h compared with salmeterol [501], or at least as effective as salmeterol [183]. So once daily oral bambuterol may be an interesting and less expensive alternative to twice-daily inhaled formoterol and salmeterol [158]. The increased efficacy of the first (single) dose compared to regular follow-up treatment should be kept in mind, being equal to a PD_{20} improvement of 1.7 or 0.7 [680]. Therefore, with the *new, long-acting β_2-adrenergics* the late reaction is inhibited and adverse effects are reduced. Nevertheless, some undesirable side effects can result, especially with continued and/or high-dose use:

- Muscular effects: muscle tremors (as a result of action on β_2 muscle receptors)
- Metabolic effects: hyperglycemia (for glycogenolysis) with hyperinsulinism, hyperkalemia and therefore hypokalemia as a result of K^+ deposits at the cellular level
- CNS effects: agitation, insomnia
- Cardiovascular effects (in cases of overdose): tachycardia, extrasystole, hypertension

Possible effects resulting from prolonged usage include:

- Tachyphylaxis (reduction in therapeutic responsiveness)
- Difficult management of the disease: asthma worsening, BHR increase [571] due to tolerance increase [456]

An Assessment of β_2-Adrenergics

We draw attention to the results of certain studies focusing on β_2-adrenergic use, especially when used over a prolonged period and/or in high dosages [697].

1. Sears et al [571] obtained better results when β_2-adrenergic drugs were used only as needed. Control of the disease is reduced in patients who treat asthma with bronchodilators continually, for a long time and regularly, patients becoming dependent, and thus inhaling ever higher doses: in this way desensitization of β-adrenergic receptors occurs, that is repeated administration reduces the bronchodilator effect.
2. According to Page [467], this is probably caused by a disrupted equilibrium between inflammatory and anti-inflammatory factors, as a result of reduced anti-inflammatory release, caused by the powerful antidegranulation accomplished by β_2-adrenergics on mast cells. In time, this leads to the deactivation of natural defense mechanisms, allowing the inhaled allergens to penetrate in the bronchial tree more deeply [467], with loss of the action inhibiting BM thickening and smooth muscle hypertrophy, deleterious aspects for asthmatics [516] likely leading to an irreversible chronicity [467].
3. According to Spitzer et al [608], these drugs aggravate asthma, rendering the airways more susceptible to stimuli. In effect, though reducing the acute episode, they promote delayed bronchial inflammation, which is at the basis of chronic asthma.
4. Burrows and Lebowitz [62] agree with these findings and advise against regular, high dosages of β_2-adrenergics.
5. Prospective studies in children have shown that prolonged usage of β_2-adrenergics does not reduce BHR [571].
6. In patients treated with terbutaline, a rebound type of BHR can occur when treatment is stopped: conversely, in children 1.5–11 years admitted to an ICU, the same drug was shown to be safe and effective [288].
7. It should be noted that for β_2-adrenergics, dosages that double the usual ones, even if only for 7 days, amplify airway reactivity even in the late reaction [110]. Chronic use of high doses results in hypokalemia, because ATP stimulation causes K^+ passage within the skeletal muscles, an effect that is strengthened by hypercapnia, hypoxia and hypokalemia, characteristics of acute asthma-status asthmaticus [310, 697]; even theophylline can provoke hypokalemia, and together with CSs, hyperkaluria [310].
8. Few and contradictory results have been obtained with these drugs in bronchiolitis: epinephrine was more efficacious than salbutamol [401]. Probably, the negative results depend on having measured the Raw index of seriously ill infants with widespread edema and mucous secretions, thereby reducing the dose of the aerosolized drug [112]. Moreover, the total resistance of upper airways can be reduced by 50% at this age, making measurements unreliable [206]. This can also be related to a reduced response to β-adrenergic stimuli effected by respiratory viruses and therefore to that of β-adrenergic drugs [73].
9. In conclusion, there is no clear benefit of using β_2-adrenergics in the management of recurrent wheeze in the first 2 years of life, although there is conflicting evidence [140].

Anticholinergic Drugs

These drugs stimulate the muscarinic receptors with reduction in intracellular cGMP by competitively inhibiting α-adenylcyclase [77]. The bronchodilator effect works on medium- or large-caliber bronchi; it is less rapid (15 min after administration, maximum effect after 30 min to 2 h), but longer-lasting than short-acting β_2-adrenergics (exhausted after 3–5 h). They should be used in the intercritical periods, or in association with inhaled β2-adrenergics, which allows the dose of the latter to be reduced. This also reduces the risk of side effects as a consequence of the therapeutic margin of these drugs [79].

IB has an anticholinergic activity that is similar to that of atropine, but also a reduced systemic absorption. IB is most often used with other drugs, providing good bronchodilator action and few side effects (mucosa dryness) [371, 663] when utilizing a DPI – preferred by young children rather than an MDI [663] – or a spray with spacer [371].

Theophylline Drugs

Theophylline drugs are enjoying a renaoissance mainly because of their rediscovered anti-inflammatory properties [274]. Theophylline is a methylxanthine similar to theobromine and caffeine. The mechanisms of its action [124, 635, 740] and the anti-inflammatory effects [101, 114, 461, 658] are summarized in Tables 11.17 and 11.18 [101, 114, 124, 461, 635, 658, 736], from which the induction of apoptosis in eosinophils clearly emerges (Fig. 11.41). Bronchodilation is caused by PDE inhibition, which causes an increase in cAMP levels. It also displays considerable anti-inflammatory properties (Table 11.14) and promotes the production of anti-inflammatory IL, IL_{10}, deficient in asthmatic airways, depressing instead that of IFN-γ [513]. Significantly, in young asthmatics, abatement of IgE levels occurs with slow-release theophylline, but not with cromolyn or BPD [658].

In examining the pharmacological aspects, it is useful to review a few basic facts [404, 706]:

- *The therapeutic range of theophylline* is between 10 and 20 µg/ml (56–111 µmol/l), even though it is known that bronchodilation can take place with therapeutic levels of 5–15 µg/ml. Below the minimum level the effects are few and side effects – even severe – can occur when the theophylline level exceeds 15–20 µg/ml. Thus the therapeutic range is extremely close to the toxic range.

Table 11.17. Anti-inflammatory action of theophylline

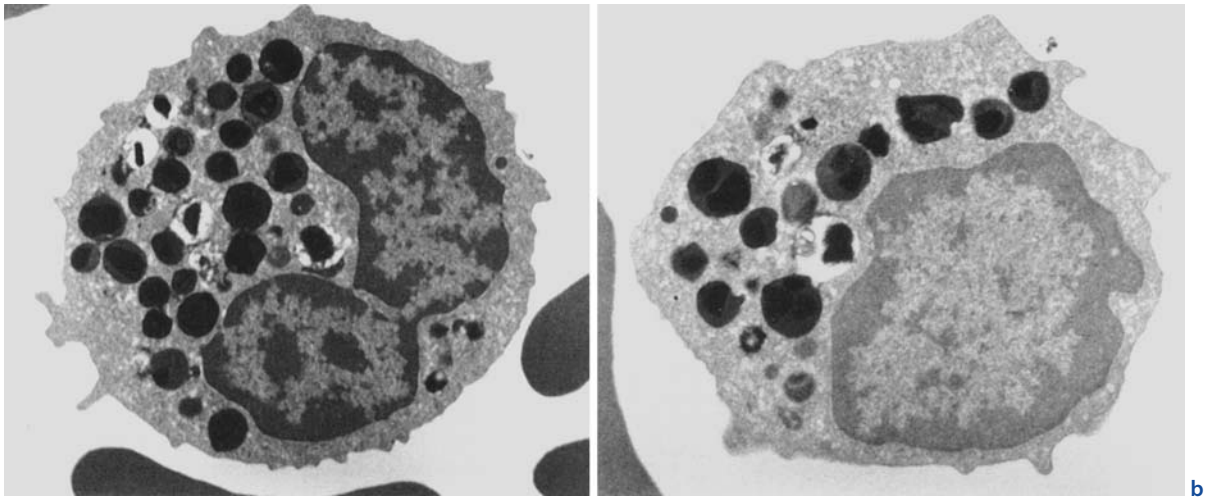
Increases mucociliary transport
Increases diaphragmatic contractility
Decreases muscle work
Bronchodilation
Inhibits phosphodiesterase
Suppresses histamine release by mast cells and basophils
Inhibits vascular permeability
Inhibits PG and LT
Increases cAMP intracellular concentrations
Inhibits immediate and delayed asthmatic reactions, a change not observed in any other group
Inhibits airway responsiveness

Data from [124, 635, 735].

Table 11.18. Immunomodulatory effects of theophylline

Inhibits neutrophil and mononuclear cell chemotaxis
Suppresses IgM, IgG and IgA synthesis
Reduces serum IgE levels in 4- to 6-year-old asthmatics
Inhibits TNF-α and $IL_{1β}$ expression and release
Reduces CD3, CD4, CD8, CD15, and CD25 cell counts
Enhances trafficking of peripheral blood-activated T cells
Inhibits eosinophil influx after allergen challenge and cationic protein production
Enhances eosinophil apoptosis

Data from [104, 114, 658].



a b

Fig. 11.41 a,b. Morphological changes of eosinophils by adding theophylline to culture medium with IL_5. **a** The eosinophils, without additions, are "normal" in shape. **b** By adding theophylline the cells show apoptotic changes including aggregated chromatin, smooth cell surface and cytoplasmic vacuoles

• *Theophylline metabolism* results in 85% of theophylline being metabolized by the enzymatic system of hepatic cytochrome P450, so all factors or drugs that interfere with this system can alter its metabolism (Table 11.19) [244], increasing or reducing theophylline clearance, with reduction or, respectively, increase of its concentrations [706].
• *Theophylline clearance* (distribution volume × unchanging level of elimination) varies according to age [404]:
– From birth to 7–9 months, it is reduced.
– Between 7–9 months and 9 years of age it increases (1.44 ml/min/kg); therefore, proportionately higher doses are required.
– From 9 to 16 years the clearance is reduced again (9–12 years=1.26; 12–16 years=0.9 ml/min/kg).

Such levels are appropriate for good theophylline distribution and function. Other factors that must be borne in mind are [244]:
• Individual variations in the rate of absorption.
• Differences of half-life in children are half that of adults (≈3.5 h instead of 7 h).
• If the patient is obese, the correct dosage must be prescribed according to ideal standard weight, and not to the actual weight.

Theophylline absorption also depends on *circadian rhythms*. The indispensable interval of time to reach peak concentration of the medication is significantly shorter (and absorption increased) when oral doses are taken in the morning, compared to evening effects. Analogously, clearance is influenced: the elimination rate is greater with morning doses compared to evening doses in children treated with slow-release or IV medications, so a standard dosage with equal doses at regular intervals will provoke an increase in nocturnal serum levels compared to daytime levels, to the advantage of nocturnal asthma sufferers [32]. All this is of great importance in establishing dosages which must be *personalized* whenever constant monitoring for an entire 24 h period become necessary. Similarly, for the study of theophylline pharmacokinetics, the hours at which both doses and blood samples were taken must be recorded [244].

Indications

• Children with acute asthma who can benefit from theophylline, but reducing the respective doses when associated with β_2-adrenergic.
• Mild or moderate forms of acute attacks, if there has been no response to the β_2-adrenergics. Eventually it can be associated with them, again reducing the respective doses.
• Moderate to severe forms of chronic asthma resistant to other medications [707].

The scientific rationale behind theophylline lies in its anti-inflammatory quality, not shared by other medica-

Table 11.19. Factors and drugs affecting theophylline serum concentrations

? Unknown rate.

tions, which we have always taken into consideration. Logically it holds an undisputed and, to this day, unique place ensuring the compliance of young and very young children who are not used to taking inhalation drugs. According to Szefler [634], the clinical effect of chronic therapy with theophylline, cromones, and anti-LT on symptom scores, PEFR, and acute exacerbations (morning, or evening) is comparable.

Dosages and Methods of Administration

1. IV in severe asthma attacks to achieve a more rapid therapeutic effect.
2. *Per os* the absorption is slower; depending on the nature of the case the following can be used:
- Fast-acting theophylline.
- Long-acting theophylline, which, having a greater serum half-life, is preferable for long-term treatment. Also, it is suitable for the very young [77].

Dosages advised for fast-acting theophylline are as follows, four doses every 6 h [244, 707]:
1. Initial dosage for children 6 months old: about 10 mg/kg/day up to a maximum of 300 mg/day. *After 3 days, if the dose is tolerated:*
- First increment: about 13 mg/kg/day up to a maximum of 450 mg/day. *After a further 3 days, if the dose is tolerated:*
- Second increment: about 16 mg/kg/day up to a maximum of 600 mg/day.

In view of the rapid metabolism that the drug undergoes in the child, an early and periodic monitoring of theophylline to verify that the levels are not subtherapeutic (5.6 µg/ml) is indispensable. We suggest measuring theophylline levels after at least 3 days to coincide with the administration of the maximum dose tolerated, *4 or 8 h after the morning dose,* depending on the medication being used. Once theophylline levels have been monitored, the dosage should be adjusted based on serum concentrations in µg/ml [244]:

<7.5	Increase dose about 25% (check serum theophylline levels for guidance in further dose adjustment).
<7.6–10	If tolerated increase dose about 25%.
10–15	If tolerated maintain dose (recheck serum theophylline levels at 6- to 12-month intervals).
15.1–19.9	Consider a 10% dose reduction (to provide greater margin of safety.
20–25	Skip next dose and resume treatment based on the last increase tolerated.
25	Skip next two doses and resume the initial dosage, or that of the last increase.

Whenever side effects occur, dosage for all children should be reduced to the minimum dose previously tolerated.

2. Dosages for infants <1 year of age [244]:
- Initial dosage in mg/kg/day: (0.2) (age in weeks) +5.0; this equation results in levels of theophylline between 5 and 10 mg/l [244]. Serum theophylline concentrations should be monitored within 6–12 h after start of treatment [256].
- Subsequent dosages should be based on serum theophylline levels measured at least 3 days after start of treatment.

The average dosage of long-acting theophylline is 7–10 mg/kg every 12 h [83]. This formula, having a greater half-life, is recommended for treating nocturnal asthma, among other reasons because of its protracted bronchodilator effect. Additionally, capsules that can be emptied and mixed with foods minimize the child's opposition [83]. For cases using long-acting theophylline, a noninvasive, reliable, and convenient method for measuring theophylline levels in saliva has been proposed [640]. Three different controls are recommended, to characterize around-the-clock theophylline profiles:
- Good symptom control, no side effects: measurement 4 h after morning dose, every 3–6 months
- Nonoptimal control: as above with the addition of a further measurement just before evening doses
- Poor or no clinical response: 24 h profile, even at home [640]

In conclusion, the use of theophylline has but one disadvantage: for safe treatment we recommend measuring theophylline levels to reach and maintain levels encompassed within the therapeutic range [706]. This is also valid to avoid undesired side effects [244].

Notwithstanding what has been said, *theophylline is completely safe*. A study of 35,000 patients who filled 222,000 prescriptions for 9 years registered only one case of seizures in a child (without specifying the cause), equal to 0.003% of cases and to 0.00045% of the prescriptions [404].

Theophylline Assessment

From time to time, North American and North European authors have underlined the negative effects of theophylline with the result that experts tend to relegate this drug to a secondary role among the forms of treatment [272, 435, 504], thereby contributing to an unjustified decline in its use [536, 635]. In particular, three recent studies [89, 148, 622] excluded its use in hospital treatments of children aged 2–18 years with moderate to severe asthma and, specifically, in association with MDI-delivered albuterol and IV-administered methylprednisolone, even though no undesired side effects were found to justify the exclusion [622]. Nevertheless, the studies *did not include patients in severe conditions*, a limitation that prevents the evaluation of theophylline ability to preclude the necessity of ICU admission and/or assisted ventilation. Furthermore, in our opinion, the above-mentioned associations have not been

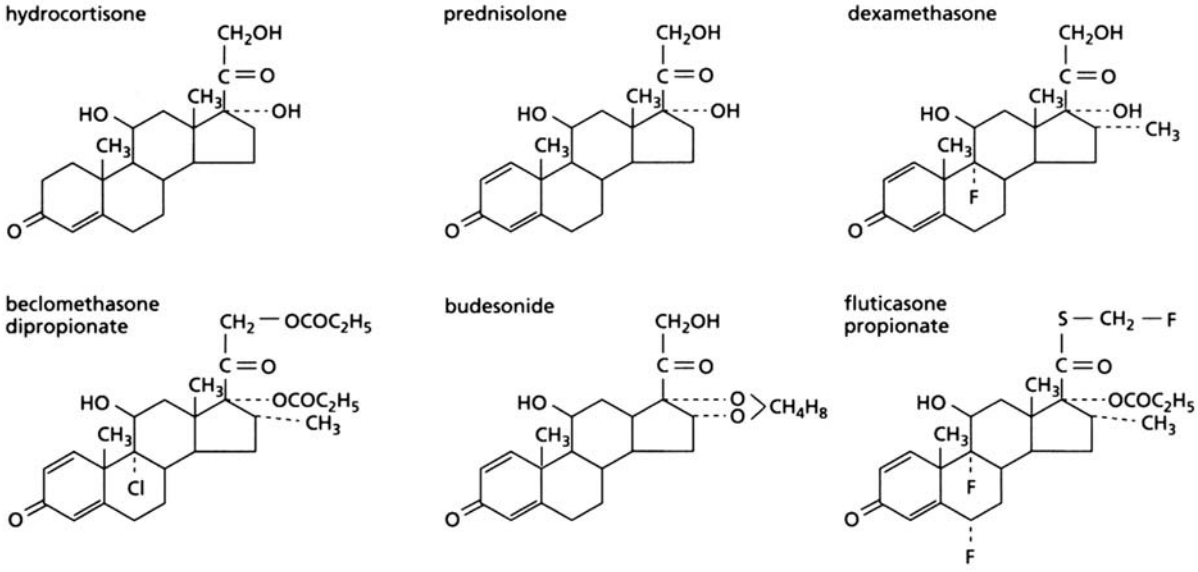

Fig. 11.42. Structural formulas of common corticosteroids.

properly evaluated since children had already reached maximum bronchodilation with "liberal and elevated" doses of nebulized albuterol [89]. Even in children or teenagers with nonsevere asthma treated with albuterol and IV-administered methylprednisolone, DiGiulio et al [148] did not find clinical differences between theophylline and placebo, although at the cost of possible type II errors. Although concern was expressed about the dangers of improper use of theophylline [89], no related adverse effects were reported in either study: nausea was the most toxic symptom encountered [622]. On the other hand, several studies have shown theophylline effectiveness (ref in 615). In patients admitted to ED and treated with theophylline, discharges were more frequent than admittance to hospital (6%), which differs from patients treated with metaproterenol and cortisone (21%), and with an overall cost fivefold lower [740]. Mechanical reasons, especially in life-threatening forms of infantile asthma, can impede β_2-adrenergic passage. This is theophylline's strong point: administered IV in these forms it produces an almost immediate clinically detectable, objective bronchodilation [664]. In 94 children aged 1–17 in severe status asthmaticus admitted to the PICU theophylline safely hastened the recovery of these children who were also receiving albuterol, IB, and CS therapies [49, 515].

On a therapeutic level, other side effects were noted [706] such as learning and behavioral problems. Re-examined by various researchers in ten studies, they were unable to definitively verify this correlation, partly due to methodological errors [123], or because the former were completely absent, whereas the rest normalized, or improved, within 2 weeks [613]. No school-related differences were found between asthmatics (whether theophylline-treated or not) and controls [353]. Parents were unable to decide to which treatment (theophylline or placebo) to attribute the improvement in memory and attention [34]. Other researchers, not finding any side effect, suggest that the potential vulnerability only concerns children already suffering from similar problems [562]. In a systematic review of 12 pediatric studies, no behavioral or cognitive adverse effects of theophylline were identified [597a].

Corticosteroids

The CS action mechanism (Tables 11.20 [23, 249, 284], 11.21 [120], 11.22 [23, 203, 284, 633] and 11.23 [56, 117, 437, 581], Fig. 11.42 [105]) is performed on adenylyl cyclase by increasing cAMP levels, and on the inflammation, reducing the edema and inhibiting histamine release [703]. In particular, cAMP level maintenance within a normal range is useful for bringing the adrenergic receptors back to a functional state in which they can again become activated [703]. CSs inhibit the metachromatic cell mediators and basophil releasability, and reduce circulating eosinophil number and presumably also those in the tissues, but not of macrophages [212]. These effects are due to IL inhibition that activates these cells and stimulates them into reaching inflammatory sites [570]. In asthmatic children (80% atopic), serum concentrations of IL_5, CD25, and ECP remained significantly higher than controls, even after treatment with oral CSs. Thus, T cell-mediated inflammation may persist in childhood asthma despite apparent clinical remission associated with conventional treatment [172]. The most powerful action of endogenous CSs is directed against inflammation, markedly exacerbated if the adrenal gland is removed [570]. In this process, the main activity is aimed at suppressing the transcription of genes involved in inflammation, and, to this end, their re-

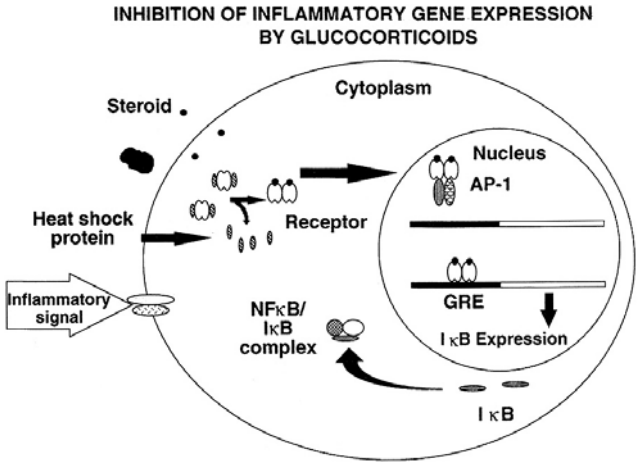

Fig. 11.43. Inhibition of inflammatory gene expression by CSs. *AP-1* apolipoprotein 1, *IκB* inhibitor of NF-κB, *NF-κB* nuclear factor kB

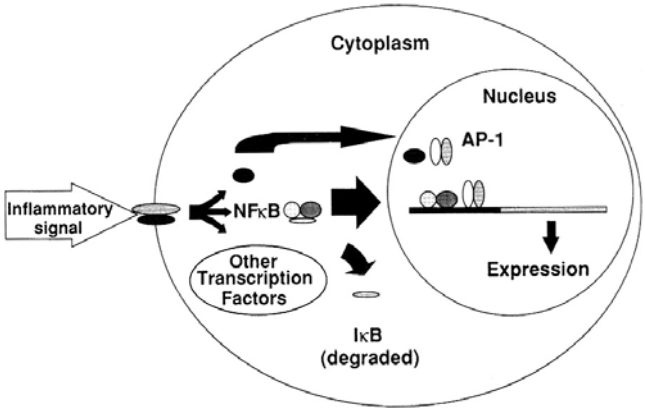

Fig. 11.44. Activation of inflammatory gene expression. *AP-1* apolipoprotein 1, *IκB* inhibitor of NF-κB

ceptors interact with AP-1 (activator protein-1) and NF-κB (nuclear factor of chain κ of Bs) (Fig. 11.43) [568] or, diversely, render more potent the inhibitor of the chain κ of B, type α (κB-α), inhibitor of NF-κB (Fig. 11.44) [568]. However, the bronchial smooth cells lack the CCAAT/enhancer binding protein α (C/EBPα) required to form a complex with the CS receptor, therefore CSs cannot contrast the ADAM33 accelerated proliferation of bronchial smooth-muscle cells and the resulting BHR [539]. From a clinical point of view, the latency time is lengthened (6–12 h) compared to other drugs [683], and a maximum bronchoprotecting effect can be attained after many months of continuous treatment [570]. Consequently, although CSs are an effective treatment on ameliorating asthma symptoms and represent the most effective anti-inflammatory therapy of asthma, *this therapy is symptomatic since the disease flares when treatment is stopped* [517, 645, 671, 680]. If ICSs are discontinued, the asthmatic children return to

Table 11.20. Molecular mechanisms of corticosteroid (*CS*) action in asthma

A. Specific effects of CSs on transcription of genes relevant to asthma
Increased transcription
a. Lipocortin-1
b. β_2-Adrenoreceptor
c. Endonuclease
Inhibition of transcription
a. Leukocyte protease
b. Cytokines
Decreased transcription
a. Cytokines (IL_1–IL_6, IL_8, IL_{11}–IL_{13}, IL_{16}, TNF-α, GM-CSF)
b. Chemokines (eotaxin, MIP-1α, RANTES, SCF)
c. iNOS
d. Inducible cyclooxygenase
e. Inducible PLA_2
f. ET-1
g. CD54
h. $N\kappa_1$ receptors
B. Effect on IgE synthesis
a. Reduction
b. Probable enhancement[a]
C. Effects on mast cells, basophils and eosinophils
a. Reduction in mast cell number
b. Inhibition of mast cell proliferation
c. Inhibition of mediator release
d. Inhibition of histamine synthesis
e. Inhibition of eicosanoid release
D. Effects on lymphocytes
E. Reduction in lymphocytes with activation markers (CD3, HLA-DR)
F. Reduction in cellular traffic and functions
G. Effect on specific processes
a. Inhibition of late reactions
b. Reduction in vascular permeability
c. Inhibition of mucosal secretion
d. Induction of vasoconstriction
H. Potential relevant mechanisms
a. Anti-inflammatory action
b. Increase in number and sensitivity of β-adrenergic receptors
c. Adenylate cyclase activation
d. Increased cAMP
e. Eosinophilopenia, basophilopenia, monocytopenia

The IL-13 inhibition by steroids may, at least in part, account for their therapeutic effects [150].
See Tables 7.17 and 7.18 for side effects of CSs employed topically in atopic dermatitis.
Data from [23, 249, 284].
[a] See text.

Table 11.21. Adverse effects of inhaled CSs in 163 children (%)

1. Hypertension	88
2. Cushingoid features	66

5. Osteopenia	46
6. Growth suppression	39
7. Obesity	30
8. Hypercholesterolemia	30
9. Posterior subcapsular cataracts	14

Osteopenia was strongly associated with growth suppression (odds ratio, 5.6). Note: 50% of children required chronically administered oral CS therapy.
Data from [120].

their baseline PFT and indices of airway inflammation *after 2 weeks* [593]. CSs do not relieve symptoms promptly and children may not improve within a few days [517]. So CS efficacy is significant in late asthmatic responses, chronic asthma and, more generally, in suppression of chronic inflammation [570]. This effective anti-inflammatory action on mast cells and eosinophils occurs in the epithelium (each 2.5-fold) and in submucosa (from 2- to 10-fold, respectively) and, on clinical grounds, in BHR improvement [258] (Table 11.14). Basically, there are no definitive effects, since *the underlying inflammation is still active in childhood asthma* despite apparent clinical remission even after years on ICSs [476]. Thus, any beneficial CS effect on BHR is not due to the prevention or resolution of remodeling of the airway wall [645]. The reason is that CSs have marked effects in inhibiting T-cell activation, but these effects are not reflected in changes of overall cell numbers in the circulation. So there is neither a discernible effect on the underlying mechanisms of inflammation [208], nor on methacholine responsiveness [645]. In addition, during the period of alveolar development, CS administration may result in decreased lung-cell mass and in the presence of too few abnormally large alveoli [727]. Also, for this reason it may be prudent to avoid CS use in the very young, because they appear not to be very effective, as is also demonstrated by their lack of impact on PFT [620]. FP, mometasone furoate (MF) and, to a lesser extent, BDP are thought to be second-generation ICSs in that they display both increased anti-inflammatory potency and systemic bioavailability [434].

An Assessment of Corticosteroids

In addition to dysphonia and oral candidiasis, several undesirable effects of inhaled CS (including osteoporosis) occurred in 163 children aged 14.4±2.1 years with

Table 11.22. Mechanisms possibly explaining a poor response to CSs in asthma

1. Additional respiratory disorders (cystic fibrosis, vocal cord dysfunction, etc.)
2. Overwhelming allergen exposure
3. Irreversible airway hyperreactivity
4. Poor compliance (children, parents, etc.)
5. Psychological problems
6. Inadequate dose for severity of asthma
7. Pharmacokinetic motives
a. Rapid metabolism
b. Poor distribution at the site of action
c. Poor/partial absorption from oral administration
8. Immunological resistance
A. Monocytes
a. Unable to decrease MCR and CRI expression
b. Unable to decrease PHA-induced proliferation
c. Unable to decrease cytokine production (TNF)
d. Quantitative and functional defect of intracytoplasmic receptors
B. Lymphocytes
a. Unable to decrease PHA-induced proliferation
b. Unable to decrease cytokine production (IL_2, IFN-γ)
c. Unable to inhibit activation (CD25, HLA-DR)
C. Abnormal receptor or postreceptor down-regulation

The use of high doses of inhaled β_2-agonists in acute asthma exacerbations may result in resistance to high-dose intravenous CSs in the treatment of these exacerbations [23].
Data from [23, 203, 284, 633].
cAMP cyclic adenosine monophosphate, *CRE* complement receptor increase, *HPA* hypothalamic-pituitary-adrenal, *MCR* monocyte complement receptor.

severe asthma receiving high-dose inhaled CS therapy (1675±94 µg/d), 50% of whom required chronic oral CS therapy [120] (Tables 11.20–11.22) [21, 120, 203, 249, 284, 633]. Pharmacokinetics studies suggest that the fraction deposited in the airways is absorbed in an active form in variable concentrations, and passes, in turn, into the circulation. In fact 80% of the amount deposited in the oropharynx is absorbed by the intestine, passing through the liver where most of it is metabolized. Part of it reaches the systemic circulation where it joins with the amount originated in the airways. These two rates are aggregated, but are continually reduced as a result of recirculation and hepatic deactivation, as is evident from Fig. 11.45 [703]. Nonetheless, there is a different *bioavailability* (the drug rate bypassing the hepatic filter) and a rapid CS metabolic clearance CS reaching the circulation [22, 359]. Substandial differences can

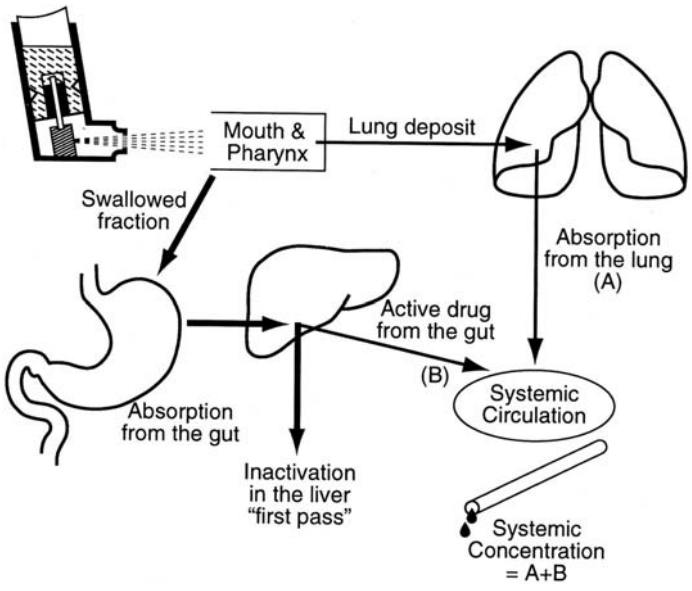

Fig. 11.45. The fate of inhaled CS.The amount of an inhaled CS that reaches the systemic circulation is the sum of pulmonary and orally bioavailable fractions. The fraction deposited in the oral cavity will be swallowed and systemic availability will be determined by absorption from the gastrointestinal tract and the degree of liver inactivation. The systemic concentration will be reduced by continuous recirculation and liver inactivation

Table 11.23. Usual dosage for corticosteroids in pediatric asthma

Medication	Route	Dosage form	Dose
Beclomethasone Dipropionate	Aerosol	Metered-dose inhaler	42 µg inhalation 2–4 puffs × 2–4 daily
	Inhalation	Dry-powder inhaler	100 µg 4 inhalations daily
Betamethasone	Oral	Tablets, 0.6 mg Solution, 0.6 mg/ml	0.1–0.2 mg/kg daily
Budesonide[a]	Aerosol	Metered-dose inhaler	200 µg inhalation 1 inhalation × 2 daily
Deflazacort	Oral	Tablets, 6–30 mg	1.2–2.4 mg/kg daily
	Oral	Drops, 1 drop/mg	1–2 mg/kg daily
Dexamethasone	Oral	Tablets	0.1–0.2 mg/kg daily 0.5–0.75 mg
Flunisolide	Aerosol	Solution 0.1 % (1 mg/ml) Metered-dose inhaler	0.5–1 mg × 2 daily 250 µg × 2–3 puffs daily
Fluticasone propionate	Aerosol	Metered-dose inhaler DPI 30, 100, 250 µg/dose	44 µg × 2–4 Puffs 50 µg 2–4 inhalations
Methylprednisolone	Oral	2-, 4-, 8-, 16-, 32-mg tablets	0.25–2 mg/kg daily as needed
Mometasone furoate	Inhalation	Dry-powder inhaler	440 µg once-daily
Prednisone	Oral	1-, 2.5-, 10-, 20-, 25-mg tablets	1–2 mg/kg daily
Prednisolone	Oral	2.5- to 5-mg tablets	0.5–2 mg/kg daily
Triamcinolone acetonide	Aerosol	Metered-dose inhaler	100 µg inhalation 4–8 puffs daily

Data from [56, 117, 437, 495, 581].
[a] by Turbohaler.

also derive from the metabolism of single molecules. BDP is metabolized in monopropionate in various tissues, including the airways, but it is not clear which rates are absorbed or metabolized in humans. FP (fluticasone propionate) and BUD, among the commercialized molecules, appear to be equipped with the lowest oral bioavailability as a result of a very high liver metabolism of first passage, so that 99 % of FP and 90 % of BUD are

deactivated by the liver, and only a limited amount, equal to 1% and 10% [23], reaches the circulation. Side effects are few with preparations *active by inhalation and with reduced systemic absorption*, which, undoubtedly, have resulted in therapeutic progress – among these preparations are BDP, BUD, deflazacort, flunisolide [26], even if giving rise to controversy [668]. FP, because of its more favorable risk–benefit ratio, is preferable to BDP for the long-term treatment of children with asthma, especially if moderate doses are required [135]. It should, however, be clarified that with inhaled doses of 400 µg/day and using a valve spacer, the systemic absorption is reduced to zero, given that all of the drug ingested remains in the spacer, thereby eliminating any difference in the bioavailability of different medications [359]. Both BPD used with the Volumatic or the Jet as well as BUD taken with Nebuhaler have a lesser systemic activity compared to the same dose inhaled with an MDI or a DPI, even if rinsing the mouth after use reduces or abates ingestion, as previously mentioned [26]. Additionally, drop formulations (deflazacort is prescribed in doses of 1–2 mg = 1–2 drops/kg) favor personalized prescriptions and ensure compliance in younger children.

Suppression of the Hypothalamic-Pituitary-Adrenal (HPA) Axis

Other adverse phenomena, such as HPA axis suppression, growth retardation [120, 285], and are, in our opinion, provoked by prolonged treatment and by administering high dosages, chiefley orally [120], which can lead to a potential axis inhibition, with reduced ACTH secretion due to negative feedback mechanisms and the adrenal gland inability to respond to adrenocorticotropic stimulation, giving way to severe risks in patients prone to respiratory arrest during severe acute attacks [517]. A complete functional restoration may require up to 1 year, whereas treatment limited to 1 week is usually devoid of negative consequences: 8–10 days after stopping treatment, HPA function returns to normal [560]. In adults, a possible axis deficiency can be revealed only through metapyrone or insulin tolerance tests, or through a CRH test [560]. Recent data suggest that CRH and its CS regulation may be essential for the control of airway inflammation and the maintenance of lung homeostasis in asthma [588]. Several studies have not found such anomalies [487, 684], or a small but significant degree of growth impairment in children receiving only 400 µg/day of BDP [157]. Regarding the dosage factor, important undesired systemic effects of chronically and systemically administered medications (Tables 11.20–11.22) are found in children 7–10 years old with severe asthma, treated with doses of FP increased from 800–1500 µg up to 2,250 µg/day, leading to an increased risk of systemic side effects such as undetectable cortisol levels [650]. Acute adrenal crises have been reported by several studies, all in children treated with inhaled FP [630, 650–652, 736, 757] (see "Linear Growth"). Similarly, 22 children aged 3.3–10 years (with an incidence of 3.1% of total cases) treated with inhaled FP (91%), with doses ranging from 500 to 2,000 µg/day presented with acute adrenal crisis, acute hypoglycemia, and with decreased levels of consciousness, coma, or coma and convulsions. The remaining six children presented mainly with lassitude, weakness, nausea, and dizziness [652]. Severe growth retardation and adrenal suppression were described in children taking FP doses >1,000 µg/day [715], and acute adrenal crisis associated with inhaled FP in three children presenting with hypoglycemic coma and convulsions [651]. A probable explanation for these findings is that FP taken twice a day accumulates in the blood, which has a half-life of 7–8 h and a distribution 4 to 5-fold greater than other drugs, leading to an increased risk of systemic side effects such as growth retardation and adrenal insufficiency [61]. HPA was also reported in 4 children aged 4.2–4.8 years receiving FP 500 µg/day, in 1 child aged 7.2 treated with FP 1,000 µg/day, in 3 children aged 4.8–6.1 treated with BUD 400 µg/day and a 9-year-old treated with BDP 600 µg/daily [475]. Adrenal suppression was found in 9–18 children aged 7–17 receiving FP 477 µg/m^2/day for 5–16 weeks [368]. Given to asthmatic children in high dosages, flunisolide has provoked no negative effects on the axis, nor on glycolipid metabolism [215, 494]. These results have been confirmed with BUD, administered for 3–5 years in doses of 200 µg/day [685], with measurement of 24-h plasma and urine cortisol [684, 685], 24-h urinary cortisol alone [157, 487]. Yet, other studies found no HPA deficiency, nor growth deficiency in children [541] or in schoolchildren undergoing treatment with BUD [646]. In asthmatic children under treatment for 3 months with inhaled BDP in doses of 400 µg/day, a 63% decrease of plasma cortisol after evening doses and a 29% decrease after morning doses [637] was observed. Such data were subsequently confirmed by reductions of serum cortisol [493], urinary cortisol [505], or both [439], after treatment with BDP and BUD in doses of 400 µg [445], or with FP in doses of 250 µg [757], and with an MDI without a spacer [220]. Among the possible causes could be *the use of MDI spray cans without spacers,* given that they increase oropharyngeal deposits [220].

Bone Density

Another question being debated is whether inhaled medications, properly used, have a negative effect on bone density, an effect which, however, is independent of HPA-axis suppression, possibly related to the inhibition of insulin-like growth factors [517]. Using the equivalent of 8 µg/kg of BDP [649], a child should be considered at risk of HPA-axis suppression or of delayed growth [198]. The effects on the skeletal system have been evaluated by dosing two markers correlated with osteosynthesis and growth rate, osteocalcin and the carboxy terminal propeptide of type I procollagen (PCIP), showing a growth decrease after 1 and 5 months of

treatment with BUD, both in full doses of 800 µg/m^2/day and half doses, with no variations in growth measured by conventional parameters [603]. The combined examination of PCIP and amino terminal propeptide of type III procollagen (PCIIINP) has shown the suppression of both bone turnover and collagen after twice-weekly treatment with DPI BUD and BDP(800 µg/day), more evident in the latter case [42]. The effects on PCIIINP [734] and on osteocalcin were subsequently confirmed by other studies [655, 733]. Bone density was also measured using a densitometer and an absorptiometer, without noting any significant differences between asthmatic children and controls. Vice-versa, osteocalcin was shown to be reduced in the densitometer compared to the absorptiometer, a result that can be ascribed to the disease and not to BDP, according to the authors [312]. Some maintain that osteocalcin is not a marker sensitive to bone turnover, in that asthma *per se* can decrease it tangibly, making it of little use in evaluating the effects [312]. Others have measured bone density without finding any significant difference [17, 300].

Linear Growth

Concern has been raised that the use of ICSs in children may be associated with growth suppression. Recent evidence presents conflicting results regarding reduced [157, 593, 649, 690] and normal growth [444, 684, 718], including a wide and well-documented study [8] that meta-analyzed 21 pediatric studies, based on statistical analysis and excluding the studies employing different methods of evaluation [729]. A recent meta-analysis [583] has concluded that moderate doses of the inhaled steroid BDP in children with mild to moderate asthma has been shown to significantly affect linear growth. Also, for the effect of moderate doses of inhaled fluticasone, a statistically significant difference was revealed. However, two recent long-term studies have been reassuring [6, 645]. The growth of a cohort of 142 children with mild to moderate asthma was followed until they reached adult height; the subjects received a mean dose of BUD of 412 µg/day for a mean of 9.2 years. The adult height of this cohort on long-term inhaled BUD therapy was 0.3 cm greater than expected. Its sole weakness was a high rate (72%) of drop-outs in the control group [6], as in other conventionally treated children [568]. In the Childhood Asthma Management Program (CAMP) study, a randomized trial for more than 5 years in >1,000 children with mild to moderate asthma, neither inhaled BUD nor nedocromil was better than placebo in terms of PFT, but BUD provided substantial clinical improvement as compared with nedocromil or placebo [645]. Significantly, both studies reported a transient reduction in growth velocity *only in the 1st year of treatment* [6, 645]. In longer clinical trials, despite a strict selection process, compliance problems can be noted. Problems increase with duration of participation, increasing child age, and the presence of less family cohesion or attention problems in children [625]. Height may diminish with an increase in dose and return to normal when treatment is reduced or stopped [646]. The attitude of inhaled CS overdosing in children was recently clearly documented. In 8,913 children, the CS inhaled at daily dose ranges equivalent to BDP were 350–*2400* µg, 265–*3400* µg, and 300–*4800* µg for the 0–4, 5–11, and 12- to 16-year-olds [171]. We believe that many results not associated with HPA-axis suppression may depend on the use of safe doses of 100–200 µg/day, which should proportionally be reduced as compared to adult doses, better in µg/kg, as has previously been pointed out. Although inhaled FP was found to reduce morning serum cortisol concentrations by 17%–43%, even at low doses of 176 µg/day [169] or of 200 µg/day; prepubescent children treated with FP 100 µg and 200 µg daily for 1 year showed no statistically significant differences in growth rates, similarly to placebo-treated control subjects [7]. FP DPI 100–200 µg administered daily to 437 children (4–11 years old) with persistent asthma for 12 weeks in a randomized, DB, parallel-group, multicenter trial did not affect 24-h urinary free-cortisol excretion, and improved PFT in children even as young as 4 and 5 years old [484]. Often, good results are obtained in children with *low doses* [205, 438, 487, 684, 729], and even in adults, doses can be reduced with the same results [231, 285]. A 12-month 100-µg daily treatment of FP in 625 children aged 1–3 years with mild to moderate recurrent wheeze resulted in improved symptom control with no effect on growth rate, and a serum and urinary cortisol concentration suppression of 10% and 14%, respectively [45]. A recent study has set up a milestone in the treatment of pediatric asthma, having demonstrated that repeated bursts of oral CS at 1–2 mg/kg/day (maximum=50 mg) for a 5-day period are not only effective, but above all are *safe in children*, since they are not associated with any lasting perturbation in bone metabolism, bone mineralization or adrenal function [160]. In addition, low cortisol levels normalized after discontinuing inhaled FP [757]. Others have noted that growth decline is reduced after the first 6 weeks or at most within 18 weeks [159]. A 6-month treatment with inhaled BUD and FP did not induce body fat accumulation in 21 of 26 asthmatic children; however, in five children aged from 4.3 to 5.3 years, the treatment was associated with growth velocity below the third percentile [550]. The magnitude of these changes in linear growth has varied between other studies using different ICS preparations, indicating on the one hand that either study design or specific steroid preparation/dose may be important considerations [434], and on the other the lack of reliable data on compliance may seriously confound the study of long-term growth effects of ICSs [732].

DB, randomized placebo-controlled tests have also been carried out [729–731, 733], employing knemometry (from κνημη, leg), which ensures reproducible findings (Figs. 11.46–11.48) [365], to evaluate ICS effects on lower limb linear growth, which always proved to be re-

Fig. 11.46. A knemometer. The child is positioned so that the knee is positioned at a right angle and the feet are comfortably placed. At the first visit a template is made by drawing around the child's feet, so that at the subsequent visit positioning is identical.

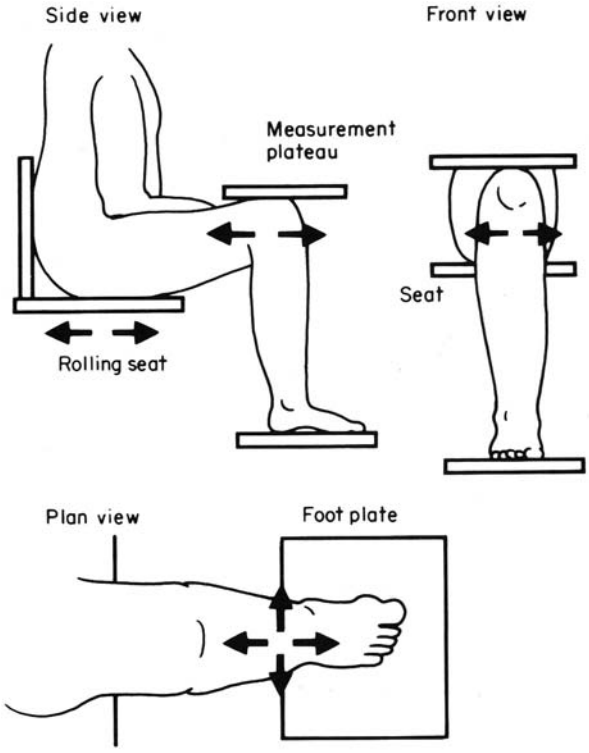

Fig. 11.47. Diagram showing knemometer and manipulation of the lower leg. The lower leg is moved around in order to gain maximum reading of the digital ruler. Alternatively, knemometry may be measured by a hand-held knemometer, provided with an electronic caliber, which measures the length of the lower leg from above the knee to below the heel. Measurements are taken with the child in a supine position with a 90° flexion in hip, knee, and ankle joints. A fixed cap is held against the knee and the other, adjustable cap is placed under the heel. Both caps are parallel, and the distance is ongoing measured electronically with a resolution of 10 µm. An investigator stabilizes the knee cap with one hand, while slowly compressing the heel cap up to a predefined pressure of 80 g with the other hand, as determined by an interposed spring. At this pressure, a microswitch is activated and the reading is recorded on a computer

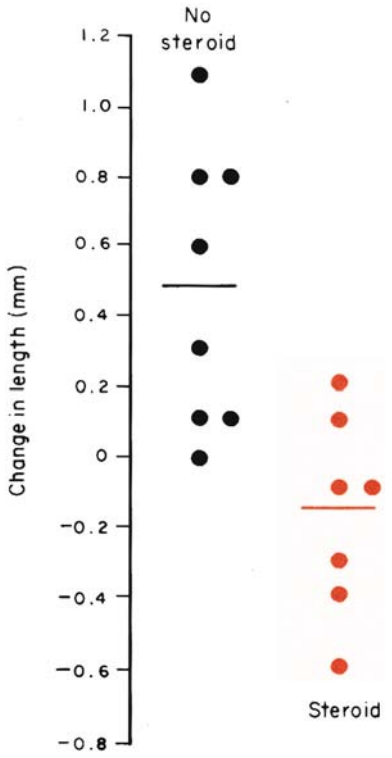
Fig. 11.48. Changes in total length on alternate day steroid dose



duced, though not with FP [731]. The results on PCIIINP of the same group [734], completed by measuring cortisol and insulin-like growth factor levels [735], and additional data have confirmed these studies [365]. In children aged 0–3 years, within a 3-week period the increases in the lower-leg length during placebo, BUD 400, and FP 400 treatments (200 µg inhaled twice daily) were 85, 45, and 34 µm/d, respectively [11]. Nevertheless, some aspects of the *assessment of safety are unique to younger children,* including the rapid growth velocity and their different metabolism. The rapid growth in the first 2–3 years of life may make the child more vulnerable to the adverse effects of drugs and/or disease. More seriously, the safety findings in adults and schoolchildren *cannot be extrapolated uncritically to younger children* [11]. We deem that the concern about potential dysfunc-

tions is valid in cases of oral and/or high doses as an intercurrent necessity [347]. A meta-analysis suggests that moderate doses of inhaled BDP in four studies and 450 children and FP in one study and 183 children with mild to moderate asthma cause a decrease in linear growth velocity of 1.51 cm/year and 0.43 cm/year, respectively [583]. However, the increase in height of 277 children aged 4–11 years with chronic asthma was greater with FP than with BDP, 5.01 vs 4.10 cm/year, respectively [151]. These findings should not limit ICS administration in children with moderate/severe asthma [28, 282]. A possible choice is flunisolide, which is freer of adverse effects [215, 228, 494], provides better penetration and a more homogeneous distribution in the distal airways, also parenterally administered if asthma is more severe [706]. In moderate to severe asthma, the benefits may outweigh the risks associated with continuous use [703]. Various immune parameters are normal in long-term ICS-treated children [347], but eosinophils are reduced only in patients taking monodoses [497]. In conclusion, *short-term and/or alternate-day treatments are safer* [438], with a return to normal basal parameters in a short time, as already detailed [285, 757]. To further reduce potential damage, preparations should be chosen with a longer duration of action and to begin treatment between 3:00 and 5:00 PM (monodose), as there are no differences with qid therapy, nor does it influence 24-h plasma or urinary cortisol levels [497]. It will be sufficient to monitor the effects of treatment in individual patients, while in other cases the risk–benefit analysis is strongly in favor of preventive drugs and of theophylline [285]. However, refer to the comparison of SIT/steroids in Chap. 13. We deem, however, that periodically measuring the growth of asthmatic children on long-term treatment with ICS is a useful practice [728]. An FDA mandate (November 9, 1998) requires labels on inhaled and intranasal CS warning of a potential reduction in linear growth in children demonstrates this concern (accessed from: http://www.fda.gov/cder/news/cs-label.htm).

Table 11.21 enumerates CS side effects and the consequent measures required, and indicates a few possible causes of treatment failure with these drugs. No posterior subcapsular cataracts have been observed in children treated with ICS [592], which were seen, however, in 11.3% of 274 children [718], and in 15%–21% of 163 children [120], most probably related to *chronic oral treatment.* Synthetic CS prime IgE synthesis in vitro [304, 452] and the increase in serum IgE levels after 7 days of steroid treatment – viewed as being caused by steroid immunomodulator effects on T lymphocytes – which is also associated with an FEV_1 reduction [754]. Such effects were not seen *ex vivo* even after 1 week of steroid treatment [304]. It is not excluded, however, that with larger doses and/or long-term treatments, significant increases in IgE can be seen [318]; such reports require further evaluations; however, in this respect ICS may not be suitable in children. An in vitro study has demonstrated that hydrocortisone enhances total and allergen-specific IgE production by PBMCs from atopic subjects in vitro. The induction of Der p-specific IgE synthesis in subjects with high serum allergen-specific IgE levels was even greater than that of IL_4. This is the first report to show that hydrocortisone enhances Der p-specific IgE production from circulating B cells in atopic asthma [101]. The immediate in vivo interpretation of these findings would be that CSs promote allergy, which in theory would mean that the most efficacious treatment for allergic diseases is detrimental regarding disease progress. However, the underlying mechanism by which CSs enhance IgE production in vivo is unknown [101]. High dosage can cause an increase in anxiety, depression, memory reduction, and psychological vulnerability, with a potentially negative impact on asthma severity and on the child's own ability to cope with the disease and its treatment. If, on the other hand, CSs are used in brief cycles, school performance, memory and behavior remain unchanged [432]. In conclusion, CS-induced adverse effects in 163 children with severe asthma are inadmissibly high. Given the frequency with which they occur, evaluation and close monitoring of potential adverse effects is clearly warranted, even in those patients who are not CS-dependent but require high-dose ICS and frequent rescue oral CS therapy [120].

Comparison of the Various Forms of Drugs

Some data will be useful in making a more prudent choice regarding medications to be used, especially in cases of severe asthma (Table 11.14) (in parentheses the variable effects) [284]:

- Muscle relaxant: β_2-adrenergics, theophylline
- Antiedematous: β_2-adrenergics, theophylline
- Anti-mucus secretion: CS, (β_2-adrenergics, theophylline)
- Prevention of late reaction: CS
- Inhibition of mast cell degranulation (β_2-adrenergics, theophylline)
- Attenuation or resolution of hyperreactivity: CS

β_2-Adrenergics, compared to other drugs, are characterized by:

- Greater selectivity
- Quick relief (greater effect on early asthmatic response)
- Very brief latency time by inhalation (a few minutes)
- Lower incidence of side effects

Duration of effectiveness: catecholics 2–4 h; resorcinol and salagen 4–6 h; clenbuterol and procaterol >6 h; fenoterol and salmeterol 12 h, and oral bambuterol 24 h [158].

Anticholinergics, compared to β_2-adrenergics, induce a lesser degree of bronchodilation, are more delayed but more prolonged in duration (compared to most β_2-adrenergics. IB is to be preferred because of the lesser

impact of side effects and protracted duration of its action: 4–5 h. Nevertheless, other controlled studies are needed before they can be used effectively and safely in maintenance therapy.

Theophylline drugs, compared to β_2-adrenergics, have a more gradual action with more frequent and more significant side effects. *Long-acting theophylline* [83] has proved useful in young children who do not readily accept inhaled procedures, in children with asthma or wheezing in the morning as the only symptom, in cases of chronic asthma to avoid waking the child during the night, and in adolescents with severe symptoms before adding CS to their maintenance treatment [706], or to reduce doses when possible [566].

CSs compared to β_2-adrenergics and theophylline drugs have a greater latency time and are the preferred choice for use in severe crises for short periods. In prolonged treatments, the wide spectrum of side effects makes it preferable to use hydroxylase compounds in acute phases because of their short plasma half-life and the faster bioavailability of their active principle [633]. Preparations that interfere less with the metabolic processes are preferred for chronic forms [633].

β_2-Adrenergics can be combined – depending on the case – with anticholinergics, theophylline and CS:

- In the first case *a functional synergy* is obtained without causing an amalgamation of the side effects of the two drugs considered individually.
- With the combination of β_2-adrenergics and theophylline, *an increased bronchodilation* in cases of severe acute asthma and a better control of the symptoms in the several forms with a chronic trend could be achieved, but there are few recent studies that could confirm the usefulness of this association, when carried out on a regular basis, whereas if doses and the frequency of administration of inhaled β_2-adrenergics are reduced, the association with theophylline is effective on bronchodilation.
- CSs together with β_2-adrenergics *enhance their therapeutic efficiency* by acting on cAMP; cAMP levels are maintained within normal limits, with the above-mentioned effects, also improving oxygenation [545]. Furthermore, β_2-adrenergics with long-term half-life provide better control of asthma when symptoms persist, notwithstanding treatment with CS, and considering that this association can be useful in covering the CS latency period [359].

Assessment of Guidelines and Pediatric Compliance

One major problem is the treatment guidelines, an issue frequently quoted: written guidelines are often difficult to read. In the US, the mean grade levels obtained for the leading guidelines ranged from 4.9 to 9.2 [191]. Only 2.1±1.0% of the directors from 376 sampled EDs reported the use of written protocols or guidelines [121]. These guidelines are likely adopted by 5.7%–7.9% of readers of NIH guidelines [121]. Even within private practice, patients' race and ethnicity are associated with clinician nonadherence to national guidelines [463]. In a recent study of children who presented to an ED, 71% of children (mean age >8 years) did not have a written plan. Only 7% of those with a plan consulted it at the onset of wheezing and 4% consulted it before going to the ED. Also, 48% did not use a holding chamber with their MDIs and 66% did not use their PEF meters. Regarding exacerbation response, 71% did not have a written action plan, and 89% did not maintain a symptom diary [557]. In 1114 children aged 6 (mean) evidence-based guidelines for pediatric asthma demonstrated an improvement of asthma management plans, but failed to influence patient outcome [385]. Moreover, US guidelines are structured "for children 5 years of age and older" [435–437], while European consensus guidelines [698–700] consider children aged 0–5 years as well. Guidelines do not master factors associated with lower adherence to the medical regimen in young children, such as *medication taste,* and the *congestion of too many medications with multiple dosing intervals* [27]. Children with many risk factors experienced 0.80 more days of wheezing and 1 more day of activity restriction as a result of asthma compared with children with few risks for nonadherence [27]. For *children younger than 5 years,* expert recommendations are based on *extrapolations of studies in older children* [434]. The issues related to minorities in the populations are pertinent: black and Latino children had worse asthma status and less use of preventive asthma medications than white children within the same managed Medicaid populations [351].

The parents may not always be aware of the severity of the disease: in one trial, 36% of parents stated that they would administer a β_2-agonist, but 57% would go to the ED without giving a β_2-agonist first. Also, fewer than 5% would call the physician and use a PFM [696]. In a separate sample, the figures were 13% and 1%, respectively [338]. One-third or fewer parents followed other NHLBI recommended steps, including using a PFM, calling or going to see the doctor, or going to the ED [557].

Bronchiolitis

Definition

Bronchiolitis is an acute respiratory disease that affects infants, generally between 2 and 10 months of age [499] and involves chiefly the small arteries, is characterized by an acute onset of wheezing, expiratory dyspnea, tachypnea, fever, with or without diffuse fine crepitations of rhonchi and rales on auscultation, and with radiological appearance of emphysema [69]. This definition prevails in Europe and Australia, and by American authors all first-time wheezing associated with a respi-

ratory tract infection in infants is included [674] as wheezing-associated respiratory infection (WARI). It probably represents the first episode of asthma disease. Episodes of lower airway illness labeled bronchiolitis in the 2nd year of life is more likely to be asthma [747].

Prevalence

Bronchiolitis is highest in infants (50%–60% of cases), but can also be seen in the 2nd year of life, even if with a much lower prevalence. It is more frequent in winter months and usually affects males, as does asthma. Since 1980, the rate of hospitalization for children with bronchiolitis has increased from 5.4% to 16.4%, whereas mortality rates for the disease have remained constant [372]. In the Netherlands, the national number of bronchiolitis hospitalizations significantly increased from 1991 to 1999 in children aged 0–4 years [674].

Predisposing Factors

The host's characteristics stand out in the clinical manifestation of the disease [226, 271, 391, 417, 512, 611, 711]:

- Age (<1 year) holds first place, given the reduced caliber of nursling bronchioles. Our studies indicate that the onset age <6 months is even more significant (Tables 11.24, 11.25) [69].
- Genetic predisposition.
- Patient's immune state.
- Prematurity.
- Lungs more or less immature (additional effects from smoking).
- Male sex.
- Bottle feeding.
- Presence of cardiopathies, pneumopathies, polymalformative syndromes.
- Poor socioeconomic status and/or living conditions.
- Exposure to allergens and/or pollutants.
- Passive smoke, particularly maternal.

Breast feeding plays a key role, since maternal milk contains *anti-RSV sIgA*. Breast feeding for at least 1 month and, negatively, parental smoke equal to >20 cigarettes are highly significant compared to controls [391]. Assay of cotinine levels emphasizes a significant relationship between admissions to hospital and mother's and parents's secondhand smoke ($p<0.0005$), compared to a similar group not affected by bronchiolitis ($p=0.0181$) [519]. In the cohort of 240 infants, 29% had a smoking mother [747]. The impact of daycare attendance on the incidence of infantile LRTI amounts to a doubled increase in the risk of such infections. In a cohort of children prospectively studied in the first 3–6 months of life by a polyfactorial analysis, the factors increasing the risk of a care setting different from the child home have been defined. They include repeated transfers from one place to the other, twice-daily changes of the environment (both heralding potential infections), worries, probably lesser care by persons replacing the mother, and higher prevalence of infections (8.6%) [257]. Compared to the age of 4 months to 3 years, the presence of >3 children of the same age, and/or that of smoking persons in daycare settings (personal experience) exposes the child to the risk of acquiring respiratory infections, but not at home, even with > three siblings, and persons caring for the child or sharing the bedroom, etc. [257].

Etiology

In 87% of cases, bronchiolitis is caused by *respiratory viruses* such as RSV (see Chap. 4) and the remaining rate to parainfluenza 3 and 1 viruses, adenovirus, etc. About 25%–50% of young babies show seroconversion for RSV or parainfluenza virus in the 1st year of life, though only a certain number of babies manifest signs of disease. RSV provokes, in most subjects, nonsevere or imperceptible clinical features, while in infants it can cause bronchiolitis with all ensuing symptoms, showing its greater impact on young infants. With passing time, the number and severity of the episodes decrease [323]. Regarding the frequency of reinfections, it has been reported that a second infection recurs in 75% of cases and a third in 65% of cases, thus being the major cause of lower airway disease in infancy. As with all infections sustained by respiratory viruses, bronchiolitis can occur in epidemic forms, more severe in some years and less so in others, and more than once in the same child during the 1st year of life [546].

Genetic factors such as FHA [271] (71%, [499]) or allergic sensitization [586] and family predisposition to asthma (43%, [499]) are crucial elements that condition the onset of bronchiolitis, as well as the persistence of bronchoconstriction. It is important to emphasize that one atopic or asthmatic parent is a highly predictive factor relating to the insurgence of asthma in the child [271] (Tables 11.24, 11.25). In a prospective study of 47 infants, it is interesting that among children with RSV, 6/11 (54.5%) children with FHA developed asthma compared with 5/36 (13.8%) matched controls without FHA. In these children at age 7 $^1/_2$ asthma was found in

Table 11.24. Family history and asthma development in 70 children with bronchiolitis (Follow-up, 6 years)

11/47 (23%) of the RSV group and in 2/93 (2%) of the controls, and in 7/47 (14.9%) of the children with FHA and 1/93 (1%) of the matched controls without FHA (RR = 13.88). A positive test of IgE to inhalants was found in 14/44 (32%) of the RSV group and in 12/87 (14%) of the controls (RR = 2.31) [586]. Moreover, a positive test for IgE was found in 14/44 (31.8%) RSV children and in 8/92 (8.7%) control children [587]. In a cohort of 240 2- to 10-week-old infants, 61% had a FHA and 40% a history of asthma [747].

Pathogenesis

If we consider the infant's still immature immune system, already Th2-controlled at birth, it is evident how, with the decrease of passively acquired antibodies and with the addition of the aggravating factor of low IFN-γ generation and progressive decrease in anti-RSV sIgA in maternal milk, the infection can progress. The functional characteristics of young infants are dominated by an insufficient development of bronchial cartilages, smooth muscles and the number of alveoli, and by reduced elastic recoil [512]. RSV has a certain tropism for small airway epithelial cells, whereas, for example, the parainfluenza virus prefers the subglottic epithelial cells [125]. The viruses have immunosuppressive and cytopathic effects on monocytes, macrophages and T lymphocytes, subsequently interfering on the normal process of macrophage-induced lymphocyte activation [503], as previously seen (Table 11.9). It can be assumed that in a selected number of children, either affected previously, or at the time of primary RSV infection, there is an alteration of T-cell regulatory mechanisms [523]. Therefore, bronchiolitis can be regarded as an immune system disorganization related to host immaturity, in which T-cell hyperactivity is unraveled, in parallel with persistent and elevated IgE-mediated responses, which, via increased histamine and other mediator release, can, in future, predispose to asthma and BHR [611]. Infants affected by bronchiolitis have a markedly lower number of $CD8^+$ lymphocytes (inversely proportional to IgE maximum titers) than infants suffering from other types of RSV infection [715] during convalescence. Similarly, CD8 T cells are reduced during bronchiolitis [523] and in infants manifesting >3 episodes of wheezing during their 1st year of life [546].

From the fundamental studies of Welliver et al [714–716], the presence of anti-RSV sIgE in the nasopharyngeal secretions of children after an episode of bronchiolitis or of pneumonia with wheezing provoked by RSV has been noted, but not in controls also affected by RSV-induced respiratory infections and without bronchoconstriction. Also known is the longer persistence of anti-RSV sIgE in the study babies compared to controls (Table 11.26) [714]. At the same time, an elevated histaminemia and a clear correlation of anti-RSV sIgE titers with hypoxia as the objective measure of disease severity has been displayed, results that are totally overlapping those following infection by parainfluenza viruses [716]. Furthermore, the higher the levels of anti-RSV IgE in children suffering from bronchiolitis, the more easily the wheezing relapses (70% compared to 20% of those whose levels are not measurable) [715]. IgE produced by RSV therefore has immediate implications on atopic asthma, resulting in the IgE-mast cells linking and mediator and IL release. A subsequent direct mast cell intervention could be inferred from tryptase levels present in BALF of 91.8% of infants, but not so elevated as compared to the levels found in controls, to imply a confirmation [184].

Table 11.26. Mean RSV-IgE responses in nasopharyngeal secretions according to the illness group and related to respiratory symptoms

Symptoms	No. of children with positive RSV IgE titers/number of babies tested	
	Acute	Convalescent
I. Upper-respiratory-tract disease only	0/9	0/4
II. Pneumonia without wheezing	0/9	1/7
III. Pneumonia with wheezing	3/10	6/10
IV. Bronchiolitis	21/43	17/25

Statistically significant differences between groups III and IV and groups I and II (combined) and between groups III and IV (combined) and groups I and II (combined).
Data from [715].

By an aspecific phagocytosis of RSV by the cells or an interaction with a receptor on eosinophils, RSV prime the eosinophils to start the chain of $O_2^{\cdot-}$ generation and activation and to release mediators in greater quantities, confirming the hypothesis that some inflammatory signs seen in the airways of these children are *eosinophil-induced* [298]. Such RSV-induced effects on inflammatory cells in bronchiolitis may be much more pathogenic than was formerly believed, as demonstrated by their relationship, which has come to light in recent years, with *eosinophils,* whose activation appears pathogenically to be more important than that of neutrophils/macrophages and is characteristic of bronchiolitis but not of other respiratory disease [298]. Significantly higher ECP levels have been reported in infants with RSV-induced bronchiolitis than in controls suffering from URTIs and LRTIs that were also RSV-induced. High ECP levels in the nasopharyngeal secretions are predictive of the development of bronchiolitis at the time of RSV infection, and in parallel of clinical severity [201]. Especially in males, ECP levels are associated with the disease and its severity more than with peripheral eosinophilia, presenting as markers of disease progression [202]. The same difference was observed in infants with other RSV infections, but in females rather than males [751]. ECP was not predictive of asthma development in 6/34 children 2 years old after hospital admission at the age of 3 months [585].

There is, however, a correlation between LTC_4 and RSV-specific IgE levels in the nasopharyngeal mucosa [686, 714] of 67% of children with RSV bronchiolitis, vs 33% of controls with URTIs, also caused by RSV ($p<0.001$), who, moreover, showed LTC_4 concentrations fivefold lower than the study children ($p<0.02$) [686]. PaO_2 titers were lower in children with detectable LTB_4 than in those with undetectable LTB_4, and LTB_4 titers were inversely correlated with initial PaO_2,values which suggests a connection with disease severity [203]. Therefore, the *damage produced by RSV at the bronchial epithelium,* associated with toxic effects of basic proteins, and edema and bronchospasm triggered by LTs, could induce an *airway obstruction,* followed by a postinfection persistent BHR [323]. Other than BHR, bronchiolitis is dominated by activation of cellular immunity with production of Th2-like T cell ILs, clearly indicating an immune response to RSV and predictive of the development of asthma. An increased rate of $CD4^+$, $CD25^+$, and $CD23^+$ lymphocytes was found in infants at 5 months compared with the time of bronchiolitis and with healthy subjects of the same age. Moreover, the $CD4^+$ increase is not associated with CD8 increase, which remains low, whereas IL_4 increased in both groups. Eosinophils also increase significantly and are related to the number of days of wheezing – therefore, a classic Th2 response [523] manifested by RSV-induced IL_{13} production [670]. It is unclear whether genetic factors condition the phenotypic expression of RSV-induced bronchiolitis and the development of asthma, or RSV predisposes infants to asthma.

Even more pathogenetic is soluble CD14 (sCD14), a predictor of subsequent wheezing in children aged 2–14 months with RSV-induced brochiolitis, although not influenced by FHA+, sex, or breast-feeding [601].

Anatomopathological study shows that RSV replication in the airways has cytolytic effects on the epithelium. Significant changes in airway morphology are seen in animals with acute viral respiratory infection: the airways become edematous and infiltrated with inflammatory cells. The lower airways show marked bronchial narrowing and collateral ventilation and elastic recoil reduction. The reduction in caliber of distal airways makes the small bronchi and bronchioles obstructed by cellular debris from virus-specific epithelial necrosis, increased mucus secretion, intraluminal secretions of relatively dense and viscid exudate, bronchiolar inflammatory infiltrates and edema of both submucosa and adventitia. The lesions are aggravated by replacement of necrotic cells by cuboid nonciliated cells, thus impairing mucus clearance, which condenses in obstructive and potentially occlusive plugs [611].

From a functional viewpoint bronchospasm can be absent. Vice versa, alterations of the respiratory mechanism are present, denoted by a 50% increase in FRC compared to normal, reduced pulmonary compliance, increased resistance to air passage, especially during exhalation, since during exhalation – especially if forced – the airway caliber is reduced as a result of bronchiolar obstruction. The work of breathing is aggravated by air trapping with pulmonary hyperdistention or atelectasis, which are at the basis of hypoxemia – warning signs of ventilation-perfusion imbalance [271].

Clinical Presentation

Bronchiolitis is an acute disease with a sudden onset and a steady worsening in the first 24 h. *It presents a severe clinical situation in young infants* caused by respiratory changes, with prolonged exhalation, cough, sustained resting polypnea (RR ≥70–80/min), and obstructive type dyspnea, sometimes cyanosis and/or lethargy [474]. Moreover, symptoms can include coughing (100%), nasal congestion (94%), wheezing (89%), difficulty breathing (87%), poor feeding (70%), poor sleeping (69%), irritability (67%), fever (59%), vomiting (51%), and choking (41%) [499]. If the disease worsens further, RR decreases (Appendix 11.1) [302, 544] and signs of hypoxia and difficult breathing occur 22% to 46% of children so affected are admitted to hospital, especially if RR is >70 [499] or are admitted to the PICU at a median age of 1.7–2.27 months [506] and requiring mechanical ventilation in 31.4%–34.1% of cases. Tachypnea makes breast-feeding difficult, not leaving a sufficient interval of time for sucking and swallowing.

The child can become dehydrated as a result of an increased *perspiratio insensibilis* and of shock. Fever if present, in most cases does not rise beyond 39 °C [270].

Objectively, nasal flaring, use of accessory respiratory muscles due to intercostal retractions can be noted. During auscultation, a prolonged expiratory phase can be heard, together with expiratory wheezing and fine diffused rales or rhonchi. The rales indicate an obstruction of the main bronchi, and the rhonchi an alveolar hypoventilation. High-pitched expiratory wheezes in all lung fields may be audible. *Hypoxemia and hypercapnia* deriving from the alteration of the ventilation-perfusion balance and of pH and $PaCO_2$ are present. Aspecific symptoms can also be noted in young infants such as lethargy and irritability or other neurological symptoms of hypoxemia. Apnea and/or cyanosis can be the only symptom [512, 594].

Diagnosis

Diagnosis is above all clinical. SaO_2 monitoring is determinant to ascertain the degree of airway obstruction, and in cases of severe respiratory distress it should be integrated with the acid-base balance test; arterial samples may verify $PaCO_2$ levels. Pulsus paradoxus is a clinical correlate of cardiopulmonary interaction during asthma and correlates with the severity of the asthma attack. The degree of pulsus paradoxus can be measured directly with a hand-operated BP cuff or estimated from pulse oximetry [372, 717], a noninvasive method for detecting severe cases and for measuring O_2 saturation (SaO_2), but not always reliable [512] because it can be affected by the child's movement and by peripheral vasoconstriction, which occurs in the more severe cases [509]. This pulse may be related to RR in young children [372], but it cannot always be utilized because of HR increase; nor is there a clear correlation between peripheral pulse increase and asthma aggravation [738]. If it is >20 Torr, a moderate to severe obstruction is present [174]. In a survey of 519 physicians, the decision to transfer children to an appropriate emergency setting was significantly influenced by the 2% difference between SaO_2 values of 94% and 92%. This finding may help to explain the increased numbers of admissions for bronchiolitis since the popularization of pulse oximetry [372]. However, in 67% of cases oximetry is done in pediatric ED as part of the initial procedure and to document improvements after treatment [121]. Full blood counts are normal [125] in 80% of children [512]. Chest X-rays show typical airway emphysema resulting from air trapping, chest hyperinflation, diaphragmatic flattening and accentuation of the bronchial network; multiple areas of atelectasis can mimic areas of thickening. No correlation between these findings and severity of bronchiolitis is found [512].

Cytological examinations of nasopharyngeal aspirates and titers of specific antibodies may facilitate the etiological agent identification. Confirmation is obtained by using the indirect immunofluorescence technique and by ELISA. In any event, these are roundabout methods and can take more than 10 days to carry out [125]. Even if in 3%–10% of cases *Chlamydia trachomatis* and *Mycoplasma pneumoniae* [514] are isolated, both illness severity and prognosis are parallel to cases in which only RSV has been found.

Differential diagnosis is summarized in Tables 11.27 and 11.28 [594]. It is made difficult in babies by the frequent analogies between the clinical picture, the objectivity and the X-ray results.

Bronchiolitis has characteristics other than those of asthma [125]:

- It manifests itself in the cold seasons.
- It occurs in epidemic waves.
- Episodes are frequently preceded by rhinorrhea and fever.
- It is particularly common in daycare settings.
- In the same family other members suffer from influenza.
- It is primarily a disease affecting babies in the 1st year of life, which is why diagnosis can be limited [747], whereas asthma normally occurs after this age (Figs. 4.14 and 5.3).

However, pediatricians generally do not need to differentiate virus and nonvirus-induced severe wheezing, since treatment of airway obstruction is unaffected, apart from an epidemiological interest in etiology [594].

Treatment

Treatment is symptomatic. If breathing difficulties are severe, there is need to humidify the air and to hydrate the baby adequately (not >1,500 ml/m^2, correcting the acidosis), also to choose the diet and to control hydrosaline balance: *in young infants rehydration is cardinal* even though cases of severe dehydration are rare [26, 222]. Electrolyte concentrations should be carefully monitored in all infants with acute bronchiolitis [512]. If cyanosis is present and SaO_2 is ≥95% in room air, warm and humidified O_2 can be delivered into a tent or headbox, adjusting O_2 saturation. If necessary, give a dose of epinephrine 1:1,000 (Table 11.16), with a vasoconstriction action and, therefore, an antiedematous action, which can, if required, be repeated after 15–20 min, since it is rapidly metabolized. Inhaled epinephrine is discussed in Chap. 20. *Racemic epinephrine* [551] (not registered everywhere) has proved most effective, as shown by concrete improvement and few or no side effects. The effect of the racemic form derives from its action on α-adrenergic receptors, capable of reducing microvascular leakage by causing constriction of precapillary bronchial arterioles and hence bronchial mucosal edema [551]. The drug is administered through a nebulizer in doses of 0.1 ml/kg [551]. In severe cases, assisted breathing is needed [271]. Racemic epinephrine proves

Table 11.27. Pediatric differential diagnosis of bronchiolitis based on clinical features

Symptoms/signs	Diseases associated with wheezing	
	In infants	In older children
Association with positional changes	GER, anomalies of great vessels	GER
Failure to thrive	Cystic fibrosis, tracheoesophageal fistula, bronchopulmonary dysplasia	Cystic fibrosis, chronic hypersensitivity pneumonitis, α_1 antitrypsin deficiency, bronchiectasis
Association with feeding	Tracheoesophageal fistula, GER	GER
Environmental factors	Allergic asthma	Allergic asthma, acute hypersensitivity pneumonia
Sudden onset	Allergic asthma, croup	Allergic asthma, foreign body aspiration, croup, acute hypersensitivity pneumonia
Fever	Bronchiolitis, pneumonia	Acute hypersensitivity pneumonia, croup
Rhinorrhea	Bronchiolitis, pneumonia	Allergic asthma, croup
Concomitant stridor	Tracheal or bronchial stenosis, anomalies of great vessels, croup	Foreign body aspiration, croup
Finger clubbing		Cystic fibrosis, bronchiectasis chronic lung disease (CLD), allergic asthma

Table 11.28. Pediatric differential diagnosis of bronchiolitis and asthma

Parameters	Asthma	Bronchiolitis
Positive family history	Frequent	May be frequent (Table 11.22)
Etiology	Allergens, viruses, etc.	RSV
Age at onset	50% by 2 years of age 80% by 5 years of age	<2 years, frequently at <1 year
Recurrent wheezing	Characteristic	70% (≤2 episodes) 30% → asthma (≤3 episodes)
Onset of wheezing	Acute if allergic or exercise-induced	Insidious
Association with allergic disease	If allergic asthma, allergic rhinitis, atopic dermatitis	Commonly absent
Concomitant symptoms of RRI	Infrequent	Yes
Chest auscultation	High-pitched expiratory rales	Fine, sibilant rales, coarse inspiratory and expiratory wheezes
PRIST	May be elevated	Usually normal
Nasal eosinophilia	With allergic rhinitis	Absent
Response to bronchodilators	Characteristic	Scarce or wholly absent

Updated from [594].
GER gastroesophageal reflux, *RRI* recurrent respiratory infections, *RSV* respiratory syncytial virus.

to be better, as has been confirmed in the US [551] where a shorter length of hospitalization of children compared to a group treated with albuterol has been documented [399]. If the mean percent SaO_2 at 60 min was significantly higher in the epinephrine group [399], either the acidity of the solution (pH 3.2), or the content of

metabisulfites, present in levo-epinephrine preparations as a preservative [543], or in epinephrine acid tartrate as a vehicle [689] or both, might have been responsible [543]. These causes may explain why no improvement was shown in infants with acute bronchiolitis when compared with placebo [2, 226, 689].

Four recent randomized, DB studies have evaluated *nebulized epinephrine* in the treatment of infants with bronchiolitis. The delivered types of epinephrine were L-epinephrine [2], racemic epinephrine [237], epinephrine diluted in normal saline solution [373], or epinephrine acid tartrate, 1% [689]. Nebulizations were administered using a nebulizer and face mask, and O_2 was given as needed as above. No significant overall differences were found between the groups [689] or between treated and placebo groups [2, 237]. A decrease in symptoms and length of hospitalization was reported in 54 infants [373]. When epinephrine diluted in normal saline was nebulized to these infants with viral bronchiolitis, the in-hospital stay was reduced by 25%, from 4 days in the 0.9% saline solution group (group 1) to 3 days in the 3% saline solution group (group 2) [373]. This outcome could bear an important economic and clinical impact worldwide; in the US, $>10^5$ children are hospitalized annually at a cost of US $300 million. Decreasing this burden by almost 25% could theoretically save nearly US $75 million annually in the US alone [373]. A Cochrane review concludes that there is insufficient evidence to support the use of epinephrine for the treatment of bronchiolitis among inpatients *aged ≤2 years* except a significant change in clinical score at 60 min post-treatment [239]. Usually, severely ill, hospitalized infants are aged a few days [2, 470] or 3–6 months [69, 237, 372, 373, 470, 474, 499]. We analyze the differences in epinephrine preparations in Chapter 20.

As has been discussed, the use of bronchodilators is controversial, since usually they increase the state of agitation of infants in whom bronchiolar smooth muscles are barely developed before the 18th month, even if muscular tissue appears at the 23rd week of intrauterine life and by the 25th week is uniformly distributed at all levels of the bronchial tree [632]. As stated, bronchospasm is not a main component of bronchiolitis, and in acutely ill infants the production of mucosal edema and increased mucus secretion may impair medication effects [206]. In some cases, β_2-receptors in healthy infants of 5.6 months [206] have been found, even in reduced numbers, and the efficacy of nebulized albuterol has been reported in infants 1–24 months old [565]. A causative factor, as noted, is the β-adrenergic receptors' desensitization caused by RSV. The safety of β_2-adrenergics for use in infants of 7.5 months [36, 370, 371] has been ascertained, whereas in infants <1–6 months [199, 250] β_2-adrenergics induced a significant HR increase and a SaO_2 reduction. Even if tachycardia can be viewed as an index of effectiveness [199], we believe that β_2-adrenergic may be useful in older children who can no longer be diagnosed as having bronchiolitis. This could account for the controversies summarized elsewhere [323]. As an alternative, consideration should also be given to forced nasal respiration of the infant and to the greater aerosol residual in the oropharynx compared to an adult [549]. In the survey from 519 physicians, most respondents recommended use of bronchodilators (96%), and few recommended steroids (8%), or antibiotics (2%). Inhaled albuterol was the most common drug specified (84%). Inhaled epinephrine (57%) followed by inhaled albuterol (35%) were the most commonly second recommended treatment [372]. Epinephrine was given to 58% of 237 infants in pediatric EDs in Canada [499]. In 149 infants hospitalized with bronchiolitis, there were no group differences in the effectiveness of therapy of either nebulized epinephrine or albuterol every 1–6 h. This is probably because by the time infants present to medical care, the amount of virus-induced necrosis may already be substantial [474].

Much debated is CS use in 5% of cases [499]. The rationale for their use is in direct relation to the anti-inflammatory power carried out on the bronchiolar walls and the restoration of β_2-receptors; but the small airways of these infants are, for the most part, unresponsive [711]. Furthermore, since they retain fluids in the tissues, CSs should be used with caution [594] in view of the inappropriate secretion of ADH (antidiuretic hormone), potentially present in these babies along with hyperreninemia [222]. Five percent of infants received CSs while in the hospital and 4% on discharge [499]. Antibiotics have no therapeutic value in a viral disease; unless a bacterial association is suspected (in 2% of cases), or confirmed by clinical or laboratory evidence, and severe, clinical signs, such as persistent febrile condition and/or an increase in the indexes of inflammation [512]. However, there are concerns about risks of adverse reactions, and the effect of antibiotics on bacterial resistance (Chap. 19).

Good results have been achieved with *ribavirin,* a synthetic nucleotide with virostatic properties on many viruses including RSV, interfering with the expression of mRNA of RSV itself, the effects of which on clinical parameters are noticeable 24–48 h after therapy [599]. The drug is administered by a small-particle aerosol generator and is delivered to a head box, face mask or O_2 tent in a solution containing 20 mg/ml of water, for 12–18 h consecutively per day for 3–7 days, depending on the disease progression [599]. Given the potential for environmental contamination during treatment, it is preferable to administer it in high doses by means of an O_2 hood at 6 g/dl water for 2 h instead of 18 h, achieving the same effects [176]. After the initial positive results, reservations were expressed, due also to the unfavorable cost-benefit ratio [712], its limited strength and the drug's possible toxicity and environmental contamination [176], which is why it is recommended as an optional choice [235].

Prevention

Immunoglobulins with high titers of anti-RSV antibodies [227], IV administered (RSV-IVIg), in a prospective blinded randomized, multicenter study over 3 years, with high (750) or low (150 mg/kg) monthly infusions can be used for prevention. Compared to controls, *high-dose RSV-IVIg* reduced the incidence of LRTI, RSV-associated hospitalizations, ICU days, and ribavirin doses (p=0.01–0.05) with 3.3% adverse reactions. The protection was extended to the follow-up with a clear reduction in severe consequences, even among subjects who were at greater risk [227]. In premature babies, the efficacy is the same, compared to controls, with a reduction in the number of days spent in hospital or ICU associated with RSV infection [226]. Even though offering a valid defense, it is not preventive in 100% of cases; nor has it lowered the mortality rate [9]. It is administered IV (750 mg/kg/2 h, once a month, during the RSV season: November to March-April): it causes overhydration, requires the same monthly controls and has an elevated cost, as does ribavirin [235]. In 1996, the FDA approved the use of RSV-IVIg as a prevention against RSV infections, excluding, however, children with congenital cardiopathy. Other DB, randomized studies are further testing the advantages and limitations of RSV-IVIg [9].

Another molecule, *palivizumab,* a monoclonal antibody directed against RSV, is now marketed for preventing respiratory tract infection by RSV in infants. The results of six trials suggest that the optimal dose is 15 mg/kg palivizumab by monthly injection throughout the seasonal epidemic period. The AAP has restricted its use to infants with CLD and congenital heart disease (CHD) [9]. Two recent studies [225, 515] have shown that the hospitalization rate for RSV bronchiolitis decreased significantly (46.2% vs 11.8 and 3.8%; $p < 0.01$) in premature infants with a gestational age ≤32 weeks and with CLD [225]. The emerging problem is that 83% of the children needing PICU admission for mechanical ventilation for the RSV bronchiolitis treatment from 2000 to 2002 born at term did not have CLD and were not candidates for RSV prophylaxis according to the current recommendations [9, 515]. Certainly RSV prophylaxis would increase the net cost of care if palivizumab were administered to the population of infants with bronchiolitis.

Prognosis

Generally speaking the prognosis is favorable. The mortality rate in hospitalized infants is 1%, which rises to 3.5% in premature infants and babies born with heart diseases, chronic respiratory disease, primary and secondary IDs, etc. [323].

Long-term prognosis can be complicated by asthma. Many studies have examined why children with genetic predisposition to atopy develop bronchiolitis more frequently or, afterwards, an asthmatic condition, especially if with IgE elevated levels. The influence of predisposing and confounding factors is well known: passive smoke – especially maternal – environmental pollutants, etc. Nevertheless, RSV infection remains the main factor that facilitates the insurgence of asthma. In this context, the report that more than one-third of children who have asthma during childhood have suffered from RSV-induced bronchiolitis (Tables 11.24, 11.25) seems particularly relevant. Consequently, PRIST is useful for identifying children with persistent wheezing who will continue to suffer from asthma [69], in many of whom the IgE increase is followed by sIgE development [70]. Several studies have indicated the predictive nature of total IgE [300] and/or of CBIgE [368]; others underline SPT effectiveness as a screening method (Chap. 6).

What is the role of atopy? Several authors have expressed controversial opinions [69, 70, 184, 383, 391, 453]. Often the studies have proved inconclusive, some linking the unfavorable prognosis to atopy and maternal passive smoke [391]. Others do not confirm FHA+ with atopy, emphasizing instead the association with parental smoke and sibling presence [400]. The results of Rylander et al [545] appear to be very eloquent: re-examining 79 children 4 years after their admission to hospital, they observed in only 22 of those with recurring wheezing a statistically relevant association with FH and an equally significant PEF and MEF_{25} reduction. In 83 children followed-up to the age of 8 [313, 314, 320], the risk of atopic children developing asthma or BHR during their school age was significantly related to recurring wheezing that appeared in the 1st year of life and to a premature IgE increase [314] compared to controls. At age 19 wheezing in early childhood was a significant predictor of asthma, and also seemed to predict PFT abnormalities in early adulthood. Thus, although the outcome of children with early wheezing is good at school age they may become symptomatic again as adults [495]. In other entrants, at the age of 4 years, asthma was present in 62.5% of ex-bronchiolitis sufferers vs 6.3% of controls and in 88.5% of children with high IgE titers compared to 32% of those with normal IgE levels [555]. In children of atopics, at the age of 11 atopy and wheezing were closely related [609].

Many different lines of research agree that *RSV-induced bronchiolitis is responsible for a subsequent asthmatic syndrome*, persistent for many years after the primary infection. In particular, it is hypothesized that anti-RSV IgE production can constitute a marker for the predisposition to develop specific response to VRI of early and late infancy, able to trigger recurrent asthmatic episodes [453] (Table 11.29) [4, 117, 161, 178, 214, 241, 246, 302, 381, 375, 423, 447, 454, 470, 495, 587, 616, 637, 644, 713, 726, 745]. Studies fail to clarify the pathogenesis of this higher prevalence of asthma in these subjects [585, 587]. It can be speculated either that the atopic risk preceded and/or provoked RSV-induced bronchiolitis and wheezing episodes, or that, at the origin, a reduced

Table 11.29. Bronchiolitis, IgE antibodies, atopy and asthma development: a meta-analysis

Relationships between bronchiolitis and IgE antibodies
Viral infections do not provoke an IgE antibody expansion and a higher atopic risk in children aged <2 years, frequent at 2–4 years and more frequent after 4 years [161]
Development of specific IgE in 44% of asthmatic children and in 17% of nonasthmatic children up to 2 years [587]
Significant association between FHA/asthma and RSV infection at 3 years, with similar differences in specific IgE titers between study children and controls [587]
Atopy in 67% of ex-bronchiolitics (aged 19) and in 50% of controls [495]
Children who were current wheezers at ages 7–8 had detectable RSV-specific IgE during their initial episodes but no relation to alteration of spirometry tests at age 7–8 years [712].
Relationships between bronchiolitis and asthma/recurrent wheezing
Recurrent viral infections unrelated to BHR at 1 year [644], 3–6 [4, 725], 7–8 [724], or at 13 years [616]
Aspecific BHR at methacholine inhalation challenge (MIC) in 80% of children of 12 years hospitalized in the 1st year of life due to severe bronchiolitis, vs 15% of controls [178]
BHR to MIC was present in 48% of ex-bronchiolitics and in 32% of controls [495]
Recurrent bronchiolitis not followed by asthma in 85% of cases within the 10th year of life (despite numerous episodes experienced during the 1st year of life), or significantly predictive of spirometry value reduction, also in RAST-negative children, moreover in 45.2% of cases methacholine challenge was correlated with dust mite-positive RAST [246]
Among 6-year-old children who were hospitalized with RSV bronchiolitis as infants, there was a ≈ 3-fold increase in wheezing [423]; at 9–10 years of age, 33% of these children with RSV bronchiolitis in infancy required bronchodilator therapy, compared with 3% of the control group [447]
Infants with reduced conductance have a fourfold greater (in males tenfold) virus-induced risk of wheezing within the 1st year of life; in females the risk is 16-fold greater in case of reduced FRC before the illness [382]
Elevated Raw and reduced FRC are predisposing factors for long-term wheezing respiratory illness in infants [381]
Children with wheezing in the 1st year of life and at least one episode in 3 years of follow-up, experience at birth, compared to controls, a 22%–25% PFT reduction [382]
In children with chronic cough and previous LRTI, the intercellular spaces are 17-fold increased with notable edema and the inflammatory cells increased sevenfold (91% of lymphocytes, 9% of mast cells and eosinophils), whereas ciliated cells are reduced threefold [241]
In prematurely born babies with gestational age of 29 weeks, a high Raw is significantly associated with respiratory manifestations at 2 and 3 years of life [214]
Prematurely born babies with birth weight of 0.5–1.5 kg who suffered from >1 wheezing illness in the first 2 years of life develop asthma at 5 years in 18.1% and at 8 years in 21.3% of cases vs 10% of controls [302]
BHR is observed at birth in healthy neonates [744] or at 8 months, 3.6 months after having suffered from bronchiolitis [644]
In conclusion:
A high proportion of infants hospitalized with bronchiolitis go on to develop asthma-like symptoms [712]; such infants are more likely to have reduced PFT at 1 month of age [637], thus raising the chance that bronchiolitis may identify the infants with poorly developed airways and therefore at an increased risk of developing asthma-like symptoms in response to respiratory infections
Viral bronchiolitis in infancy enhances the risk of asthma and recurrent wheezing in later wheezing by increasing the likelihood of Th2 sensitization to subsequent respiratory infections and to aeroallergens [470]
25%–56% of bronchiolitic subjects are eventually diagnosed with asthma, more commonly with a personal or family history of asthma [117]
PFT abnormalities may persist in asthmatic children up to 17 years of age and recur in the adult age [454]
Decreased indices of small airway obstruction (PEFR, FEV_1, FEF_{25-75}, FEV_1/FVC) and increased Raw have been found in children following bronchiolitis [117]

BHR bronchial hyperreactivity, *FRC* functional residual capacity, *PFT* pulmonary function testing.

PFT is already present in the first weeks of life [747]. In fact, these alterations, years after an episode of bronchiolitis, can reflect pre-existing damage in the pulmonary system and/or in airway's mechanical properties, already present at birth [381, 638, 747]. A meta-analysis [453] did not find a causative connection between the initial type of infection and subsequent respiratory changes [611]; therefore bronchiolitis during infancy might not cause a greater morbility for respiratory disease in older children [747], or the long-term prognosis

is open to all types of complications. It is likely that a percentage of children will suffer from asthma (15%–63%) [130, 320, 417, 453, 555], especially with FH+ and/or high titers of total and/or specific IgE and PC_{20}-histamine >2 mg/dl, $FEF_{25–75}$ over 70%, and FEV_1/FVC over 70%) of predicted status asthmaticus [453], or independent of FH [523, 616], but with Th2 producers of IL_4, virtual absence of CD8 T cells and almost undetectable IFN-γ [523]. In 7- to 8-year-old ex-sufferers of severe bronchiolitis, RSV infection primes memory T cells that make strong IFN-γ responses. However, IL_4-producing T cells responding to RSV and cat antigens are significantly more frequent in ex-bronchiolitics, thus increasing the risk of allergic sensitization by providing a local IL_4-rich environment in which aeroallergens are first encountered [470].

The other important question remaining to be clarified is that together with children in whom wheezing associated with atopy and BHR (development that is a prelude to asthma) began after the age of 2 [423], there are others with early onset of wheezing (<2 years), which ceases, more or less without consequences, at about 10–11 years of age [726], in relation with reduced airway development in this period, and with the particular vulnerability to VRIs [725]. Similarly, the age which should be taken as a reference has proved to be a relative factor [723]. To this end, let us stress that 49% of children labeled as asthmatic at the age of 5 years were asymptomatic at 10 years [471]. A more valid criterion is allergen sensitization, which is not only linked to the diagnosis of asthma, but is also predictive of asthma in children with wheezing [142]. The differential diagnosis between the two forms is summarized in Table 11.30 [383, 723], and that of asthma and bronchiolitis in Tables 11.27 and 11.28.

For the prevalence of wheezing, see Tables 5.10 and 5.12. Wjst et al show that it is on the increase from 10.9% to 17.6% in the 1- to 3-year age group, then decreasing from 16.4% to 9.7% from 4 to 9 years [726], while others report figures of 60% [638] or 50% [383]. In this study, the children examined at birth and re-examined at the age of 3 or 6 based on the time of onset and pattern of wheezing symptoms were divided into three wheezing phenotypes:

- 19.9% with transient wheezing only in the first 3 years of life
- 15% with late-onset wheezing, not present in the first 3 years, (but with symptoms beginning between 3 and 6 years)
- 13.7% with persistent wheezing in the first 6 years of life.

Children with transient wheezing showed significantly altered PFTs, to a greater degree than the other groups, and also with a smoking mother (only the 2nd and 3rd group had asthmatic mothers), IgE titers significantly high (higher in the 3rd group), SPT+ and normal PFTs at 1 year of age and altered PFTs at age 6: this is the minority with a predisposition to asthma [383]. Persistent wheezing is more commonly seen in children with asthmatic parents who have significant LRTIs with RSV [616]. The three groups can be further reduced to two: one with a viral infection and one with an atopic disease, probably aggravated by the infection [547]. Measuring specific Raw (sRaw), 200 children who wheezed at least once during first 3 years of life had significantly higher sRaw than the 303 who had never wheezed in the first 3 years of life, who had significantly higher sRaw if they were atopic or were at high genetic risk of atopy. These high-risk children, even if they had never wheezed, had a higher sRaw than children at medium and low risk. Atopic children had significantly higher sRaw than those who were not atopic, but nonatopic children at high risk had higher sRaw than those at medium risk [351]. Therefore, higher sRaw predominates in atopic or high-risk children independently of the number of wheezing episodes. Persistent symptoms after 3 years of age are associated with the concrete risk of developing asthma [152]. At the age of 11, 17 of 21 children still had wheezing and 12 of 21 had BHR [609].

Table 11.30. Differential diagnosis between wheezing and wheezing/asthma

Characteristics	Wheezing	Wheezing/ asthma
Aspect	Episodic	Alternating/ episodic symptoms
Age	0.5–3 years	>3 years
Etiology	Viral, passive smoking mostly maternal	Atopy (+ viral infections)
IgE	±	+ +
BHR	Normal	Increased
Prognosis	Transient, up to school age	Persistent

Data from [383, 723].

Asthma

When asthmatic children encounter the allergen, an acute asthmatic episode is triggered that can evolve in three stages. The first begins 20–30 min after allergen exposure and essentially consists of a bronchospasm, a clinical consequence of metachromatic cell degranulation; the airway caliber generally returns to normal within 2 h. The second stage reaches its maximum intensity about 6 h after the provoking event, coincident with the eosinophil inflammatory response in the airways. The third stage, which can last up to 3 weeks, is sustained by the intense inflammatory response induced by mediator release and progressive recruiting of

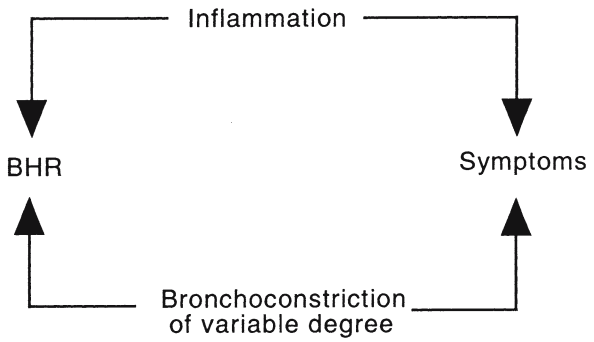

Fig. 11.49. Inflammation contributes to clinical manifestations. (Modified from [454])

[a] Early symptoms.

inflammatory cells: in this stage the airways react acutely to contact irritating substances. All these events lead to the noted effects of inflammation and bronchoconstriction, which, as shown in Fig. 11.49 [454], are expressed by clinical features.

What is defined as asthma is therefore structured on two levels: the asthmatic attack and the intercritical period. The first is the final link in a chain of events and reactions whose immediate causes do not represent the core of the issue. It could be better to analyze the predisposing factors carefully, the latent anomalies, the causes predominating at the beginning of the process and the pathogenic mechanisms at the basis of the re-exacerbations. Clinical features do not present clearly defined aspects and are *extremely variable from an almost normal state to one of extreme severity*. The onset can be gradual and often the diagnosis is not clear. The early recognition of premonitory signs (Table 11.31) [25] before wheezing is perceptible can be finalized by an often resolutive immediate therapy. The hallmark is *wheezing* during expiration provoked by air rushing through larger but narrowed airways in sufficient force to generate air vibration, heard as a whistling sound associated with breathing. Additional symptoms are a feeling of a tight chest and a hacking, recurrent cough, especially at night, which can also be the only symptom. After the age of 1 year, the bronchospastic component predominates in acute attacks, which are rapidly reversible. The hypersecretion component dominates in chronic asthma and in more prolonged, severe attacks that are less responsive to therapy with bronchodilators (*status asthmaticus*). In addition to respiratory dyspnea, children often complain of abdominal pain, or headache, or a general sense of feeling unwell as the first subjective signs. Abdominal pain, particularly in younger children, is secondary to the use of abdominal muscles and of diaphragm. The dry, irritable, nonproductive cough of the first stages is often accompanied by a feeling of anxiety and is found together with tachypnea and tachycardia. The child is almost recumbent in bed, has difficulty in walking and talking, generally adopts particular postures to facilitate breathing, for example, sitting in a rigid position or leaning forward, to better use the auxiliary respiratory muscles. Wheezing may be a late symptom. It results from air being exchanged through partially obstructed airways and occurs in the larger airways where airflow is turbulent. The small airways do not produce wheezing since the airflow is laminar rather than turbulent. Consequently, marked small airway obstruction may be unrecognized on auscultation [481]. This fact, objectively important, does not always reveal the obstruction and precisely defines its evolutive stages. These limitations can be overcome by spirometry.

Classification

Infantile asthma is classified as acute and chronic; however, rigidly following structured frameworks can lead to imprecise evaluations. Table 11.32 [481] illustrates the assessment of varying factors that trigger the clinical features and the differential prevalence according to age. *Classifications of asthma based on clinical presentation* (Tables 11.33–11.35) [1, 435–437, 494, 592] are also useful in defining the several phases of treatment [437].

Aas staging [1] is often requested for the purpose of publication in international journals. Table 11.36 [186, 279] presents a summary of the causes of persistent cough. Figure 11.50 [694, 695] presents an indicative diagram on the diagnosis of asthma, which, in most cases, can be made on the basis of history, objective examination and instrumental proofs [102].

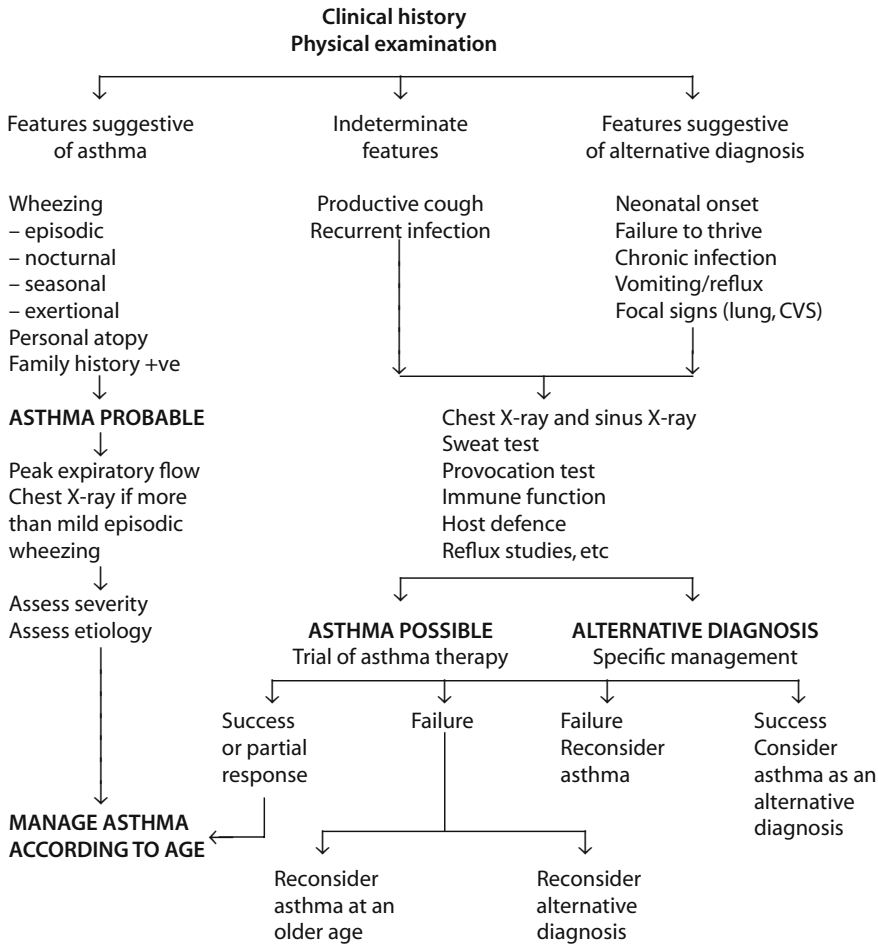

Fig. 11.50. Algorithm for the diagnosis of asthma in children unable to perform lung function tests. *CVS* cardiovascular system. (Modified from [698, 699])

Table 11.32. Assessment of the parameters underlying the clinical manifestations and the higher age-related incidence

Parameters	Age			Relative weight (%)
	<2 years	2–5 years	5–12 years	
Foods	++	+	±	
Exercise	+	++	+++	70
Emotional factors	±	±	++	
Irritant factors	+	++	+++	100
Environmental inhalants	+±	+++	+++	
Viral infections	++++	+++	+±	90
Pollens	+	++	+++	
Allergens on the whole				80

Modified from [481].

Table 11.33. Stepwise approach for managing infantile asthma based on symptom frequency

Type	Clinical manifestations
Episodic	75% of cases; an exacerbation every 4–6 weeks with infrequent symptoms (<5 symptomatic days every month); long periods of well-being, moderate wheezing after prolonged effort; no urgent therapy, normal PFT between exacerbations
Frequent	20% of cases; recurrent symptoms (<once a week), asymptomatic periods interrupted by more frequent attacks and wheezing after modest efforts; urgent therapy: from never to often; rare hospitalization; PFT variability 20%–30%
Chronic	4% of cases; frequent symptoms with no periods of well-being (symptoms >5 days/month, over >3 months and 50% of days of each 1st month of disease); wheezing after mild effort; urgent therapy: rarely/less than once/month, variable PFT
Seasonal	Symptom development similar to the chronic type, but restricted to seasonal periods due to exposure to inhalant allergens

Data from [434–437, 494, 592].

Clinical Presentation

Recognition of the different patterns is useful to evaluate the symptoms based on age (Table 11.32), frequency and severity of the symptoms (Tables 11.33–11.35), and risk factors (Table 11.37) [310, 336, 481, 485, 623]. The procedure will distinguish between noncomplicated/nonsevere cases or a severe asthmatic attack reflecting status asthmaticus.

Noncomplicated/Nonsevere Cases

History

The guidelines indicated in Chap. 6 are followed, examining the content of Table 11.38 [164, 584]. If it is ascertained that the child has already manifested recurring episodes of cough and wheezing, likely linked to EIA, diagnosis is almost achieved. Also, it is possible that the child under observation belongs to a group of young patients with chronic and nonproductive nocturnal cough, or with laborious breathing after running, etc., but never wheezes (Table 11.36).

Physical Findings

The physical examination includes thoracic examination as well as verifying:

- The general condition of the subject
- The state of nutrition, including weight and height
- The possible presence of effort-induced dyspnea

Diffuse hyperphonesis, unequal reduction of breathing sounds according to the conditions, wheezing, expiratory whistling, prolonged expiration, and rales of varying loudness (sometimes only rales can be heard) reflecting airflow limitation are ascertained; liver and spleen are often palpable as a result of diaphragm depression, following marked lung hyperinflation. Wheezing is *the tip of the iceberg* as most of the iceberg is not noticeable, airway obstruction begins well before the tip is evident, and wheezing is heard, therefore its presence can be measured by spirometry before clinical objectivity reveals wheezy breathing [481]. When symptoms occur gradually, it is surprising how children are able to get used to the reduced respiratory function, considering it a normal condition and even expressing a mild sense of well-being so that a <50% fall in PEF, and the related reduction of dynamic parameters can be underestimated for a long time. The symptoms that should arouse suspicion in these children are asthenia, a lessened ability to concentrate and persistent sinusitis.

Diagnosis

Laboratory Examinations

- Eosinophilia is often higher than 250–400 cells/mm^3. The count can be repeated in the expectoration. In children this could be unrelated to ECP levels; however, 27% of 92 children aged <2 years had serum ECP ≥8 µg/l, 76% of this group developed physician-diagnosed wheezing, and 48% had hospital admissions for wheezing.
- PRIST is often elevated. SPTs and RAST can be carried out to spot allergic asthma.
- Spirometry can provide useful information with collaborating children [429].
- If necessary, PFTs and/or BPTs (Chap. 6) can exclude other causes of wheezing (Tables 6.2, 6.3, 6.11). Even if BPT has proved useful in excluding the diagnosis of asthma, especially in adolescents, BPT with histamine is not a substitute for traditional medical diagnostic ability; children aged 2 years may be able to perform BPT (Fig. 6.25b).
- Other research has proved futile or misleading. For example, leukocytosis >15,000/mm^3 may be related to child age, the effect of stress and of adrenergic drugs [41].

Table 11.34. Stepwise approach for managing infantile asthma based on symptom severity

Classification	Mild intermittent	Mild persistent	Moderate persistent	Severe persistent
Clinical manifestations				
Symptom frequency	Intermittent ≤2 times a week	Intermittent >2 times/week, but <once a day	Daily Daily symptoms	Continual Frequent severe symptoms
Exacerbations	From a few hours to a few days	May affect normal activity/sleeping	Affects normal activity/sleeping ≥2 times a week	Frequent
Between exacerbations cough/wheeze	Asymptomatic	Asymptomatic	Often cough/wheeze	Continual
Nocturnal asthma	≤2 times a month	≥2 times a month	≥Once a week	Frequent
Exercise tolerance	Not reduced	Reduced by vigorous effort	Reduced	Very reduced
School attendance	Regular	Regular	May be affected	Frequent absences
Lung function				
FEV_1 or PEF % of predicted	≥80%	≥80%	>60–<80%	≥60%
Daily variability	<20%	20%–30%	>30%	>30%
Spirometry				
Signs of obstruction	Absent	Absent or minimal	Modest	Severe
Response to bronchodilators	Normal	>15%, normal values or modest increase	Incomplete normalization	Incomplete/ absent normalization
BPT to methacholine (PC_{20})		>20 mg/ml	2–20 mg/ml	<2 mg/ml

Data from [435, 437, 494, 592].

Table 11.35. Grading of clinical severity

Grading	Clinical criteria
1	<5 episodes per year with >7 days duration of symptoms and functional restriction each time, and long symptom-free intervals with apparently normal PFT[a]
2	5–10 episodes per year with >7 days duration of symptoms and functional restriction each time, and long symptom-free intervals with apparently normal PFT[a]
3	More than 10 episodes per year with <7 days duration of symptoms and functional restriction each time, and long symptom-free intervals with apparently normal PFT, or more prolonged periods (totaling 12 weeks or more per year) with symptomatic bronchial obstruction or apparently impaired PFT[a]
4	More than 5 episodes per year with prolonged obstruction (totalling ≥6 months per year) following most episodes, or chronic symptomatic obstruction with restriction of function. Bronchial asthma in need of institutional treatment and/or continuous use of corticosteroid medication (any route) to classify for grade III or better[a]
5	Chronic, incapacitating asthma with severe, acute exacerbations despite continuous medication following appropriate and safe dosage regimen

The subgroups are formed according to those in Table 11.32 (episodic, frequent, chronic) or Table 11.33 (mild intermittent, mild persistent, moderate persistent, severe persistent) and to FEV_1 values between exacerbations.
Modified from [1].
PFT Pulmonary function testing.
[a] If children have symptoms and signs of more prolonged bronchial obstruction (including subclinical obstruction) the next higher grade is given; simple exercise-induced asthma is not taken into account provided that recovery is complete with rest and/or a single dose of bronchodilator.

Table 11.36. Differential diagnosis of persistent cough

System	Causes
Central nervous system	Psychogenic
Upper airways	Irritation: foreign bodies, cigarette smoke, dust
	Inflammation: typical asthma, tracheitis, bronchitis, pertussis, recurrent infections by virus and *Chlamydia* and *Mycoplasma*
	Tumors: benign, malignant
	Extrinsic compression: lymphadenopathy, tumors
Pulmonary parenchyma	Inflammation: bronchiolitis, alveolitis, pneumonia
	Vascular: pulmonary emboli, cardiac insufficiency
	Respiratory disorders: cystic fibrosis, measles, bronchiectasis, bronchomalacia, tuberculosis
Extrapulmonary	Stimulation of vagal auricular branches
	Pleural, diaphragmatic or pericardial irritation
	Sinusitis
	Esophageal disease: tracheal fistula, foreign body aspiration, gastroesophageal reflux
	Humoral immune deficiencies
Others to be specified	
Medications	β-Agonists, inhibitor of angiotensin converting enzyme

Data from [186, 279].

Table 11.37. Risk factors for status asthmaticus

Asthma since infancy
Age <6 years especially if <3 years
Males with severe chronic asthma
Barrel chest
Small height
Weight lower than normal
Recent need for oral steroids
Poor compliance
Poor family support
Previous severe asthma attacks without warning
Poor response to an appropriate treatment
Discontinuity of medical care
Subjects at high risk
Younger children:
a. Diagnostic doubts
b. Develop respiratory failure more rapidly
Older children:
a. Weaning of oral steroids after hospitalization
b. Hospitalization for asthma in past year
c. History of prior severe attacks
d. Poor compliance
e. Psychosocial problems
Children and adolescents
a. Prior admissions to pediatric emergency department
b. ≥2 admissions in past year
c. ≥3 admissions in past months

Data from [310, 336, 481, 485, 623].

- Chest X-ray and ECG are not necessary in cases of uncomplicated asthma.

Chest X-ray shows hyperinflated lungs, depressed and not very mobile diaphragm, increased thoracic anterior-posterior diameter, peribronchial interstitial infiltrates, and sometimes parenchymal opacities often leading to atelectasis are found.

In all cases of recurring bronchoconstriction especially with increased susceptibility to infections (Chap. 22), it could be necessary to evaluate immunological parameters such as quantitative serum (Table 1.15) and secretory Igs, and lymphocytes and subpopulations levels (Tables 1.34–1.41, with BALF data). Determination of IgG subclasses is superfluous in the asthmatic child, as there are no differences compared to healthy subjects, with the exception of a few specific cases [468].

If a differential diagnosis with other conditions that should be differentiated from asthma is indicated, specific tests can be asked for such as PFT, BPT, as above, bronchoscopy, diagnostic imagining, bronchography, CT (computerized tomography), scintigraphy, etc., functional and cytological analysis of ciliary structures, and the sweat test.

Differential Diagnosis

Differential diagnosis includes the most common clinical conditions that mimic asthma at various age levels: Table 11.39 [481] shows the relative prevalences. Table 11.40 [186, 481, 584] shows the most common precipitants of asthmatic symptoms and Table 11.36 those of persistent cough. A brief description of the condi-

tions that most frequently present difficulties [186, 469] follows, also based on Appendix 11.2 [186, 469]:

- *Aspiration of a foreign body:* 40% of cases occur in children ≈2 years old; if not recognized and treated promptly, it can cause disease and even death. Usually it begins abruptly in otherwise normal subjects. Limited wheezing reduced to a single hemithorax is characteristic; it can be confused with asthma. Nevertheless, it does not respond equally promptly to bronchodilators, potentially implying that inappropriate treatments were instituted. Smaller bodies may induce progressive symptoms. Chest X-rays are not always discriminatory, since many foreign bodies are radiopaque.
- *Vocal cord dysfunction* is a functional disturbance that mimics asthma with paroxysmal attacks and severe dyspnea and is unresponsive to any treatment. Sounds can be heard on auscultation during inspiration and expiration that is otherwise normal. Instrumental analysis gives consistently negative results.
- *Hyperventilation syndrome* and panic attacks can coexist with the basic disease. The patient complains of being breathless. There are asthmatic symptoms that contrast with negative objective findings, as do most other tests.
- *Bronchiolitis:* see Tables 11.27, 11.28, 11.30 and 11.32.
- *Pertussis* can lead to a mistaken diagnosis that should be avoided through a lymphocyte count and nasopharyngeal cultures.
- *Cystic fibrosis:* there can be initial asthma-like symptoms and BHR. The sweat test is a decisive means of providing a definitive answer, also necessary, especially considering the marked frequency in Caucasians [469].
- *Bronchiectasis:* wheezing and BHR are found. CT enables differentiation from asthma.
- *Ciliary dyskinesia* is suspected when a chronic obstructive respiratory disease is seen, accompanied by rhinosinusitis, otitis and X-rays showing emphysema [469].

Severe Asthmatic Attack – Status Asthmaticus

Definition

Status asthmaticus is an attack that lasts more than 1 or 2 days, in whom conventional forms of therapy have failed, and may require admittance to hospital, with the child often in progressive respiratory failure. It is a medical emergency in which the child with acute asthma fails to improve following appropriate aggressive treatment in an ED or outpatient setting [717]. However, children 3–5 years old are significantly more likely to have an ED visit (OR – odds ratio 1.6; 95% CI, 1.3–2.0; $p < 0.0001$) or a hospitalization (OR 2.9; 95% CI, 2.0, 4.3; $p < 0.0001$) than older children [5].

Risk factors of status asthmaticus are summarized in Table 11.36. The risk of hospitalization is very high with on household smoking (Table 4.25). The risk is greater in children aged <2–4 years as a result of the above-mentioned physiological particularities. Bronchial smooth muscles are particularly reduced in children

aged <3 years, in whom the obstruction is more a result of edema than of bronchospasm. On the other hand, mucosal glands are numerous, with a consequent increase in the Reid index (mucosal glands/thoracic wall). Furthermore, the relative scarcity of diaphragmatic fibers, which contributes to a reduced muscle resistance to the work required of them, the increased pulmonary peripheral resistance and reduced alveolar surface should not be forgotten. Pulmonary mechanics and volumes are markedly altered in status asthmaticus. Caused by severe lower airway airflow limitation, premature airway closure leads to increases in closing capacity and FRC. Inspiratory muscle activity persists throughout expiration, attempting to counteract expiratory airway closure by increasing the forces holding the airway open. Hyperinflation results [717]. Nonhomogeneous distribution of areas of premature airway closure and obstruction causes ventilation/perfusion mismatching and hypoxemia results. Increased work of breathing under hypoxic conditions and some degree of dehydration combine to cause accumulation of inorganic acids. This acidosis is initially offset by respiratory alkalosis, but once respiratory failure ensues, a rapid and often profound decrease in pH will occur [717]. The combination of these factors explains the increased severity of asthma, the higher incidence of hospitalization, and the relatively scant response to bronchodilators in the pediatric population aged <5 years, and particularly <3 years.

History

It is of major importance to ascertain [509]:

- Chronology of the episode underway
- Apparent cause
- Severity of the symptoms
- Oral solid and fluid intake in the last 12 h
- The performance – or the contrary – of normal activities
- Type and duration of sleep
- Moods
- Name, dosage, and administration time of any medication ingested during the last 24 h
- Effect of the treatment
- Outcome of the preceding episodes
- Possible admittance to hospital or ICU
- Family ability to carry out necessary therapy

Objective Examination

Objective examination (Table 11.41) [273, 435–437, 485, 623] requires that on inspection, the general conditions and the presence or lack of be observed:

- Possible signs of risk affecting the psyche (anxiety, agitation, apathy, drowsiness)
- Inhalatory retractions and use of the accessory muscle
- Dehydration
- Polypnea
- Forced posture
- Cyanosis
- Sweating
- Tremors
- Breathlessness

After the evaluation of the general conditions, hydration, decubitus, etc., and of thoracic objectivity, several other parameters can be considered to make a diagnosis as quickly as possible and initiate treatment. Table 11.41 provides a general assessment; therefore it is not necessary for all parameters under consideration to be present. However, *the greatest risk in respiratory failure during episodes of severe asthma regards young children* (Table 11.36), in whom PEFR measurement is not always easy; therefore an evaluation of these parameters can permit a strict control of the child's condition [436].

Vigilance is the participation in the environment and can help in evaluating the child's fatigue.

Dyspnea is the parameter most noted by parents and doctors and can be helpful in evaluating the level of airway obstruction. It can be evaluated semiquantitatively by asking the child to repeat a phrase or count to ten within a single breath. The condition improves if the length of the phrase or the numbers counted increase.

The *use of auxiliary muscles* is an indication of bronchoconstriction. Sternocleidomastoid use is linked to PEFR or FEV_1 <50 % of predicted value. *Flaring of nasal wings* (Fig. 11.51) is a visible sign of dyspnea and shows the involvement of auxiliary muscles in respiration. Diaphragmatic depressions can be noted and inspiratory retractions, especially intercostal [481] (Figs. 11.51, 11.52).

Status asthmaticus is an ingravescent asthma, resistant to therapy, that progresses to a state of emergency [310]. The symptoms given in Table 11.41 can assist in its diagnosis. It eventually becomes hypercapnic, caused by CO_2 accumulation with ensuing development of respiratory acidosis.

On *auscultation,* prolonged expiration, wheezing, due to obstruction worsening, is audible during both inspiration and expiration, while respiratory sounds are re-

Fig. 11.51. A 13-month-old baby with acute asthma: note the marked indrawing of lower sternum

Table 11.41. General assessment of a severe asthmatic attack in children

Symptoms	Mild	Moderate	Severe	Resp. arrest imminent
Dyspnea	Absent/mild	Moderate	Severe	
Older child	Walks, plays	Walks, speaks	Resting, poor speaking	
Infant	Softer, shorter cry	Difficulty feeding	Stops feeding/suckling	
Decubitus	Can be down	Prefers sitting	Sits upright	
Talks in:	Normal sentences	Short phrases	Words or single letters	
Alertness	May be agitated	Usually agitated	Always agitated	Drowsy or confused
Color	Normal/reduced	Pallor	Cyanosis ±	
Accessory muscles	Absent/mild retractions	Modest retractions, use of sternocleido-mastoid muscles	Marked retractions, nasal flaring during inspiration	Paradoxical breathing
Wheeze	Moderate, end-expiratory	Loud, expiratory inspiratory	Reduced air penetration →	Silent chest
RR by age [485]				
<3 months	<60/min	60–70/min	>70/min	
3–12 months	<50/min	50–60/min	>60/min	
1–6 years	<40/min	40–50/min	>50/min	
>6 years	<30/min	30–40/min	>40/min	
HR by age [485]				
<1 year	<150	150–170	>170	
1–2 years	<120	120–140	>140	
>2 years	<110	110–130	>130	Bradycardia
Pulsus paradoxus[a]	Absent <10 mmHg	Present ± 10–20 mmHg	Often present 20–40 mmHg	Absent[b]
PEFR (% of predicted or personal best) (pretreatment) see Figs. 6.26 to 6.28)	>80%	50%–80%	<50%, life-threatening	<33%
SaO_2	>95%	91%–95%	<91%	
$PaCO_2$	<35 mmHg	40 mmHg	>40 mmHg, possible cyanosis	
PaO_2 (room air)	90–100 mmHg	60–90 mmHg	<60 mmHg, possible respiratory insufficiency	

Children exhibiting moderate symptoms should be considered for admission. Normal age-related RR values are in Appendix 11.1

Data from [273, 435–437, 485, 623].

SaO_2 O_2 saturation, *PaO_2* partial pressure of O_2 in arterial blood, *$PaCO_2$* partial pressure of CO_2 in arterial blood, *RR* respiratory rate.

[a] It is more reliable when >20 mmHg (see text).

[b] Suggests respiratory muscle fatigue.

duced. In children with signs of respiratory distress, wheezing is absent because of airway obstruction.

The severity can also be measured by means of a respiratory score (Table 11.42) [174, 476], especially for children aged <6 who have little experience with PFM, or children in significant respiratory distress, in whom it is difficult to obtain an accurate PFM measurement [102].

Laboratory Evaluation

Blood gas analysis: measurement of $PaCO_2$ is the parameter most indicative of severity [485].

Appendices 6.6–6.12 indicate PEF values according to sex and age. No response to a β_2-adrenergic, whether evaluated clinically or instrumentally, is a sign of severe obstruction related to the degree of asthma severity.

Table 11.42. Pediatric clinical score to estimate the severity of an acute exacerbation of asthma: clinical score

	0	1	2	3
Wheezing	Absent	Expiratory	Expiratory and inspiratory	Silent chest (presence of severe obstruction)
RR increase	Normal	Normal to 30%	30%–50%	Over 50%[a]
HR	<120–140	≈	≈	>120–140[a]
Accessory muscle use	Normal	Mild retractions (negligible)	Moderate (intercostal retractions)	Severe (marked tracheosternal and intercostal retractions)
Muscle retractions	–	+	++	+++
Orthopnea	Normal		Inconstant	Constant
Activity	Normal	Limitations on vigorous exercise	Very reduced, nightly disturbance, anxiety	Stops feeding, stops sleeping, agitation and/or prostration
Duration	<1 h	1–4 h	4–8 h	>8 h

Severity: mild exacerbation <7 points, mean exacerbation 7–12, severe exacerbation >12.
Data from [174, 476].
[a] With other parameters reaching a score value of 2–3.

Table 11.43. Pediatric clinical score to estimate the severity of an acute exacerbation of asthma: respiratory score

	0	1	2
$PaCO_2$	<36	40	>40
PaO_2 (mmHg)	90–100	60–90 (room air)	<60 (in 40% O_2)
SaO_2	>95%	91%–95%	<91%
Cyanosis	Normal	Room air	In 40% O_2
Pulsus paradoxus (mmHg)	<10	10–20	20–40
Accessory muscle use	Normal	Moderate	Marked
Auscultation (wheeze)	End-expiratory	Inspiratory and expiratory	Loud or absent
Alertness	Normal	Normal/decreased	Decreased

To each parameter is assigned a score from 0 to 3. Summing up the single scores, the severity of asthma exacerbations can be estimated according to the following scale: 0–4, no immediate danger; 5–6, impending respiratory insufficiency; 7 or more =, ongoing respiratory insufficiency.
Data from [174].
SaO_2 O_2 saturation, *PaO_2* partial pressure of O_2 in arterial blood, *$PaCO_2$* partial pressure of CO_2 in arterial blood.

The respiratory score (Table 11.43) evaluates the need for hospitalization and monitoring the outcome of clinical symptoms in a hospital setting.

Particularities of Small Children

- Inspiratory retractions at rest and nasal flaring (in infants rhythmic head flexion during inhalation and extension during expiration).
- HR and RR: RR can vary from 20%–30%, depending on whether the infant is awake or asleep. It is advisable to measure it also during sleep.
- SaO_2: toddlers tend to develop hypoxemia earlier than adults [435].

Treatment

Treatment of Acute Asthma Attack

An acute attack or asthma exacerbation always requires the greatest medical care [559]. The aims of treatment are summarized in Table 11.44 [79, 604]. On the basis of the flow chart in Fig. 11.53 [174, 435, 436] and the scores in Tables 11.42, 11.43, it is possible to establish the most

Table 11.44. Targets of antiasthmatic treatment in children

Maximum clinical improvement by minimal use of medications
Reduction of both frequency and severity of acute attacks
Efforts must be made to reduce visits to emergency wards and hospital admissions
Maximum improvement of lung function tests
Patient education to asthma and its treatment
Normal night rest
No symptoms at awakening
No missed day from school
Participation in physical, sport and social activities with no restrictions
Improve their quality of life
Minimize potential adverse effects of asthma medications
Normal growth

Data from [79, 604].

appropriate therapeutic approach, but there are others that are equally valid. Given the variability of the clinical picture, however, they cannot constitute a rigid guide, but should be interpreted on the basis of clinical evidence [268] in which history and progression of clinical symptoms are important [485]. To evaluate the severity of an acute asthma attack in the child, follow Table 11.41. Immediate management in the hospital receiving room can reduce hospital admissions for acute asthma, allowing more children to be safely managed in the community [115]. As a consequence, >70% of asthma hospitalizations could be cared for in alternative settings with supplemental O_2, nebulized medication treatments, and close nursing observation [392]. Depending on symptom relevance (mild, moderate or severe), various drugs or combinations of drugs in sequence can be used. Diagnostic tests, if convenient, with the aid of a respiratory score, can evaluate the necessity for recovery: a score of 0–4 is reassuring, in that an immediate danger of respiratory failure can be excluded; it must, however, be monitored at regular intervals. With scores >5, admittance to hospital could be unavoidable [174]. Because of RR variability, it is recommended that it be measured as described below, as well as pulsus paradoxus: if the score is >20%, a serious airway obstruction is present.

If the child is old enough or can collaborate, the reduction in pulmonary volumes and flows can be measured (spirometry, PEFR) [437]. These findings, if possible, should be obtained at once, then at 30- to 60-min intervals, which must be reduced to 15–30 min if the child does not respond to treatment [268]. If spirometry cannot be carried out, even because of the severity of the child's conditions, ascertain PaO_2 (Table 6.25) and $PaCO_2$ by measuring arterial blood gas level.

Figure 11.54 [140, 174, 435–437, 559, 699] indicates various treatment plans, either at home or in an ED. Therapeutic interventions should be integrated, according to the case, with good hydration, correction of acidosis, and *O_2 therapy* when necessary (see below).

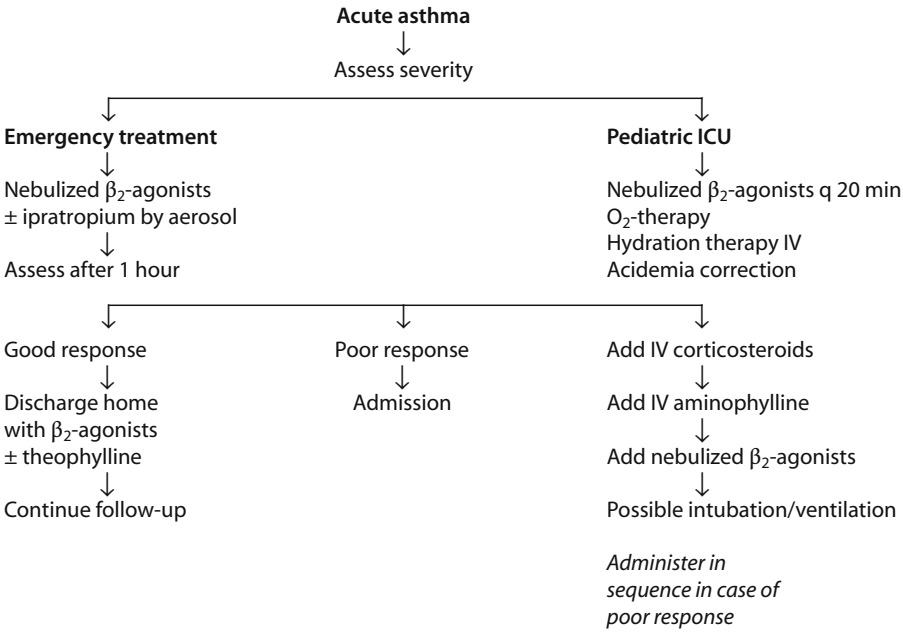

Fig. 11.53. Flow chart for severe pediatric asthma management in a pediatric emergency department or pediatric intensive care unit. (Data from [174, 434, 436])

We repeat that *in early infancy rehydration* is cardinal, since dehydration can easily occur as a result of RR increase and the reduced supply of nutrients and water: a 5% dehydration should be corrected when necessary.

Children experiencing an asthmatic attack, even if not severe, become hypoxemic more easily than older children [605] as a result of perfusion-ventilation [554]. The degree is related to respiratory obstruction and, above all, to PaO_2 and FEV_1 [267, 605].

$PaCO_2$ increase is an index of severity. The respiratory silence associated with hypoxemia (PaO_2 <50 torr) and/or hypercapnia ($PaCO_2$ >45–50 torr), or SaO_2 <91%, is also an index of severe respiratory insufficiency, which makes recovery in an ICU urgent [406].

The AAP recommends, as the first treatment in a child whose condition may be defined as severe, the use of SC epinephrine in standard dosages [509]. Moreover, the α-stimulating action makes epinephrine the drug of choice [485]. If a moderate attack occurs, which can be treated at home, the first treatment to be done at once should be with epinephrine, which has specific indications in cases of severe asthma, particularly suitable for use with children who, by definition, do not suffer from cardiovascular disturbances, apart from effects due to overdose. For the inhaled racemic form see above and Table 11.16; otherwise it can be substituted with inhaled β_2-adrenergics, for example albuterol: unit dose 100–200 µg with dosed MDI, or else 150 µg/kg diluted in 3 ml of saline to be nebulized in 10 min by facemask or spacer + VHC, measuring periodically the above parameters. All β_2-adrenergics are equivalent, but because of its wide international use, albuterol remains the drug used as a reference point [406].

If, after the use of epinephrine/β_2-adrenergics, an efficacious clinical response is obtained, a home maintenance treatment can be suggested, without disregarding subsequent treatment plans (Fig. 11.54). If no obvious improvement is observed, IB can be added to nebulized solution (150–250 µg according to the age, to be repeated every 6 h). ICS can be added to the treatment [406]. Interestingly, in children with acute asthma a single inhaled dose of BUD decreases ENO and is correlated to a PEFR increase [659], and two doses of dexamethasone may provide similar efficacy with improved compliance and fewer side effects than five doses of prednisone [510]. In two studies in ED children aged <5 [149, 556], the treatments compared with prednisone were nebulized dexamethasone 1.5 mg/kg and nebulized BUS 800 µg three doses at 30-min intervals, there were no significant differences in admission rates, with a nonsignificant trend favoring ICS (OR 0.49; 95% CI, 0.22–1.07); thus oral CS appear to be at least as effective as ICS in children with exacerbations of asthma. Another ED trial specifically including 100 children aged >5 with the most severe asthma on presentation (FEV_1 <60% predicted) found prednisone better than 2 mg FP by MDI and spacer at 4 h (FEV_1 45% predicted at trial entry, admission rate 31% on FP vs 10% on prednisone) [567]. Using much higher doses, the bulk of evidence suggests that ICS may be as effective as oral CS in all but the most severe episodes. One trial compared nebulized BUD (2 mg/8 h) with two doses of prednisolone 2 mg/kg on admission and at 24 h in 46 children admitted to hospital with severe asthma. Life-threatening episodes were excluded. Outcomes were comparable at 24 h and at 3- and 24-day follow-up [386].

Predictors of hospitalization in children with acute asthma are five variables: previous ICU admission, baseline SaO_2 ≤92%, 4-h SaO_2 92% or less, 4- h clinical asthma score 6/9 or higher, and hourly albuterol dosing intervals, associated with long vs short therapy, all with high odds ratio (OR). Probability of long therapy was 91.5%–99% for ≤3 predictors, but only 40.6%–61.8% for individual variables [291].

Otherwise, follow what is indicated in the treatment of status asthmaticus, or take the child immediately to a pediatric ED, especially if *there is no response to the β_2-adrenergic* administered by MDI of parenterally [41]. *Persisting with treatment at home in a child with little response to the bronchodilators leads only to a worsening of the episode*, which becomes even more refractory to drugs [267].

Treatment of Status Asthmaticus

Ingravescent asthma *unresponsive to treatment* is a life-threatening condition usually requiring admittance to ICU. Table 11.45 [434, 435, 485] indicates the dosages of the drugs to be used in an acute severe attack of status asthmaticus. The clinical characteristics, to be evaluated together with the clinical asthma score in Tables 11.42 and 11.43, are summarized in Table 11.46 [56, 336, 476, 485]. Monitoring of clinical parameters is integrated with laboratory parameters only under a regimen of hospitalization and observation. In emergencies, it is better to treat the child rather than waste time in consulting textbooks or prescribing tests [485]. It should be underlined that because of potential hypoxemia, SaO_2 (which must always be >93%) should be measured regularly. Nevertheless SaO_2 decrease is often an early sign of moderate or severe obstruction. If it is found to be <91%, it is an indication that hospitalization is required [663]. Therapy is summed up in the following points [267, 268, 435, 485, 564, 683, 699, 717] (Fig. 11.54, Table 11.45).

An urgent strategy in a child with status asthmaticus is a controlled ventilation. Over 11 years, 11.3% of 290 PICU admissions for status asthmaticus required ventilation: 13 children (aged 2–18) presented with rapid respiratory failure en route, or within 30 min of arriving to the ED [366]. Pressure-controlled ventilation (PCV) in 40 children with severe respiratory failure was an effective strategy. Four hours after starting PCV, median pH increased to 7.31 (6.98–7.45, p<.005), and Pco_2 decreased to 41 torr (21–121 torr, p<.005), which were

below 7.21 (range, 6.65–7.39) and 65 torr (29–264 torr), respectively. For children with respiratory acidosis (Pco_2) (>45 torr) within 1 h of starting PCV, the median length of time until Pco_2 decreased to <45 torr was 5 h (1–51 h). SaO_2 was maintained >95% in all patients. Median duration of PCV was 29 h (4–107 h), PICU stay was 56 h (17–183 h), and hospitalization was 5 days (2–20 days). Therefore, PCV represents a therapeutic option in the management of such children [554]. Children with rapid respiratory failure had greater improvements in ventilation (significantly shorter) and oxygenation than those with progressive respiratory failure [366].

Status asthmaticus must be treated with IV therapy. Many children are dehydrated due to excessive insensible loss from respiratory effort, hyperdiuresis, and vomiting. Initial therapy must include intravascular volume repletion with normal saline, correction of electrolyte imbalance, and fluid and electrolyte maintenance.

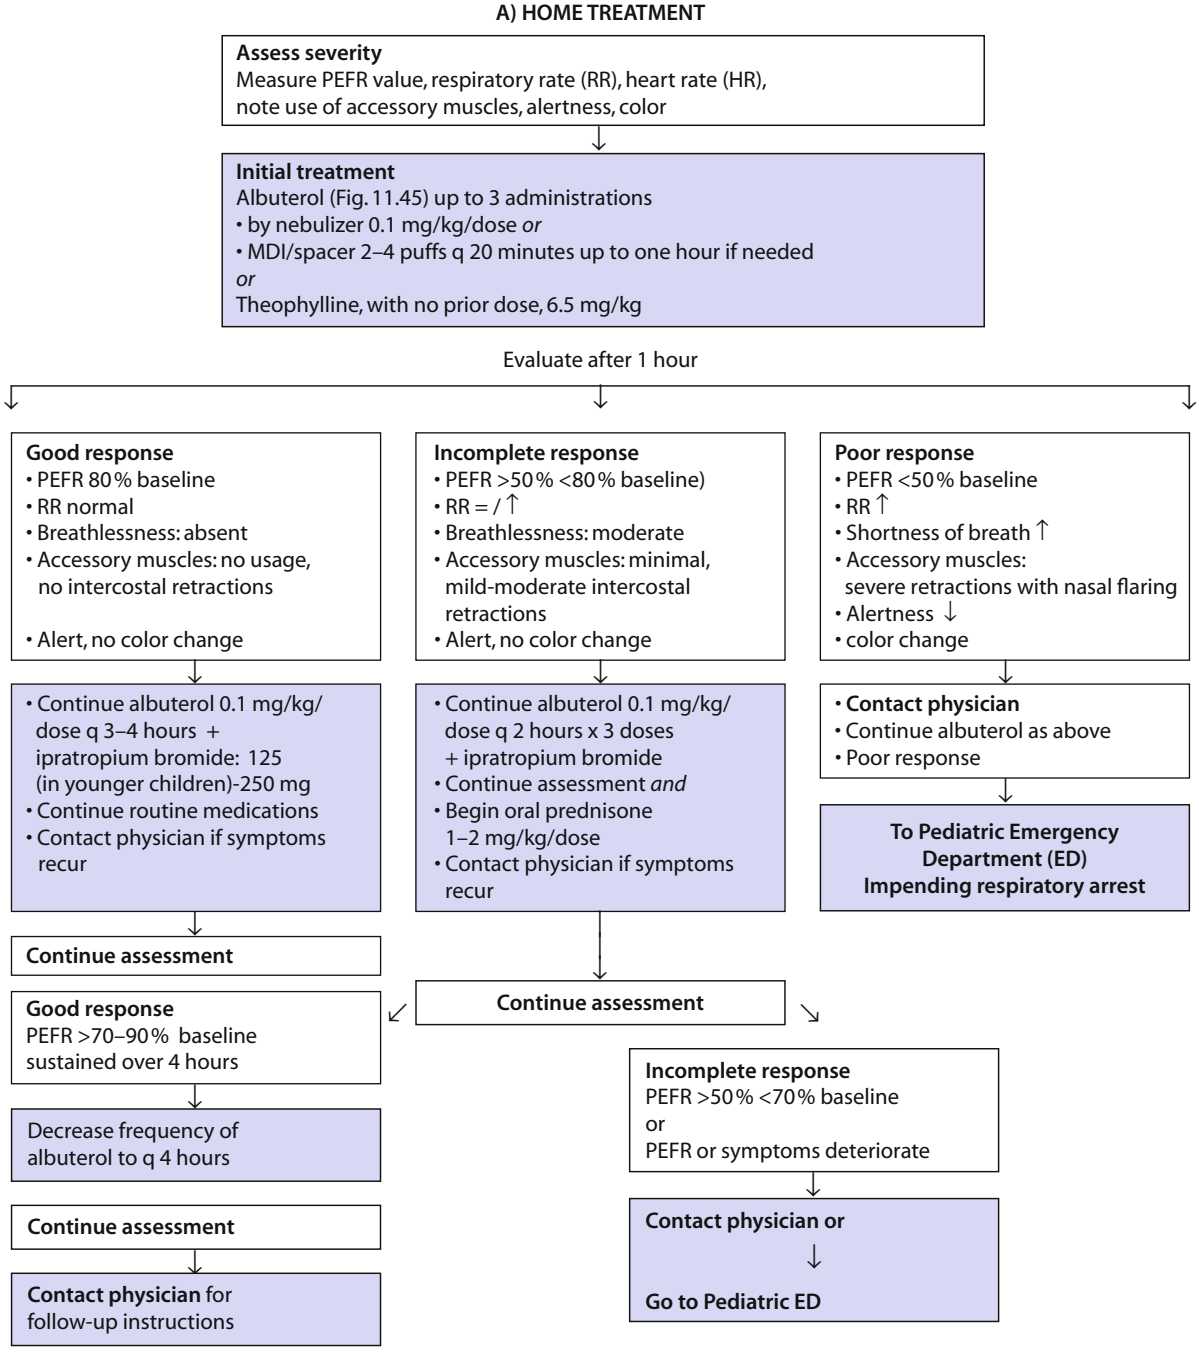

Fig. 11.54. Flow chart for the treatment of pediatric acute asthma exacerbations. **A** Home treatment.

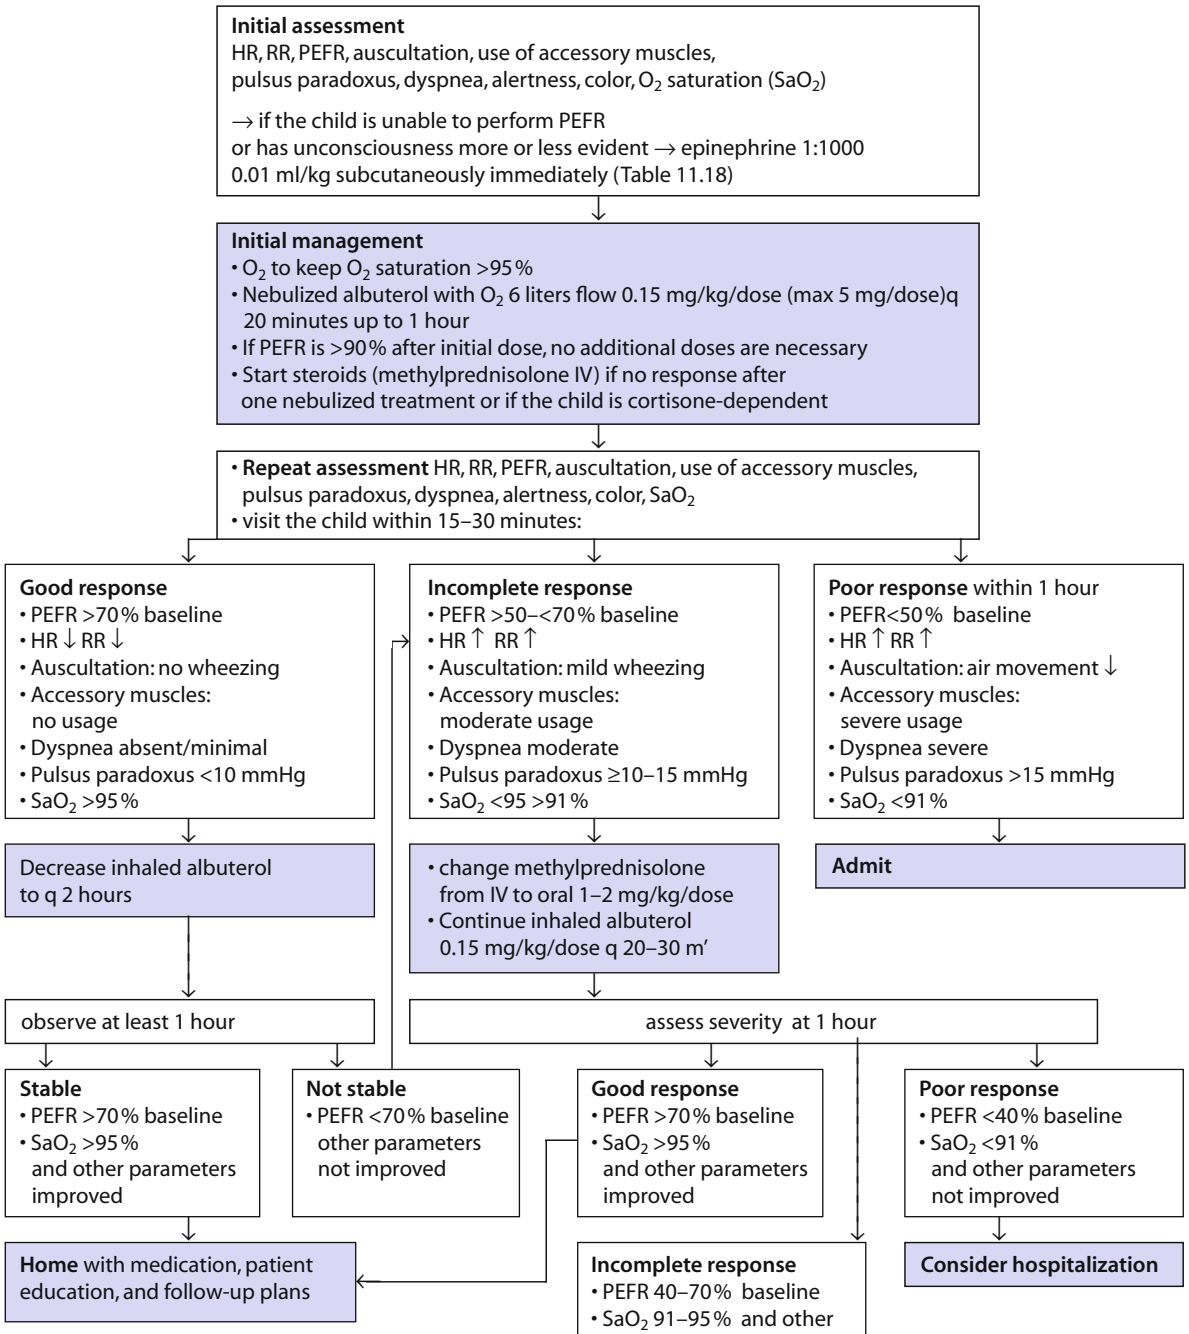
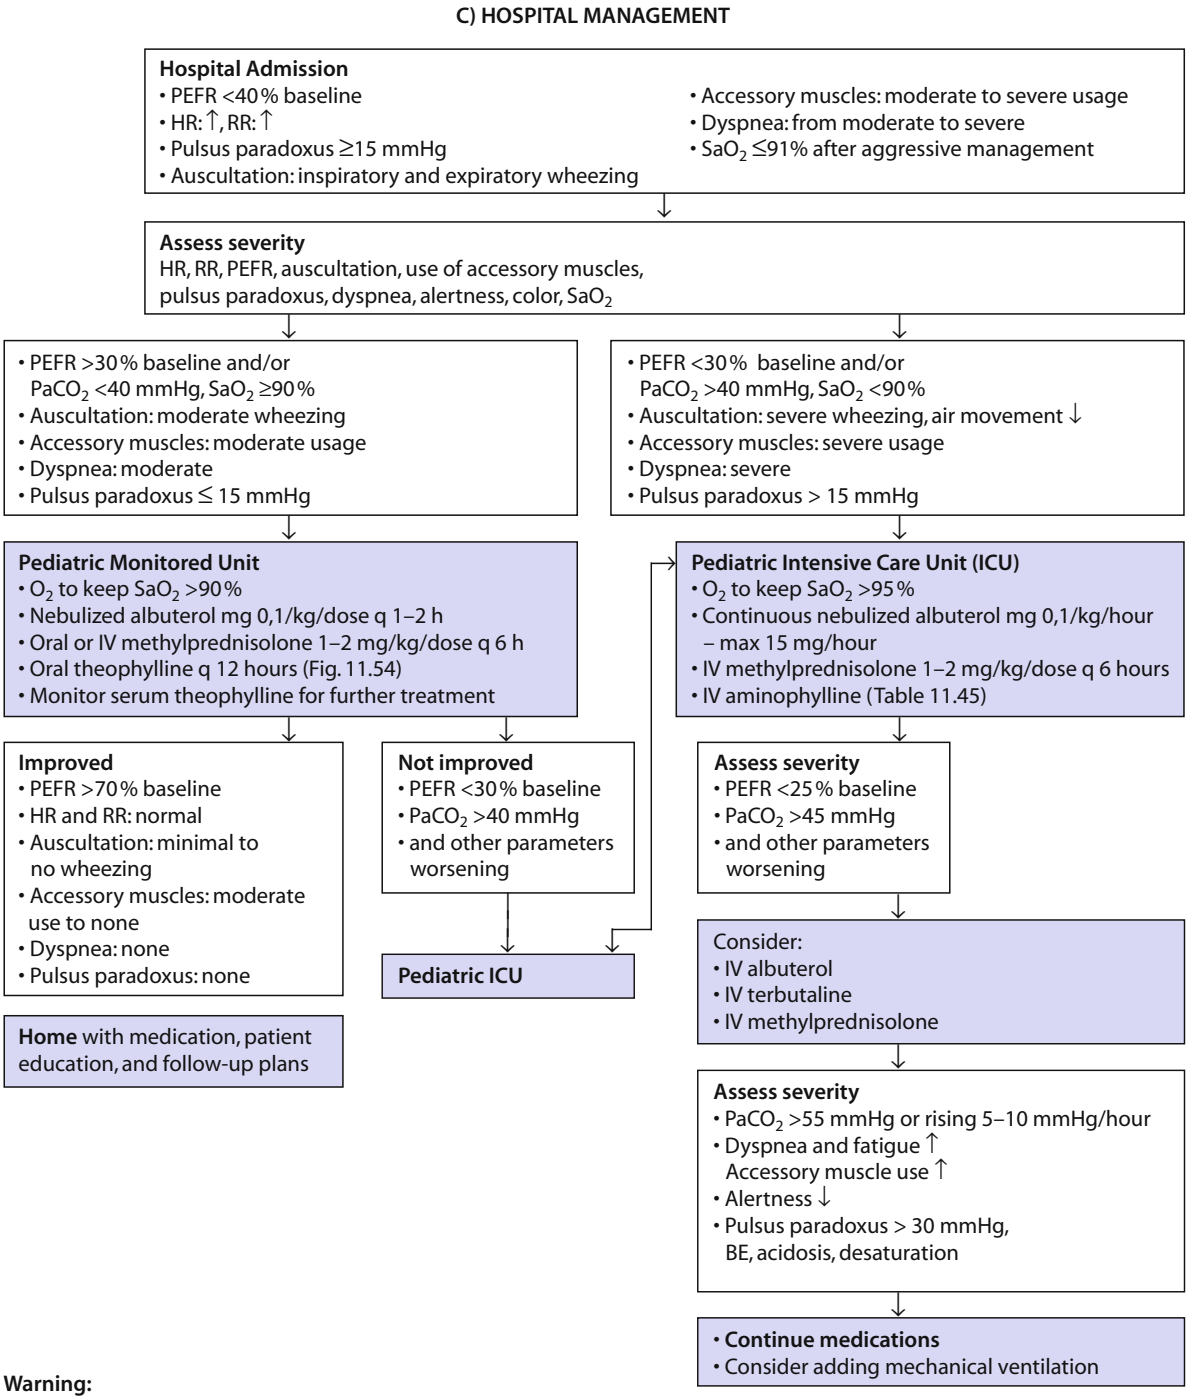
B) PEDIATRIC ED



Factors suggesting hospitalization:

1) Inadequate response to treatment within 1–2 hours from start of treatment
2) PEFR < 40% of predicted or personal best
3) Past history of acute asthma exacerbations, especially if hospitalization was required
4) Presence of high-risk factors (Table 11.40)
5) Prolonged increase in asthma symptoms before the emergency department visit
6) Inadequate access at home to medications and medical care
7) Difficult home conditions, without sufficient monitoring facilities and nursing care
8) Discontinuity of medical care and failure to attend a general practitioner between attacks

Fig. 11.54 (continued). Flow chart for the treatment of pediatric acute asthma exacerbations. **B** Treatment in the ED.



Warning:
In any moment the child presents:
- excessive fatigue /weakening
- confusion or drowsiness
- PEFR is <50% and/or hypercapnia and hypoxia persist or worsen admit the child to ICU

Note: in most cases holding chambers could be substituted for nebulizers to deliver β_2-agonists in acute asthma in the ED [140].
Data from [174, 435–437, 559, 699]

Fig. 11.54 (continued). Flow chart for the treatment of pediatric acute asthma exacerbations. **C** Hospital Management.

Table 11.45. Medication and dosages for pediatric status asthmaticus

Medication	Preparation	Doses
A. Inhaled β_2-agonists		
Albuterol		
Metered-dose inhaler	90 µg/puff	4–8 puffs q 20 min × 3, then 4–8 puffs q 1–4 h
Nebulized solution	0.5 % (5 mg/ml)	0.10–0.15 mg/kg (minimum dose 2.5 mg, maximum 5 mg) in 2- to 2.5-ml saline q 20 min × 3
		Or 0.15–0.3 mg/kg q 1–4 h
		Or 10–20 mg/h in saline nebulized continuously
Terbutaline		
Metered-dose inhaler	200 µg/puff	2 puffs q 5 min up to a total of 12 puffs
B. Systemic β_2-agonists		
Epinephrine	1:1,000 (1 mg/ml)	Tables 11.16, 11.17
Terbutaline	Solution (0.1 %) 1 mg/ml	0.01 ml/kg up to 0.3 ml SC q 2–6 h prn
		Or IV: load 10 µg/kg over 10 min maintenance dose: 0.4 µg/kg/min; increase by 0.1–0.2 µg/kg/min every 15–20 min
C. Inhaled anticholinergic		
Ipratropium bromide		
Metered-dose inhaler	18 µg/puff	4–8 puffs q 2–4 h
Nebulized solution	500 µg/ml	<40 kg: 250 µg (0.5 ml)/dose =40 kg: 500 µg (1.0 ml)/dose q 20 min × 3 doses, then q 2–4 h
D. Methylxanthines		
Theophylline		IV: initial dose (load): in 20–30 ml saline in 20–30 min
		If theophylline serum levels are known :1 mg/kg/IV for each increase of 2 µg/ml of theophylline levels
		If theophylline levels are unknown:
		If the child in the past 24 h *has not taken oral theophylline,* 5 mg/kg of aminophylline IV
		If the child has taken oral theophylline, 3 mg/kg of aminophylline IV
		Maintenance IV doses (5–6 doses up to clinical improvement = stable concentration of 10–12 mg/ml)[a] or: 1–6 months 0.5 mg/kg/h[b] 6 months – 1 year 0.7 mg/kg/h 1–9 years 1.0 mg/kg/h 9–12 years 0.8 mg/kg/h 12–16 years 0.7 mg/kg/h 16 years 0.6 mg/kg/h
E. Corticosteroids		
Outpatient children	Prednisone, prednisolone, methylprednisolone	1–2 mg/kg/day (single or divided doses)
Hospitalized children	Prednisolone	Loading dose 1–2 mg/kg/dose (max 60 µg), then 2 mg/kg per 24 h divided into two doses
	Methylprednisolone	Loading dose: 1–2 mg/kg/dose q 6 h per 24 h, then 1–2 mg/kg/day in divided doses q 8–12 h

See Figs. 11.50 and 11.53.
Data from [434, 435, 485].
[a] Theophylline is indicated in children who have responded to theophylline or who are taking theophylline, have low levels, and are not improving.
[b] Monitor theophylline serum levels (see text).

- *Rehydration:* in general not >1–1.5-fold the normal daily needs, monitoring fluid and electrolyte balance because of potential hypersecretion of ADH and osmolality [336]. Do not exceed the dosage because the high negative pleural pressures during inhalation encourage fluid accumulation in interstitial spaces and therefore the insurgence of pulmonary edema [174]. Provide adequate K^+ chloride (25–40 mEq/l) also because β_2-adrenergics may produce hypokalemia, and fluid supplementation, 300–400 ml/m^2 body surface in the first hour, with 24 h continuation of 200–300 ml/m^2.
- *O_2 treatment* is O_2 humidified to 30%–40% via a face mask or nasal cannula or via a partial or nonrebreather mask at a flow rate of 4–6 l/min not longer than 30–60 min, to keep PaO_2 >85 torr. It must not be excessive to avoid increased ventilation.
- *Inhaled β_2-agonist* with albuterol at 0.15 mg/kg (maximum, 5 mg) per dose should be started every 15–20 min for at least 1 h, even if some improvement occurs after the first inhalation; inhaled albuterol should be continued at the above doses at 30 min intervals over an additional 1–2 h, then at hourly intervals for another 2–3 h, and at decreasing intervals, by nebulization with mask in the very young and with MDI-spacer in older children.
- If *children fail to respond* within 2 h to β_2-adrenergics, start IB via MDI in the doses indicated; it could be added to IV β_2-adrenergics.
- *Continuous infusions of aminophylline* in children who do not respond satisfactorily to β_2-adrenergics only. A reasonable starting point is a bolus of 3–6 mg/kg over 10–20 min, followed by 1 mg/kg/h depending on whether the theophylline level is known or not or the child is following an oral therapy (Table 11.45). Measure the theophylline level as soon as possible; it must be within 10 and 20 µg/ml, considering that 1 mg/kg of aminophylline increases by 2 µg/l the serum concentration [707].
- *IV CSc.* It has been shown the best results by administering a single IV dose: hydrocortisone 4–6 mg/kg/dose or methylprednisolone 1–2 mg/kg/dose, both every 6 h. Continue with inhaled doses. If ICSs are not available the oral type can be taken, but it requires 6 h to reach peak levels. It is recommended that the first dose be administered as soon as bronchoconstriction worsens [683].
- *Measure pH* and *base excess* (BE) to correct acidosis with $NaHCO_3$ = mEq required to be calculated with the formula: BE × 0.3 × kg in weight.
- The use of sedatives to reduce the state of agitation should be employed with great caution because they depress the respiratory centers [272] (see "Death by Asthma").

If monitoring of the above parameters shows a continuous and significant clinical improvement for at least 4 consecutive h, drug doses can be gradually reduced, but monitoring the drugs necessary in case intensive use be made of β_2-adrenergics. Some children can worsen

Table 11.46. Immediate treatment of status asthmaticus

Severe symptoms
Dyspnea associated with severe functional limitation ongoing from >8 h
Response to β_2-agonists poor or of short duration requiring frequent administration <2–3 h).
Child stops sleeping, must sit upright.
Agitation or confusion.
Too breathless to speak: children talk in single words.
Visible accessory muscle retractions.
Pulsus paradoxus: if >20% a severe bronchoconstriction is impending.
PEFR (if available) <50% of best
Life-threatening features requiring immediate treatment without carrying out labor test
Cyanosis, sweating
Paradoxical thoracoabdominal movement
No expiratory rales (silent chest)
Fatigue/exhaustion/drowsiness
Agitation, or reduced level of consciousness
Bradycardia and/or severe RR alteration (<50%)
Young children develop respiratory failure more readily than can be assessed
PaO_2 ≤91%
PEFR (if available) <33% of best (in collaborating children >6 year)

The presence of any of these life-threatening features should alert the doctor.
Data from [56, 336, 476, 485].

Table 11.47. Indications for hospitalization

1. Deteriorating alertness
2. Suprasternal retractions
3. Retractions of sternocleidomastoid and diaphragmatic muscles
4. Pulsus paradoxus >20%
5. PEFR <50% of best
6. SaO_2 <91%
7. $PaCO_2$ >40 mm Hg
8. PaO_2 <60 mm Hg
9. Poor response to treatment in the 1st h
10. Fatigue or exhaustion
11. Insufficient care at home
12. Poor access to medical care

Data from [56, 485, 509].

however, with progressive respiratory failure. Therefore, dependent on their condition, they should be *transferred to the ICU.* Table 11.47 [56, 485, 509] lists data evaluating the relevance and *urgency of hospitalization.* The first item on the list of decisive factors is if the equipment for blood gas level tests or drugs necessary to continue treatment are unavailable.

We recommend that O_2 be administered as needed in a hospital environment and, during treatment and that HR, RR, PA, blood gas level tests and/or SaO_2 and electrolyte levels be monitored [406]. In life-threatening cases, to avoid the need of assisted ventilation [47], terbutaline and albuterol have been injected IV. The first by a bolus of 10 µg/kg administered over 30 min and repeated after a further 30 min, followed by maintenance dose of 0.5 µg/kg/min over 44 h [146], the second by a bolus of 10 µg/kg over 10 min, followed by a gradually increased maintenance dose up to an average of 1.7 µg/kg/min over 36 h [47]. Kelly et al administered terbutaline to children 4.5–14 years old, nebulized continuously in doses of 0.4 mg/kg for an average of 9.4 h, for up to 24 h [288]. Current guidelines [434–436] suggest starting with an albuterol dose of 0.15 mg/kg (minimum of 2.5 mg, maximum of 5 mg) per nebulizer treatment for all age groups. For infants <6 months, half the dose (1.25) can be used if 2.5 mg provoke unacceptable tachycardia. During the first hour of wheezing, 3–4 *albuterol* nebulizer treatments are given every 15–20 min. If there is an inadequate response to treatment, the child is placed on continuous nebulization. Others have shown that doses of 0.15 mg/kg of albuterol repeated every 20–30 min are better than doses of 0.05 mg/kg and both have no side effects, and that children (under careful surveillance) respond more promptly to higher doses [564]. High doses of albuterol, especially in very young infants, are devoid of side effects and can be justified by above-mentioned studies [488]. Therefore, aggressive doses of albuterol (every 30 min) are more effective than those administered every 1–4 h [116]. To achieve positive results, higher doses of albuterol, which are needed because the decreased airway caliber decreases the aerosol penetrance, and the quantity of drug reaching the airways decreases as the child pattern of respiration is altered [607], provided that β_2-adrenergics are nebulized with an appropriate face mask, thus ensuring a more rapid improvement, which either makes it unnecessary to send children to an ICU, or shortens the period of hospitalization [683].

A note to explain the rational behind the use of *theophylline* in severe, life-threatening cases, above all in children [615] who, for anatomical reasons, experience bronchoconstriction more than bronchial obstruction. *Inhaled β_2-adrenergics* may not reach the inflamed bronchus because of severe bronchospasm, not because of bronchus failure to dilate. On the contrary, the theophylline reaches it systemically, performing anti-inflammatory effects (Tables 11.17, 11.18) and producing a diffuse bronchodilation that reaches the bronchi obstructed by edema and mucus [393]. At this point, β_2-adrenergics, inhaled or nebulized, can take advantage of the opening and reach the terminal airways to the point of inducing a therapeutic effect. Table 11.48 [332, 536] compares the use made in 1988 of various drugs in 118 pediatric EDs in the US, compared to data 6 years later [332], to evaluate the effect of 1991 guidelines [435]. It should be noted that the great use made in the US of epinephrine and the marked increase in albuterol (first choice in 95% of cases) and CS use, whose route of administration is not specified. In a survey of 376 directors of ED settings, 80% reported the use of inhaled β-agonists as the initial treatment. Only 44.7% ±2.9% reported the use of steroids if there was a poor response to the initial treatment [121]. Also, in 125 children nebulized β_2-adrenergics in ICU and at home were used in 100% of the cases (Table 11.49) [615]. A subsequent survey of 348 ED directors confirmed the high preference for inhaled β_2-adrenergics (96.5%), significantly more public (24.6%) and community hospitals (17.1%) than pediatric EDs (3.5%) reported the use of SC epinephrine as the first medication, compared to steroids (18.1%) as a routine part of the treatment [121]. However, North American authors have shown that *epinephrine is comparable to inhaled β_2-adrenergics* for its rapidity of action, effectiveness and duration of effect [537]. Also notable is how much easier and more practical it is to use epinephrine in the doctor's office, at the child's home or in a busy ED [536, 750], especially if auto-injectable (Chap. 20). It has been noted that if a visit to the ED is followed by treatment with albuterol every 30 min for 4 h, and by giving prescriptions to continue treatment at home, after 4 h 43% of children are released, rising to 61% if *a dose of oral prednisolone* is added [116]. Also in asthmatics with acute forms and admitted to ED and hospitalized, relapses are reduced by 50% and nocturnal disturbance by 75%, if referral to an asthma specialist is facilitated and treatment continued thereafter, compared to patients treated by a family doctor [750].

The effectiveness of treatment in subjects with status asthmaticus is such that on the 3rd day of hospital treat-

ment there is a significant reduction – correlated with amelioration of bronchoconstriction – of T, IL_2R, HLA-DR cell levels, present in higher concentrations than in normal controls [119]. An intubated child with status asthmaticus was treated with two doses of intratracheal recombinant human DNase (*rhDNase*) therapy, a mucolytic agent used to relieve peripheral airway obstruction. The child was *extubated 26 h after receiving* the rhDNase treatment with no adverse effects [163]. A dramatic sustained improvement followed this treatment in a 3-year-old boy with acute life-threatening asthma in whom 48 h of aggressive therapy had failed [473].

Comprehensive Post-Attack Care

If symptoms evolve towards a concrete improvement, it is suggested that children remain under observation for 12–24 h, monitoring both symptoms and parameters, weaning the child to a drug regimen that includes bronchodilators and steroids, either inhaled or orally, then discharging the child, prescribing therapy for 3–5 days and ensuring that the child is able to follow the inhalatory technique correctly, with a follow-up with the family pediatrician about 1 week after discharge [272, 406, 437], which was positive in 59.8%–74.% of cases [121]. Drugs prescribed at discharge were bronchodilators (95.3%), CSs increasing with age group, and theophylline (21%–34%) [121]. Having achieved remission, the therapeutic strategy continues the drug regimen for at least 3–4 weeks, during which the family pediatrician will check the clinical progress by means of twice daily measurements of PEFR and sending the child to a center for infantile respiratory physiopathology for necessary PFT follow-up [164]. The month-long interval can be usefully spent establishing how the problems related to environmental and pharmaceutical prophylaxis will be managed, and in informing both the child and family how to handle the situation [434], also to work on a plan of action for frequent asthma, which is dealt with in the next section. We underline that in children aged <5, the necessary compliance for PEFR measurement is missing, while the child is at greater risk of a symptom worsening. Therefore attention paid to the clinical parameters (Tables 11.31, 11.34, 11.38 and 11.41) can prove equally valid for defining a post-attack strategy [436]. Given that BHR and/or PFT changes tend to persist for an indeterminate time in the form of chronic coughing, nocturnal asthma, or as a result of physical activity [359], therapy must overcome all of these, before a possible treatment discontinuation can be considered (though not in <2 months), also and above all to ensure the *normal quality of life* [164] recently ensured by omalizumab [342] and formoterol [183] treatment. The family and older children should understand that if asthma is not dealt with decisively and controlled effectively it will eventually become a disease that will render the sufferer an invalid in adulthood [218].

Treatment of Episodic, Frequent, Chronic and Other Forms of Asthma

Treatment of asthma must be personalized according to the frequency and severity of symptoms (Table 11.32). The main points for consideration are [571, 700]:

- Deciding which drugs to use, whether continuously or prn (if required)
- Determining the most suitable means of administering treatment
- Using an MDI suited to the child's age, if a drug should be inhaled
- Making sure that the medicine is working
- Regularly verifying the effectiveness of treatment
- Discussing with children and their family the general lines of treatment
- Listening to the problems that asthma or its management provoke in children and their family
- Keeping a clinical diary in which daily variations are noted

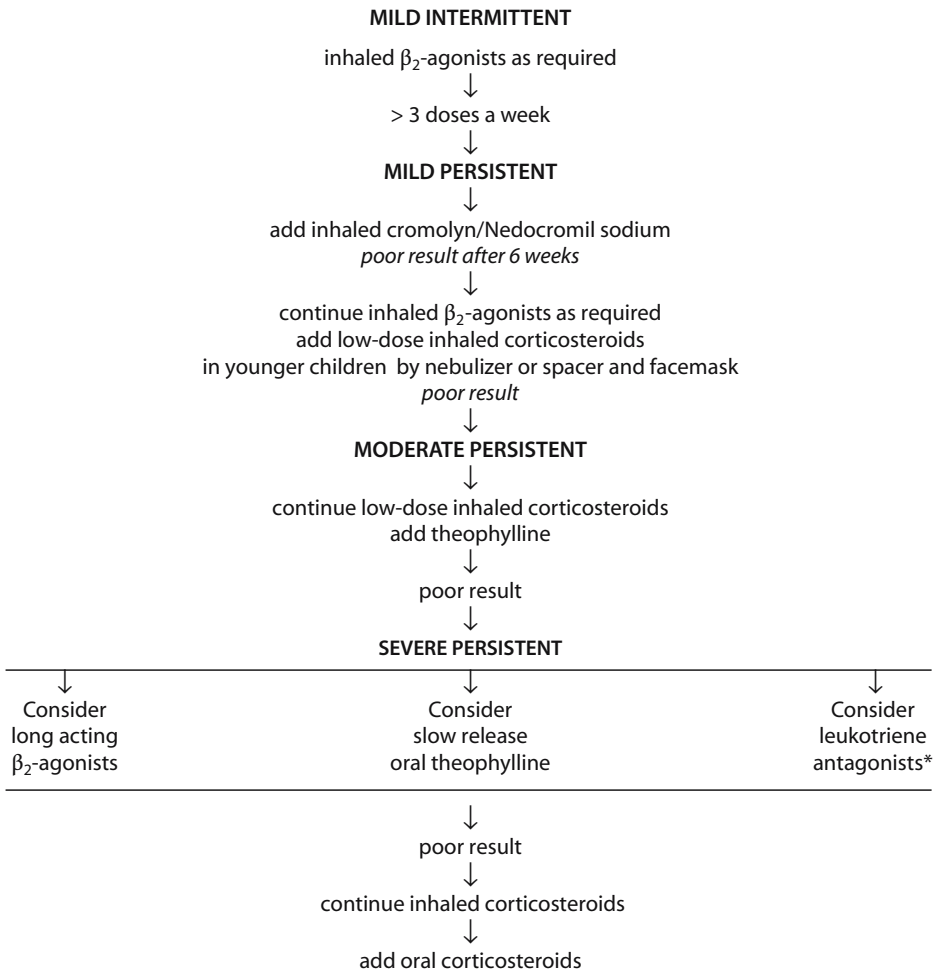
Below, in order of severity are listed the different types of asthma:

1. Episodic asthma
2. Mild intermittent asthma
3. Chronic asthma (mild, moderate, severe) (Figs. 11.55 to 11.58)
4. Administration of drugs at various age levels
5. Specific forms (asthma associated with VRI, EIA, nocturnal asthma, cough variant asthma)
6. Unresponsive asthma
7. Collateral pathologies
8. Complications

Differentiating among these types of asthma is essentially didactic, to better understand the various therapeutic particularities. The possibility of finding the therapy suitable for the control of the symptoms will enable asthmatic children to experience a quality of life that as much as possible resembles that of their healthy companions. From a therapeutic point of view, many treatment alternatives exist, proposed by several authors of proven experience, all of which are usually effective. The problems most frequently met with are represented by asthmatic attacks, by severe forms and by *the day-by-day or maintenance treatment*. We will try to give precedence to the aspects correlated to symptom severity *based on the child's age*. Evaluating these factors separately, even if in practice a certain overlapping between frequent, more demanding forms and moderate, chronic forms is possible, it seems to us useful for ensuring greater clarity.

Episodic Asthma

This is a mild and infrequent form; ≈75% of asthmatic children experience mild episodes of coughing and wheezing every 2 months on average (in relation to season and stimuli), then remaining asymptomatic for



* see Fig. 11.56. Data from [435–437, 699, 700].

Fig. 11.55. Therapeutic algorithm for pediatric mild intermittent asthma: a stepwise approach (step 1)

relatively long periods. They are therefore able to play, attend school and take part in sporting activities without any problems, and usually their sleep is not interrupted by coughing. Prophylactic treatment should be sufficient in most cases. Measurements of PEF in 75% of these asthmatics is usually of no use [700].

Mild Intermittent Asthma (Step 1)

No daily medication is usually required. It is characterized by frequent or infrequent attacks, but of moderate severity, use of bronchodilators prn, persistent airway obstruction not correlated with clinical symptoms, reduction of physical activity, night awakenings by asthma 1–2 nights a month, routine reduction in school attendance. A course of treatment is illustrated in Fig. 11.55 [434–437, 699, 700]. Recommendations for treatment of infants and young children with moderate or severe cases of asthma are based on extrapolations from studies in older children and adults [434]. As can be seen, the first choice of drugs is always for inhaled or nebulized β_2-adrenergics. If results are good, step-down treatment with cromones (see "Prevention"); if insufficient, consider stepping in with ICSs and anti-LT or theophylline [434], associating flunisolide with albuterol inhalation [228]. However, albuterol bronchoprotection lasts <4 h, formoterol DPI at least 8 h in 2-to 5-year-old asthmatic children [441] and bambuterol (once daily dose) [158] (see Tables 11.12, 11.16 and 11.23 for doses). This therapy is recommended in children with persistent cough or asthma. In moderately severe cases, one or two doses should be sufficient. Furthermore, BUD, DPI or BPD by spacers + VHCs as indicated can be used as a good alternative. In children with almost continuous relapses or suffering from chronic asthma and steroid-dependence who are undergoing systematic treatments, we advise ICS once the acute phase of the crisis has been overcome. Given that steroid maximal effects are usually delayed 6 h, it is necessary that children be under control with antileukotrienes, active on immediate and late reactions.

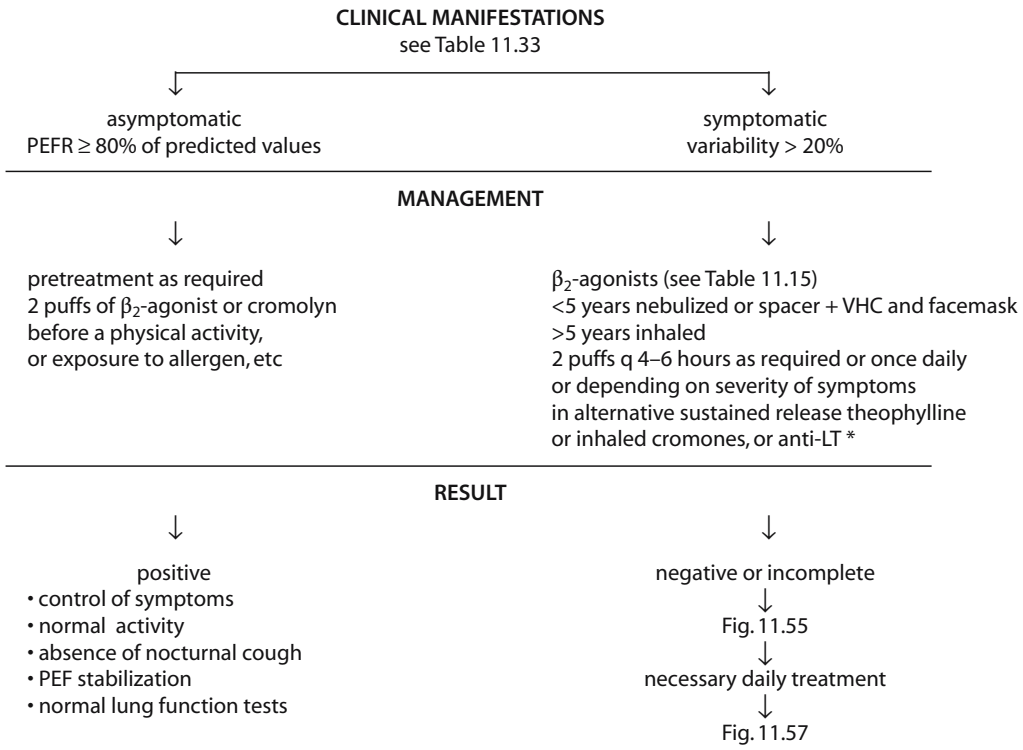
Chronic Asthma

As we have already stated, asthma is an inflammatory process that, beyond the immediate episodes, continues in chronic form as a result of the persistence of inflammatory cells. Usually, chronic asthma is related to children affected with asthma in the first few years of life, but the disease assumes its maximal severity after the age of 5 years. At recruitment the children with severe asthma totaled 8 (11%), but at age 42 the people with severe asthma totaled 33 (47%) with reduced lung function [264]. Generally, the symptoms appear early without an allergic nature being promptly identified, nor proper treatment started. Often, a careful study leads to the discovery of a variety of allergic diseases, for example AR, frequently complicated by *sinusitis*. It is therefore necessary to ascertain its presence, especially in children affected with chronic asthma. Usually frequent symptoms without perceptible periods of well-being are observed, given that bronchoconstriction and effort-induced dyspnea are constantly present, in practice children learn to live with asthma. This form, whose prevalence is 4%–5%, often induces invalidating symptoms, which can be summarized as follows: persistent bronchoconstriction, almost daily symptoms, frequent night-time coughing and limited physical activity [476]. In 37 randomly recruited children with chronic asthma compared to 37 controls with episodic asthma, we noted significant early onset of symptoms, delayed diagnosis, and poorer spirometry results, in addition to a positive personal or FHA, as always a potent determinant of atopy. Especially significant was the greater number of children sensitized to multiple aeroallergens. A strong influence of environmental factors on the development of severe asthma is demonstrated by the significant prevalence of maternal smoke during pregnancy, parental smoke, damp houses, and viral infections. Among the drugs available, we have four possible options: cromones, β_2-adrenergics (even with a long half-life), ICSs, and theophylline in drops or the long-acting type from 2–3 years of age onwards.

Chronic asthma is subdivided into three types, according to whether symptoms are mildly persistent, moderately persistent or severely persistent, each subclass being present in 60, 30 and <10% of cases, respectively [476]. The intermittent form [436], which could be defined as the transitory form between acute and chronic asthma, is considered to belong to the mild forms, to be treated only as needed [437], with four stages: *mild intermittent, mild persistent, moderate persistent and severe* [437]. It should be noted that NIH guidelines (Expert Panel Report 2) tabulate treatment as follows: first-line therapy may begin first with ICSs (low dose), then with cromolyn, or nedocromil as preferred therapy, or alternatively with sustained-release theophylline, or an anti-LT [437], or GINA (global initiative for asthma) guidelines introduce a daily base treatment with CSs, adding cromones only for mild forms and using β_2-adrenergics as symptomatic (rescue) drugs [436]. The Expert Panel Report 2002 believes that a *diagnostic trial* of inhaled bronchodilators and anti-inflammatory medications may be helpful; however, infants consistently requiring symptomatic treatment more than twice a week should be given daily long-term-control therapy, and ICSs should be the preferred treatment [434]. These guidelines have not been confirmed by three longitudinal studies [210, 465, 575], and the Melbourne 37-year longitudinal study *in asthmatic children followed up to adulthood* show no differences between those who did and those who did not take steroids [210], nor has the proposal to introduce CS use from the onset of the infantile asthma been validated, *not even in the mild forms* [465]. The PFT impairment in the group with persistent asthma was greater in those with persistent BHR and in those treated with ICSs [575]. *Cromones and/or theophylline* are important for reducing CS doses [437, 566]. Nor are GINA guidelines productive, since a retrospective study of 175 children followed on average for 8.4 years concluded that, contrary to what the guidelines suggested, starting treatment with cromones and not with CSs improves the outcome, while in the mild-moderate forms positive effects are obtained with bronchodilators [311]. Without doubt, further prospective studies are needed. For our part, we have seen the *positive results of early treatment with cromones,* in agreement with the 3rd Consensus for infantile asthma [700]. One of the tasks of a pediatrician is to strive for a better compliance and quality of life for asthmatic children. There are often reasons for noncompliance to long-term medications when these are numerous, including in adolescence the fear of CS side-effects, a poor understanding of treatment, and a wish to be like one's peers [158]. To our knowledge, one proposition consists of simplifying the treatment program by reducing the frequency of drug administration from twice daily, as usually recommended, to once daily. However, if efficacy is preserved, can prophylactic asthma treatment be prescribed once daily for each drug and for each child, whatever the age, the device and the asthma severity [158]?

Mild Persistent Asthma (Step 2)

Normally, PFT basic anomalies are absent in mild persistent asthma (Fig. 11.56) [435–437, 699, 700]. There are asymptomatic periods between exacerbations, symptoms often follow physical activity, exposure to environmental allergens or respiratory infections, with a decrease in FEV_1 of 20% or less [198]. PEF offers adequate indications, even if in children of 3–5 years the results may be not significant. Symptoms must be carefully checked: coughing, wheezing, difficulty in daily activities or physical exercise, nocturnal disturbance, even if intermittent [589]. Treatment is begun at the first signs of the illness or if PEF measurement is underway, when



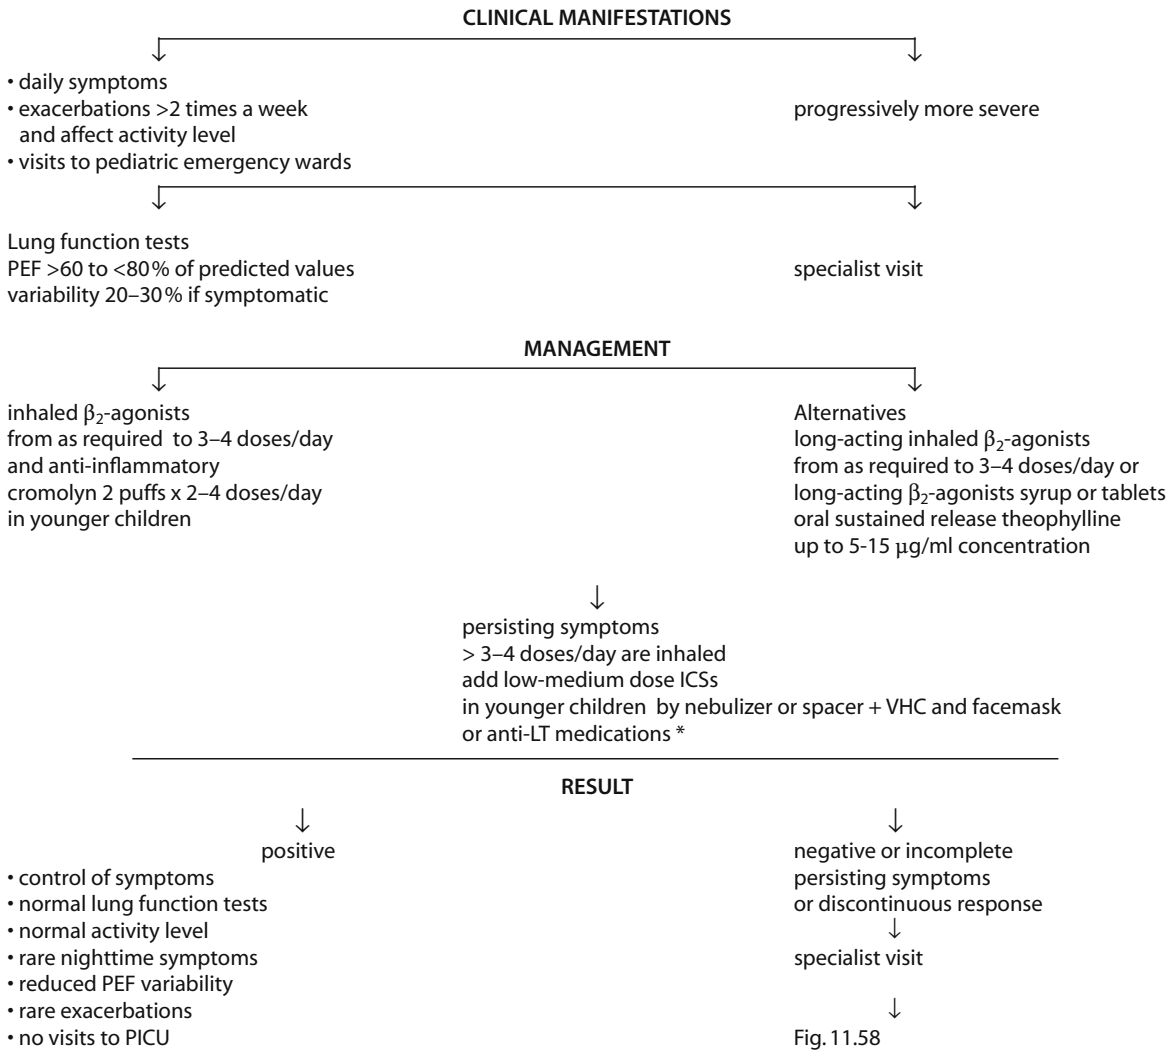
* anti-LT oral administration is preferred by children: montelukast for children aged ≥2, zafirlukast for children aged ≥7, zileuton for children aged ≥12.
Data from [435–437, 699, 700].

Fig. 11.56. Therapeutic algorithm for pediatric mild persistent asthma: a stepwise approach (step 2)

it decreases by 10%–20% [273]. During symptomatic periods, children should be treated with nebulized β_2-adrenergics (Table 11.16), every 4–6 h prn for the duration of the episode, until PEF is stabilized or there is a clear and constant improvement [566]. In children <5 years of age, PEF measurements can be substituted by clinical parameters, such as coughing and dyspnea, while in children >5 years of age, starting a continuous PEF monitoring period at home to evaluate the severity of asthma is suggested [699]. The choice of drugs is less difficult, since response to β_2-agonists is often variable *in young infants*, provided they are used correctly [26]. Inhaled β_2-adrenergics can be used prn if control of symptoms can be coupled with a normal level of activity, absence of nocturnal coughing and PEF stabilization, [697]. If, on the other hand, the condition progressively worsens and β_2-agonists are taken more than twice a week, reaching the point of daily intake dosages or 3–4 times/day, long-acting theophylline or cromones can be introduced. In children ≥2 years we suggest that anti-LT can be considered when inhaled medication delivery is suboptimal because of poor technique or adherence, or BUD which fared well at a dose of 0.25, 0.5, or 1 mg once daily in 359 children aged 6 month to 8 years [290]. If control is missing or incomplete, Fig. 11.57 will be useful to reach the most appropriate decisions.

Moderate Persistent Asthma (Step 3)

Moderate persistent asthma (Fig. 11.57) [435–437, 699, 700] is characterized by two or more weekly acute asthma exacerbations with a 60%–80% PEF decrease and with PFT values up to 20% below existing readings or personal best [198]. For treatment, cromones are considered, which, in addition to their anti-inflammatory action, have the advantage of not being absorbed throughout the system, which renders them preferable to theophylline, remembering that for some cases a long-term prophylactic treatment might be required. If cromones have no effect within 4–8 weeks, the use of ICSs, which have a good anti-inflammatory action, can be started. We have treated with inhaled BUD (200 µg/day) 74 children aged 3.5–5.9 years (mean 4.2 years) and affected by moderate to severe asthma, despite conventional therapy, compared to 71 controls of similar age range and treated with antihistamines. The primary outcome measure was the change in asthma severity, as measured by the mean asthma score during the last 2 weeks of a baseline period and the last 2 weeks of each treatment. The mean difference in asthma score between BUD and antihistamines was: –7.5; 95% CI, –11.70 to –3.29 (p<0.0001). Spirometric data demonstrated a significant improvement. ICSs are suitable for



* for anti-LT medications see Fig. 11.56.
Data from [435–437, 699, 700].

Fig. 11.57. Therapeutic algorithm for pediatric moderate persistent asthma: a stepwise approach (step 3)

children >5 years who take cromones, but who also need β_2-adrenergics 3–4 times a day, or who have nocturnal asthma [476]. Recently, with once daily morning treatment, *monometasone furoate* DPI 440 µg significantly changed FEV_1 compared with BUD DPI 440 µg [117]. β_2-adrenergics, especially those with a long half-life and limited to 1–2 doses a day, are useful together with IB [566]. Long-acting theophylline has the advantage of oral administration. Regularly monitoring its serum concentrations and recording any adverse symptom [198], it proves to be very effective in this form of asthma, as in mild forms [649]. With regular use of these drugs, β_2-adrenergics can be stopped, or retained as part of the treatment only as needed [435]. When prescribing long-term treatment, parents should be informed of the latency time of the drugs being used.

Severe Persistent Asthma (Step 4)

Severe asthma increases the risk of the airways progressing into a persistent and unresponsive airflow narrowing [274]. Children with severe asthma (Fig. 11.58) [435–437, 699, 700], despite appropriate treatment, often display PEF variations >30%–50% and PFT <60% of predicted or personal best, which can worsen during most severe exacerbations [198]. For daily therapy, bronchodilators are prescribed, namely long-acting theophylline and β_2-adrenergics prn, up to 3–4 times a day, in association with CSs [559]. In children 16 months and older [136], ICSs are suitable for anti-inflammatory effects, recurring to oral preparations if problems of compliance or financial difficulties arise. Infants use the more economical formulations *per os* [435, 476] more readily and willingly. Steroids with short half-life are

CLINICAL MANIFESTATIONS
- continual symptoms
- frequent exacerbations
- limited physical activity
- frequent nighttime symptoms
- visits to pediatric emergency department and hospitalizations

EVALUATION OF LUNG FUNCTION
PEF < 60% of predicted values
Variability of 20–30%
with a routine treatment

DAILY MANAGEMENT
short-acting inhaled β_2-agonists
from as required to 3–4 doses/day *
< 5 years by nebulizer or MDI + facemask
> 5 years inhaled:
2 puffs x 4-6 doses/day
in case of need with spacer + VHC
and
antiinflammatory
- low-dose ICSs
  2–4 puffs x 2–4 doses/day
- long-acting inhaled β_2-agonist;
  adding or not in case of need
- cromolyn 2 puffs x 2–4 doses/day
  to minimize ICS dose
  adding or not in case of need
- sustained release theophylline
  (especially for nocturnal asthma)
  up to a concentration of 5–15 µg/ml
  to minimize ICS dose

PEF variability > 20–30%
during severe exacerbations
↓
Consider oral corticosteroids
- < 5 years 5–10 mg tapered to the lowest alternate morning regimen that provides control of symptoms and PEF
- > 5 years the lowest AM schedule is tapered over several days to a week depending on symptoms and PEF

RESULTS
- PFT improvement
- reduced PEF variability
- almost normal activity level
- rare nocturnal symptoms
- reduced incidence of relapses
- little need for relievers
- little need for ICSs
- little need for visits to PICUs
- normal growth and development

* if control is not achieved with 3-4 doses/day consider step up or review the therapy plan: eg adding anti-LT medications: see Fig. 11.56.
Data from [435–437, 699, 700].

Fig. 11.58. Therapeutic algorithm for pediatric severe persistent asthma: a stepwise approach (step 4)

preferred, such as flunisolide = h 1.6±0.35 and BUD = h 2.8±1.1, compared to the 15 h of BDP [633], tapered to the lowest effective single regimen (which provides the same results as that of dividing the administration into four doses) [497] taken on alternate days in the early afternoon (3:00–5:30 PM) [378, 497] to wean to the least undesirable effects, chief among which is that of inhibiting the HPA axis [198, 633]. The ICS dose should be gradually stepped down to the lowest possible doses of medication required to maintain asthma control and perhaps discontinued if a child remains asymptomatic for more than 1–2 months [198, 290, 418, 566, 634]. By following this guide, danger of the baby or child encountering any sort of problem can be avoided; most of the symptomatic benefit obtainable from ICSs occurs by reducing doses of BUD to 100–200 µg/day, with little effect from dose increments [487]. Such lines have been confirmed in a 4-month pediatric trial, which evaluated many varied parameters: BDP achieved the best clinical results, but associated with albuterol and theophylline proved to be most effective in reducing asthma attacks, and in 10 out of 16 parameters that evaluated the most frequent adverse reactions, it registered the smallest rate (albuterol + theophylline the greatest), including the critical points such as asthma attacks and symptoms [396].

All CS-treated children should receive specific medical advice regarding *calcium intake and vitamin D supplementation.* Review treatment every 1–6 months; a gradual stepping down in treatment may be possible and is needed to identify the minimum therapy required to maintain control. If control is not maintained, consider stepping up after reviewing patient medication technique, adherence, and environmental control (M•Plan Asthma Expert Panel).

In conclusion, being the cause of acute and chronic symptoms, infantile chronic asthma should be viewed *a multiform pathology,* whose therapeutic strategy should be based on multiple grounds, that is treating other allergies and eliminating food, environmental and infectious triggering factors, as well as on SIT, which recorded excellent results in asthmatic and rhinitis-suffering children (Table 13.2). The pharmacological choices summarized in Table 11.50 [335, 698, 699] can be recommended, according to age and symptoms. Table 11.51 focuses on the difficulties that can be encountered in the treatment of the very young [472].

Table 11.50. Stepwise and age-related approach for managing children with chronic asthma symptoms

Type of chronic asthma	Younger children[a]	Older children
Mild persistent	Cromolyn/nedocromil sodium or inhaled β_2-agonists with MDI and face mask	Inhaled β_2-agonists as required for symptoms or cromolyn/ nedocromil sodium
Moderate persistent	Cromolyn/nedocromil sodium Inhaled β_2-agonists	Cromolyn/nedocromil sodium Low-dose inhaled corticosteroids Long-acting theophylline
Severe persistent	Inhaled β_2-agonists up to 3 times a day Oral/inhaled corticosteroids	Medium-dose inhaled corticosteroids Inhaled β_2-agonists up to 3 times a day Antileukotriene medications and/or cromones

Data from [335, 698, 699].
[a] Inhaled medications by nebulizer or spacer and face mask.

Table 11.51. Issues in the treatment of asthma in the very young

Recurring wheeze and cough have a typical onset with viral respiratory infections, often without positivity of family history
The diagnosis relies almost wholly on clinical symptoms that may be variable, without the objectivity of pulmonary function tests
Treating young babies with inhaled therapy presents unique challenges due to inappropriate devices prescribed for age and capacity of the child, or inadequate training given to enable the child to use spacing/holding chambers effectively
There are very few controlled studies on asthma therapy and they are often related to older children
The response to bronchodilators is variable, at the first place remains epinephrine in case of need
The younger the child is, the more conditions there are that may masquerade as asthma

Modified from [472].

Administration of Drugs at Various Age Levels [485, 566, 698–700]

- In *babies and infants up to 1 year of age* (Fig. 11.59), it is unnecessary to treat mild and infrequent symptoms, especially if there is no interference with daily life, night-time sleep and behavior. Often the infant whistles as a result of the greater elasticity of the bronchial tree or for intercurrent VRIs, thus rendering CS use difficult [620]. If the child is well and growing normally, only follow-ups are necessary. If symptoms intensify, even if infants show little therapeutic response to β_2-adrenergics, treatment with spacers/nebulizer and face mask is called for, with recourse to cromones or to theophylline if the desired effect is not achieved. If the condition deteriorates, intervention with IB and/or CS by nebulizers and/or with epinephrine, and O_2 therapy in emergencies is suggested.
- In *children 1–3 years of age* (Fig. 11.60), inhaled drugs must be administered by nebulizer and face mask. If symptoms are mild, satisfactory results can be obtained with β_2-adrenergic and/or theophylline. If attacks should become of moderate intensity, with persistent wheezing and coughing, the use of associated cromolyn/nedocromil sodium is advised, making use of CSs in the case of a further deterioration of the symptoms, always by nebulizer and face mask and orally in the minimum effective dose, on alternating days in single-doses.
- In *children 3–5 years of age* (Fig. 11.61) and with mild asthma, β_2-adrenergics may be useful. If coughing and wheezing persist and inhaled bronchodilators fail to elicit a significant improvement, prophylactic treatment with cromolyn/nedocromil sodium or, alternatively, theophylline is called for. The combined use of β_2-adrenergics and MDI + spacer CSs should be reserved for when symptoms become acute again. A further worsening will require a CS treatment in the forms indicated, such as inhaled BUD at a total dose of 800 µg daily, which significantly improved symptom scores, asthma exacerbation rates, PFTs, and BHR in asthmatic children aged 2–5 years [440]. Anti-LT medications should be introduced as symptoms step up.
- In the *age range from 5 to 18 years* (Fig. 11.62), the differences separating cases of mild and medium/moderate asthma should be observed, alternating or combining the drugs and modifying the routes of administration. As can be seen in the figure, if asthma is severe and persistent, recourse to CS use is necessary. Asthma improves only in 41.3%–47.5% of cases (Table 5.15) (the earlier the age of onset, the greater the risk of relapses) [575], so in most adolescents who are not SIT-treated, delivery of medical care may also be challenging [476]. Anti-LT medications should be introduced as symptoms step up.

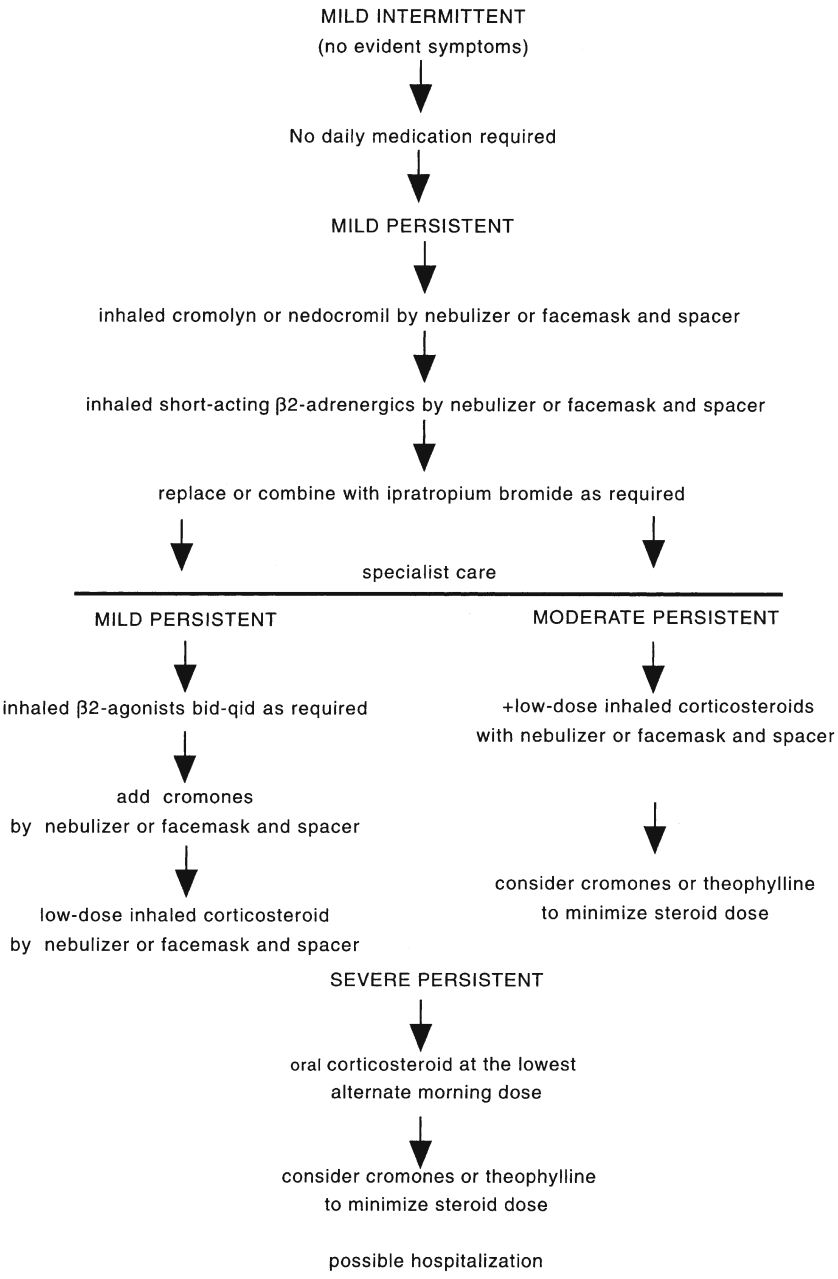


Fig. 11.59. *Algorithm for management of asthma in children aged 0–1 years:* a stepwise approach. Inhaled medications are delivered by pMDI/with spacer + VHC with face mask or nebulizer. Face mask devices should be close fitting, especially if a valved spacer is used, with nebulizers the mask should be held as close fitting as practicable without undue disturbance. Any gap reduces the dose dramatically. (Data from [485, 566, 698–700])

In conclusion, the necessity for a targeted use of the diverse drugs should be recognized in relation to the characteristics of age-related clinical symptoms. Cromones are effective even in the very young, and advantage can be taken of their preventive abilities and of their use in combination with albuterol + flunisolide, all inhaled. Anti LT-medications should be introduced as symptoms step up in alternative with SIT. A three-part *respiratory diary* should be kept, divided into symptoms (asthma, EIA, malaise, cephalea, abdominal symptoms, insomnia, nervousness, etc.), prevention and therapy, noting in addition PEFR and school absences. Symptoms are classified on a graded scale as follows: 1 intermittent, 2 mild, 3 moderate, 4 severe.

Specific Forms of Asthma

Asthma Associated with Viral Respiratory Infections

URTIs make patients vulnerable to asthma development or recurrence and potentially to the establishment of chronic forms. The considerable impact on the asthmatic child who experiences irritations more frequently, often more coincident with VRIs than with the numerical increase of mites in the air or in mattresses, should not be forgotten. For this reason, as virus trigger relapses, CS preventive administration caused a significant decrease in the number of wheezing days, attacks, ED visits, and hospitalizations [60].

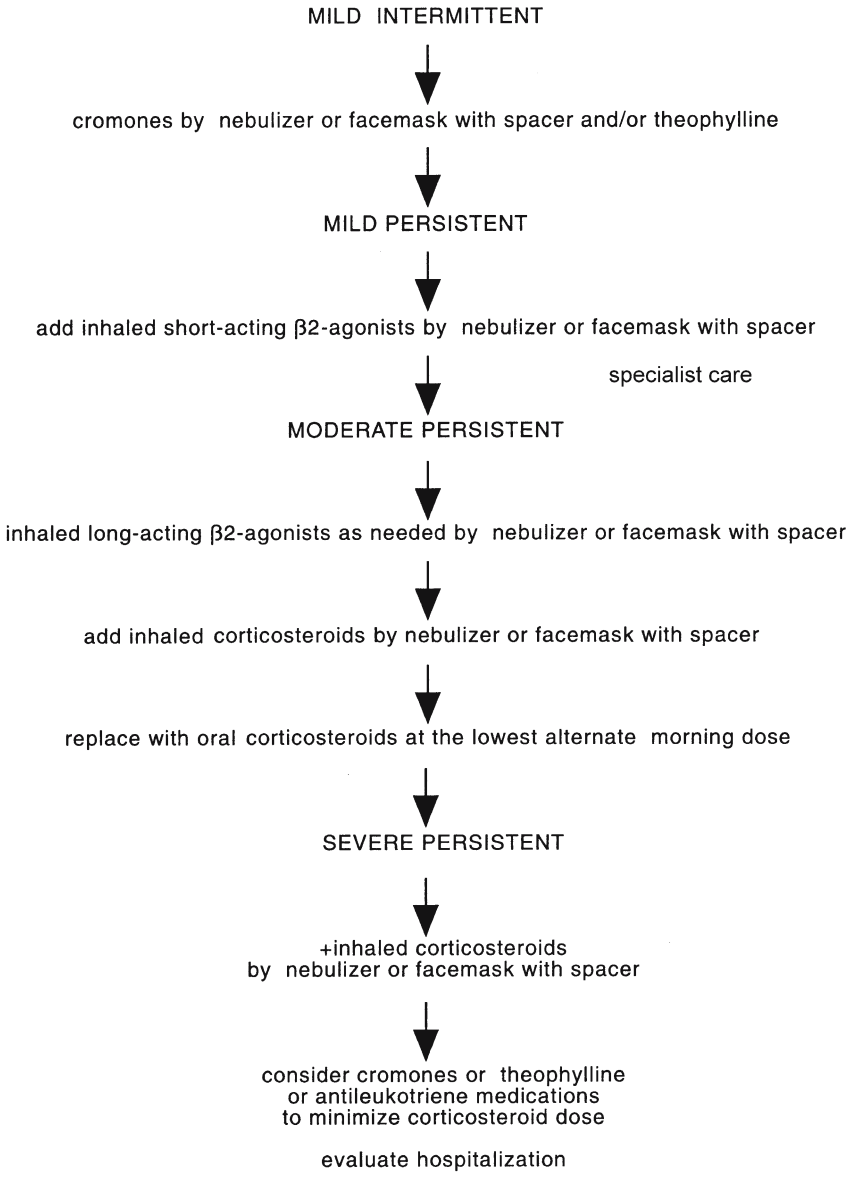

Fig. 11.60. *Algorithm for management of asthma in children aged 1–3 years:* a stepwise approach. Inhaled medications are delivered by pMDI/with spacer + VHC with face mask or nebulizer. Face mask devices should be close fitting to the face, especially if a valved spacer is used; with nebulizers the mask should be held as close fitting as practicable without undue disturbance. Any gap reduces the dose dramatically. (Data from ([485, 595, 698–700])

Exercise-Induced Asthma

The fact that parents often make no mention of their children's EIA seems more closely related to the objective difficulties of not being able to recognize EIA than to its absence; but its occurrence in 63 % of 273 subjects is relevant, the greater part of whom asthma had not been diagnosed [446]. Whereas EIA diagnosis should be made with urgency, given that it can be prevented, thus allowing the child to enjoy a *normal social life*. Children depend on taking part in sporting activities for correct mental, social and physical development. Parents, often easily troubled by the parallel between exercise and the onset of an attack, often constrain their children to limit, or even stop, these activities, forcing them to adopt a sedentary and solitary life, with negative repercussions. It is therefore indispensable that parents be instructed on the significance of and how EIA can occur, since EIA worsens the prognosis of asthma [214]. The cornerstone on which diagnosis relies is history. Typical EIA appears in asthmatic children, but it may also become clinically manifest with exercise in children experiencing a subclinical degree of obstruction [214]. EIA diagnosis was possible in 88 children of 12.4±3.2 years by employing a treadmill test in which the speed was gradually increased, with positive results in 73 %; 35 of 36 boys complained of pain and dyspnea, but not of wheezing, entirely reduced after albuterol inhalation [720]. Significantly, without these tests, 64 % of those affected [542] and, often, also 40 % of children complaining of thoracic pains [720] remain undiagnosed. Correct identification therefore is essential. Sporting activity must represent in an asthmatic infant or child – as it does in a healthy one – an appreciable part of life, and the child should be made aware of his or her *virtual competitiveness even with healthy subjects* [214]. EIA can be effectively pre-

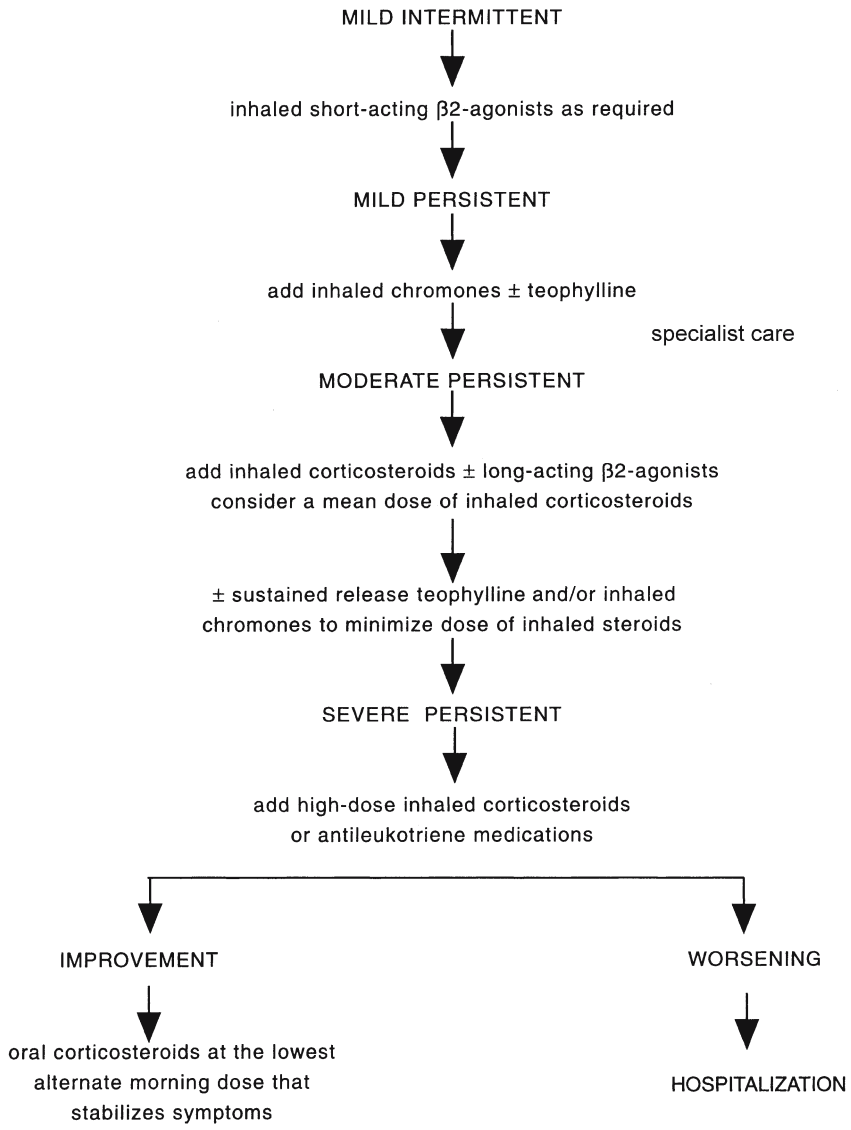

Fig. 11.61. *Algorithm for management of asthma in children aged 3–5 years:* a stepwise approach. Inhaled medications are delivered by pMDI/with spacer + VHC with face mask or nebulizer. Any gap reduces the dose dramatically. (Data from [566, 698–700])

vented both by warming up, as well as by inhalations of β_2-adrenergics about 5 min, or cromones about 15–20 min before beginning the activity [476]. This has proved effective in 70 % of cases [39]. Studies in children have yielded significant results: after administration of *cromolyn/nedocromil sodium,* 10 or 4 mg, respectively, with MDI [113, 134, 451], there was a significant lowering of FEV_1 compared to basic tests [134, 451]. Cromolyn remained effective for up to 4 h and procaterol up to 8 h after the test, though with reduced effect [419, 450]. *β_2-adrenergics* are preferred due to the better clinical results obtained as well as to their duration of action. Despite recognized shortcomings in the treatment of moderate to severe asthma, cromones are preferred for limited or zero incidence of adverse effects [603]. In more resistant cases, β_2-adrenergics can be associated with cromones: both offer equal protection to children after only 30 min. Formoterol in doses of 9–12 µg has an action lasting 6.5 h in reducing 50 % of symptoms, while albuterol in doses of 200 µg lasts for 1.5 h. Using halved doses, albuterol was shown to be equal to formoterol [247]; therefore effectiveness is linked to a dose of 100 µg/puff. Salmeterol has a lasting action of 12 h [343] and bambuterol even more [159]. *Long-acting theophylline* administered to 12-year-old asthmatics 2 h before the challenge prevented both IAR and LAR (8 h), thereby covering an ample time period [270]. Among *CSs*, BUD is indicated in modest doses; 53 % of the maximal effect is reported in children with doses of 200 µg/day, and 83 % with doses of 400 µg/day, registering significant differences with 100 µg/day [487], and parallel results with doses of 400 µg/day [216]. Often, children forget preventative medical measures or are reluctant to be seen while they are taking the medication. In such cases, oral bambuterol [158], salmeterol [343], formoterol [441] and theophylline [270], anti-LTs [482],

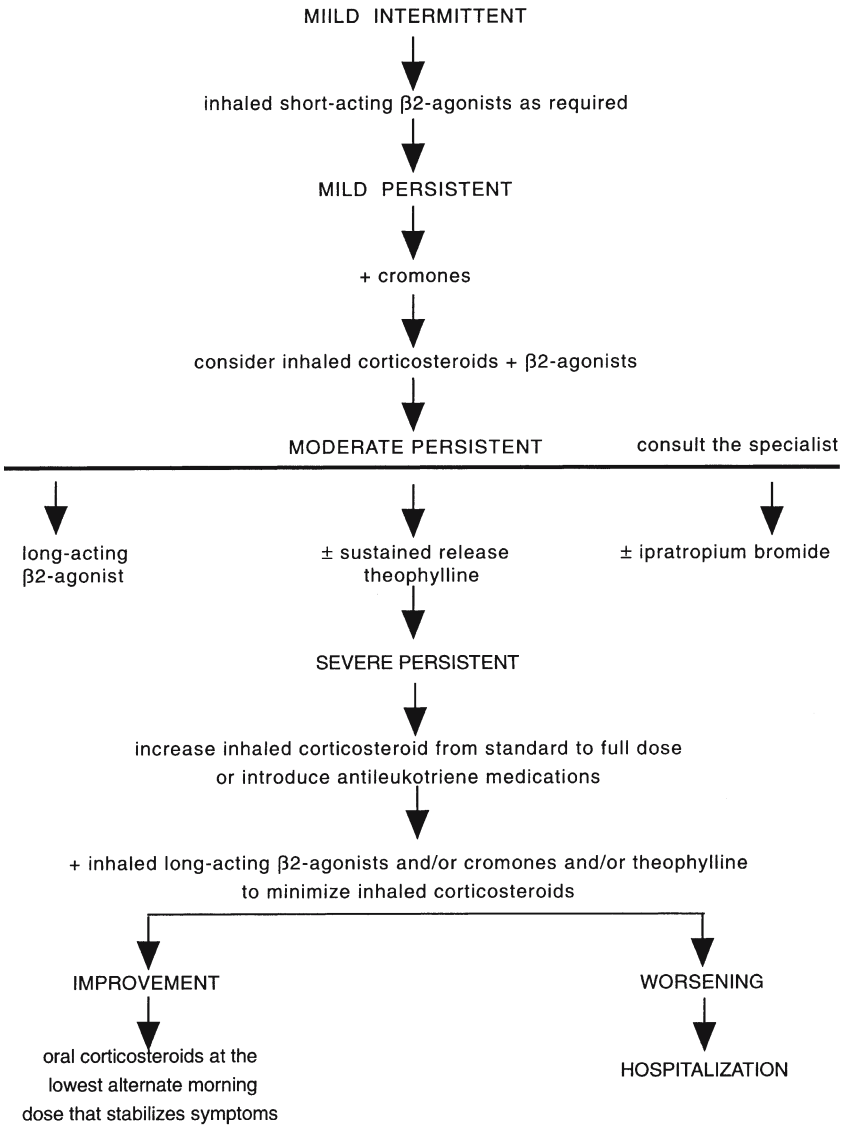

Fig. 11.62. *Algorithm for management of asthma in children aged 5–18 years:* a stepwise approach. (Data from [566, 698–700])

levo-cetirizine, and oral bambuterol [158] are useful. As an alternative, the following measures are suggested:

- *Before beginning* whatever form of activity, choose a warm, humid environment: free running in cold and dry ambient air causes much greater bronchoconstriction than swimming [214].
- *Nasal respiration* is preferred because, as noted, it humidifies the inhaled air and reduces the cooling effect on the airways.
- Do a *gradual warming up* exercise almost to the point of provoking a bronchospasm, thus delaying an asthmatic attack about 2–3 h.
- Alternatively, wear *a mask with a filter* that retains heat and humidity and that has proved to be effective [618].

Usually, the pharmacological pretreatment is followed by a warm-up period of 10 min requiring light effort. This is followed by intermittent training, which alternates more demanding exercises with lighter ones; and finally a training period (for 6–8 weeks, 2- to 3-fold a week for 45–60 min) with a submaximal work-load in such a way that HR does not go beyond 160–170 beats/min in prepuberal children and 180 in the younger ones [214].

Another frequently encountered problem is the child doing sports. Commonly, asthmatic children seem to be unwilling to take part in sports, but this presumed inaction toward sports in general is often caused by the limitations imposed by the EIA of which they suffer [617]. As for athletes in all branches from sport, including those taking part in athletic competitions, EIA is not a contraindication for children. Not all children are natural sportsmen, but all children should have a chance to share sporting with companions. Usually limitations imposed by asthma on daily childhood activities are not recognized until the child begins to participate, and then gains interest in physical activity [617]. In addition to pretreatment, children should avoid activities in

places with excessive air pollution and/or high concentrations of allergens; if all conditions are optimal, warm-up exercises can begin [419]. Swimming, ball games, relay races and dancing are examples of useful activities in the training and rehabilitation of children and adolescents with EIA. We suggest that asthmatic children and adolescents be helped to participate with others in the most suitable sports (in asthmogenic ascending order): swimming, water polo, canoeing, long-distance skiing, volleyball, free dance, speed walking, baseball, basketball, etc. When treatment does not control the problem, then further diagnostic evaluation should be done to rule out conditions other than EIA, and all children with cough, shortness of breath, or history of recurrent bronchitis should be followed to make sure that the correct diagnosis is made and to make sure that treatment is effective [482].

Nocturnal Asthma

Cough is the distinctive characteristic of asthma and nocturnal symptoms may be so dominant and bothersome as to disrupt the sleep of both the child and family. Much has been written on the condition, but a significant trend was found with more nights awakened in the past 4 weeks and with reduction in the quantity and quality of sleep and daytime sequelae of nocturnal asthma, including missing school, educational problems, and parents missing work or other usual activities [147]. Nocturnal cough generally reflects PEFR diurnal variations. Usually, examining at what time the episodes occurred, it can be seen that they do not always coincide with PEFR minimum level. Cough is more frequent about 2 h after the child goes to bed, and then again before awakening in the morning, and not between 3:00 and 5:00 AM when PEFR is lowest, reaching its nadir around 4:00 AM [32]. BALF studies in adults with nocturnal asthma have shown an extraordinary correlation: at 4:00 AM, BALF was found to contain a significantly greater number of lymphocytes, eosinophils, neutrophils and epithelial cell than at 4:00 PM [379]. This data shows that BHR is greatest at 4:00 AM compared to the corresponding afternoon hour, in correlation with FEV_1 and PC_{20} equivalent variations [380]. Such are the effects of *circadian rhythms*, linked to the hypothalamic clock, which is linked in turn to the solar clock, with night and day alternation, which is why night-shift workers register the best test scores during nocturnal hours [32]. Another potential factor is the *nocturnal body cooling* independent of ambient T, correlated with clinical evidence that small reductions of body T provoke cold-induced bronchoconstriction [378]. Relative to allergen influx on circadian rhythms, it has been noted that exposing mild asthmatics without nocturnal asthma to an allergenic burden, they all responded with IAR both in the daytime and night-time, but also showed LAR after the evening test [364]. The connection existing between nocturnal asthma and circadian reductions in histamine concentrations is cited as evidence of a so-called permissive effect on mast cell histamine release, a mechanism that could explain the asthmatic attacks recurring over several consecutive nights following a single exposure to provoking allergens [32].

The relationship between nocturnal asthma severity and PFT during the daytime is still the subject of study, in that as yet no conclusive results are available. A controlled study in children has confirmed that nocturnal asthma is not dependent on an increase in bronchoconstriction [665]. Concerning treatment, the drugs used for daytime treatments, especially inhaled bronchodilators, do not last long enough to cover the night-time as well [364]. In these patients, a dose of long-acting theophylline at the time of sleeping is generally effective [83, 760]. On the basis of previous analysis on theophylline and circadian rhythms, a treatment with equal doses at regular intervals will be able to increase theophylline serum levels at night compared to daytime levels [760]. The persistence of nocturnal symptoms may indicate the necessity of including an anti-inflammatory treatment [379]. This option generally seems to be unnecessary since at precisely 4:00 AM the drug blocks the flow of inflammatory cells in BALF, an effect mediated by LTB_4 [316]. If theophylline, and inhaled β_2-adrenergics and steroids taken as late as possible do not control night-time symptoms, it will be necessary to resort to the usual therapy for day-time asthma. In children, slow-release terbutoline is more effective than inhaled β_2-agonists in preventing nocturnal asthma [398], while ICSs are more effective and less harmful if taken between 3:00 and 5:30 PM, as noted above. A pre-eminent position might be held by formoterol [183], salmeterol, bambuterol [159], and long-acting antihistamines may ensure overall night-time symptom reduction, which of course do not offer the anti-inflammatory potency of theophylline [760].

Differential Diagnosis. Nocturnal asthma might identify those children at risk for severe exacerbations caused by lability of airway function, total IgE levels, changes in clinical symptoms and need for albuterol, which are more likely to predict nocturnal awakening than a decrease in PEF [626].

Maximum environmental prevention is essential against dust mites and pet epidermal derivatives, particularly in children allergic to dog or cat when there is a large amount of dog or cat allergen in the environment also rich in Der p 1 [626]. The bulk of evidence stresses the time the child spends at home; the largest part of which is sleeping, commonly spent for the most part in this environment (see Chap. 24). The influence of environmental factors also relies on the threshold of bronchial reactivity in hyperreactive subjects that is further reduced at night, not related to airway obstructions, but to fluctuations of circadian rhythms [380]. In some cases, the possible association with GER, often occurring during night-time because of the lack of opposition

by gravitational forces and, by means of a reflexive obstructive mechanism stimulated by gastric juices, could also be critical [221]. Furthermore, GER could increase bronchoconstriction by activating a vagal reflex (see "Collateral Pathologies"), but the links with nocturnal asthma are not yet clear [398], also because of a lack of precise correlation between esophagus acidity and altered respiratory function [170].

Cough Variant Asthma

A general summary of the many causes of persistent coughing is given in Table 11.36. This is considered to be a mild form of asthma that is frequently unrecognized, resulting in inadequate treatment. Persistent coughing is a form of asthma that is not always well defined, which, according to recent data, is commonly found in all age groups as a variant of clinical asthma and presents symptoms that frequently result in asthma escaping detection and correct classification. At least one-third of asthmatics suffer from chronic cough [741] and among 10,063 asthmatic children, 785 (7.8%) had cough variant asthma [100]. Several groups of children with and without wheezing [306, 472, 741] and aged <18 months [279] were kept under observation. With the meta-analysis of the data collected from these studies [151, 306, 455, 472, 653], we have ascertained that the risk of developing asthma is statistically very significant (p=0.0001) and we agree with those authors who have defined it as *hidden asthma*.

Regarding the pathogenesis, the cough depends on the following [151, 306, 455, 472, 653]:

1. Upper airway obstruction where cough receptors are more numerous
2. Respiratory difficulty due to peripheral airway obstruction where receptors are scarce
3. Use of anti-cough medications, potentially in relation to cough receptor hyperresponsiveness
4. Possibly a higher wheezing threshold, apparently with no difference in BHR.

In children with classic asthma as well as in those with the variant form, a marked FEV_1 reduction has been noted, as though there was an increased bronchoconstriction.

Symptoms may be summed up in a few points [741]: symptoms reminiscent of a mild form of asthma with chronic, persistent, nonproductive cough that causes interference with sleep, vomiting, and interrupted school attendance, exacerbated by airborne viral infections, physical exercise and inhaled cold air [279].

For diagnostic purposes, the algorithm of Fig. 11.63 [279, 472] can be followed. Moreover, chest objectivity is scarce; PFT and BPT can be normal and the only diagnostic confirmation is the positive response to bronchodilators [741]. However, since the prevalence of risk factors (atopy, FHA, and allergy) are similar to classic asthma, it is not easy to diagnose those children who, subsequently, have wheezing [472, 741]. Among the 785 children, only 1/3 had a correct diagnosis [100]. Above all, differential diagnosis is needed (Table 11.36), and atopy may distinguish groups of coughers from groups of wheezers [395]. The natural history is highly variable: 9%–75% of children (on average 40%–50%) develop full-blown asthma over 6–96 months [279], while a number of cases not easily quantified (about 50%) evolves toward a disappearance of clinical symptoms. In two groups of children aged 5.7 (mean) [653] or 7–15 years [306] to 54% [653] to 55% [306] developed classic asthma. Interestingly, asthma-positive children developed cough variant asthma at a young age [653]. For example, GER may be the cause of chronic cough and BHR [170]. In children with clinical wheezing the methacholine PD_{20} test significantly decreased as these children developed wheezing [306]. On the other hand, 83% of a group who were SPT+ to inhalants and asthma-like night cough and worsened by exercise, was found to have improved at follow-up 2 years later, while 25% developed recurrent wheezing [348]. In 93% of cases, these children enjoyed the benefits of antiasthmatic therapy [151, 279]. To achieve satisfactory control of the disease, it is also necessary to eliminate the triggering mechanisms.

Unresponsive Asthma

Some infants, children or adolescents continue to suffer from asthma that is either greater or lesser in severity, despite the apparently appropriate treatment they are undergoing. This could be caused by various factors (Table 11.52) [476]: inappropriate doses of medication, poor child compliance, and inability to regularly follow the treatment. A more uncommon cause is a variety of atypical outdoor antigens to be considered in all children with nonresolving chest disease or unresponsive asthma [137]. It could also be the result of objective elements related to asthma severity requiring the continuous use of steroids, especially if elevated doses are needed [633], as well as GER [179]. From a pathogenic point of view, this could be a result of anomalies of the CS receptors (CR) (Table 11.22), whether for an IL-induced reduced linking ability [23] due to a receptor irreversible reduction or because different T subpopulations are active, which, in resistant subjects, are more activated as they have an increase in CD25 and HLA-DR [131] or because of different CR links to DNA [23].

A cohort of 103 entrants aged 9–17 suffering for years from poorly controlled severe asthma and admitted several times, were hospitalized on average for 75 days to rationalize their treatment [624]. After a year, follow-up visits, admittance to hospital as well as days requiring hospitalization, visits to EDs or doctors' offices for acute asthma were found to be significantly reduced, with an obvious amelioration in 82% of the hospitalized chil-

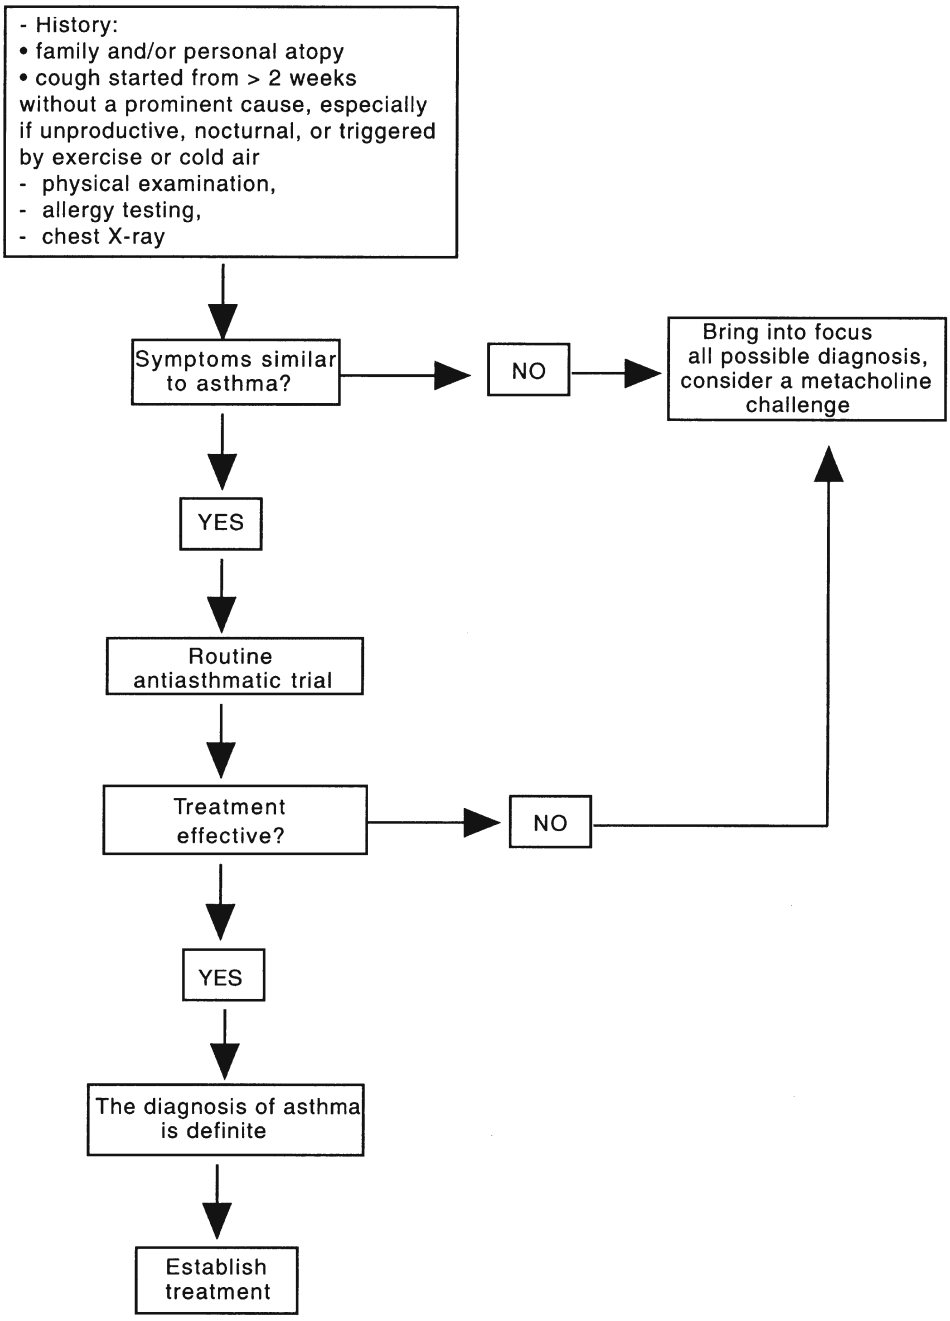

Fig. 11.63. Algorithm for the diagnosis of cough variant asthma. (Data from [279, 472])

dren [624]. On the other hand, children with similar clinical characteristics did not gain any benefits from treatment at a hypoallergenic center [489]. New horizons could be opened by high-dosage IVIg treatment (2 g/kg/month) on steroid-dependent children. After 6 months, doses of oral cortisone for the maintenance and control of asthma exacerbations were reduced 3.2-fold, with an equal reduction in PEFR, clinical score and SPT results [388]. The only doubt is that the sample of this study was not very representative: IVIg treatment could be appropriate since in severe chronic asthma there is a deficiency of one or more IgG subclasses, which respond favorably to IVIg treatment [468]. The effect could also be due to the correction of steroid-induced hypogammaglobulinemia [253]. A trial with recombinant IFN (rIFN) in a group of children with analogous dependency did not prove effective [46], although rIFN reaches the airway epithelium [276]. In adolescents with unresponsive asthma, only theophylline proved to be effective [707]. Use of methotrex-

Table 11.52. Apparent failure of therapy: possible causes

1. Inefficient inhalation technique
2. Lack of confidence in efficacy of the drug
3. Difficulty with the method of administration
4. Poor child compliance
5. Introduction of prophylactic drugs without a clear-cut indication
6. Difficulty with the timing of administration
7. Psychosocial factors
8. Complications (aspirin intolerance, gastroesophageal reflux, etc.)
9. Inappropriate therapeutic intervention (no SIT prescription, cough medicines, antibiotics, etc.)

Modified from [476].

ate and cyclosporine in the pediatric age raises motivated doubts [365], as they provoke toxicity at the pulmonary and hepatic level and blood alterations as well as nephrotoxicity and hypertension [131].

The collaboration of both children and parents is of primary importance to make a treatment successful. In recent years several *educational programs* have been proposed. We have mentioned the relevance of psychotherapeutic and psychosocial factors in the whole spectrum of treatment for pediatric asthma. We believe the intervention of a specialist in this area to be particularly appropriate and productive. On the other hand, a group of pediatricians has devised a program aimed at improving the quality of life of children, with particular *emphasis on educating the family,* who received basic physiopathological information and were followed by a specialized team who tended to the cleaning of the environment, in addition to participating in meetings aimed at ensuring maximum compliance with the prescribed therapy. At the end of the follow-up, an overall improvement was noted in all clinical and psychological parameters [708]. An analogous program should be centered on the following points: an informative meeting, distribution of preprinted forms to assist in the recognition and treatment of acute attacks and *follow-up visits every 2 months.* At the end of the program, the disappearance of ED visits, the better understanding by parents of the measures to be taken during acute episodes and a greater confidence in their own ability to effectively handle their child's disease are necessary.

Collateral Pathologies

GER may be one of the possible contributing factors in any child with recurrent and persistent respiratory complaints, so evaluation for GER should be considered in infants with persistent wheezing [170]. Children with GER-associated cough often show signs of BHR, and therefore the presence of GER should be suspected when faced with persistent wheezing. Symptomatic or functional GER therapy also appears to be necessary for the possible complications related to nocturnal asthma. The basic principles are:

1. Small meals, but more frequently, with food-thickening agents for bottle-fed babies
2. Avoid eating and drinking between meals and 2 h prior to reclining
3. Avoid excessive intake of lipids
4. Keep the head elevated, in a prone position on a surface inclined 30° adopting an anti-Trendelenburg position. To this end we suggest placing pillows (10–15 cm depending on the child's age) to raise head of the bed and keeping the child upright by lifting the upper part of the body with foam rubber supports or air cushions

Especially in young children, early diagnosis and antireflux therapy in cases with GER-related respiratory complaints can result in significant improvement in symptoms. Drugs heightening lower esophageal sphincter pressure are used, for example domperidone 0.1–0.2 mg/kg/ 3- to 4-fold a day 20 min before meals or metoclopramide 0.1 mg/kg qid by monitoring side effects. If esophagitis is present, antacids, H_2-receptors, or in severe cases, omeprazole or lansoprazole are indicated. During follow-up visits to the age of 4.5 years, in 25% of infants (age, 4–11 months) asthma treatment was necessary [170]. Omeprazole (0.3–1.0 mg/kg daily) was effective in 78 children. After 8 weeks of therapy, rebounding was reduced by 66%, heart burn by 56%, vomiting by 33%, abdominal pain by 64% [132]. The use of H_2 antagonists (to impede the production of gastric acid) such as ranitidine 5–10 mg/kg/day divided into two doses for 8 weeks as an attack therapy, to be subsequently halved during the maintenance phase (in the evenings for 6 months), is justified in the presence of GER-induced disease, documented by endoscopy. We suggest making PFT control before and after antireflux therapy [170]. The outcome over 1–4.5 years of follow-up was excellent; only one patient required further asthma medications [170].

Finally, asthmatic symptoms present in children with FA (Table 9.12), the numerous triggering foods (Tables 9.18, 9.19) and pseudoallergy from additives (Chap. 10) should not be neglected.

Complications

The clinical situations which can complicate asthma are pulmonary and extrapulmonary [41].

Pulmonary Complications. Atelectasis can be either segmental or subsegmental and often involves the middle lobe. In the absence of immunological deficiencies or of aspiration of foreign bodies and with negative results to the sweat test, even though having undergone regular treatment, hypoxemic children affected with

middle-lobe syndrome can have frequent relapses, or cough, wheezy breathing or dyspnea persistency, etc. [336]. Using fiberoptic bronchoscopy and a count of BALF cells, a study on 3.3-year-old asthmatic children showed the presence of pathogenic bacteria in 47.6% of cases, re-evaluating the role of infections [610], often favored by malformations and, in 11.5% of cases, by GER [336]. In these children, the possibility of underlying asthma must be suspected, especially if faced with a documented parenchymal thickening [481]. In a group of 56 asthmatic children, only 5 of 63 episodes had physical symptoms of middle-lobe syndrome [577]. This was the case of a 7-year-old boy with intubated status asthmaticus complicated by refractory mucus plugging and atelectasis [163]. Atopy is present in 35% [577] to 38% of cases [336]. The right middle lobe is most commonly involved due to anatomical factors, which facilitate its obstruction, further aided by the combined action of bronchospasm, edema, mucosal thickening, and mucus plugging, with the possible complication of bacterial infection. It follows that the bronchus tends to twist with hyperinflation, resulting in a partial occlusion with repercussions on the middle lobe [41]. Atelectasis and hypoventilation are also sustained by the particular relationships of this lobe with the others, which are not ideal for ensuring a collateral circulation of alveolar gases [41]. It is not clear if the occlusion of the right middle lobe is more prevalent among females [41, 481, 577] or males [163, 610]. The boy was successfully treated with two 10-mg doses of intratracheal rhDNase (see "Treatment of Status Asthmaticus") [163].

Pneumomediastinum presents itself as a sudden complication in 5% of children with status asthmaticus [554]. The most common cause in children is asthma [93], but it is not a characteristic of severe asthma and rarely is manifest before the age of 2 [336]. The only exception is an 18-month-old girl who also had subcutaneous emphysema [211]. Paroxysmal cough and bronchospasm superimposed on hyperinflation, or related to atelectasis, pneumonia, structural weakness, intermittent positive pressure breathing (IPPB), cause air to rupture alveolar bases and spread along vascular sheaths, consequently causing *pulmonary interstitial emphysema*. This may lead to severe cardiovascular insufficiency with reduced venous return, cardiac output and blood pressure [41]. If the air makes its way to the mediastinum and reaches the pericardium, one has auscultatory findings of a crackling sound synchronized with heart beats (Hamman's sign), pathognomonic of pneumopericardium. In other cases, air, through the fascial planes, may escape into the subcutaneous tissue of neck, shoulders and axillae, releasing the mediastinal pressure [41]. Diagnosis is made following tachycardia, retrosternal pains that spread to the arms and neck aggravated by breathing and sometimes by swallowing [336]. However, the association with severe hypoxia, tachycardia, metabolic acidosis, and high ventilation pressures indicates clinically significant tension in the mediastinum [93]. Pneumomediastinum generally resolves spontaneously within a few days, 6 in the girl or 1–5 days in 5 asthmatic children [211], meaning that ambulatory treatment is usually appropriate. Management consists of treating the underlying cause, rest, analgesics, and simple clinical monitoring [93].

Pneumothorax is the rarest complication of acute infantile asthma, which can, for example, also become present following paroxysmal coughing or as a result of IPPB. It should be suspected in cases when the child suddenly worsens together with signs of hyperphonesis and reduction of the murmur of the affected side [41]. If it is not widespread, is self-limiting, but in case of pneumothorax tension, it provokes respiratory breathing difficulties and continuous aspiration is necessary [313]. Pulmonary infiltrations are frequent radiological findings, but they do not require urgent interventions. Conversely, total pulmonary collapse can be provoked both by the severity of asthma as well as external incidental factors [41].

Extrapulmonary Complications. Generally, extrapulmonary complications are rhinitis, sinusitis and secretory otitis media that interact with asthma, but see Chaps. 12 and 15 for the appropriate treatment. Nonetheless, *sinusitis* (whether acute or chronic), common among allergic children, can accompany the worsening of asthma or forms of difficult asthma [334], whereas suitable therapy reflects positively on asthma (Chap. 15).

Other Complications

Other complications are more or less frequent and diverse according to whether the asthma is acute or chronic (Table 11.53) [584]. The most frequent compli-

[a] Associated with status asthmaticus.

cations are bacterial infections, especially in asthmatics <5 years, acute and chronic asthma and viral infections, to which asthmatics are particularly susceptible. Another possible complication is vasopressin excessive production (*inappropriate ADH secretion*): such levels are high in patients with severe asthma, independent of natremia, probably as a result of the effect of severe asthma on pulmonary circulation. Vasopressin levels fall parallel to patient improvement. Since during an asthma attack hyponatremia can occur, in case of hospital admission BE must be carefully monitored as well as electrolyte levels, and the subsequent parenteral fluid administration must be handled accordingly [41].

Death by Asthma

For a long time asthma mortality was low: only during the first half of the 20th century was it observed that it could be fatal in children [623]. Starting in the 1960s, a few English authors noted a sudden increase in the mortality rate among asthmatics, attributing the cause to the β-adrenergic isoproterenol, the use of which was discontinued though the doubts had not been clearly proved [479]. The pharmaceutical industry introduced new β_2-adrenergics on the market, but in the 1970s, other scientists from New Zealand spoke out against the most widely diffused of these: fenoterol. These authors said that the problem was not due to the drug's direct toxic effect, but rather to its abuse because it provided immediate relief [326]. Both isoproterenol and fenoterol are relatively nonselective potent full agonists with both greater long-term and immediate adverse effects than other β-agonists. Likely the regular use of these agonists led to worsening asthma control and their overuse to treat life-threatening asthma attacks caused an increased risk of death resulting from adverse cardiac effects in the presence of severe hypoxia [569]. In the US, high-dose fenoterol and isoproterenol were not approved for use. In effect, after the ban on the drug, the mortality rate among 5- to 34-year-olds fell from four to <1 case/10^6 [480]. Consequently, albuterol was given preference as it was less dangerous according to New Zealand scientists [738] since fenoterol prescription was associated with an increased risk of death compared to albuterol [608]. We have prescribed albuterol without noting adverse effects and a case–control study recognizes that such alarm was unjustified [738]. Recent studies have instead documented that mortality rates decreased, while sales of ICSs increased [628, 630], as well as of β_2-adrenergics [331]. Some ecological studies conducted in various countries state that the introduction and sharp increases in the use of ICSs correlate to important reductions in the asthma death rates, whereas other cohort or case–control studies indicate that ICSs might not prevent asthma death [628]. An analysis of 96,258 UK asthmatic patients has confirmed in vivo that regular use of ICSs is associated with a decreased risk of asthma death [331].

Increase or Decrease in the Mortality Rate Due to Asthma

Despite the progress made in the diagnosis and therapy of asthma, since 1980 the mortality rate is again on the increase at the rate of 6.2 ± 1.2% a year, especially among 5- to 14-year-old children [710]. As can be seen in Fig. 5.19, the increase in the world population (1985–1987) places Israel in the first position, followed by Finland and Denmark, but if the rates in the 5- to 34-year-olds in 1987, compared to the level in 1980, is calculated, Australia ranks first, followed by Singapore and New Zealand, whereas Israel is in ninth place and Finland and Denmark are absent [569] or in the last places (Table 5.17). These rates in patients with severe asthma are markedly greater than mortality rates in asthmatic patients in the general US population, which can be estimated at 0.02% if the death rate is 1.5×10^5 and asthma prevalence is 3%–5% [595]. After a gradual decline in asthma mortality rates in the 1960s and 1970s, rates have increased progressively in the US during the past 2 decades. In most other Western countries, the rate of asthma mortality decreased during the 1990s after progressive increase through the 1980s (0.36×10^5 in some European countries vs 0.47×10^5 in the US. The underlying reasons, including the role of management, will require further investigation if strategies are to be implemented successfully to reduce asthma mortality rates [29]. In a PICU, a 6-year study resulted in an 8.9% incidence of acute severe asthma, while all pediatric admission totalled 1.9% [464]. However, the marked underestimation, varying between 36% and 127% for 5- to 34-year-olds, should be noted, results from a position common to other European countries with the highest levels [375]. *Contrary to the statistical findings, beginning from the 5th year*, an epidemiological study has established a mortality rate among 11- to 14-year-olds of 0.34×10^5 (Tables 11.54, 11.55) [190, 192]. The inclusion of 45.5% of 13- to 16-year-olds and of *32% of 1- to 4-year-olds* is very significant [190] (p=0.0006). In another cohort [192], the death rate among 1- to

Data from [192].

19-year-olds dropped and among 15- to 24-year-olds doubled, with a male prevalence in the former (55% of cases) and of females in the second group (59%) [190]. Underdiagnosis is more common among females; therefore the cases of death seem to be more frequent precisely in the groups that statistically appear to be least at risk, that is the 15- to 34-year-olds, 5- to 14-year-old females [14] and children 1–4 years of age in general [190].

Examination of Possible Causes

Tables 11.56 [80, 145] and 11.57 [67, 403, 579, 623] indicate the possible causes of a worsening of the prognosis, including so-called self-management and possible undertreatment [623]. This assumption is based on the fact that asthma is a very common disease, implies a substantial impairment in children's quality of life and requires challenging medical interventions and treatments often accepted by children reluctantly [375]. Moreover, the deeper understanding of asthma by patients, along with the undeniable positive aspects can, in some cases, give way to *a loss of the doctor–patient relationship*, which on the contrary is indispensable [67]. Among other frequent disadvantages of *self-management* is the improper use of some drugs, particularly β_2-adrenergics [569]. Continuous drug dependency occurs, which is reflected negatively on the quality of life and involves a condition of *undertreatment*, since the patient does not use, or misuses, those drugs that are needed in his or her case [478]. Chronic underuse is also attributable to a false feeling of safety occasioned by masking the effects that systematic use of medications has on symptoms [109]. Thus, on the one hand a masking or an underestimation of the underlying inflammatory process can occur, so that when a sudden emergency materializes, the use of ICSs and/or cromones is delayed [67, 375]; on the other hand, the rapid beneficial effects on clinical features prevents the patient from realizing that *hypoxia worsens* [296], dangerously postponing a doctor's visit. Undertreatment increases death cases, since the moderate reduction in mortality is related to the progressive increase of ICS sales [596, 628, 630]. It is recommended to closely follow subjects who have experienced fatal crises or near-fatal attacks [326].

Table 11.56. Features of children at risk for asthma death

Early onset of asthma, especially in the 1st year of life
Severe episodes:
Asthmatic episodes frequently requiring hospitalization
Increasingly severe airway obstruction persistent all day long
Respiratory insufficiency requiring mechanical ventilation
Hypoxic seizures associated with asthma attacks
Nighttime asthma in rapid progression
Attacks precipitated by foods
Unperceived severity of attacks
Weaning medications, especially oral CSs after exacerbations
Excessive β_2-agonist use neglecting CSs during acute episodes
Steroid dependence with an increase in oral or inhaled CS doses
Inadequate medical and asthma care during hospitalization
Psychological disturbances, overt depression, self-treatment of asthma

Data from references [80, 145].

For example, in Australia, the government has been engaged in distributing guidelines among doctors for treating asthma [598]. A correlation between the increase in both death and asthma prevalence has also been hypothesized; nevertheless, in some countries the mortality rate has diminished, despite the increase in prevalence [598].

Subjects at Risk

Epidemiological studies have shown that in addition to the age factor, the following categories of pediatric patients are particularly at risk (Table 11.57):

- Children in a home where *family interference is dominant.* A paradigmatic case of late referral is that of a 5-year-old male whose parents had objected to steroid treatment and had even hesitated 5 days in taking him to hospital [464].
- Adolescents suffering from chronic asthma and from a recent episode of acute asthma, who frequently *do not regularly follow treatment* for a variety of reasons [478], whose family rarely looks after him or her or on the contrary whose supervision has been rejected [326].
- *Adolescents who do not go to their doctor* and do not follow their therapy, with periodical relapses of status asthmaticus as a result of *undertreatment* [595], only occasionally undergoing therapy with insufficient doses

Table 11.57. Patterns of asthma death in children and adolescents

Risk factors

A. Onset of asthma before 3–4 years of age, especially in the 1st year of life

B. Age between 10 and 20 years of age

C. Generally severe asthma or near death episodes:
   a. Past history of severe asthmatic attacks
   b. Frequent admissions to hospital or emergency wards in the past year or
   c. One or more emergency department visits for asthma in the past year with probable intubation and/or mechanical ventilation

D. Insufficient patient education from the physician

E. Poor patient collaboration

F. Problems arising from self-treatment:
   a. Improper perception of airway obstruction
   b. Decreased use of prescribed medications
   c. Lack of adherence to asthma therapy
   d. Blunted perception of asthma

G. Poor family support for ongoing and acute care

H. Family history of atopy

I. Increasing use of short-acting β_2-agonists

J. Use of three or more antiasthmatic medications

K. Active and passive smoking

L. Respiratory infections

Contributing factors

1. Telephone prescriptions
2. Poor compliance with long-term treatment
3. Discontinuity of treatment or medical care
4. Psychosocial factors
5. Failure of family (and physician) to recognize severity of the attack
6. Delays in hospital admission
7. Undertreatment during the last attack: delays in instituting an appropriate treatment, no use or inappropriate use of CSs

Fatal attack

a. Delay in seeking care
b. Failure to recognize severity of deterioration
c. Excessive reliance on bronchodilators
d. Insufficient use of systemic steroids
e. Unclear criteria for initiating treatment of exacerbations

Negative effects of sedatives during acute asthma

1. Sedatives mask the agitation that is usually a sign of hypoxemia and delay an adequate clinical evaluation of progressive bronchial obstruction or of response to therapy
2. Sedatives suppress both ventilation and cough

Prevention strategy

A. Physicians should emphasize to parents and/or children the necessity of initiating medication to be taken at the onset of symptoms and of prescribing rapidly effective medications

B. A maintenance therapy should be followed on a regular basis, with peak flow readings test and PFTs checked by frequent visits to determine the first symptoms of airway obstruction

C. An inadequate response to bronchodilators should advise to initiate prednisone therapy

D. Parent and physician nonrecognition of asthma severity is often the cause of delays in care during the attacks and in planning admission to an ED

E. Physicians should ensure patients and/or parents of his (her) fully availability

F. Such patients should have home epinephrine for rapid use and require Medic-Alert bracelets

Data from [67, 403, 579, 623].

[377], to the point that the prescribed drug serum levels are between 0 and subtherapeutic levels [43]. This is especially alarming when these drugs are ICSs: their regular, uninterrupted use significantly reduces the risk of death from asthma by at least 50%. Instead, treatment interruption is associated with an almost fivefold increase in asthma deaths [630], likely because the *CS effect disappears after 2 weeks* [593].

- Young patients under proper observation, who are faced with *sudden attacks, progressively becoming worse* to the point of respiratory insufficiency and death within 20 min to 3 h [190], probably because of the effect of a heavy allergenic load or the intervention of other highly negative factors, but who did not avail of help quickly enough [409].

Risk Factors

It happens, however, that children and/or adolescents do not fall into this classification and die as a result of insufficient management of asthma [623], or for excessive delays in the final moments [190]; 80% of the cases studied were preventable. They can be divided as follows:

- A long period of *undertreatment,* or of scant medical care (64%)
- *Inadequate care* in the final stage (45%) or delays in asking for help, or insufficient physician knowledge of emergency treatments

Some families hesitate to call a doctor during weekends or at night [190]; In fact 75% of deaths occur between 7:00 PM and 6:00 AM [375] and life-threatening attacks and deaths show a pattern of occurring on Sunday [527]. Two studies showed that 68% of Swedish children and 35% of English children died within 3 h of the onset of the attack [190, 192]. Therefore, there is an impact of unpredictability that could also be due to *overlooked nonsevere cases* [192], whereas in dispatching an ambulance with a doctor on board (the person making the request had indicated asthma to the hospital operator), the arrival of help was shortened by 64% and the mortality rate decreased sixfold [595]. Survival in the period after the attack is made difficult by mistakes, for example, inadequate monitoring [377] or inadequate actions on the part of patients, especially those at high risk. Some consented to regular check-up requesting a medical visit after 7 h, others refused and died, having requested the medical visit only after 3 days [410].

How Patients Die of Asthma

The cause of death in cases of severe asthma can vary [76, 578]:

1. Some patients, who *died suddenly of a heart attack* preceded by tachycardia and extrasystoles, had in all likelihood taken drugs in excessive doses. To this end an abnormal pharmacological mechanism could be regarded as being the cause (possibly prostaglandins), triggered by an exogenous agent [578]; such cases habitually occur at home [190]. However, postmortem examinations carried out on some children have shown equal amounts of specific cardiac lesions among those who had abused β_2-adrenergic drugs and those treated with other drugs [595], although probably the severity of the complications in these patients was due more to hypoxia than to cardiac factors [409].
2. Often the *abuse of inhaled drugs,* such as β_2-adrenergics [375, 569, 578] has been stressed, both because they are very handy to use as they are supplied with dispensers, and because some have a longer and more intense action and an MDI dosed at 200 µg/puff [479], whereas, for example, the dosage of albuterol is reduced by half.
3. The theory that the *abuse of β_2-adrenergics* can lead to a masking of worsened underlying disease, whereas CS treatment could be needed [571], is, however, contradicted by the increase in sales for both classes of these drugs [480].
4. Another probability is that in *status asthmaticus* the lack of use or underuse of CSs, if taken in a timely manner, prevents the formation of obstructive plugs [76]. In fact, postmortem findings are often marked by highly thickened bronchial walls, with mucus plugs blocking the bronchial lumen and diffused throughout the airways [578].

Death by asthma can be sudden or progressive: in the first instance, the preponderant role of an intense bronchospasm is suspected, as it has been ascertained that recovery from a near-fatal attack occurs more quickly in these forms than in those that evolve more slowly, characterized by respiratory insufficiency following generalized bronchoconstriction and long-term inflammatory phenomena [578] similar to that found in status asthmaticus. Two potentially contributing causes should not be underestimated: *drug cardiotoxicity,* especially if hypoxemia is present, and the *onset of respiratory insufficiency,* rapidly aggravated by severe hypoxia [409]. Thus, the underlying mechanism can be represented by a reduced perception of dyspnea and by a very low chemosensitivity to hypoxia [296].

Controversies Surrounding the Risks Linked to Drugs

Sears et al returned to the risks associated with continuous therapy (in adults) with high doses of fenoterol, including a worsening of asthma and an increase in aspecific BHR [569, 571]. At the end of a retrospective study on 12,301 Canadian asthmatic adults, Spitzer et al [608] declared there was a danger related to the use of bronchodilators in MDI spray cans, maintaining that *all β-adrenergics, including albuterol, but also theophylline and oral steroids, worsen asthma and can be related to fatal cases,* without in effect providing clear evidence related to a cause–effect relationship [109]. Cromones as well as ICSs are totally excluded from a careful analysis in this data, as is albuterol if not taken in combination with fenoterol, which was the most common drug used among the deceased [608]. Following the publication of the preliminary results, the North American press underlined the serious dangers deriving from the abuse of β_2-adrenergics and the American College of Allergy and Immunology sent photocopies of the articles to all its associates as well as its Position Statement on the matter [185]. The dissertation by Spitzer et al [608] brought in a large number of controversial letters. The New Zealand authors exclude that in their country the use of albuterol had increased the cases of death between 1969 and 1976 [738], which occurred when the less selective fenoterol was commercialized [571], and therefore it is *the prolonged use at high doses* that is correlated with the risk of death by asthma or near-fatal asthmatic attacks [331]. The same group [629] subsequently quantified the risk in 10^5 asthmatics/year. The statistics are 42.8% for nebulized β_2-adrenergics and 19.2% for oral β_2-adrenergics, 44.6% for oral CSs; in direct comparison, fenoterol alone vs albuterol alone was 60.2% vs 7.4%, so the conclusion is that *albuterol is safe if inhaled alone*

with MDI, as are inhaled cromones and CSs [629]. Abuse is dangerous because β_2-adrenergics exacerbate BHR. Studies [110, 456] have reconfirmed that β_2-adrenergics show tolerance with continued exposure with a loss of clinical effect that can worsen asthma. Abuse and high doses during acute attacks lead to hypoxemia and/or hypokalemia as well as a delay in seeking medical assistance [409, 410, 479].

Therefore the use of bronchodilators is not intrinsically dangerous, but the substantial irrationality of treatment based only or mainly on β_2-adrenergics should be pointed out; its use should be associated with regular anti-inflammatory and preventive therapy [62, 68]. The main risk in the use of fenoterol is a dose-effect ratio between mortality and prescription [30], potentially caused by excessive basic dosages, as mentioned above. In line with such reports, on the one hand there is a recourse, as urged by some authors, *to halve the dosages* [612]; on the other hand the drug has been shown to be effective in moderate forms even in dosages between 10 and 50 µg, even reduced up to 1/20 of the recommended dosage [196]. However, the adverse effects of fenoterol became known when it was compared to placebo for *6 months* [571]. What criteria is used to freely commercialize β-adrenergics controlled by studies lasting barely *4 weeks* [133]? In a large sample of 16,787 patients treated for 16 weeks with salmeterol, the number of cases of death by asthma were 12 [91], among which only *one boy 14 years of age* (0.006%) [197]. There were only two deaths in the group treated with albuterol, one of whom was 20 years old [197]. Therefore we do not agree with the concerns raised by the potential danger of salmeterol in young people, provided that – as with formoterol – it is not used to treat acute asthmatic attacks since it has no effect in a short time, a specification included in illustrated leaflets only in 1994. Therefore it should not be taken too often because of the risk of accumulation causing adverse effects. As a consequence, it is necessary to start preventive maintenance therapy [76] with cromolyn, nedocromil sodium, ICS or long-acting theophylline, resorting to inhaled β_2-adrenergics prn [467], while taking care to eliminate the environmental allergenic load [76]. Theophylline (RR, 1.0), cromolyn and steroids (RR, <1.0) were associated with decreased mortality [331].

It has been highlighted that exposure to high titers of *Alternaria alternata* spores (Fig. 1.79) can trigger severe asthma exacerbations and is a risk factor for respiratory arrest in asthmatic children and young adults [457], with mortality cases significantly correlated with spore counts >1,000/m^3 [641]. In a total of 6,840 children with respiratory allergy, we have evaluated *Alternaria* prevalence. Only 89 of 6,840 children (1.3%) had monosensitization to this allergen, and all were asthmatic. Of these, 29 had perennial manifestations, 18 seasonal prevalence, which was in autumn-winter in 13 of these 18, and in spring-summer in 5. Thus, this allergy should not underevaluated, due to its protean manifestations with possible life-threatening reactions [84]. It is therefore necessary for infants and children allergic to this aeroallergen to wear an *identification bracelet* so that they can be quickly identified in case of need, as well as asthmatic *adolescents or children also suffering from FA*. Of children who died or suffered from severe shock (see Chap. 20), 92.3% were in fact asthmatic.

It is assumed that some fatal episodes have occurred in countries lacking a widely available National Health Service, or that such fatalities should be related to an absence of specialized medical assistance as well as to a lack of proper facilities to deal with such emergencies in schools [596].

Prevention

Prevention comprises a series of articulated measures aimed at reducing the occurrences or severity of re-exacerbations, to possibly enable children to enjoy a normal life similar to that of their healthy peers. In 1881, it was clear that "to prevent a return of new attacks one must advise the patient to avoid all harmful influences... to all asthmatics one must recommend *to live in pure, dry air, to avoid places exposed to dust, smoke and wind...*" [82]. As will be seen in Chap. 24, numerous factors have contributed to the increased prevalence of allergic disease. Proof of the negative influences of these factors in children with FH+ is provided by the double reactivity in 74% of children to Der p 1 and to pets and in 84% to pollens and molds [483]. Given the severity of infantile asthma, it can be understood how important it is that interventions for allergen avoidance are scrupulously carried out, which, we note incidentally, are overlooked in several guidelines where emphasis is placed above all on drug therapy [272, 435, 504, 545, 698–700]. Some *environmental measures* are truly effective. It is known that asthmatics improve markedly in aseptic environments, residence in dust-free places can have positive effects on clinical features, children improve when transferring to houses so meticulously cleaned of allergenic factors as to be comparable to a hospital room, with 50-fold reduced Der p levels [624].

Preventive Therapy

Preventive therapy is required once allergic asthma has been recorded to adopt appropriate measures to prevent recurrences. It is carried out using cromolyn, nedocromil sodium (Figs. 11.64, 11.65), ketotifen and other preventive medications [105]. The indications for prophylactic therapy, especially for a long-term therapy, are summarized in Table 11.58 [476]. These medications have no particular role in international [272] and US guidelines [434–437]. It was proposed to remove cromolyn from international guidelines recommending it as a first choice in prophylactic asthma treatment [642]; however,

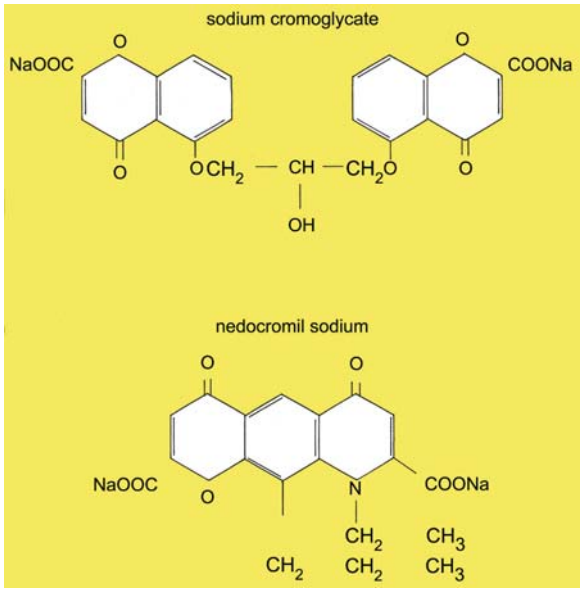

Fig. 11.64. Structural formula of sodium cromoglycate and nedocromil sodium

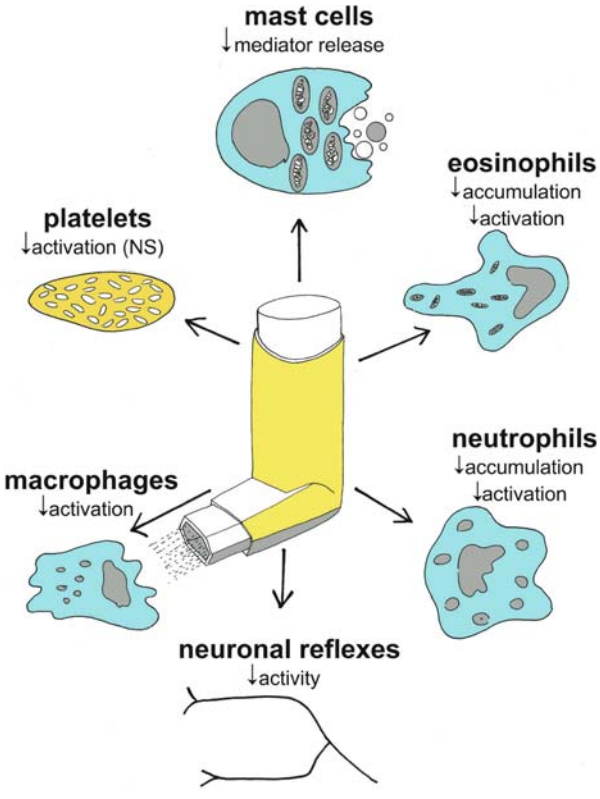

Fig. 11.65. Target cells and tissues for sodium cromoglycate and nedocromil sodium. Cromolyn sodium cromoglycate, *NS* nedocromil sodium

Table 11.58. Targets for prophylaxis in childhood asthma

Cough and wheezing more than 1–2 times a week or more than 1–2 nights a week
Necessity of bronchodilator use more than 1–2 times a day
Persistent PEFR alterations, an index of airway obstruction
Frequent exacerbations (>1 every 4–6 weeks) and of >24 h duration
Frequent hospital admissions

Modified from [476].

the Expert Panel's opinion is that cromolyn for children of all ages and nedocromil for children >5 years of age could be considered in the treatment of persistent asthma, but they *are not preferred therapies* [434].

Cromolyn is a widely used preventive drug that, by blocking mast cells mediator release, inhibits both early and late bronchospastic reactions induced by allergen inhalation, cold or nebulized air, fog and various irritating chemical substances. Thanks to these characteristics, it is currently used in the prevention of asthma and EIA symptoms in childhood [134, 419, 458, 476], starting from 13 months of age [107], having the advantage of inhibiting the response to BPT with allergens both in the early and late phases, and that of reducing aspecific BHR [251]. The numerous and extensive long-term studies that have been referred to so far in this book have confirmed both its clinical safety and its therapeutic efficacy. A recent meta-analysis on 24 trials out of 251 selected and mostly on hospital-based populations of children [642] demonstrates no improvement in the outcome of 1,000 children aged 1–4 years with mild asthma given inhaled cromolyn at a dose of 10 mg tid. However, cromolyn had a statistically significant effect on cough and wheeze compared to placebo (95% CI) and an additional decrease in cough score compared to placebo (0.13 to 0.27) and in wheeze score (0.11 to 0.26) [166, 642]. Usually, the relatively low dose of cromolyn used and the inclusion of only children with milder symptoms makes it difficult to draw conclusions about the efficacy of cromolyn in children who are given higher doses for moderate asthma [282]. Several letters commented negatively on the paper, one very well documented [166]. A meta-analysis followed reaching the same conclusions [643]. In our clinic and personally, it has always been prescribed *because of its preventive capacity,* which has been recognized by two International Consensus papers on the treatment of pediatric asthma [698, 700], which places it in the pole position in the prophylaxis of asthma.

Its effects can be summarized as follows [86, 105, 251, 258, 545]:

- Stabilization of mast cell membrane, which can be explained by:

– Closure of Ca channels, with a subsequent inhibition of mediator release
– Inhibition of phosphodiesterase, with an increase of cAMP intra-mast cell levels
– Blockage of oxidative phosphorylation that prevents mediator release
• Inhibition of the activation of leukocytes, neutrophils, eosinophils and blood platelets
• Inhibition of PAF action
• Attenuation of contractile response to acetylcholine, histamine, serotonin, bradykinin and $PGF_{2\alpha}$
• Up-regulation of PGE_2 and β_2-adrenergic-mediated bronchodilation
• Prevention of mucociliary clearance alterations
• Inhibition of macrophage degranulation via the following mechanisms of action:
– Inhibition of macrophage lysosomal enzymes (for example β-glycuronidase)
– Inhibition of chemotactic factor release (for instance LTC_4)
– Inhibition of O_2 metabolite production
• Additional properties inhibiting CD4, CD8, CD19 (B cells) and PBMCs expressing sCD23, demonstrated at the skin level (Chap. 7), making cromolyn potentially useful for treating asthma
• In vitro inhibition of IgE synthesis by B lymphocytes [297], probably by blocking their IL_4-primed isotypic switching [358], suggesting an early prophylactic effect
• Enhancement of IgG production by B cells [297], also with tachykinin antagonizing properties (Chap. 7).

Based on what has been stated, cromolyn's use in acute forms is not advisable.

Cromolyn is administered:

• By DPI, in capsules each containing 20 mg, with a predosed dispenser (Spinhaler, see "Predosed Pressurized Sprays"), with a dose of 60–80 mg/day, in 3 fractionated doses
• By MDI (20 mg/2 ml of solution),
• By pressurized MDI, with 5 mg release (average dose of 2 puffs qid).

In the US an MDI formulation of 1 mg/puff is available, which is less able to decrease BHR compared to the MDI formulation of 5 mg/puff which is available elsewhere, thus possibly delivering less medication to the lower airways [252]. Compared with the convenience of 1–2 daily doses of BUD inhalation, the dosing of cromolyn bid–qid likely increased caregiver burden [422].

Several weeks of regular use are required before it is able to carry out its effect on LAR. However, the delivery system may by a limiting factor in the efficient cromolyn delivery to young children [549].

Cromolyn is indicated:

• In *short-term prophylaxis:* 15–30 min preceding the allergen encounter, or before intense physical exercise
• In *long-term prophylaxis:* from 4–6 weeks preceding the critical period until the end of exposure
• If *a small airway obstruction* remains after bronchodilator administration

Cromolyn associated with CSs confers a *significant protection* against asthma exacerbations, asthma drug therapy, inhaled anti-inflammatory agents, *hospitalization, and ED visits* [5].

All asthmatic children can derive benefit from cromolyn therapy [436], which is virtually devoid of any side effects [86].

Nedocromil Sodium

Nedocromil, disodium salt of pyrano-quinoline-dycarboxilic acid, is an antiallergic and anti-inflammatory drug endowed with the following properties [397, 407, 424, 507, 578, 659, 704]:

• *In vivo:*
– It *inhibits mediator release* by sensitized mast cells, induced by the specific antigen and anti-IgE antibodies.
– It *reduces the amount of histamine and* PGD_2 released by sensitized mast cells, both spontaneously and following aspecific stimuli.
– It *suppresses IL-dependent IgE* production.
– It *inhibits chemotactic responses* by eosinophils (to FMLP and NAP-1/IL_8) that are stimulated by cytokines (GM-CSF and IL_3).
– It *inhibits neutrophil chemotactic* action.
– It *inhibits BHR induced by* IL_3*R*-stimulated PAF.
– It may inhibit the activity and functionality of T cells.
• *In vitro:*
– Even in very low doses, it *inhibits* chemotactic factor-induced *activation of neutrophils and eosinophils,* probably acting on proteinkinase C.
– It inhibits the *PMN-mediated mechanisms* that lead to histamine release.
– It inhibits the *release of mediators* by neutrophils and eosinophils and the release of LCB_4 and 5-HETE by alveolar macrophages.
– It prevents the *IgE-mediated monocyte* and blood platelet activation and, in high doses, activation of complement-induced proteins associated with eosinophil granules.
– It reduces *the release by the bronchial epithelial cells* exposed to asthmogenic stimuli of arachidonic acid metabolite able to induce mast cell degranulation and mucus hypersecretion.
– It inhibits the *variation in density of eosinophils* and LTC_4 production.
– As opposed to cromolyn, it also *acts on MT mast cells* and on *basophils*.

Moreover, nedocromil mitigates or halts MBP-induced harmful mucociliary dysfunction [648].

Several clinical studies have documented its efficacy in adults, also noting that it is less so in children [71, 113, 134]. In children, it significantly reduced urgent case visits and courses of oral prednisone as compared with placebo [645]. In our experimental double-blind placebo-controlled (DBPC) study [71] in children affected by grass-induced bronchial asthma, the results showed an

overall improvement both in asthmatic symptoms and in PFT compared to controls. The different opinions expressed by both physicians and parents were statistically highly significant.

The *dosage i*s two puffs (2 mg) qid.

Table 11.14 details the cromone's action mechanism.

Ketotifen has a mechanism partially analogous to that of cromolyn and is capable of the following: [105, 462, 528, 545]:

- It *inhibits mast cell mediator release,* in particular of PGD_2 [462].
- It interferes with the action carried out by some of these mediators.
- It carries out *antihistamine activity* at the level of H_1 receptors.
- It is active on the two phases of the asthmatic response.
- It inhibits *blood platelet migration and PAF release,* so that anti-PAF activity can explain many positive effects [528].

Additionally, it prevents β_2-adrenergic hyporesponsiveness and restores their responsiveness, thus improving in asthmatics β_2-adrenoceptor function and β_2-adrenergic bronchodilation [528].

In five DBPC pediatric studies [74, 511, 545, 589, 667], the following effects were documented:

- Reduction of asthmatic attacks and auscultatory findings of long-term wheezing
- Reduction in the number of days of disease
- Statistical reduction in the use of other drugs [511, 545]
- Anti-asthma prevention in 91% of cases after 3 years of therapy [74]

The effects in other pediatric studies were controversial [589, 667]. In one DBPC study, ketotifen proved less effective than cromolyn, possibly because one dose of syrup 4 ml/day was used on subjects weighing 14–18 kg; no data regarding compliance was noted [127].

Dosages. For dosages, see Table 7.19. Younger children find ketotifen particularly pleasant since it is also available in syrup form, has a pleasant taste and is easily administered. Drowsiness is its only side effect [406], which, however, we noted disappears after a few days of use. The prescribing physician should inform parents of this effect. In older children, the capsule form can be taken, preferably at night.

Antihistamines

For some years *second-generation antihistamine drugs* have been utilized and experimented in pediatric treatment of asthma [259] (Fig. 11.66). It should be noted, however, that experimental studies have yielded no consensus since there are noticeable variations regarding the type of molecule or the dosages [105]. While azelastine can reduce IAR, several other drugs seem to express their effect on LAR, an important result for the known correlation between these reactions and symptom severity [139, 303]. Table 11.59 [105, 139, 303, 528] summarizes the principal effects that are attributed to these

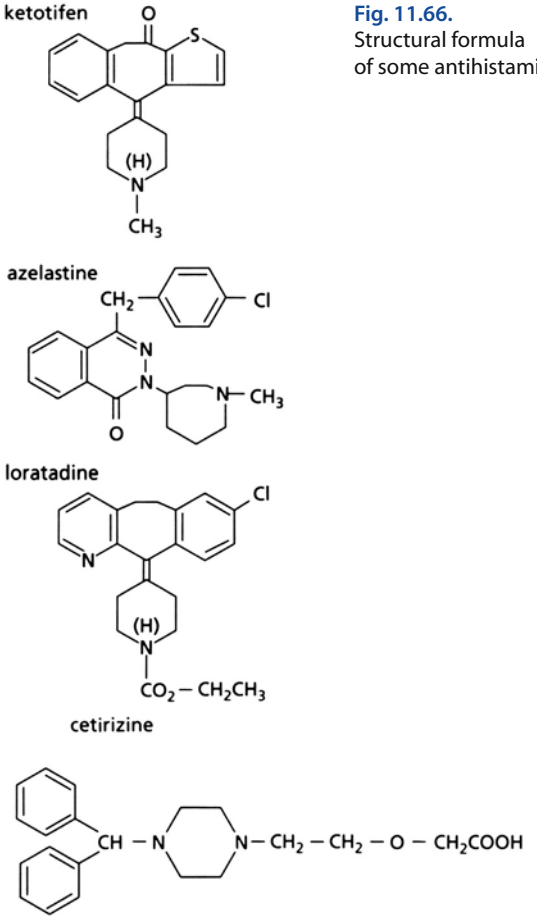

Fig. 11.66. Structural formula of some antihistamines

Table 11.59. Possible antiasthmatic effects of second-generation antihistamines

Data from [105, 139, 303, 528].

drugs; therefore we will simply clarify a few points (see Chap. 12). These drugs fulfill a protective activity related to their half-life with a variable interval of time, ranging from 4 to 12 h [105, 139].

Azelastine

Azelastine has proved to be a powerful inhibitor of histamine-induced bronchoconstriction. Once optimal serum levels have been reached, however, it is not also able to antagonize LTC_4-induced bronchoconstriction, though it is able to significantly reduce SP levels in BALF [439]. A randomized DBPC study has concluded that azelastine is capable of significantly inhibiting IAR, without, however, having any noticeable impact on LAR [662].

Cetirizine

Various studies on humans have shown that cetirizine can reduce eosinophil, neutrophil and basophil recruitment by 75 % [303], as well as PAF-induced bronchoconstriction, without leading to a similar LAR reduction in the airways, as demonstrated by PFTs, [636]. An antiallergic effect is produced on epithelial cell CD54 expression [81]. Recent evidence suggests that it inhibits eosinophil adhesion to endothelial cells [322]. A randomized DBPC study among adults has shown that cetirizine is able to reduce the number of eosinophils in BALF and inhibit their enrollment [519]; cetirizine's ability to induce consistent reductions of FEV_1 and of histamine-induced bronchoconstriction is also known. In 348 children and adolescents with grade II and III asthma, cetirizine reduced the number of days with symptoms as well as the need for other drugs, on a par with cromolyn [303]. The formulation in drops has allowed us to treat very young children (aged 6 months and older), always with very good results.

Long-term *Levocetirizine* has proved to have a first-rate preventative activity in >200 asthmatic children aged 5–6 years and older treated by us (one tablet = 5 mg/day).

Fexofenadine is a new drug that can be given to children. It is more useful in the treatment of AR and has no effects either on the cardiovascular system or the CNS.

Loratadine

In vitro, loratadine significantly inhibits PAF-induced eosinophil activation, superoxide generation, and nasal secretion of histamine and PGD_2 after the challenge [165]. Another long-term antihistamine is *desloratadine* (a loretadine metabolite), with anti-inflammatory and anti-allergic activities in addition to its antihistaminic activity, it has a 27-h elimination half-life, which facilitates once-daily dosing. Desloratadine does not cause sedation or prolong the corrected QT interval, can be administered without regard to concurrent intake of food and grapefruit juice (Chap. 12), like the other antihistamines. We have prescribed doses of 2.5 mg (1.15 ml of syrup)/day to children aged 2–5 years and of 5 ml (2.5 ml of syrup)/day to children aged 6–11.

Oxatomide

In addition to having an antidegranulation effect on mast cells, inhibiting even the activity of serotonin at the receptor level and, partially, of LTs with spasmogenic activity, oxatomide reduces the bronchoconstriction induced by methacholine and by physical exercise, as has been demonstrated by a DBPC study in asthmatic children [301].

The formulation in drops has allowed us to treat young children, always with effective results.

Nonpharmacological Therapy

Asthmatic children are strongly encouraged to participate in a sport. As a preventive measure, the family doctor should be consulted on the choice of the most appropriate activity. Though not everyone agrees [359], *swimming in a swimming pool* is most certainly advisable because the effort is well balanced, warm and humid air is inhaled, it helps to develop respiratory functions and it tones up the body. It is useful to know in advance the percentage of Cl in the water, because high levels could be an irritant. We have seen how an airway cooling down linked to hyperpnea can provoke EIA. As previously suggested, a preventative measure for this form of asthma – *a filtering mask* – could protect bicycling or motorbiking asthmatics or those engaged in long-distance skiing in the winter, by covering the nose and mouth and thus avoiding the continued inhalation of asthmogenic cold and dry air [618]. It is possible that the increased prevalence of asthma in long-distance skiing [335] is dependent on the lack of attention given to preventive measures.

Other Interventional Measures

The disease impact on the asthmatic's everyday life: information on asthma and on its treatment provided to the family (in the manner deemed most appropriate) enables children to better face their disease and follow their medical therapies with greater diligence; moreover, performing their breathing exercises more frequently to help them relax, leads to a possible reduction in the sometimes excessive use of their medications [272].

Greater education also improves the quality of life: by reducing problems such as cough, wheezing, trouble

Table 11.60. Limitations on the quality of life in children and adolescents

breathing, activity limitation, anxiety, loss of sleep or frequently interrupted sleep and worry over the physical symptoms of their disease and the possibility of future attacks, the array of stressors that a child has to face as a consequence of suffering chronic asthma [448], the patient can be ensured a life that is as normal as possible, even regarding school, sports and above all social activities, etc.

The overall situation can be made easier and improved *if pediatricians act promptly and effectively* not only during the critical attacks, but *also in the intercritical times,* via focused treatments aimed at preventing future attacks. We are referring to the serious problems faced by a child prone to EIA who will return to play and take part in sporting activities as a direct result of an adequate preventive therapy. A good pediatrician–patient relationship will undoubtedly be beneficial to the psychology of asthmatic children and adolescents and will assist them in facing the disease and daily activities.

In adolescents, psychological problems occur more frequently: the doctor should treat these special aspects of the disease, including the refusal to acknowledge symptom presence, widespread emotional problems including lack of cooperation, social aspects, excessive recourse to inhalers, smoking, etc.

Even some aspects *related to school* can require the doctor's assistance. In schoolboys, schoolgirls, young adolescents, problems related to modifications of behavioral attitudes or learning disabilities caused by medication are often present. It is for this reason that doctors must educate both children and parents about exceptional cases of disturbances possibly occurring, and that such problems often last not less than 2 weeks [711].

To better illustrate the seriousness of the problems relating to pediatric asthma, the results of two studies done on 100 asthmatic children aged 9–13 years [657], and in 4,161 adolescents (958 asthmatics and 3,203 nonasthmatics) and 1,104 of their teachers [213] (Table 11.60 [213, 657]) are reported. The trial showed that 42%–59% of the subjects believed that asthmatics can become addicted to their drugs, 70%–82% that there could be fewer problems if the drugs could be taken in class, 36%–45% that asthmatics are embarrassed about using their inhalers and 47%–56% that teachers are worried about taking asthmatics on school outings or to summer camps. Even if comprehension toward asthmatics was greater among students than among school teachers ($p<0.0001$), the teacher's positive participation in asthmatics' problems is significant [213]. The results of a subsequent trial on 381 students aged 8–18 years are more optimistic: the findings showed that there is only a 30% restriction on their participation in youth activities [41]. Nevertheless, it is difficult to quantify that many young children will not be able to fulfill their dreams, for example that of being *able to run and play football* like so many other children with no restrictions whatsoever.

Table 11.61 [284, 435] summarizes the advantages and disadvantages of the main therapeutic methods outlined so far.

Outcome

We have gathered the relevant data in Table 5.15, defining positive outcome in 41%–47% of cases. In the last few years, a high percentage of children (43%–76%) whose asthma persisted as they grew into adulthood has been noted. A large number of children or adolescents who remain asymptomatic can have relapses and/or anomalies in their PFT that do not return to normal, even after 3 years [219, 575]. It is important that these children are regularly examined by their pediatrician, enabling a timely identification of those subjects who are at risk of suffering from relapses on reaching adult-

Table 11.61. Advantages and disadvantages of medications for treating pediatric asthma

Medications	Advantages	Disadvantages
β-Agonists	The most potent and rapid bronchodilator drugs available at the moment	The regular use may mask the airway inflammation and disease progression
Corticosteroids	The most potent anti-inflammatory drugs for treating both asthma and airway hyperreactivity currently available, topical steroids offer the most secure therapeutic range	Oral: the side effects suggest their use as a maintenance therapy in the most severe forms Inhaled: unconfirmed growth hypothalamic-pituitary-adrenal axis suppression.
Theophylline	The best available drug to add an extended bronchodilation and anti-inflammatory effects	Narrow therapeutic range, variable clearance, requiring careful monitoring of theophylline levels, unconfirmed negative effects on temper, learning, etc.
Antihistamines	See Table 11.59	Continual anti-inflammatory therapy
Anticholinergic	Delivered by nebulizers may be added to β-agonist therapy in acute conditions	Modest bronchodilators less potent than β-agonists
Cromolyn	Reduces symptom scores, airway hyperreactivity and necessity of other medications	Prophylactic, is less potent than corticosteroids, not effective in all children
Nedocromil sodium	Reduces symptom scores, airway hyperreactivity and necessity of other medications	Prophylactic, is less potent than corticosteroids, not effective in all children
Allergen avoidance	Allergen-specific, may reduce and eliminate symptoms	None, major discomfort for children and families
Immunotherapy (Chap. 13)	Definitive cure of asthma, abatement of symptoms, airway hyperreactivity and need of medications	Poor compliance in small children, high cost, children should be observed 30 min after injection should be started early, well before that asthma aggravates

Data from [269, 419].

hood. On this matter, in the studies cited in Chap. 5, various parameters were predictive of asthma at an adult age. Up to the present time, no study has demonstrated that pharmacotherapy is able to modify the natural history of asthma, whereas SIT is able to do so. On the contrary, as has been noted, the discontinuation of a therapeutic cycle is followed by a reappearance of symptoms [671], which also confirms our experience. The inflammatory process at the basis of asthma persists even after years of CS treatment, even if it can be reduced [652]. Nonetheless, it can resurface displaying all its functional characteristics [671]. As we have seen, there are various antiasthmatic treatments available for use at an infant age and we could additionally recommend ensuring a timely diagnosis and early adoption of preventive measures.

Present and Future Prospects

In the long term, anti-inflammatory strategies could include nonactivation of T lymphocytes or of IL_4, inhibition of the isotypic conversion after the second signal emitted by the cytokines, and direct elimination of B_{IgE} cells through anti-IgE monoclonal antibodies [24, 301]. There are two treatments that *cure* asthma, in addition to SIT.

Anti-IgE

In a randomized DBPC study, a cohort of 334 entrants aged 6–12 years with moderate or severe allergic asthma received a recombinant humanized monoclonal antibody that binds to free IgE at the same site as the high-affinity (FcεRI) receptor (omalizumab). A 28-week treatment reduced the requirement for ICS while protecting against disease exacerbation, while serum free IgE was reduced in 95 %–99 % of cases [405]. Children in the omalizumab-treated group reported significant improvements in the activities and symptoms domain scores as well as in the overall asthma-related quality of life compared with placebo [342], but also formoterol [183]. In a pooled analysis of three multicenter, randomized DBPC studies, omalizumab reduced the rate of serious asthma exacerbations and the need for unscheduled outpatient visits, ED treatment, and hospitalization in children with moderate-to-severe allergic asthma [118].

Leukotriene Modifiers

Anti-LT could have a positive influence on ASA and/or block bronchoconstriction responses in BPT, leading to a decrease in CS use [329]. Figures 11.60 and 11.61 sug-

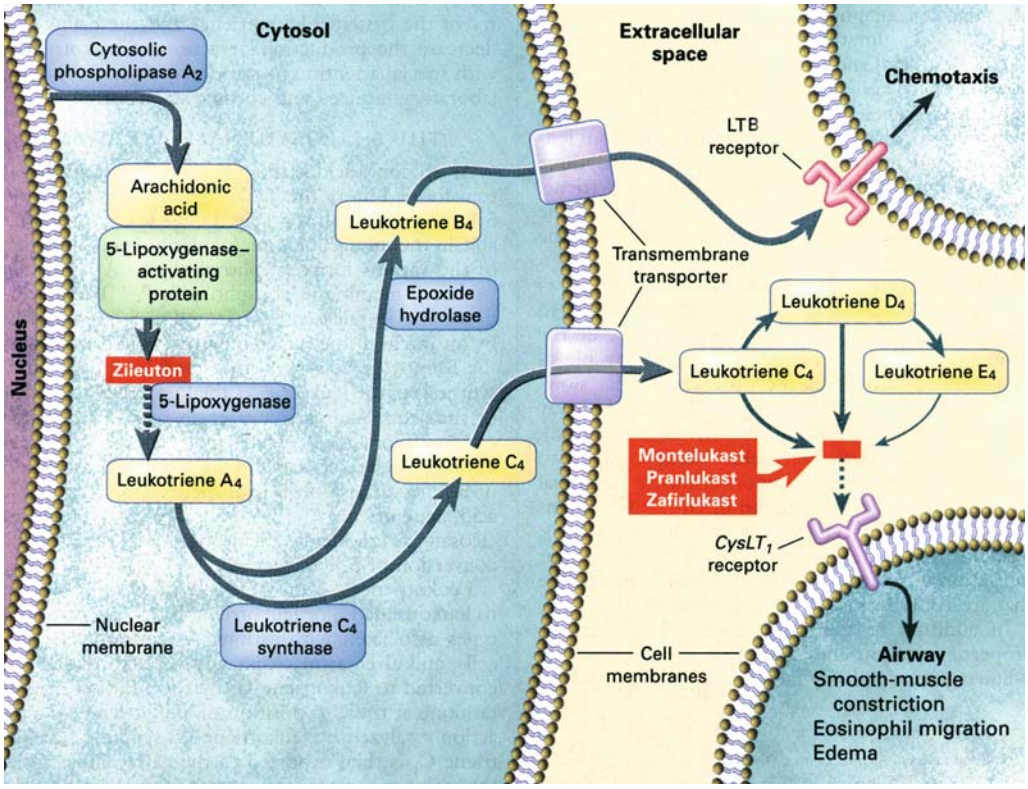

Fig. 11.67. Biochemical pathways of LT formation and action and sites of action of LT-modifying drugs. Enzymes are shown in *blue*, products in *yellow*, essential cofactor in *green*, and drugs in *red*. Although the synthesis of LTB4 and LTC4 probably takes place in close proximity to the nuclear membrane, for clarity they are shown throughout the cytosol. *LTB* denotes the LTB receptor. An individual cell may produce the cysteinyl leukotrienes, LTB4, or in rare cases both

gest the use of anti-LT drugs, though they have yet to be thoroughly tested: zileuton, an inhibitor of LT synthesis and montelukast, pranlukast and zafirlukast, competitive LT receptor antagonists, as well as pobilukast, tomelukast and verlukast, though the last three are more properly inhibitors of the activation of cysteine-derivatives receptor (LTC_4, LTD_4 and LTE_4). The spirometric data of children of 6–14 years with chronic asthma, who were treated with montelukast (oral monodose of 5 mg), demonstrated a net improvement [308], added to BUD in 279 children aged 10.4 ±2.2 years, it induced a clinically relevant decrease in the number of asthma exacerbation days [591]. A DB, multicenter, multinational study at 93 centers on 689 children (aged 2–5 years) with persistent asthma given 12 weeks of treatment with 4 mg of oral montelukast has shown significant improvements compared with placebo in multiple parameters of asthma control, including daytime and overnight asthma symptoms, percentage of days with and without asthma symptoms, need for β-agonists or oral CSs, physicians' global evaluations, and peripheral blood eosinophils [309]. We have treated 40 children aged 3.1–5.1 years (mean, 3.7 years) with montelukast. Compared to 41 controls, there was a significant reduction in the mean incidence of day (74%) and night (69%) wheezing in addition to a significant amelioration in EIA compared with controls, and in younger children a significant increase in weight. A mean difference between study children and controls was evidenced by spirometric data. We conclude that in pediatric asthma management, chewable tablets of LT modifiers can be used as substitutes of long-acting β-agonists and ICSs, especially in young children who may have difficulty in using in-

Table 11.62. Antileukotriene drugs: route and doses of administration in children

Anti-LT	Route	Doses/Ages
Montelukast (at bedtime)	Oral	4 mg once daily/2–6 years
		5 mg once daily/6–14 years
		5 mg once daily/6–14 years
Zafirlukast (1 h before or 2 h after a meal	Oral	10 mg bid/ 5–12 years
Zileuton	Oral	Children aged 12 years and older

Data from [159].

halers. Montelukast was significantly effective when cat-sensitive children aged 6–14 years with mild persistent asthma were exposed to high levels of cat allergen [492]. Table 11.62 reports the related doses, and Fig. 11.67 shows the biochemical pathways of LT formation and action. It should be noted that in 32 children 6 to <24 years old the 4 mg dose was equally effective and free of untoward adverse effects [402].

Montelukast administration also reduced the increased Th2-like T cell IL mRNA expression in lung tissue and protein in BALF found in OVA-sensitized or challenged mice, and markedly reduced the increased lung mRNA expression of Th2-like T cell ILs [246]. In other animal studies, CD54 modulation during treatment with CSs could represent a new and more selective treatment for the control of the chronic airway inflammation and BHR that characterize asthma. *The effect of CD54 could be associated with significant reductions of* eosinophilia and consequently, of *BHR* [230]. Apart from other immune effects, CSs (Figs. 11.43, 11.44) inhibit IL action on eosinophils, and cetirizine and picumast inhibit their activation in vitro, even though not originally introduced for this purpose [528]. The initiative to positively alter the levels of PAF by means of SIT [265] or ketotifen [528] and, finally, that of blocking BHR by inhibiting iNOS by means of CSs [443] is a stimulating prospective. Of special interest would be a method that could monitor NO production in infants and young children, aiming at focusing on the role of the inflammation in early asthma and fostering a strategy for timely intervention [759].

The list of new compounds for the pharmacological control of asthma is long and, in addition to new applications of antihistamines, also include PDE IV inhibitors, anti-TXA_2 and anti-TXA_2-synthetase, tachykinin antagonists, inhibitors of peptide releases from C-fibers, K^+, Ca and Cl channels deactivators, M_3-selective antagonists, inhibitors of IL_5, CD antagonists of adhesion molecules, and inhaled NSAIDs [418]. Also foreseeable are antagonists of PAF, tryptase, quinines and of some chemokines, inhibitors of FLAP and of PLA_2, antagonists of α-adrenergic receptors, modulators of transcription factors and new antimuscarinic drugs. Finally, the antagonists of tachykinin receptors could eliminate bronchial smooth muscle contractions [426] and cold-induced bronchoconstriction [744].

Most strikingly [243], an anti-IL_{17} mAb (monoclonal antibodies) treatment regimen has been shown to abate bronchial neutrophilia in parallel with reduction of bone marrow and blood neutrophilia. This treatment also raised eosinophil counts in the bone marrow and bronchial IL_5 production, without alteration of allergen-induced BHR.

A crucial role may be played by TARC (thymus and activation-regulated chemokine) CCR4 receptor expressed by Th2 cells in bronchial airway epithelium. Asthmatic patients exposed to a relevant allergen release large amounts of TARC in their BALF; costimulation with IFN-γ, but not with the duo IL_4–IL_{13}, stimulated human bronchial epithelial cells to further increase TARC mRNA and protein expression. TNF-α amplifies IFN-γ ability to induce TARC 30-fold [38]. TARC concentrations are elevated in childhood asthma [345], thus TARC up-regulated in bronchial epithelial cells may play a role in the pathogenesis of allergic asthma [38]. This marker is also linked to plasma total IgE levels and cat allergen sensitization [345]. As a consequence, CCR4 antagonists may have a substantial impact in treating allergic asthma.

In another area of increasing interest, administration of a stable analog of lipoxin A4 (LXA4) blocked both BHR and pulmonary inflammation, as shown by decreased leukocytes and mediators, including IL_5, IL_{13}, eotaxin, prostanoids and cysteinyl LTs [349]. Moreover, blocking IL_{13} [150], receptors, or the downstream signaling pathway activated by their ligation, could provide one strategy to improve the specificity of asthma treatment [321].

In the animal model, TrkAd5 is able to modify the airway late hyper-responsiveness to histamine, brg sequestering endogenous NGF. Notably, the TrkAd5 administration causes the contractile response to histamine to be lower than control after ovalbumin challenge, thus showing potent effects in allergic asthma [686a].

Other Pediatric Allergic Lung Disease

These are pulmonary interstitial disorders having an immunological pathogenesis, caused by the inhalation of various antigenical agents active in subjects who are particularly vulnerable; such disorders are rare at the pediatric age.

Extrinsic Allergic Alveolitis

Also known as hypersensitivity pneumonitis, farmer lung disease (described by Ramazzini in 1713, Chap. 4), and pigeon breeder's, EAA can occur in children aged 3–15 years [111, 319, 395]. It is rare in infants [168] and >80 pediatric cases are known [111, 137, 168, 223, 248, 319, 389, 411, 748]. The pathogenesis is of sensitization to inhaled allergens, generally thermophilic actinomycetes or avian antigens [111, 319]. In addition to the classic cases of actinomycetes that contaminate fodder [111] or of other mycetes that pollute houses [319], there is evidence of a growing number of cases related to contaminated heating and air-conditioning systems [132] and to birds in cages, pigeons, etc., in the barn, house, and the child's bedroom [248, 319]. The latter form is the most widely studied in children, with cases caused by free-roaming city pigeons [137], a problem in most countries. There can be type III reactions with formation of antigen–antibody complexes at the alveolar level [411], but by studying BALF a significant lymphocytosis

during the acute period, with CD8 predominant intervention, has been demonstrated. These reactions could therefore assume a more significant pathogenetic role [319]. Pulmonary damage is the result of the immune response characterized both by antigen-specific antibodies and cellular hypersensitivity with IL releasing PBMCs. Complement activation in the airways and the irritating effect of thermophilic actinomycetes [95] should also not be overlooked.

The *insidious onset of acute forms,* secondary to exposure to high concentrations of avian antigens, includes increasing lethargy, weight loss, a febrile bronchopneumopathy with a prevalence of respiratory symptoms such as breathlessness and cough, which can also be spasmodic, and effort-induced dyspnea appearing 4–8 h after exposure, with auscultatory findings of rales at pulmonary bases [111, 319]. Complications may occur in the form of sudden respiratory failure [111]. If exposure is prolonged or repeated, the process becomes chronic with aspecific insidious signs such as worsening of the overall general condition, effort-induced dyspnea and even at rest [411], and marked weight loss [319]. More frequently, the picture is subacute with coexisting respiratory and systemic symptoms; among these a general feeling of ill health, anorexia, asthenia, etc. [111].

Diagnosis depends on history of exposure to birds, clinical findings, positive avian precipitins, restrictive defects on PFTs, and a suggestive chest X-ray appearance [223], and in children exposed to birds or playing in barns with a history of breathlessness, or strolling amidst city pigeons [137]. X-ray results reveal a fine miliary pattern, diffused to both lungs with interstitial infiltration in the lower fields and hilar enlargement in acute forms, and diffused interstitial fibrosis with accentuation of the network in chronic forms (Fig. 11.68), but may be unremarkable [248]. PFTs show a restrictive ventilatory defect with reduced lung volumes and compliance [111, 319]. SPTs positive to pet danders provide both immediate and delayed results [411]. Lymphocytosis is found in BALF (>50%), a net reduction of both CD4 and CD8 rates and of NK cells, with 87% sensitivity and 72% specificity [319], or 85% of CD8 expressing the activation marker HLA-DR and 32% of $CD4^+$ and 16% of $CD56^+$ [389]. Follicle-like aggregates of B cells in the lung interstice may indicate that local antibody synthesis may be involved in an antibody-dependent cellular cytotoxic mechanism [389]. Differential diagnosis is illustrated in Table 11.63 [319] and should be extended to children presenting with unusual respiratory symptoms and signs early [223].

Avoidance of triggering agents entails that clinical findings subside within a few days [425]. CSs are effective and resolutive, especially if accompanied by environmental clearance [75], unless insufficient child compliance or a relapse due to a new exposure to specific allergens occurs [319].

Allergic Bronchopulmonary Aspergillosis

Though rare in children, ABA is often found in adult studies reporting the onset of symptoms in childhood [75]. Often it is caused by airway colonization by the mold *Aspergillus fumigatus* (AF) (with 18 different allergens, Table 1.74), which proliferates in soil in great numbers where it can be isolated (Fig. 1.77). In addition to being found in wheat fields and more generally wherever there is vegetation, it is also found in humid houses, trash cans, vegetable substances, rotting wood, freshly cut grass, old hay, fallen leaves, in bedding and

Table 11.64. Differential diagnosis of allergic bronchopulmonary aspergillosis (*ABA*)

Diagnostic criteria	Comments	ABA	Allergic asthma	Cystic fibrosis
		(%)		
Chest X-ray infiltrates	Present in some studies	100	0	100
SPT+ to *Aspergillus fumigatus*	Diagnostic, not specific	100	13–38	30
Raised total serum IgE	Markers of ABA activity	80–100	50	20
Precipitant antibodies to Af	Not specific to ABA	60–90	25	35
Eosinophilia	Absent if treated with steroids	100	40	20
High specific IgE/IgG to Af	Essential and specific to diagnosis	100	<5	<5

Data from [95].

in common household floor dust [95]. Since it is very small, with an average diameter of nearly 3 µm, inhaled spores can reach the peripheral airways where they can proliferate, aided by internal temperature [95]. In ABA other species of AF, *Candida albicans*, *Mucor*, *Penicillium* spp., *Cladosporium herbarum, Helminthosporium* spp., *Stemphylium* spp., *Torulopsis* spp., *Curvularia lunata, Rhizopus* spp., *Drechslera* spp., *Pseudallescheria* spp. [416] are likewise implicated. Mold growth is accompanied by an intense type I, III and IV immune response: antigen release with production of IgE and IgG antibodies. Activation of Th2 T cells orchestrating pulmonary inflammation has also been shown in ABA together with the expression of genes for several ILs present on the *5q* chromosome [95]. They are restricted by HLA-DR2 and HLA-DR5 and produce high concentrations of IL_4 but few of IFN-ɣ [99].

ABA is characterized by five stages: I acute, II remission, III recurrent exacerbation, IV progressively ingravescent and steroid-dependent, which, if not treated, evolves into stage V, with diffuse pulmonary fibrosis [75, 95]. Some 28 pediatric cases have been reported [75, 292, 369, 416, 425, 631, 693], aged 0.11–18, including 3 girls aged 0.11–8 with cystic fibrosis [292, 369, 425], two girls aged 6–7, with GER of asthmatic origin and multiple sensitizations to mycetes [75] and a 6-year-old boy with *cladosporiosis* [416]. The symptoms are an asthma-like syndrome with recurring afebrile bronchospastic episodes, coughing, dyspnea, wheezing, and pulmonary infiltration [95].

ABA diagnosis is made on the presence of classic hyphae in the sputum (Fig. 11.69) and on X-rays pulmonary parenchymal wedge-shaped shadows, typical of ABA can be observed depending on the phase of activity (Fig. 11.70a). In the pediatric age, a CAT scan is more appropriate, as it permits a more rapid diagnosis [580]. The presence of marked eosinophilia serves as a guideline. The presence of precipitant antibodies, findings of fungal hyphae in the sputum and fungal isolation in cultures [95] may have diagnostic value. SPTs reveal immediate and/or delayed reactions to the molds. For the diagnosis of the condition, high levels of total IgE (>1,000 ng/ml) [369] and IgE antibodies are relevant

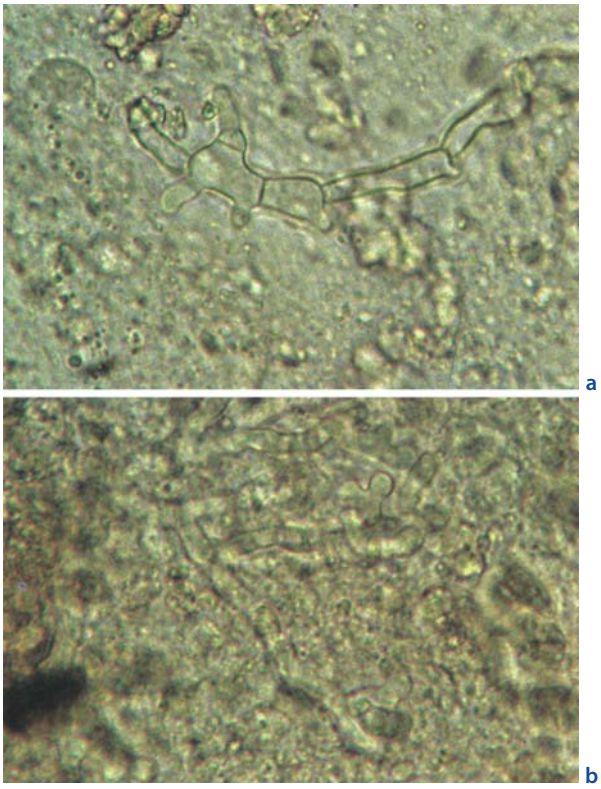

Fig. 11.69 a,b. Allergic pulmonary aspergillosis. Note the characteristic appearance of the hyphae (branching separate structures) in the sputum of a 10-year-old girl

such as the significant association with sIgE and IgGs to AF [75] (Table 11.64) [95]. Children with CF [292, 369] also have anti-AF sIgE [369]; therefore, to obtain a higher specificity, it is safer to take sIgE for CD46 measurements using ELISA [355], but a child with CF and acute symptomatic ABA with low serum IgE levels has been reported [369].

Steroid therapy for a few months causes remission (stage II), which continues after 10–15 months of follow-up [75, 416, 693]. Under steroid treatment, clinical findings improve, regression can be seen in the X-rays (Fig.

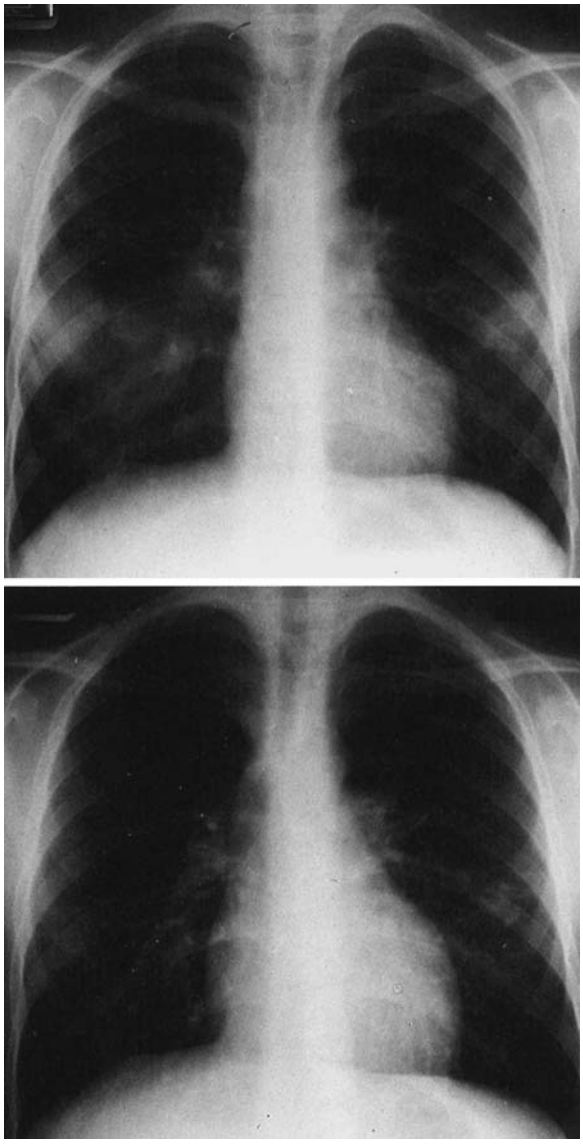

Fig. 11.70. **a** Chest radiograph of an 8-year-old girl with ABA. **b** Note the improvement of the girl after 2 weeks of treatment with high dose oral corticosteroids

11.70b), peripheral eosinophilia serum IgE titers are reduced, and fungal hyphae are cleared from the airways [75]. Total IgE decrease from 1,596–2,900 kU/l to ≈1,000 ng/ml after treatment [75, 416] and blood eosinophil count from 1,690 mm^3 to 980 mm^3 [416]. Monitoring total IgE and sIgE/IgGs titers is an excellent index of ABA activity, since their levels are newly increased in case of progression from stage II to III [95]. However very high titers of serum IgE may also be present in several other illnesses, including AD and parasitic disorders.

Pediatricians and Pediatric Asthma

Apart from pulmonary disease caused by mycetes, the secret of successful management in asthmatic children is to avoid prescribing only symptomatic therapies, but to *try to find the casual factors first,* specific to each child; therefore every form of treatment should *be tailored to the individual child.* The negative psychological factors to which we have already referred can trigger asthmatic symptoms, aggravate the attacks and negatively influence compliance with the therapeutic regimen. From our examination of doctor–patient relationships the importance of the pediatrician's role emerges. This doctor must not appear to be simply one who prescribes drugs or tests, but must also fulfill the role of being a friend full of enthusiasm, encouragement and understanding, both to young patients and their families. He must also instill a responsible attitude toward the disease and bring them to an understanding that asthma that is not treated effectively can, more often than not, result in the child or adolescent growing into an invalid adult. Especially in cases such as these, pediatricians should be particularly close to children and their family. Following an asthmatic child for a long time provides an opportunity for acquiring important information on the course of disease and the physical and mental repercussions asthma can have on those involved. Problems related to quality of life and limitations to leading a normal life, or playing and participating in sports are problems with which children must contend. Here we underline the different character of both asthmatic children and adolescents. The real difference is school absenteeism, chronic infirmity, the causes of delayed growth and the effects of HPA-axis depression, which should be considered carefully, especially if alternative treatments are available. The positive aspect, which we have always preferred, is that of giving value to the intercritical periods rather than to side effects, recommending the practice of sports, which can improve quality of life. On the other hand, self-treatment programs have yielded disappointing results, or are based on cycles of hospitalization and do not always achieve positive results. In other cases that we have regularly noted, treatment of children may involve their families in a better understanding of the clinical effects after giving an informative overall picture.

Allergic Rhinitis

The Airway Entrance

Allergic rhinitis (AR) is a very common disease. This condition, which predominates during the childhood years [48], is found most often in boys up to 10 years of age, and at equal rates with girls from the ages of 10–20 years. Studies conducted in many countries in recent years, thanks chiefly to the ISAAC study (Table 5.21), have revealed a significant increase in its prevalence, especially among 13- to 14-year-olds, *reaching a rate of 80% in Paraguay*. There is an increase in prevalence from the age of 15–17 years, of 18% in girls vs 14% in boys [184]. As for the minimum age of onset, Table 5.5 shows that children *as young as 1–3 months are sensitized to pollens*. At this age children may be sensitized to HDM (house dust mite), pets and pollens [78]. While 50% of cases were diagnosed within the 1st year in the United States, this took place in an area with a dry climate and thus lacked the most well-known allergens [149]; however, the case of a little girl shown in Fig. 5.23 is eloquent. A recent study from Denmark [174] during a 6-year follow-up in a population of 7- to 17-year-old subjects reported a significant association between the SPT (skin prick tests) sensitization to grass (RR=2.6) and HDM (RR=2.7) or a positive IgE screening test (RR=2.4) and the development of AR. Children of primary schools with pollen sensitization have a significantly higher risk of developing AR symptoms (OR, odds ratio = 2.63) and of getting pollen asthma, but only *0.69% of doctors* have diagnosed their symptoms as such [139]. This is a sound demonstration that AR is a disease largely neglected in the literature as well as in clinical care. We have seen how pollutants are a contributing factor in the onset of pollen-induced rhinitis (Fig. 4.18) and we wonder to what point other similar interactions increase its prevalence. The complications due to unexpected cross-reactions (Table 1.73) also between distantly related plants are commonly attributable to a group of proteins, such as profilins, present in 13 different pollens (Table 1.72). AR can be a source of serious problems for both the child and the family, since it is quite *frustrating* at all ages, albeit for different reasons. For example, in the youngest children, a loss of the sense of smell, a complication that frequently goes undiagnosed, may result in a loss of appetite, increasing emotional tension in the other family members at mealtimes [171]. The continuous throat-clearing, noisy breathing, annoying sniffing, snorting, and coughing often lead to social isolation at school and conflicts at home [181], all of which have negative reflections on the already suffering mind of the child, who is inclined to *skip school,* just like his classmate affected with atopic dermatitis (AD). It must also be considered that children, in particular the youngest ones, do not complain about their problems in the same way as adults do. Furthermore, for various reasons, they are often out of their parents' sight and care and, as a result, their symptoms may go unnoticed, resulting in an obvious delay in providing an appropriate treatment [120].

Nose Physiology

The airways start in the nose, one of the most vascularized organs of the body, and an integral unit that functions together with other sections of the airways, continuously under attack from contaminants and various stimuli. Tables 12.1 and 12.2 [48, 76] show the make-up of its secretions and their purposes. Thanks to its peculiar anatomy, it functions as an organ of respiration, *as a first line in host defense,* as the organ of olfaction, and to provide resonance [116]:

- It cleans and humidifies inspired air.
- It purifies, by mucociliary clearance, the air of foreign particles, thus acting as a first line of defense against respiratory tract pathogens.
- It holds moisture and heat in the front part of nasal cavities, where it is relatively cool.
- It acts as a resonance chamber for the voice.

The heating of the inspired air, made possible by the great blood flow within the nose (42 ml/100 g of tissue/min) [188], brings it to a temperature (T) of 30–32 °C in the pharynx. Environmental air is also humidified through the addition of 0.5–1 l of H_20, since the relative humidity is 79% in the nose, and 95%–98% in the trachea [180]. Thus conditioned, the air can proceed to the delicate structures of lower air passages without being irritating for them. To be able to carry out these functions, the nose must have an adequate surface area: first of all, it is practically *doubled by the septum,* together with the *three turbinate bones,* so that the nasal mucosa cover a total area of from 100 to 200 cm^2, with a thickness varying from 10 to 15 µm [180].

Table 12.1. Constituents of human nasal secretions

Mucous cell products
Mucous glycoproteins (10%–15%)
Serous cell products
Aminopeptidase
Lactoferrin (2%–4%)
Lysozyme (15%–20%)
Neutral endopeptidase
Peroxidase
Secretory leukoprotease inhibitor
sIgA (15%) and secretory component
Uric acid
Plasma proteins
Albumin (15%)
Angiotensin-converting enzyme
Carboxypeptidase N
Immunoglobulins
IgA (not secretory) (≈1%)
IgG (2%–4%)
IgM (<1%)
Kallikrein
Indeterminate source
CGRP
Urea
Inflammatory mediators

Table 12.2. Functions of human nasal secretions

Protective functions
Antioxidant
Humidification
Insulation
Lubrication
Provision of adequate medium for ciliary function
Waterproofing
Barrier functions
Macromolecular filter
Microorganism and particulate matter entrapment
Transport and elimination of entrapped materials
Defense functions
Extracellular site for multiple enzyme functions
Extracellular source of IgA/IgG antibody
Antimicrobial function
IgA/IgG antibody
Lactoferrin
Lysozyme
Rapid deployment of multiple plasma proteins

Data from [48, 76].

The purification of inspired air is provided first by the vibrissae of nasal vestibule, which block particulate material >15 µm, and then by the mucociliary action, which effectively eliminates material <10 µm. Particles and harmful gases contained in 20 m^3 of inhaled air are taken up by mucus and drained passively toward the pharynx by ciliary beat movement (400–800/min), at a speed of 6 mm/min [180]. The cilia of the front cavity *move forward,* while those in the rear cavity *move rostrally,* to remove secretions in both directions. In nasal mucosa, the epithelial surface is protected by a mucous bilayer, a superficial gel layer (85% of mucous glycoproteins) and underneath a thin liquid sol layer. The outer gel layer takes inhaled solid particles and/or debris up, while the cilia, which need a fluid medium to perform their function, grab the gel layer with their tips during the forward movement, thus ensuring the progression of solid particles; so the particles move easily within the sol layer, which, in turn, enables the beating of the cilia [188]. The mucous layer is secreted, removed, and replaced constantly: its rapid turnover contributes to the *barrier functions* [76]. Therefore, when harmful external stimuli pass across the mucosal barrier, not only do they damage the mucous membrane locally but, by interfering negatively on humectation, filtration, and heating of inspired air, they can cause disturbances in other parts of the *tracheobronchial tree:* for example, inactivation of the mucociliary system (Fig. 11.17) leads directly to sinusitis (Chap. 15).

As a consequence, it can be understood that particles >5 µm are filtered almost 100% by the nose, so few intact pollen grains would be expected to reach the lower airways provided that the nose functions properly. Amylaceous granules making up grains (<3 µm), as well as smaller fungal spores (5 µm), may reach the bronchi, causing asthma.

Pathophysiology

The human nasal mucosa is lined by ciliated pseudostratified columnar epithelium and nonciliated goblet cells. A lamina propria rich in seromucous acinar glands, blood vessels, and nerves is beneath the epithelium. An area rich in sinusoids is deeper in the tissue. The *rich vasculature* of the submucosa contributes to the onset of rhinorrhea and nasal congestion. In fact, the vascular architecture is characterized by arteriovenous anastomoses and cavernous sinusoids, which, when they become engorged, may lead to nasal obstruction [122, 187] (Appendix 12.1) [107]. The tissue may swell due to *increased vascular permeability* or sinusoidal engorgement; it may secrete mucous, serous, or goblet

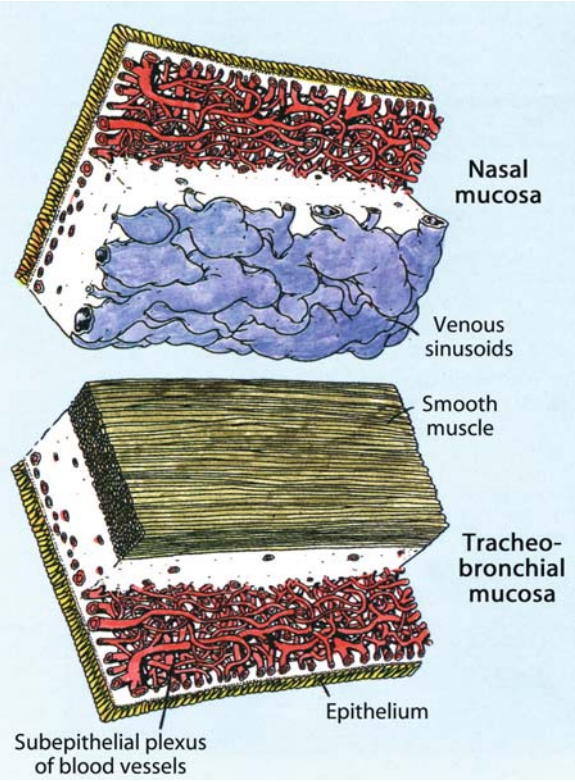

Fig. 12.1. Differences and similarities between nasal and bronchial airway tissues. Differences and similarities are emphasized: a central obstructive mechanism of nasal passage is filled with venous sinuses; tracheobronchial smooth muscle constriction in the lower airways is comparable . However, the epithelial lining and the abundant subepithelial network of microvessels are similar in upper and lower airways and so are exudative and absorptive mechanisms

cell products. The differences and similarities between nasal and bronchial tissues can be seen in Fig. 12.1 [122]. Furthermore, the openings of epithelial and periglandular capillaries permit the rapid blood circulation inside the vein walls. It is believed that these peculiarities aid in controlling the moisture and T of inspired air [48].

Histamine, an important mediator acting on nasal mucosa vasculature, may directly increase permeability, causing rhinorrhea [131, 165]; however, other authors report that histamine causes neither this increase nor that of nasal blood flow [166], whereas still others confirm the increase in permeability after histamine challenge [187]. Rhinorrhea and congestion may also be influenced by histamine indirectly [68], by stimulating glandular secretion, as deduced from the homolateral nasal provocation test (NPT), which provokes in atopics a contralateral increase in sIgA (secretory IgA) [187]. Also possibly implicated in causing rhinorrhea are histamine challenge released secondary mediators, such as bradykinin and TAME (tosylarginine methylester) [165]. TAME reproduces the clinical sequence of sneezes, and the production in nasal cavities of histamine, leukotrienes, and PGD_2. High concentrations of kinins may induce vasodilation and increase in vasal permeability and increase capillary flow [98], together with hyperalbuminemia in nasal discharge during a Rhinovirus infection [126].

The autonomous nervous system (ANS) plays an important role in rhinitis symptoms [68, 151]. Nasal mucosa is richly innervated by sympathetic neurons containing norepinephrine and NPY(neuropeptide Y) with vasoconstrictor action and by parasympathetic neurons containing acetylcholine, PHM (peptide histidine methionine), VIP (vasoactive intestinal peptide) inducing vasodilation, serous cell secretion, mucous cell secretion, and epithelial secretion [187]. Other transmitters such as CGRP (calcitonin gene-related peptide), SP (substance P), NKA (neurokinin A), and GRP (gastrin-releasing peptide), are released in the nose by C-type sensitive nerves [130] (Table 11.9). *Neuropeptides* are all mainly distributed to submucous glands, arterioles, and sinusoids. On the other hand, the binding sites are very different: the arterioles bind CGRP and NKA, the epithelium and submucous glands bind GRP, and the vessels, glands, and epithelium bind SP [130]. In other words, the sensitive fibers prime a neural reflex that stimulates nasal secretion. In AR the parasympathetic antagonists inhibit rhinorrhea, but not nasal congestion or sneezing [4]. Challenge with a parasympathetic agonist, methacholine, increases secretion, while pretreatment with atropine inhibits it; moreover, methacholine has no effect on nasal flow, which is, instead, reduced by oxymetazoline. Therefore *glandular secretion is under cholinergic* control, while *the vasculature is under adrenergic control* [131]. Cholinergic stimulation causes arteriolar dilation, thus enhancing passive diffusion of plasma protein into the glands by 50%–100% [76], while adrenergic stimulation of the mucosa has little or no effect [106].

Lastly, nasal response cannot be divided into distinct categories; in fact, even if histamine is classically identified as a mediator released by metachromatic cells, NPT with cold air causes an increase in both histamine and tryptase levels, and both itching and congestion [127, 173]. Moreover, NPT may produce a delayed response in the same way as allergens [68]. Antihistamines have no effect on cold air NPT, while they inhibit nasal response to NPT with allergens [172]. Interestingly, the allergic reaction intensity is aided by the so-called *priming effect:* repeating the NPT on consecutive days in subjects with ragweed pollinosis, but outside of pollen season, a progressively lower quantity was necessary to provoke the same clinical symptoms that appeared after the first NPT (Fig. 12.2) [38]. Repeated exposure to a pollen to which a subject is sensitive induces *nasal hyperreactivity* (NHR), not only to the pollen studied, but also to a second pollen not immunologically correlated with the first. The concept has been revisited in children with perennial or persistent AR (PAR) from Der p, in whom two subsequent NPTs with allergen doses, too low to

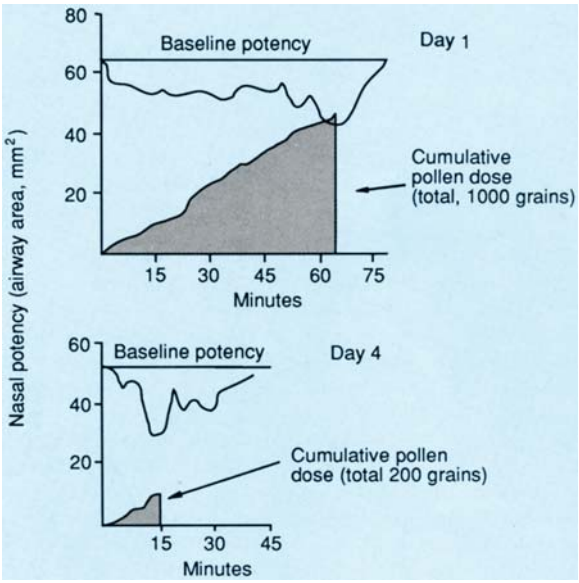

Fig. 12.2. Effect of nasal priming. On 4 successive days, an allergic rhinitis (AR) patient was given a decreasing dose of ragweed pollen (1,000, 800, 400 and 200 grains). On day 1 >60 min of exposure and 1,000 pollen grains produced a similar reduction of nasal potency as 15 min at 200 grains on day 4

cause significant responses, led to an increase in both immediate and late response [80]. Since the priming is not correlated with cumulative doses, but with repeated exposures during the natural pollen season, it may explain the symptom's chronic nature and persistence. Another important issue to be considered is the mucociliary system, which may suffer from the insults of allergens, viruses, cationic proteins, etc. In particular, in AR, allergen contact with the sensitized nasal mucosa causes the ciliary movement to progressively slow down and then stop [108].

Nasal Immunology

The mucosa covering the nasal cavity is in close contact with the *NALT* (nasal-associated lymphoid tissue), anatomically equivalent to Waldeyer's ring (Chap. 15), and is part of the mucosa-associated lymphoid tissue (*MALT*). B cell clones endowed with a rather immature memory, but with the potential to express the J chain, are initially stimulated in both tonsils and adenoids, and then in the NALT. They migrate into the glandular tissues, where they differentiate, turning into Ig/plasma cells (immunoglobulins). The sIgA antibodies localized to serous cells, as an integral part of the immune exclusion mechanism [14] (Chap. 9), are charged with the crucial duty of *defending the nasal epithelium* from infectious agents and outside irritants. In this function, sIgA is supported by aspecific defensive mechanisms such as the mucus forming a mechanical barrier against particulate material, together with the mucociliary system, lactoferrin, and lysozyme, secreted selectively by the serous glands with *bacteriostatic and bactericidal properties,* and several other substances and secretions [9] (Tables 12.1, 12.2). IgA antibodies are mainly gland-associated (76.7%) and less surface-associated (46%), whereas in inflammatory rhinitis the proportions change to 62% and 24%, respectively [14]. Other Ig isotypes are present in nasal mucosa: IgG antibodies are found in the lamina propria and are largely produced in nasal mucosa, even if no inflammation is present. On the contrary, there are few IgM antibodies that seemingly predominate in the GALT (gut-associated lymphoid tissue); moreover, many more IgD antibodies are found than in other sites of MALT and are probably tonsillar in origin [14] (Table 12.3) [9, 14, 191]. IgE/plasma cells are practically absent, even if they apparently increase in allergic subjects [58]. Whether these IgE are really associated with both mast cell phenotypes or with *Langerhans cells* (LCs), rather than deriving from an autochthonous production, is largely disputed [70]. It is not clear in what structure the isotype switching takes place and whether B cells produce IgE in nasal mucosa [4]; however, there are IgE antibodies [58], and their nasal localization is demonstrated by their cultivation [202].

Another immune function of nasal mucosa is the *defense from aeroallergens* through the production of antibodies. The immune exclusion may act by preventing microorganism adhesion, including *Haemophilus influenzae*, *Streptococcus pneumoniae*, etc. to nasal and nasopharyngeal mucosa [149]. Immune events occurring in nasal mucosa during infections or AR are connected with an IgG increased secretion in interstitial

Data from [9, 14, 191].

tissues, with consequent transudation of serum IgG into nasal secretions. These IgG responses have been designated as immune elimination [14], since the properties of these antibodies act as a *second line of defense* against invading antigens. Nevertheless, as is well known, IgG persistence may be deleterious to nasal mucosa, if immune complexes increase capillary and epithelial permeability, thus allowing bystander antigens such as food, bacterial, and viral antigens to penetrate into nasal mucosa. The vicious circle that ensues may lead to a persistence of inflammation in nasal mucosa [9].

All immunocompetent cells are represented, most lymphocytes are T cells: on the average there are 110 $CD3^+$/mm of basement membrane (BM), without differences between allergic and control subjects. Of these, 66/mm are $CD4^+$ and 23/mm $CD8^+$; therefore $CD4^+$ are 2.87-fold the $CD8^+$ [70]. Generally speaking, CD4 T cells predominate in the mucosal superficial layers, while CD8 are prevalent around the submucous glands (Table 12.3), where numerous Ig-producing cells are found, among which the IgA^+ antibodies predominate [130]. Others have demonstrated that these proportions correspond to the lamina propria, while in the epithelium of allergic subjects, CD8 T cells are 1.9-fold of CD4 [58], and NK cells account for only 5% [119]. Of the CD3 T cells, TcRγδ cells total 3% of the Vδ1 family, are more adherent to epithelial surfaces [167], where they are significantly more numerous, and are activated since they express $CD45RO^+$, but are absent in the serum [119]. We emphasize these findings, which reconfirm that *blood lymphocytes do not reflect their number in inflammation sites*. $CD25^+$ account for 0.6%, so in allergic subjects the main lymphocytes are $CD3^+$, $CD4^+$, and CD25 [70], while for $CD14^+$, $CD19^+$, and CD22 there are no significant differences [70, 110]; HLA-DR antigens were few or none in the epithelium but were present in striking numbers in the lamina propria [58]. In the serum, a reduction has been recorded of CD4, CD45RO, CD45RA, and CD19/CD23, with significant differences as compared to nonallergic subjects [58, 70]. B cells ($CD22^+$) and monocytes/macrophages ($CD14^+$) are found more in the lamina propria and perivasal sites [58, 70]. More specifically, there are 16 macrophages/mm of BM, 27 plasma cells [76], 16 mast cells, 90% of which are tryptase and chymase-containing mast cells (TCs) and 0.5/mm of lamina propria, 80% T cells, one-third of which are IgE^+ [130]. These cells are heterogeneous, yet they produce many interleukins (ILs): IL_3–IL_8, $IL_{10,}$ and TNF-α, while it is not clear which phenotype produces IL_{13} in the lamina propria [119].

Basophils and eosinophils are the main cells responsible for nasal allergic response [43, 110]. In atopic children, the close correlation has been demonstrated between the increased prevalence of these cells (highest at age 4 years in the presence of atopic disease, mainly AR), sensitization to inhalants and foods, and high IgE levels [200]. During the pollen season, activated eosinophils accumulate in both submucosa and epithelium [8], and mast cells migrate with basophils to nasal mucosa epithelium. Mast cells only penetrate [59], while basophils reach the submucosa, but neither lymphocytes nor basophils increase in number, unlike epithelial mast cells, which increase from 0–10% at rest to 40% during the season [69]. In normal subjects, there are 7,000/mm^3 in the tissues and only 50/mm^3 in the epithelium [188].

Immunopathology

In the nose, there is again a predominance of Th2 lymphocytes, and the mechanism that causes their supremacy has been clarified. Thymus and activation-regulated chemokine (TARC) has been shown to facilitate the recruitment, activation and development of Th2 polarized cells, as well as *Th2-like ILs in nasal mucosa.* Combined stimulation with IL_4 and TNF-α, as well as IL_{13} and TNF-α, synergistically induced TARC expression in epithelial cells and fibroblasts. Significantly, IL-induced TARC was higher in epithelial cells obtained by AR patients than in those from nonallergic patients [170].

Nasal mucosa is the first point of contact with inhaled allergens, and act in concert with the NALT. Since a considerable quantity of antigens penetrate into the nasal cavities, these cavities need structures that guarantee an effective protection against the harmful action of such invaders. The mucous layer is *the first innate defense mechanism,* which carries out its functions by taking up and eliminating the potential antigens via an important engagement of secretions; a crucial protection is constituted by antigen-specific sIgA. In the mucosal epithelium, the encounter between mast cells/IgE^+ and the antigen takes place, followed by histamine and other mediator release, as demonstrated by mast cell degranulation (Fig. 12.3) [69]. This has an effect not only on the mucosa, but also on the vasculature, the calyciform cells, and nasal neurons [124]. The interactions between antigens, nasal mucosa, and NALT depend on the nature, quantity, and frequency of antigen contact, and on an injured epithelial tissue. Airborne allergens penetrate into the nose and deposit on nasal mucosal epithelium, drained by superficial cervical lymph nodes. There they are taken up and processed by APC (antigen-presenting cells) LCs, which travel to the posterior lymph nodes and the adenoids, where antigen-specific T cells, homing in on the nose, are stimulated [108]. Therefore an excess of antigen material could make its way directly through the posterior cervical lymph nodes and reach the nose. In general, the inflammatory alterations of seasonal rhinitis (SAR) are milder and less persistent than those of PAR [13], as seen in the data collected on 1,002 patients before treatment (Table 12.4) [99]. The results of a study conducted on 50 children 2–7 years of age are even clearer (Table 12.5) [98]: the high levels of eosinophils and basophils in AR and those of neutrophils in nonallergic rhinitis are evident.

Figure 12.4 [14, 26, 50] summarizes a hypothesis of the pathogenesis of nasal allergic inflammation.

Immediate Phase

A secondary nasal antigen challenge triggers immediate allergic reaction (type I), which peaks within 15 min (with a corresponding peak of eosinophils), and then gradually subsides, with a consequent cascade of stored or newly synthesized mediators in nasal mucosa (Fig. 12.5). The duration of clinical manifestations is usually shorter than 1 h; however, cellular, vascular, glandular, and nervous reactions resulted in typical clinical manifestations in nasal mucosa. *Nasal obstruction* is highlighted by an increased nasal mucosal volume provoked by parasympathetic neurons inducing blood vessel dilatation. Blood levels of many mediators decrease during the initial phase, then in 20% of cases increase again 6–12 h later during the late phase [12], which explains the *symptom recurrence*. Complement *in loco* activation may also be followed by a further metachromatic cell mediator release by binding to anaphylotoxins, which have direct effects on the vascular epithelium [2]. *Histamine* plays a salient role in the immediate phase, where it is released by mast cells, while in the late phase it is released by basophils, the participation of which has been studied closely [124]; in the first hours the histamine passes from 4.3%±2.7% before challenge to 10.3%±3.8% at the 4th h [73]. There is a considerable difference with histamine in normal and nonallergic children, compared to children with AR: ≈0.2 vs ≈10 pg/µg protein [98] and, also with tryptase, in ragweed-allergic subjects and symptomatic subjects

Table 12.4. Mean percent of 1,002 patients with each cell type examined per field in the nasal cytograms of patients at the start and end of five studies (mean)

compared to control subjects [84]. After the initial phase, allergens interacting with T lymphocytes increase locally activated metachromatic cells expressing CD40L, the amount of which decreases in parallel with the histamine, from 10.1±5.4 before challenge to 4.4±2.2 by the 2nd h [73]. The *mast cell role is significant:* thanks to fixing on FcεRI, they release IL_3 (activation of basophils), IL_4 (synthesis of IgE by isotype switching of B lymphocytes piloted by Th2 T cells), and IL_5 (which along with GM-CSF interacts with eosinophils via endothelial adhesion molecules). This suggests that a positive feedback mechanism is triggered, increasing the inflammatory response. Mast cells are the only cells of nasal mucosa that carry IgE [70, 130]. They are localized in strategic sites, represented by inflammatory *foci* and small vessels, therefore near HEV (high endothelial venule) receptors, which respond with increased vascular permeability, near glands that respond by secretion, and near sensory nerves with H_1 sensory receptors that respond by starting an itching sensation, thus eliciting the sneeze reflex [51]. Mucosal mast cells produce IL_4, IL_5, and IL_6, which proliferate in the allergic epithelium [4], in addition to histamine, release PGD_2, kinins, and tryptase, responsible for the immediate symptoms: the release of these mediators shows the priming effect [172]. Compared to the total number of mast cells, the percentage of T positive cells is 26.4 in allergic subjects and 7.4 ($p<0.01$) in control subjects [70]. Most effects associated with AR symptoms can be reproduced by histamine challenge: histamine and other vasoactive substances induce vasal permeability, thus causing *immediate symptoms* such as rhinorrhea, as well as stimulating sensitive fibers that provoke sneezing, by reflex stimulation of sensitive nerves of nasal mucosa. LTD_4 (leukotriene D_4) and PAF (platelet hyper activating factor) are substances with opposite effects: LTD_4 causes nasal obstruction, while PAF reduces nasal resistance. LTs generated by 5-lipoxygenase further increase vasodilation, vascular permeability of the microvasculature, and mucous secretion [69].

Studies using *in situ* hybridization have confirmed, in parallel with skin studies, the presence of *Th2-like cytokines* (IL_3, IL_4, IL_5, IL_9, IL_{10}), with a highly significant correlation between IL_5 and activated eosinophils [4, 50]. Their recruitment is thus associated with cells expressing the mRNA for Th2-like ILs, including GM-CSF [50]. *In childhood, nasal eosinophilia is significantly correlated with allergic symptoms* [99]. The Th2 cell-driven inflammation is amplified and maintains itself (immediate-type alterations, unlike in asthma, prevail over late-type alterations) by activating eosinophils and neutrophils with their store of harmful proteins, proteolytic enzymes, and toxic O_2 radicals, with limited effects compared to asthma [99]. Further *basophil* release of HRF (histamine release factor) -mediated histamine is observed, as well as eosinophil chemotactic factors released by epithelial and endothelial cells (altered by mediators in case of long-standing inflammation),

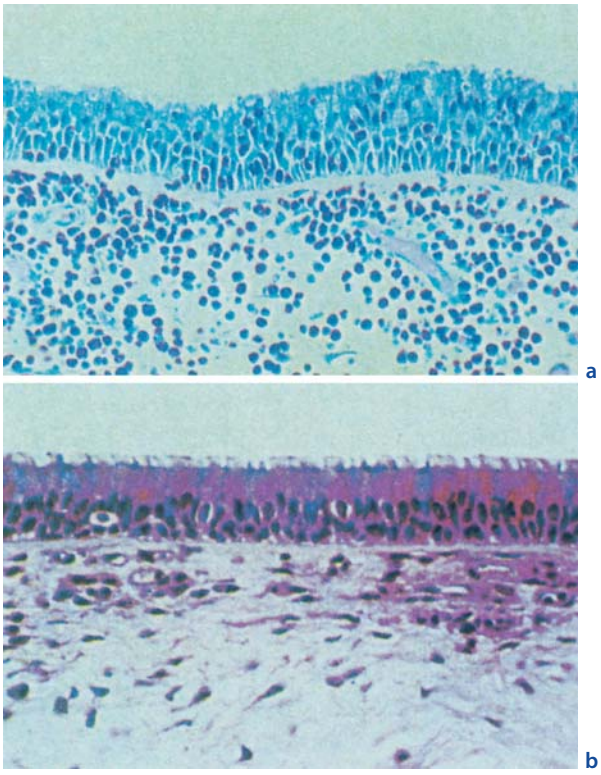

Fig. 12.6. **a** Photomicrograph of Giemsa-stained nasal tissues showing marked eosinophilia. ×400. **b** Anti-RANTES staining. ×400

tachykinin subsets including SP and CGRP, which increase capillary blood flow, fibroblasts and epithelial cells activated by TGF, IL_1, TNF, and CCL chemokines such as MIP-1α and -β [4], MCP-1 [84] and RANTES [169] (Tables 1.54–1.56). MCP-1 is significantly increased in allergic subjects during the season, while IL_8 levels are unchanged [84], and RANTES generated *in loco* plays a crucial role in *eosinophil* infiltration into nasal mucosa [169] (Fig. 12.6). The migration of inflammatory cells, chiefly eosinophils carrying VLA-4 (CD49d/CD29), is ensured by vascular endothelium only by VCAM-1 (CD106) (Table 1.2), the expression of which on the endothelium 24 h after challenge *is* significantly fostered by CD62E and CD54 [87]. Eosinophil recruitment is selective because CD49d/CD29 cannot be found on neutrophils (Table 1.45). At the pollen season peak, budesonide (BUD)-treated patients had significantly lower nasal lavage fluid IL_5, EDN and ICAM-1, and eosinophil-CD11b was suppressed, with no effects on IL_4 and IL_6 levels, ragweed-specific IgE seasonal increase, and nasal fluid IgA antibodies [79]. Unlike in asthma, there is no BM thickening [110]; the epithelial cells do not vary in number during the various phases of rhinitis. Commonly cationic proteins of migrating eosinophils promote their adhesion to leukocytes, stimulating interactions with CD11/CD18, counter-receptors of CD54 [26], induced by IL_5 in AR patients and not in

nonatopic controls [168]. The pro-inflammatory IL_{18} is up-regulated because of natural allergen exposure in nasal secretions in SAR, showing a similar pattern to IL_1, with a slow but persistent increase during the course of the pollen season. Persistence of IL_{18} high concentrations in PAR compared to SAR suggest its role in persistent allergic inflammation [177]. Instead, in children with atopic asthma or AR, polymorphisms in $IL_{12}\beta$ are not likely to be associated with the development of atopy-related phenotype [117].

Late Phase

Several hours after allergen exposure (on the average from 4 to 8) the *late reaction* occurs, with *a hyperinflux of inflammatory cells and mediators.* For example, LTs increase considerably up to the 12th h [168]. At the clinical level, sneezes and rhinitis are replaced by nasal obstruction [168]. There is also a quantitative demonstration of the different incidence of late reaction: 68% in asthmatics vs 23% in rhinitic subjects, with similar differences in FEV_1 drop (24% vs 11%), without conducive factors as in asthma such as sIgE (specific), severity of immediate reaction, and degree of methacholine response [106]. Histamine reaches a peak at ≈10 h (increasing from ≈10 ng/ml of baseline to ≈50, which corresponds to an eightfold increase of metachromatic cells, up to 79.7±39, mostly represented by basophils, as verified in vivo [73], since they do not produce PGD_2. This is further confirmed by the high correlation between increased histamine ($p<0.0001$) and CD18 coexpression, which identifies basophils in 90% of IgE^+ cells arising in the late phase [110]. The HRF can be seen bound to basophils (which increase 8- to 12-fold by 12–24 h), capable of perpetuating its flow [110]. Eosinophils are well represented [73], from $0.22\pm0.10\times10^3$ before challenge to $49.10\pm27.30\times10^3$ at the 8th h [168], more specifically from 1–2 cells/cm (baseline) to 18 at the 8th h [118]. They degranulate, leaving their entire array of cytolytic cationic proteins: ECP (eosinophil cationic protein), EDN (eosinophil-derived neurotoxin), EPO (eosinophil peroxidase), and MBP (major basic protein), which even at low concentrations reduce the frequency of ciliary beating [99]. ECP increases during both phases, more markedly in the late phase [168], where, however, it produces no harmful action [110]; nevertheless ECP levels correspond significantly to histamine levels in symptomatic SAR patients [84]. Eosinophilia can have a considerable significance in the nasal mucosa, like the change of cellular density, since the more cytolytic hypodense phenotype binds to sIgE more easily, playing a significant role in nasal inflammation [61]. Indeed, it is seen to a greater extent in the moderate to severe forms compared to those present in asymptomatic patients or those with mild symptoms, thus indicating that hypodense eosinophils may participate actively in AR physiopathology [61]. These data have not been subsequently elucidated. Furthermore, in asthmatic patients, LTC_4 synthesis stimulated by Th2-like ILs is a more sensitive parameter of the activation of density change. To date, the most endorsed hypothesis tends to reduce the finding, considering it an epiphenomenon secondary to eosinophilia (Chap. 11). It has been demonstrated that both phenotypes react to the same extent to PAF chemoattractant action, believing that normodense cells become hypodense under the action of inflammatory mediators, and that both respond to chemotactic signals in the same way [91]. Nevertheless, in childhood these eosinophils are mostly immature, which is the reason for the numerical increase observed (Fig. 1.35c). Neutrophils, with still far from understood functions, reach nasal mucosa, doubling their number [118], but they are few in both epithelium and lamina propria [55], while they persist for a long time even during periods of symptomatic remission [99].

The late phase may be regulated by *extensive interactions between APCs, nasal LCs, T lymphocytes, and ILs*: the APCs are well represented by dendritic cells forming a network below the BM, macrophages arranged in the subepithelial tissue and around adjacent glands, and PBMCs (peripheral blood mononuclear cells), which migrate from epithelial vessels after the allergic challenge [125]. Epithelial $CD1^+/IgE^+$ cells ($p=0.01$ vs controls) [58] increase quantitatively during the NPT only in allergic subjects and may bind allergenic peptides [138]. The role played by *T lymphocytes* has recently been re-evaluated, since 24 h after the reaction in nasal mucosa, there is an increase of $CD4^+$ and $CD25^+$. In both epithelium and lamina propria of nasal mucosa, T cells appear to be well expressed in all their components in atopics, but not in controls, and more in subjects suffering from PAR than in those with SAR [58]. After activation induced by allergen encounter, nasal T cells express $CD45RO^+$ and, after a new exposure, IL_4 influences mast cell proliferation (emphasizing their participation in this phase also) as well as IgE synthesis [66]. It is still being studied whether CD45RO surface antigens come from circulation or reside in the NALT or in nasal mucosa [66]. Lymphocyte infiltration has opened a new chapter in AR pathogenesis: T cells bind to HEV epithelium and then roll (Fig. 1.59) with adhesion molecule interactions; afterwards vasodilation increases [4, 87, 168]. An important contribution on the cells that are active in this phase demonstrates that *eosinophils* and *basophils* remain at high levels until the 24th h, with a *close correlation between cell count and increase in nasal resistance and obstruction* at the 8th and 24th h [118]. In the case of continuous allergen exposure or exposure to aspecific irritants, especially in patients with the most severe forms, *the late phase may take on an aspect of continuity*: in fact, in nearly 50% of patients, repeated daily exposure increases their responsiveness, associated with basophil influx and increased histamine release, significantly correlated with sIgE levels [17]. Continuing

this exposure, the number of mast cells in nasal mucosa also increases [59]. It is significant that β1 integrins such as CD49d/CD29 and VLA-5 (CD49e/CD29) [119], also common to eosinophils [87] and vitronectin receptor, are involved in nasal mast cell activation, IL up-regulation, and mast cell survival [119]. Furthermore, eosinophils and basophils respond well to CD103 [87], and IL_4/IL_{13} can strengthen its expression in epithelial cells. Therefore lymphocytes and mast cells may indirectly contribute to eosinophil and basophil recruitment into nasal mucosa [124]. It is known that the development of late phase is connected with the severity of initial challenge and not with the greater or lesser responsiveness to allergen exposure; this may be related to the heterogeneity of late-phase inflammatory phenomena [161].

It was also seen in Chap. 11 that there are other, currently not fully elucidated mechanisms that could come into play in the pathogenesis, for example ANS and neuropeptides that provide beneficial effects in addition to negative ones. Figure 12.7 [48] sums up the recent acquisitions on factors influencing the resistance of nasal airways through the ANS. Stimulating parasympathetic nerves cause an *increased glandular secretion,* not only rich in sIgA, lysozyme, lactoferrin, and other enzymes, but also useful for humidifying, lubricating, waterproofing, etc. the mucosa, combating together with the enzymes and sIgA the pathogenic microorganisms coming from the inhaled air [76], an important function in nonspecific defense. On the other hand, nociceptive nerve responses (associated with pain), even if degraded by epithelial NEP (neutral endopeptidase), in turn inhibited by cigarette smoke, viral infections, etc., are able to send the CNS (central nervous system) negative messages, initiating axonic responses: *their activation induces itching as in AD,* congestion, glandular secretion, etc. (Fig. 12.8) [4]. Neuropeptide activation involves other effects, of greater or lesser functional sig-

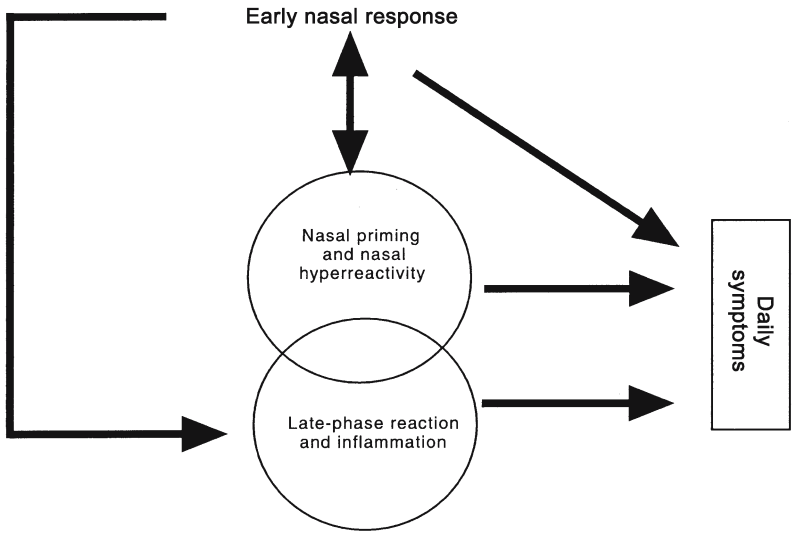

Fig. 12.9. Relationship between nasal hyperreactivity and nasal allergic reactions. (Modified from [62])

nificance such as vasodilation, edema, BM exposure, migration of leukocytes, thickening of the mucosa, and reduction of nasal patency [187]. *Neurogenic inflammation may be up-regulated by neurotrophic ILs,* such as NGF (nerve growth factor) and IL_{11} may participate in the pathogenesis of both AR and asthma [4]. Epithelial cells not only act as a barrier, but are also capable of secreting mediators both to aid and combat inflammation. Their interactions with CD54, aided by MBP, ECP, and IFN-α and -γ, which substantiate the intervention of eosinophils in nasal mucosa [124], explain the peculiar susceptibility of epithelial cells and nasal mucosa to Rhinovirus infections, which have in CD54 their receptor [1], whose counter-receptors on leukocytes are CD11/CD18, thus ranking CD54 first in the pathogenesis, as demonstrated by its absence in healthy volunteers [36].

The sIgE are significantly higher in allergic subjects than in controls in both epithelium and lamina propria (p=0.0001 and 0.005) [58], and also in the subepithelium (17.4 vs 3.9 cells/mm of tissue, p<0.001) [70]. On the other hand, it is possible that B lymphocytes isolated from the nose produce sIgE, distinguishing between allergic individuals and nonallergic subjects [202], as also demonstrated by the presence of anti-ragweed sIgE (and IgG_4) in nasal washing fluid [123]. Experimental data explain why, despite serum sIgE's rather short half-life, allergic symptoms can be induced in pollen sufferers when the pollen counts at the end of the season are lower, since even a few nanograms of IgE can trigger effector mechanisms [163].

NHR Role

Hyperreactivity indicates an increased mucosal and submucosal response to nonspecific irritants such as histamine, methacholine, bradykinin, hypertonic saline, and other provocational agents, also permitting the avoidance of those irritants. Therefore the onset of nasal symptoms following exposure to large quantities of dust or irritating substances, or to great T variations, is a common phenomenon. In patients with AR, these manifestations are more frequent and are triggered even by mild stimuli [62]. The priming effect, attributed to an increased nasal permeability that facilitates the allergenic invasion, is characteristically caused by exposure to immunological stimuli [62]. Recently, various studies have evaluated the role of NHR in relation to IgE-mediated allergy, specifying that when it is not possible to demonstrate its involvement the term "aspecific NHR" is used, supported for example by a change in the position of the head, changes in posture, and by nasal exposure to abrupt T changes, or irritants, cigarette smoke, perfumes, and paint smells [4]. It has also been observed that NHR to histamine correlates well with NHR to allergens, thus suggesting that there is a common pathogenesis for both. The underlying mechanisms have not yet been fully understood, so only explanatory hypotheses can be presented [62]:

- Increased epithelial permeability, possibly facilitating the direct stimuli toward the sensory nerve endings, the vessels, and nasal glands
- Hypersensitivity of sensory nerve endings (nociceptor nerves), possibly leading to an exaggerated response to normal stimuli
- A directional change in impulses afferent to SNC, possibly translated into a relative predominance of the parasympathetic system over the sympathetic system
- An increase in number and sensitivity of the receptors, especially muscarinic receptors, which could be the reason for the increased nasal secretion in patients with AR
- Mediator release after aspecific nasal stimulation, for example with cold, dry air [62]

Figure 12.9 [62] illustrates the relationships between NHR and nasal allergic reactions.

Etiological Factors

Genetic Factors

Atopic parents, mothers with asthma, and increased IgE levels at 9 months and 6 years of age were statistically very significant (p=0.01 to p=0.00002) [196]. Mean family history (FH) for atopy (FHA) was as follows: paternal 70.5%, maternal 62.2%, both 32.8% [78]. Moreover, there is an inverse relationship between rhinitis and number of children, with the only son most at risk [164]. A linkage between IgE responses, AR and chromosome *11q* as well as other markers on 12 chromosomes are reported in Table 4.2. Genotyping data of 400 microsatellite markers suggested linkage of SAR to chromosomes *1p36.2*, *4q13.3*, and *9q34.3*, as well as of serum total IgE levels, and of orchard grass RAST IgE levels [198]. It is suggested that IgE antibody responses to pollen may be controlled by genes associated with a particular HLA haplotype [10]. Epidemiological studies have suggested that AR and asthma sometimes occur together in the same family, indicating that some overlap exists in the genetic factors that contribute to the development of the two diseases [42, 65, 90]. However, PAR is associated with AR in the offspring with an OR=2.16 [105].

Predisposing Factors

Of particular importance are pollens in SAR and dust mites and animal danders in PAR.

The most common pollens [148] are grasses [34], weeds (*Compositae*) such as *Parietaria* (P) [41] and ragweed [33], trees including olive [24], birch and *Betulaceae* [40], and *Cupressaceae* [201]. SPT positive results on 129 [196] and 157 atopic children [199] are summarized in Table 12.6 and Table 12.7 [101] summarizes the prevalence of emergent pollens [101].

This demonstrates the prevalence of type I pollen allergy, a group of glycoproteins with a MW of 26–32 kD, consisting of numerous homologous and immunologically correlated isoallergens (Table 1.74). We stress that if the daily pollen count is 50/m^3 of air, 25 pollens/h are inhaled, =1 µg of Lol p (rye grass) during the whole season, but thanks to the filtering action of the nose and mucociliary system, only 0.1 µg reaches the airways [185], =1%–2% of the airborne particles of a diameter >10 mm; to cause clinical manifestations in a sensitized subject, just 1×10^{-4}–5×10^{-5} µg of pollens/h are sufficient [94]. The chief pollens have dimensions that range from 15–16 µm in *P. judaica* to 31–35 µm in *Dactylis glomerata*; in any case the microgranules have a diameter of 2 µm and rain can reduce them by 30%–60% [34]. Several indications on pollens [71, 112] and the pollen calendar (Fig. 12.10) follow:

- *Grasses* [34] (Figs. 1.68, 1.73), common and widespread practically everywhere, produce the dominating pollens, from the allergenic standpoint; flowering is in spring-summer, mostly starting in January in Australasia, April–May in northern and southern US and Europe, continuing until September in northern US and Europe, and until October in Southern US, and between October and December in Australasia [148]. Some pollens may be perennial allergens (Bermuda grass in Southern California and Florida [148]). In Europe, grasses are common in the center and south, starting in late April or early May in the north, and continuing until the month of July in the center and south and beyond in the north. There may also be a modest and inconstant increase of certain species in September with a second summer-autumn flowering).
- The *weeds* flower in Europe from July to September, in northern US from May to mid-September, in southern US from June to mid-November, and in Australasia from January to March and from October to December [148].

Parietaria [41] (Figs. 1.75, 1.76), the most widespread species of which are *P. officinalis* and *P. judaica*, is of particular importance in central and southern Europe (the Mediterranean area). Pollination goes from February–March to November, with an attenuation in July–August and a return in August–September (2nd peak), while in the north it starts in mid-May and continues without interruption until autumn.

Mugwort and ragweed [33] (Figs. 1.67, 1.74), with the first widespread and the second generally limited to northern Italy, flowers from the second half of July to late August–early September, continuing until mid-October [112]. Ragweed typically begins pollinating in mid-August and stops in October. All species contain the major allergen Amb a 1 (Table 1.74), so sensitized children may experience symptoms out of season when visiting regions where different species pollinate perennially [148]. It seems that ragweed has become considerably more widespread, in particular around airports, spread by the seeds clinging to the shoes and luggage of travelers coming from the United States.

Birch	18.8
Cypress	10
Hazelnut	19.6
Hornbeam	21.2
Ragweed	14.4

Data from [101].

Among the *Euphorbiaceae, Mercurialis annua*, which pollinates between April and September, with a peak during the months of June and August is noteworthy.

- The pollen trees flourish in Australasia from January to February and from August to December, from mid-January in southern US to May, from mid-February to May in northern United States, and from April to June in Europe [148].

Of the *Plantaginaceae,* the best known is *Plantago lanceolata*, known as plantain, which flowers from April to September, giving earlier and longer-lasting symptoms than the grasses.

The *Betulaceae,* most important in the north-northeast (Table 12.7), start to pollinate in February-March, reach their peak in April, and decline until they disappear in early May; in central regions the flowering goes from February to April–May and in the south from January to April–May [40].

Olive pollen, very common in the south, especially in Italy around Bari (54% of the territory), and in Liguria, reaches its peak in May–June; in the latter month the counts reach 1,000–2,000 granules/m^3 of air, with a peak of 4,000 [24].

The *Cupressaceae* [201], common in Mediterranean Europe and central and southern Italy, with an early season from February to late April, should be included in the SPT panel, considering how widespread cypresses are, not only as ornamental plants according to the classic usage, but also as dividing hedges and windbreaks, and without latitudinal limits.

Data from [108, 149].

• Other moderately allergenic pollens are characteristic of other trees, basically the poplar, willow (*Salicaceae*), plane or sycamore (*Platanaceae*), the dust of which comes from the fruits and is not really pollen, and horse chestnut (*Sapindaceae*), with the last two often used for decoration along streets and roads; less allergenic are fir, pine (*Coniferae*), and elm (*Ulmaceae*); hazelnut (*Corylus avellana*), hornbeam, alder, and others are emergent (Table 12.7).

A comprehensive study in 2148 children has found that sensitization to birch (OR, 6.0), timothy (OR, 2.8), and horse (OR, 4.1) were significant risk factors for rhinitis [140].

It must be kept in mind that at an elevation of 1,000–2,000 m pollination is delayed by about 1 month; however it may be *accelerated everywhere by ozone depletion* (Chap. 4).

As a result of these studies, it is reasonable to conclude that exposure to a high level of birch pollen in early infancy increases the risk of sensitization to the same allergen, as well as the risk of allergic asthma [78].

The role played by food allergy is demonstrated by food-related (fresh fruit and vegetables) AR within the oral allergy syndrome (Chap. 9), for example 39 out of 157 children (24.8%) [199]. Due to the action of profilins, also with the mediation of latex, patients sensitive to *Betulaceae* often have symptoms associated with various fruits and vegetables and correlated trees such as hazelnut and alder [40] (Table 8.14).

Children sensitized to pollens and trees may require, in 9%–13% of cases, a visit to an emergency department (ED), and in 13% of cases have been diagnosed with asthma [25].

Among fungi, spores of basidiomycetes are associated with rhinitis, especially because the spores are present between April and October, providing a longer time to exert their influence, and are severe enough to prompt children to present to an ED [25].

Other aspecific factors that may influence AR onset are summarized in Tables 5.22, 5.24, and 5.25, especially HDMs [20, 37, 85]. *Household pets* were present in 30.0%–33.3% of cases at age 0–3 months and over 3 months in 34.4%–36.7%, cats in 13.8%–15.8% and 18.4%–18.7% of cases, respectively; thus 29 cats (5%) entered the house after childbirth [78].

Another important risk factor in PAR is *passive smoke:* mothers of allergic babies smoke during pregnancy (18.9%) and when the baby is 0–3 months old (18.3%), and over (26.8%), as well fathers, more after childbirth (22.5%) than later (17.7%) [78]. The first night spent by *neonates in a nursery* may be a risk factor for developing AR (OR, 1.46) [105].

Anatomical–Physiological Factors Differentiating Children from Adults

At the otolaryngological level, apart from the different dimensions of the respiratory tract already explained in Chap. 11, the differences may be quantified as follows [48, 71]:

- *Nasal resistance* 4-fold higher than in an adult: from a maximum of 12 cm H_2O, it decreases until it reaches adult values at 16 years of age.
- *Nasal cycle:* the circadian rhythm of congestion and decongestion, related to changes of the sympathetic tone, lasts an average of 3–4 h in the adult; in the child it is limitless because of the immaturity of the vasomotor control of nasal mucosa.
- Dependence on *nasal breathing:* in the child, alterations of nasal function may negatively influence general body growth and, locally, the development of splanchnocranium and lower airways.

Classification

With regard to the allergen responsible and the temporal evolution, AR symptoms may be distinguished as follows (Table 12.8) [108, 149]:

- Seasonal, taking place only in certain periods of the year, from pollen sensitization
- Perennial, or present all year round, as in the forms caused by Der p

We continue to use this classification, because dividing the symptoms into intermittent (the symptoms are present <4 days a week or for <4 weeks) and persistent (the symptoms are present >4 days a week and for >4 weeks) [12] seems to be impractical. Also, the difference between SAR and PAR may be unfeasible since symptoms do not necessarily occur strictly in conjunction with the allergen season because of the different prevalence of pollens and molds, many being perennial allergens, and since symptoms of PAR may not always be present all year round [12].

Seasonal Allergic Rhinitis

Definition

SAR is a condition caused by pollen allergy, occurring seasonally and characterized by itching and sneezing, emission of serous or seromucous secretion, and persistent nasal obstruction for over 3 weeks, in the absence of similar symptoms in other family members [108]. SAR prevalence, within pollinosis, increases in parallel with age, until it becomes one of the most frequent clinical manifestations (Table 5.21).

Etiopathogenesis

This is related to pollens, as explained in the pathogenesis. Depending on the period of onset, the following forms can be identified in Europe:

- Early or pre-spring, from sensitization to arboreal plants
- Spring or spring-summer, the most frequent from sensitization to grasses *Parietaria* and *Oleaceae*
- Summer-fall, rarer, mainly due to *Compositae,* also referred to as end-of-season pollinosis
- Combined forms from sensitization to different families of pollens

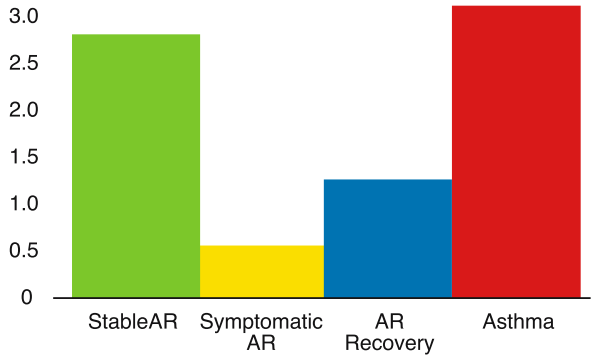

Fig. 12.11. Circulating basophil and eosinophil progenitors related to control. A large number of progenitors is evident in the off season, *stable AR*. With recovery, levels start to return to a high level, whereas in asthma sufferers, the levels of these progenitors are chronically high. *AR* allergic rhinitis. (Modified from [46])

Figure 12.11 [46] shows how the levels of hemopoietic progenitors are correlated to symptom variations.

Clinical Presentation

The characteristic symptoms, most frequent in the morning in 60%–70% of cases (p=0.008) and in the first 4 months, based on circadian rhythms and chronobiology [137], are made up of:

- Fits of sneezing (5–20 sneezes at a time)
- Rhinorrhea
- Nasal congestion
- Itching [27, 194]

With regard to chronology, itching and sneezing begin 1–2 min after an NPT, rhinorrhea after 5 min, and nasal obstruction after 15–20 min; the latter may continue even for 1–2 h [71].

Fits of sneezing, most frequent in the early morning and evening, are a frequent cause of social handicap [194].

Rhinorrhea is clear, watery, and abundant (the nose produces 20 ml of secretion/h) [194] and can become mucopurulent by secondary infection. The persistence of nasal drip (runny nose) can lead to an external irritation of nostrils, with a possible subsequent impetiginization. Postnasal drip, on the other hand, can irritate the retropharynx, which can cause a troublesome, even paroxysmal, cough. Nocturnal postnasal drip causes frequent awakenings and, as a consequence, can leave the child exhausted during the daytime.

Nasal congestion (stuffy nose) is usually less evident than in PAR: the obstruction may be accompanied by rhinolalia, a sensation of headache, and nosebleed. Because of frequent mouth breathing, the child snores while sleeping [111]. Nasal congestion may cause the infant or young child to become fretful, restless and easily tired.

Itching often precedes sneezing; when the soft palate itches, it means that the mucociliary system has transported the allergens into the nasopharynx [71]. Itching of the nose and especially the eyes is a cardinal manifestation of pollen sensitivity. In some children, the constant pruritus, excessive nasal blowing, sneezing, and picking or rubbing of the nose produces an increased frequency of epistaxis. Some complain of ear itching; this can be explained as due to the common innervation of the pharyngeal mucosa and the ear, by the glossopharyngeal (IX) nerves.

Characteristic Symptoms

The allergic salute and other particular signs pertain exclusively to SAR, most often to PAR. Moreover, several facial characteristics connected with repeated nasal rubbing, mouth breathing, and the presence of allergy-related circles under the eyes (allergic shiners) may be seen [19].

The *allergic salute* is frequently exhibited by children, who to alleviate intense, intolerable nasal pruritus (as well as to allow air into the nostril) move their nasal lobe upward and downward using a finger or the palm or dorsum of their hands (Figs. 12.12, 12.13); the continuous repetition of this movement may eventually result, above the anterior nasal extremity, in a permanent *transverse nasal crease,* across the mobile and bony part of the nasal pyramid (Fig. 12.14), which may be reduced by folding the nasal tip downward. For the same reason other mannerisms are observed, such as nasal wrinkling and mouth stretching by contracting the buccinator and orbital muscles [19].

Often *orbital darkening* (*allergic shiners*) also appear. These bluish, brownish to grayish discoloration of the lower eyelids, and swollen infraorbital tissue, most likely result from venous engorgement and stasis due to impaired infraorbital vein flow (Fig. 12.15), which anastomose with the veins draining the nasal turbinate swollen mucosa [48].

Because of persistent mouth breathing, with protrusion of the tongue and the resulting secondary hypertrophy of the peribuccal muscles, a *dental malocclusion* and the appearance of dysodontiasis may appear. With the passing of time, if chronic nasal obstruction (CNO) persists, in some children *craniofacial modifications* can be seen (Chap. 15).

Eye symptoms (itching, watering, photophobia, sensation of foreign bodies) are almost always associated with nasal symptoms (rhinoconjunctivitis) and in some cases can take on a predominating role; they are always more frequent and/or serious in SAR than in PAR caused by Der p or molds [114]. Similar symptoms are also caused by using *contact lenses* (Chap. 14), which are a risk factor 5-fold higher for SAR patients than for healthy subjects.

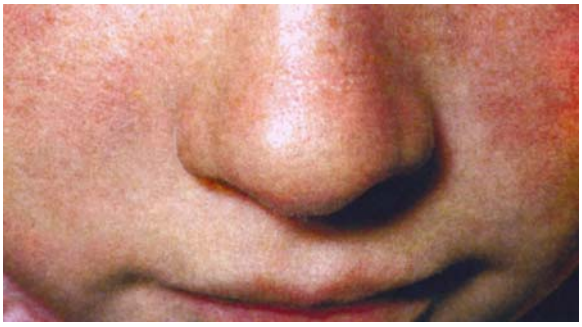

Fig. 12.14. Typical aspect of a girl with AR showing transverse nasal crease across the lower third of the nose

Oral allergy syndrome (Chap. 9) symptoms are possible owing to pollens and fruits with shared allergens and vegetables [199], as are cases of *contact urticaria* in young pollinosis sufferers who play outside in fields (Chap. 8).

The symptom presentation may be different:

- Symptoms appear during specific periods of the year.
- During the pollen season, symptoms are proportionate to the quality of environmental pollens, attenuated if it rains (pollens fall to ground), or if the child remains at home or spends time at the seashore (reduced pollen presence or absence), and accentuated by nice weather

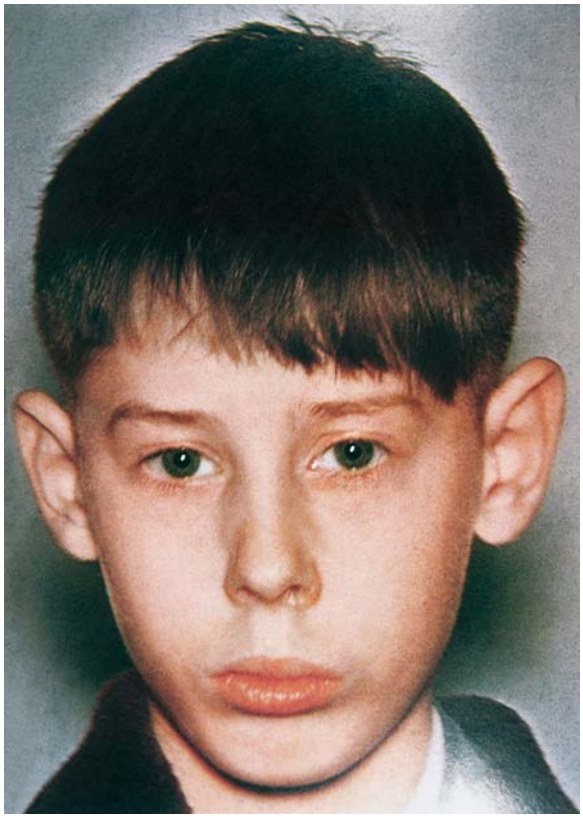

Fig. 12.15. Allergic rhinitis: note the pallor, discoloration of the lower palpebral area, mucous nasal discharge and lip edema

and wind (prolonged pollen suspension in the air), country walks, etc.

- The evolution is totally variable, with a possible remission of symptoms 1 year and worsening another year. In children with rhinoconjunctivitis of a certain severity, the appearance of asthmatic symptoms during the pollen season is frequent, but acute asthmatic episodes can occur even if no eye or nasal symptoms are present [71].

Diagnosis

Medical history may reveal a positive FH [78] (Table 4.7) and/or personal history for other allergopathies. SAR may be suspected on the basis of typical symptoms, arising on the occasion of pollen exposure (remember the month of birth; Fig. 4.11), and the child's characteristic appearance will help confirm the diagnosis (Table 12.9) [97]. Some children labeled as adenoidism sufferers actually have forms of nasal obstruction stemming from a chronic edema of the turbinates [194].

Medical examination is facilitated by data summarized in Table 12.10 [97]; conjunctival examination shows its hyperemia, with eyelid edges raised due to edema. Chest auscultation must not be overlooked, to discover possible wheezing.

The *anterior examination* with a hand-held rhinoscope equipped with a head light or head mirror or a headlamp with nasal speculum allows visualization of the anterior one-third of nasal airways. Children with AR have a pale, swollen and congested mucosa, and nasal turbinates that are often hypertrophic show a certain degree of obstruction [51]. Watery mucoid or opaque material may be noted in the nasal cavities and posterior pharyngeal wall. Findings are normal outside the pollination period. In small babies, it is usually not possible to examine the nasopharynx with mirrors [181].

Modified from [97].

The *cytological examination of nasal secretion* (Table 12.11) [97], obtained by having the child blow his or her nose directly onto two slides, or smear collected secretion using a cotton swab passed delicately over the mucosa and left *in situ* for about 2 min, may reveal the presence of a large number of eosinophils. Eosinophilia values >10% are considered positive [179] (see Appendix 12.2). The absence of eosinophils does not, however, exclude the diagnosis of AR, nor does their presence confirm it (Appendix 6.5); in fact, in nonallergic rhinitis with eosinophilia syndrome (NARES), there is also a pronounced eosinophilia (Table 12.11).

Therefore these studies have no absolute discriminatory value. For example, repeated respiratory infections may clearly modify the local picture indicated above and may also cancel the normal aspect observed during the intervals between SAR episodes [149].

As needed, further examinations and tests may be prescribed, including (Table 12.12) [116]:

- *Otoscopic examination,* which usually reveals retracted tympanic membrane and signs of fluid in the middle ears.
- *Rhinomanometry,* which records the air flow and endonasal pressure during respiration, allowing an objective measurement of the degree of nasal obstruction. Anterior rhinomanometry may be used in children, while posterior rhinomanometry is difficult in this age group [183].
- *Tympanometry,* which in children <7 months of age, indirectly measuring the compliance and impedance of the tympanic membrane and middle ear ossicles, reveals any existing alterations of the tympanic membrane system – middle ear – and the eustachian tube.

Nasal provocation test
Otoscopy
Rhinolaryngoscopy by flexible rhinoscopy or fiberoptic endoscopy
Rhinomanometry
Skin prick tests
Total and specific IgE
Tryptase dosage in nasal fluids
Tympanometry

Modified from [116].

- *X-ray examination,* with projections for paranasal sinuses if sinus (mucosal thickening, sinus opacification, presence of hydro–air levels) or adenoidal hypertrophy are suspected.
- *Rhinolaryngoscopy* with fiberoptic endoscopy, particularly useful as a complement to preceding examinations if the pediatrician suspects sinusitis. The primary function is the visualization of the upper airways, detecting any nasal polyps, endonasal foreign bodies, adenoidal hypertrophy, etc. In small babies, fiberoptic rhinoscopy is impractical since heavy sedation with local anesthetics is required [181].

Allergy Diagnosis

Complementing data recorded by medical history and physical examination, it may be useful to refine a specific etiological diagnosis, make SPTs with standardized allergenic preparations, outside of the pollen season to avoid the risk of triggering unpredictable reactions. If, considering the aerobiological calendar and where the child lives, the symptoms:

- Are *exclusively seasonal,* the test will be on grass and/or *Compositae* and/or *P. officinalis and P. judaica* pollens and, as necessary, the most common trees in the region of residence [179].
- Are *perennial or nearly perennial,* the test will include Der p and *P. officinalis and P. judaica*: in fact, *Parietaria* does not always have a circumscribed season, since it is present almost all year round in southern regions, with high pollen counts from February to November. In some areas cockroaches should be also included [179].

It should be added that:

- In a study on 1,100 schoolchildren, the SPT and RAST sensitivity and specificity showed a significant SPT difference for specificity and very poor positive and very high negative predictive values for both. With the increased cut-off point of 1.5 kU/l, almost identical predictive values for SPTs and RAST were obtained. SPT and RAST perform better in the negative than positive prediction of AR cases in epidemiological studies [147].
- In polysensitized children, the pollination season is longer, so SAR symptoms may overlap PAR symptoms.
- A child with double sensitization to pollens and dust mites [149] may show more severe and prolonged symptoms because pollen exposure increases airway reactivity to dust mites.

IgE and PRIST tests are reserved for cases where the medical history has not produced any valid indications and SPT results are not clear and unequivocal, while a NPT (Chap. 6) may be advisable in doubtful cases, for which the other examinations and tests have produced controversial results.

Specific Examinations and Tests

- Study of mucociliary transport may reveal a more or less pronounced slowdown.
- Mediator counts in nasal washing fluid.
- Studying tryptase levels makes it possible to evaluate the degree of activation of the mast cells [127] and of differentiation between active and nonactive forms [132].
- Nasal ECP level [84, 145] is an aspecific indicator of inflammation [133], in significant correlation with histamine levels in SAR patients [84].
- The NPT is the only reliable test if food allergy is suspected.

Because children, especially young children, do not or cannot complain of symptoms in the same manner that adults do, and because children are often out of sight of parents for prolonged periods of time, symptoms and signs of rhinitis may go unnoticed. This *may delay care for these children* [120].

Complications

AR can cause numerous complications, including otitis media with effusion (OME) [23], an abnormal skeletal development of the face, with orthodontic problems, dysfunction of the eustachian tube, and sinusitis. Otitis and sinusitis are results of the *continuum* formed by nasal, middle ear and paranasal sinus mucosa. *Paranasal sinusitis* is considered a factor that contributes to the development of bronchial asthma (Chap. 15).

Perennial Allergic Rhinitis

Definition

PAR is caused by allergy to non-pollen inhalants, with a nonseasonal recurrence, almost always a source of uneasiness, with symptoms that are more pronounced and longer-lasting than SAR, the most common of

which is nasal obstruction (Table 12.4). In the absence of controlled studies, it is assumed that about 2%–4% of the population suffers from it. The onset occurs at around 2–3 years of age, reaching the maximum prevalence during school age.

Etiopathogenesis

The most significant differences from SAR are mostly environmental aeroallergens, such as Der p (the main etiological agent), fungi, animal dander, cockroaches, etc. Compared to SAR, with continuation of the disease, chronic and irreversible local alterations can be seen, such as mucosal thickening, epithelial hyperplasia, more pronounced cell infiltration, and connective tissue proliferation [120].

The clinical pattern can be maintained or complicated by the possible presence of a large number of nonimmunological inciting agents, considering nasal hypersensitivity induced by chronic inflammation [48]:

1. T changes (even minimal), especially cold air, and weather variables (humidity, rain, storms)
2. Cigarette smoke
3. Perfumes and pungent odors (detergents, disinfectants, paints, especially if oil-based)
4. Alcohol
5. Gas (automobile exhaust fumes)
6. Various chemical substances
7. Bright light
8. Newspaper ink
9. Air pollutants
10. Changes in position of the head and/or body
11. Stress or mental factors in general

These stimuli, like URTI, often contribute to symptom chronicity, although the causal agent may have been eliminated [48]. Among air pollutants, it was recognized as early as in 1871 that O_3 in a particular state of activity becomes highly irritating, especially on the nasal mucosa, and excites nose secretion [32].

Clinical Presentation

Clinical features overlap SAR symptoms (except for the year-round duration), with the two differences previously listed: less frequent itching, especially of the eyes, and more pronounced nasal obstruction. The duration of the single episodes may be highly variable: from a few minutes to several hours. Generally speaking, the symptoms are less intense, and the association with bronchial asthma, urticaria, etc. may be less frequent.

Nasal obstruction is worsened by the supine position. Rhinorrhea and bouts of sneezing are more frequent and pronounced in the hours after awakening in the morning [120]. The allergic salute, transverse crease, allergy-related under-eye circles, and dental malocclusion are, in this form, even more common. The symptoms are tolerated much more by children than by adults [120].

Other signs and symptoms, mostly connected with CNO, frequently underestimated by family and pediatrician, and difficult to identify by children [183] are [120] as follows:

- *Asthenia* also caused by restless sleep
- *Sore throats* related to poor humidification from open-mouth breathing
- *Anorexia,* nausea, and sometimes vomiting, caused by the exaggerated swallowing of nasal mucus
- *Hearing loss,* mainly of transmissive type, owing to recurrent episodes of OME or nasotubal infections with intermittent occlusions of the tube. It is especially important that it is detected and treated in infants to avoid the ensuing delayed onset of speech causing inevitable learning difficulties and behavioral problems [181].
- *Anosmia* (often associated with sinusitis) and hypogeusia, complications frequently remaining undiagnosed [39], possibly leading to further appetite loss, increasing the emotional tension of family members at meal time
- *Headache,* especially frontal, caused by the chronic edema occluding the opening of the eustachian tube and paranasal sinuses
- *Restless sleep* because of nasal congestion, snoring, headaches
- *Epistaxis* (in 40% of children >12 months of age), caused by the traumas to the delicate nasal mucosa from the continuous rubbing/scratching, and from forcefully blowing the nose
- *Adenoidal facies* deriving from nasal obstruction and consequent chronic mouth breathing
- *Development of a high, narrow palate,* to which both chronic edema and venous stasis may contribute
- *Nasal voice* and other language defects, also caused by nasal obstruction
- *Poor school performance* due to concentration problems because of the continuous respiratory symptoms
- *Problems with parents,* relatives, teachers, and peers, causing social isolation at school and domestic conflicts because of frequent halitosis and continuous sniffling

Diagnosis

The diagnosis (Table 12.8 and Appendix 12.1) of aperiodic forms is based on medical history information and a clinical history of typical symptoms. The characteristic appearance of the child is also very indicative, and knowledge of the month of birth may offer some help.

A *physical examination* using a rhinoscope, *unlike with SAR,* shows nasal mucosa that may be variable in appearance Generally it is rather edematous and pale, nasal turbinates are hypertrophic, and *obstruction is pronounced* (Fig. 12.16); secretions are mostly mucoid.

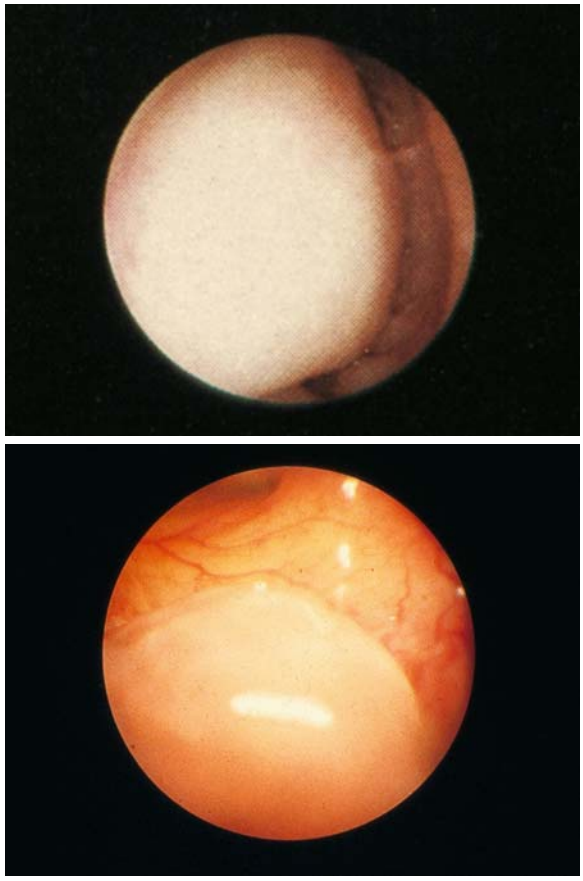

Fig. 12.16 a,b. Children with AR have a pale, swollen and congested mucosa; nasal turbinates that are often hypertrophic show a certain degree of obstruction

A similar problem of delayed care exposed in SAR babies has applicability also to PAR babies.

The diagnosis is confirmed, as in the preceding case, by otoscopy, tympanometry, and rhinomanometry; audiometric tests are discussed in Chap. 15.

Nasal cytology is useful for distinguishing between infectious and noninfectious forms (recurrent infections may be confused with PAR). Moreover, given the variable results, usually two or three tests are needed, preferably performed by the same examiner.

Allergy Diagnosis

SPT and RAST: to select the allergens to be tested, the standard probable causes are Der p, fungal spores, animal dandruff, or other allergens implicated based on medical history of individual children. The mycetes, as seen in Chap. 4 were positive in up to 19.5% of these children. Tables 5.18 and 5.19 show the high prevalence of related allergy. Pediatric studies report that Der p-positive IgE agree with SPTs, nasal IgE and NPT results agree in 82% of cases [11], and nasal sIgE appear to be a more sensitive index than PRIST for evaluating the exposure-avoidance of dust mites [144]. Therefore NPT may be a useful complement.

Specific Examinations and Tests (see "SAR")

Differential Diagnosis

Differential diagnosis (Table 12.8) may be made essentially based as follows [149, 181]:

- *URTI:* short clinical course, possible presence of fever, lymphadenopathy and neutrophils in nasal secretions
- *Chronic infectious rhinitis:* mucopurulent secretion, with fever, sore throat, cough, sickly feeling, etc. If relapsing and associated with other infections, may warn of underlying defects in host immune defense such as primary ciliary dyskinesia (two congenital syndromes) or secondarily, cystic fibrosis, and immune deficiencies.
- *Nonallergic rhinitis:* it occurs in children with intermittent and perennial symptoms, seasonal acute phases, and affects nasal mucosa, where altered vasomotor control makes it reactive to sudden changes in body T, neurogenic stimuli, and changes in environmental factors such as weather and T variations, high humidity, atmospheric pressure, odors, smoke, and pollution. It clinically mimics AR symptoms: scarce, often mucoid, rhinorrhea, nasal obstruction, pale and edematous mucosa, anosmia and hypogeusia. SPTs are usually negative.
- *NARES:* noninfectious pathology wholly similar to SAR, which is manifested with bouts of sneezing, rhinorrhea, nasal obstruction, nasal and eye itching, etc., triggered by aspecific stimuli.
- *Rhinitis medicamentosa:* congestion of nasal mucosa caused by a rebound effect following overuse of nasal decongestant drops or sprays; symptoms recede when treatment is discontinued [74].
- *Nasal obstruction* caused by deviation of nasal septum: the predominance of the symptoms affects only one nostril. A thorough inspection of the nose with a rhinoscope can help make a differential diagnosis.
- *Rhinitis from foreign bodies:* unilateral, purulent, foul-smelling nasal discharge with exceedingly unpleasant halitosis occurring after several days. It is mostly observed in young children who insert various objects into their nose; often weeks or months go by before a precise diagnosis is made.

Appendix 12.1 lists the main causes of CNO in childhood.

Complications

- *Bronchial asthma* arises in around 30% of all cases, after a variable period of time from the first AR episode. A 23-year follow-up has demonstrated that students who reported nasal symptoms but no evidence of asthma

when first enrolled developed asthma >3-fold more than students without rhinitis [146].

- In *paranasal sinusitis* particular care must be taken to detect a possible sinusitis, with an X-ray of the paranasal sinuses and, as needed, a CT (Chap. 15).
- *Other allergic diseases,* with SAR in nearly 30% of cases, determining a PAR pattern with periodic seasonal exacerbations.

Treatment

There are different treatment options (Tables 12.13–12.15) [116]. Figure 12.17 [27, 48] presents a simplified algorithm for therapy. With regard to the scientific bases of cromolyn and sodium nedocromil, see Chap. 11.

Identification and Elimination of Principal Allergens

While the elimination of allergens in the external environment is not possible (for example pollens abundantly present in the lower layers of the atmosphere, or the ubiquitous spores), the inhalants present in homes can be eliminated with precise environmental controls [19].

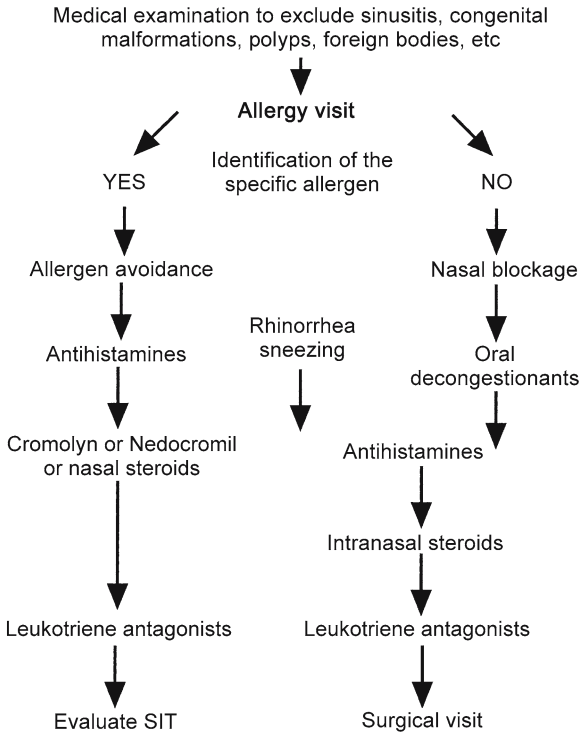

Fig. 12.17. Simplified algorithm for the management of allergic rhinitis. *SIT* specific immunotherapy. Antihistamines include azelastine, cetirizine, ebastine, levocetirizine, desloratadine, fexofenadine, etc. (Modified from [27, 48])

Antihistamines

There is no doubt that antihistamines (see also Table 11.59) have been the starting point of therapy, and are still the most valid drugs, especially with regard to the new generation of H_1-specific receptor antagonists, lacking sedative action. They mainly reduce rhinorrhea, nasal and eye itching, watering, and sneezing, while their effect on nasal obstruction is much lower. Their easy use makes them useful in any circumstance [109,

153]. An advantage of the oral preparations compared to medications for topical use is their effectiveness on the eye symptoms that invariably accompany SAR. The last-generation antihistamines – acrivastine, azelastine, cetirizine, ebastine, fexofenadine, ketotifen, levocabastine, levocetirizine, loratadine, oxatomide – compared with those of the first generation, have practically no sedative effects, since they do not cross the hematoencephalic barrier; nor do they significantly jeopardize children's learning capacity [22]. More precisely, ORs (adjusted for age and sex) for the incidence of sedation were 0.63 for fexofenadine; 2.79 for acrivastine, and 3.53 for cetirizine compared with loratadine [92]. Their dosage is shown schematically in Table 12.16. Recently several cardiovascular effects induced by terfenadine and astemizole, that is the capacity to block the cardiac K channels that permit cardiac repolarization, determining an ECG pattern (prolongation of the QT interval) known as torsades de pointes, have been reported [49]. Terfenadine has been withdrawn from the market. However, a panel of experts expressed a positive opinion on the drug, because in certain conditions the risk of adverse events is rare, especially during the pediatric years [45]. In fact, among 25 patients who had had problems there was a 16-year-old who had intentionally taken an overdose [195]. The average age was 53.3 years. Concerning the variables contraindicating terfenadine and astemizole prescription (Table 12.17) [28, 49], children may be at risk due to a coprescription of macrolide antibacterials, antifungals, etc., especially if they are cardiopathic or hepatopathic, or drinking grapefruit juice. The risks for acrivastine, cetirizine, and loratadine are even rarer, limited to $0–13\times10^6$ daily doses [89]. However, 80 atopic children aged 5–12 years, all suffering from AR and with SPTs positive to Der p, were treated with astemizole, cetirizine, loratadine and terfenadine associated with erythromycin without any cardiotoxic effects, and the increase in QT interval, caused by terfenadine, was no longer statistically significant after correction by the Bazzett equation (for heart rate correction) [45]. It is to be hoped that these data will receive further confirmation. Astemizole, the other medication withdrawn from the market, was an effective drug, well tolerated even in the youngest children [20]. However, its onset of action occurs within 2 days and its peak of effectiveness in 4 days [49]. Its half-life means that a single daily dose is sufficient to ensure 24-h protection [19]. Untoward effects could be due to its long delay in reaching therapeutic concentrations, thus some doctors could be tempted to prescribe higher initial doses, with a further increase in serum levels. A new molecule, tecastemizole, lacks CNS effects and cardiotoxic potential [153].

Acrivastine is a triprolidine metabolite, available in nasal spray form. With a half-life of 1.4–2.1 h, it requires the intake of more frequent doses than other second-generation preparations. It has no effects on the CNS [154], nor is it implicated in torsades de pointes [89].

Azelastine appears to have a triple-action effect: it is an H_1-receptor antagonist (antihistamine effect), stabilizes mast cells (mast cell-stabilizing effect), and inhibits inflammation (anti-inflammatory effect). It was evaluated in an unpublished multicenter study on 4,018 patients, 490 of whom (12.2%) were children aged 2–12 years; 87% of patients showed no undesired reactions, and the drug was effective and well tolerated by 82% of patients and 85% of physicians, with comparative results in the child cohort, data confirmed by two studies in adults [100, 134]. It has no undesired cardiovascular effects, without differences between 12- to 18-year-olds and >18 years of age [16]. Data from 489 children <13 years, including children aged 2–6 years, show that it is well tolerated and effective [86]; it is also marketed in the form of eye drops. The efficacy and safety in the treatment of both PAR and SAR have been evaluated in 211 children <13 years [192]. Azelastine efficacy was assessed by the changes in severity of ten individual symptoms of rhinitis and symptoms were rated according to a four-point scale: 62% of children exhibited a decrease in the total ocular score. General tolerance was evaluated as very good or good by 97% of the treating physicians [192]. In a DBPC trial, 125 children suffering from PAR were treated for a period of 6 weeks and the results were higher than placebo in the relief of all symptoms assessed, namely sneezing, nasal blockage, nasal itch and rhinorrhea [67].

Cetirizine possesses pharmacological actions that enable it to reduce both the infiltration of inflammatory cells and, in particular, chemotaxis and activation of eosinophils. Unlike others, which are metabolized by the liver, it is excreted by the kidneys [154]. Several studies have confirmed its clinical effectiveness, in adults and children, in treating both pollinosis and urticaria, concluding that its effects are very rapid, appearing within 40 min of intake [183]. In an unpublished study we conducted to evaluate its effectiveness and tolerability in children, a clear, significant improvement of all nasal and conjunctival symptoms was noted, while the cytological examination of nasal secretion showed a reduction in the average percentage of eosinophil (43%) and neutrophils (25%) numbers; drug tolerability was excellent. A prospective, randomized, parallel-group, DBPC study has demonstrated the safety of the H_1-antihistamine cetirizine, particularly with regard to central nervous system and cardiac effects, in infants age 6 to 11 months [158] as were several babies we treated and reported in Chap. 11. In two multicenter studies on 293 children 6–12 years of age with SAR [96] and PAR [72], very significant differences were noted in overall improvement. In three multicenter US studies on children 6–11 years, the cetirizine dose was too low (5 mg/day) for its effects to be evaluated; however, it was safe and well tolerated [75]. It is also known that cetirizine can induce sizable reductions of FEV_1 and histamine-induced bronchoconstriction; therefore we conclude that it may be successfully used in children, since it has

Table 12.16. Antihistamine H_1 commonly used for children with allergic rhinitis

Antihistamine	Doses	t_{max} after single dose (h)	Sedating	Peak plasma level after standard dose	Duration of action (h)
Acrivastine (children >12 years) Capsule 8 mg and syrup 0.8 mg/ml	8 mg × 3	1.4–2.1	–	?	8

Overdose
Heart abnormalities
Prolonged QT interval Ischemic heart disease Congestive heart failure Anti-arrhythmic medications: quinidine
Metabolic abnormalities
Hypokalemia: use of diuretics Hypomagnesemia Anorexia, fluid protein diet Severe liver disease

Data from [28, 49].

proved to be a rapidly active medication without major sedative effects, similarly to studies done in adults [182]. In a DBPC, randomized study on 69 PAR children 6–12 years with mite allergy, cetirizine was more effective than oxatomide and ketotifen in relieving nasal congestion and rhinorrhea, and significantly decreased the eosinophil number of a post-treatment nasal smear [85]. In 544 SAR children 6–11 years old, cetirizine 10-mg syrup provided significant reductions in mean symptom severity, but above all significant improvements on health-related *quality of life* (HRQL) outcomes were noted [63]. In mite-allergic children, cetirizine administered daily for prolonged periods decreases symptoms of and drug prescriptions for AR and asthma compared with symptomatic treatment [37]. The efficacy and safety of cetirizine and loratadine were compared in a prospective, randomized, DBPC, longitudinal study of 80 children, 2–6 years, with PAR caused by house dust mites or pollens: cetirizine produced significantly greater inhibition of the wheal response compared with loratadine; eosinophil counts were improved to a comparable degree with both agents. Cetirizine and loratadine produced comparable improvements in symptoms; however, cetirizine was more effective than loratadine in relieving the symptoms of rhinorrhea, sneezing, nasal obstruction, and nasal pruritus [150]. In children aged 6–11 years, cetirizine 10 mg has a rapid onset of H_1-antihistaminic activity, a 24-h duration of action, and greater H_1-activity than fexofenadine 30 mg [157].

Levocetirizine has an onset of action within 1 h and provides significant peripheral antihistaminic activity for 28 hours after a single dose. Once-daily dosing may be optimal in children aged 6–11 years. Levocetirizine tablets 5 mg reproduce and extends the cetirizine effects in children aged >6 years based on our extensive experience.

Ebastine is a new piperidine-containing, relatively nonsedating second-generation H_1-receptor antagonist. In a DB, parallel-group study of a single 5-mg or 10-mg dose of ebastine syrup used to treat AR in 20 children 6–12 years of age, both doses significantly reduced the histamine-induced wheal-and-flare areas for up to 28 h compared with predose values [154]. In 30 PAR children, ebastine improved the clinical symptoms, SPT was inhibited and sensitivity of the shock organ was reduced; no secondary effects were seen on the CNS and the tolerance of the drug was very good [6].

Fexofenadine, registered for children >12 years, is a new drug that is 80% eliminated in the feces and 10% in the urine, free of cardiovascular and CNS effects, and has been used in 8- to 12-year-olds, in whom the 30- or 60-mg single dose reached the maximum concentration in 2.4±0.2 h and inhibited the histamine-induced erythema and wheal in 2–24 and 1–8 h, respectively [156]. Fexofenadine, 15, 30, and 60 mg twice daily, was safe and well tolerated in 865 children 6–11 years old for treatment of SAR; no statistically significant mean change from baseline in any ECG parameter after fexofenadine treatment was recorded [64].

We have discussed the properties of *ketotifen* in Chap. 7 and its dosage in Table 7.19.

Levocabastine, available in nasal spray and eye-drop form, is characterized by a fast start of action and a prolonged half-life. Moreover, it does not alter the functionality of nasal mucosa [44], while it protects from symptoms caused by nasal and conjunctival challenge [176]. Data concerning 154 children 6–15 years indicate a good to excellent effect in 54% of the cases (65% in 13- to 15-year-olds), and thanks to its tolerability it can also be prescribed for children >3 years of age, at the dosages stated in Table 12.16. In another cohort of 110 entrants 6–15 years old, it had a significant effect (compared to cromolyn) on eye watering and nasal obstruction [178].

Loratadine possesses all the qualities listed so far [52] and, what is more, it reduces symptoms considerably within the 1st h. The half-life is long, so in children (from 2 years up) a single dose in the morning is sufficient, thus increasing compliance [153]. The peak plasma concentrations were 7.78 ng/ml, at 1.17 and 2.33 h after administration of loratadine. The areas under the plasma concentration–time curve to the last quantifiable time point for loratadine was 16.7 ng/h/ml; ECG parameters were not altered [141]. A meta-analysis of three studies, comprising a total of 784 children aged 3–12 years, demonstrated that loratadine is superior to placebo (61.7% vs 38.3%) with significant differences between the basic symptom score and the 7th day of treatment [77]. In 60 children 3–12 years old with AR caused by dust mites, both total symptom score and daily card scores of the loratadine syrup group 5 mg or 10 mg once a day at day 7 and day 21 was lower compared to the placebo group (DBPC study); no adverse

reactions were recorded [197]. In 25 children with pollen-induced AR, weed and tree pollens treated for 4 weeks, tryptase, IL_5, and ECP levels decreased significantly while the decrease of RANTES and TNF-α levels was not significant. Loratadine was shown to be an effective anti-inflammatory drug that affects the early and late phase of immediate hypersensitivity [82]. In 63 children 8–10 years with a history of SAR and attending a laboratory school, treated with diphenhydramine or loratadine, no treatment-related differences emerged on the verbal instruction score, reading test score, reaction time, or somnolence scale [7].

Oxatomide is 75% eliminated in the feces and has a long half-life. Like ketotifen it interferes with the mast cell degranulation and has similar clinical applications; its action inhibits serotonin and, partially, LTs [153].

Desloratadine is the loratadine metabolite and has a potent unique profile of potent antiallergic and anti-inflammatory activity, in addition to a safe pharmacological profile [141]. Desloratadine 5 mg once daily relieves the symptoms of both SAR and PAR and provides the added benefit of efficacy against nasal obstruction in SAR [175]. In 29 patients 12 to <18 years, desloratadine rapidly and safely reduced the symptoms of PAR, and its efficacy did not diminish during 4 weeks of treatment [157]. Only azelastine, fexofenidine, desloratadine and cetirizine are approved for the PAR treatment in the US [156].

Dimetindene 0.1% spray in 100 children <14 years of age suffering from SAR was compared to levocabastine in a multicenter single-blind, PC trial: symptoms associated with pollen rhinitis, nasal rhinorrhea, itching, sneezing and congestion, and ocular symptoms, lacrimation, ocular itching and red eyes were statistically reduced for both treatments [5].

Anticholinergics

In nasal mucosa there is a cholinergic innervation, so the use of these drugs is justified [21]. *Ipratropium bromide* (IB) is considered useful in vasomotor rhinitis and is effective in reducing aqueous hypersecretion, proving to be a safe and effective alternative product for patients with rhinorrhea-dominated rhinitis. On the contrary, it has no action on itching and sneezing or on nasal obstruction. Since it does not cross the hematoencephalic barrier, it has no sedative effects on the CNS; it is absorbed very little by both oral and nasal mucosa [68]. IB was safe and effective in controlling rhinorrhea and diminishing the interference by rhinorrhea in school attendance, concentration on school work, and sleep, and pediatricians may prefer a medication less likely to produce side effects [102].

Cromones

Cromolyn has an important place in AR because it leaves the mucociliary function intact, an overdose is virtually impossible, and it has proved effective and safe in various studies [21] in nasal spray form. The effect on eosinophil recruitment and/or activation is probably secondary to the inhibition of mast cell infiltration and mediator release into the nose [145]. It is particularly suitable for children, both because it has no side effects and it avoids a frequent use of steroids. Its clinical effectiveness has been proven both in SAR and in PAR, reducing rhinorrhea, nasal itching, and sneezing, while it has no effect on CNO [109]. Cromolyn reduces symptoms of AR, and, when used prophylactically, can prevent symptoms from occurring: because it is poorly absorbed systemically, it is well tolerated and not associated with drug interactions [135]. In children with AR, we regularly prescribe cromolyn spray as a prophylactic measure, two to four times a day, as needed, and cromolyn eye drops if AR is associated with ocular manifestations, usually with excellent results.

Various studies have demonstrated that *nedocromil sodium* acts on both immediate and delayed phase, with highly significant differences vs placebo [121], inhibiting almost entirely the inflammatory cell overflow and reducing their number after NPT [162]. It is available in nasal spray form. It reduces symptoms, including nasal congestion, seems to have a more effective and longer action than cromolyn, and it is tolerated just as well [68].

Corticosteroids

Corticosteroids (CSs) are very effective, used topically, in the treatment of SAR and PAR. They have an anti-inflammatory effect and reduce capillary permeability, mucosal edema, and mucus production. The rational use of this class of drugs resides in their capacity to block A_2 phospholipase, and therefore the first step in the production of LTs and prostaglandins; with the same mechanism PAF formation is prevented [26] (Fig. 12.8). They are used as needed by inhalation and in small doses, making it possible to bring the drug directly to the target organ (Table 12.18) [48, 51]; 80%–90% of all children with SAR improve and are able to reduce or replace the use of other drugs [30]. The therapeutic action is most successful with CS regular use, with pollinosis sufferers starting about 1 week before the AR season starts. In the case of severe CNO, antihistamines and/or vasoconstrictors may be associated (only for a few days, to avoid a rebound effect and dependency), to help the drug effectively reach the site of action on nasal mucosa [109]. However, ICSs, beyond the concerns for suppression of growth, bone metabolism, and the hypothalamus-hypophysis-adrenal (HPA) axis, etc., it is indisputable that their use is purely symptomatic.

Table 12.18. Dosage of pediatric inhaled nasal corticosteroids

Drug	Formulation	Dose (μg)
Beclomethasone dipropionate	Nasal spray	42
	Aqueous	42–84
Budesonide	Nasal spray	32
	Aerosol	32
Dexamethasone	Nasal spray	
Flunisolide	Aqueous	25
Fluticasone dipropionate	Aqueous	50
Monometasone furoate	Nasal spray	50
Triamcinolone acetonide	Aqueous	55
	Aerosol	55

All these formulations are marketed for children aged ″6 years, all by nasal spray or aerosol 1–2 puffs bid, all aqueous 1–2 sp bid.
Data from [48, 51].

BDP nasal spray proved effective and well tolerated in a study by us conducted on 16 PAR children aged 5–14 years, showing a significant reduction in nasal, but not peripheral, eosinophils after 1 and 3 months [53]. BDP proved more valid than the decongestant association [113], attenuated asthma symptoms [136] and reduced histamine and eosinophil levels [109]. Compared to IB, child and physician assessment favored BDP in the control of sneezing [101]. Long-term clinical use of ICS BDP in children aged 24–117 months (mean, 70 months) and treated for an average of 36 months was not associated with decreased height growth. Careful height measurements are recommended every 6 months [93].

BUD nasal spray is a topical CS, which at doses of 64–256 μg once daily has been found to be effective in the treatment of SAR in children. In a recent pediatric study, BUD reduced all symptoms, with significant differences compared to controls [60]. In another, administered by Turbohaler (200–400 μg in a single dose), it proved effective without causing problems detectable by knemometry [193]. In 202 children 6–16 years old with PAR, BUD ICS spray, 128 μg once daily, was significantly more effective than placebo in improving peak nasal inspiratory flow (PNIF), combined and individual nasal symptom scores, and the overall evaluation of treatment efficacy. The onset of action was found to occur within the first 12-h time interval evaluated for combined nasal symptoms and within 48 h for PNIF [60].

Deflazacort, in the form of oral drops, helps in personalizing the prescription (1–2 mg = 1–2 drops/kg/day) and in the compliance of the youngest children, overcoming the problem of a lack of cooperation in the administration of other forms of medications.

Flunisolide ICS proved significantly effective in reducing the clinical symptoms, number of nasal and peripheral eosinophils, and concentration of total and nasal IgE in 22 children suffering from PAR and two from SAR, with no significant variation of the number of peripheral eosinophils, a result that confirms the absence of systemic symptoms with flunisolide [32]. Other studies produced positive results in 80% of 49 children 5–16 years old vs 8.3% of controls [21], with an improvement statistically higher than placebo and a reduction of ECP nasal levels in 38 other entrants, aged 4–14, while cromolyn remained at the limits of statistical significance [145].

FP studied in a wide range of SAR children 4–17 years old was used with excellent effects vs placebo, with statistically significant effectiveness and tolerability, in four randomized DB pediatric studies [18, 115]. This drug is credited with clinical reduction of both early and delayed reactions and of immunological reduction of T lymphocytes, $CD25^+$, and IL_4 [129], with a decreased peripheral eosinophilia as an added result [18]. An interesting meta-analysis study in 1,002 patients documented the statistically significant reduction of nasal eosinophils in SAR and PAR [99] and comparable results in 499 children 4–11 years of age, in whom the single 100-μg/day dose was equivalent to the 200-μg/day dose [3], and in 106 more children treated the same way with the 100-μg/die dose [115].

Monometasone furoate (MF) has been evaluated in 990 pediatric patients studied in phase I, II, and III clinical trials. The 100- and 200-μg daily doses of MF were found to be more effective than 168 μg BDP or 25 μg MF given daily. In clinical efficacy and safety trials, MF was given to 381 children aged 3–11 years for 4 weeks and was found to decrease symptom scores from baseline significantly better than placebo [47]. To examine MF effects on growth, a study on safety and tolerability of once-daily MF in children assessed short-term lower-leg growth by knemometry [15]. In a randomized, PCDB, multicenter study, 1 year of treatment with MF 100 μg daily was found to be well tolerated, with no evidence of retardation of growth or suppression of HPA-axis function in 98 PAR children as young as 3 years. The absence of systemic adverse events, combined with the established efficacy and safety profile of MF nasal spray in children, indicates that it may be an appropriate therapy for children of this age [143].

Neither *triamcinolone acetonide* (TAA) nasal spray 110 μg or 220 μg nor FP nasal spray 200 μg had a clinically significant effect on lower-leg growth velocity. In contrast to FP, TAA nasal spray did not significantly affect HPA-axis function when used over a 2-week period [160].

Table 12.19 [51] shows a comparison of all treatments discussed for AR. A review has compared ICSs with antihistamines: the former produce greater relief from most nasal symptoms than do antihistamines, are more cost-effective than oral antihistamines and both show

Table 12.19. Effects of medications on pediatric nasal and ocular symptoms

Drugs	Symptoms				
	Congestion	Sneezing	Discharge	Itching	Eye symptoms
Oral antihistamines	–	+	+	+	+
IN corticosteroids	+	+	+	+	+
IN cromolyn	–	+	+	+	–
IN antihistamines	+	+	+	+	–
Anticholinergic	–	–	+	–	–
Leukotriene antagonists	+	+	+	+	+

Data from [51].
IN intranasal.

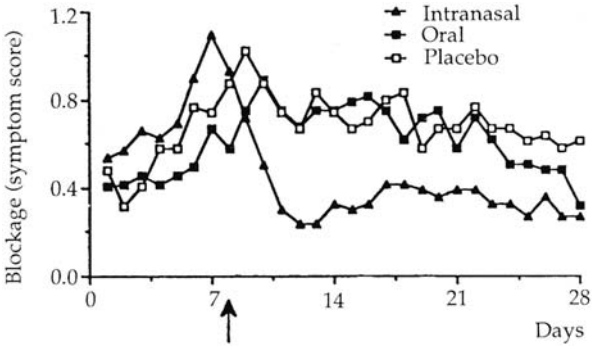

Fig. 12.18. Topical administration of glucocorticoids by nasal spray is effective in treating nasal obstruction in AR; an equivalent oral dose is no different from placebo

no difference in the relief of the eye symptoms of AR [186]. Figure 12.18 [88] shows the difference between CSs taken by young adults orally and by nasal spray.

Anti-LT

Anti-LT have been associated with nasal CSs in adult studies with variable results, favoring BDP over zafirlukast [128], and BUD over montelukast, but both treatments significantly reduced AR symptoms [189]. In the comparison with antihistamines, once daily fexofenadine as monotherapy was equally effective as the combination of once daily montelukast plus loratadine in improving nasal peak flow and controlling symptoms in SAR [190]. In 14 children with PAR, montelukast treatment reversed a typical Th2 cytokine pattern (IL_4 and IL_{13}) toward a Th1 (IFN-γ) predominance [35].

Specific Immunotherapy

Specific immunotherapy (SIT) in AR children is considered useless and expensive, and it is not substantiated by direct comparisons with pharmacotherapy [109]. We have achieved excellent results in children with pollen- and *Alternaria alternata*-induced AR, in whom control children were treated with all the usual medications, but without obtaining the excellent results of study children [29, 31]. Pollen SIT showed an OR of 2.52 (1.3–5.1) in favor of the hypothesis that it can prevent the development of asthma in SAR children [104]; thus SIT may be a means of *preventing asthma completely in AR children* [139]. In SAR, SIT is followed by an improvement in symptoms that entails cellular and humoral changes, and a switch from Th2 to Th1 lymphocytes [50]. Thus SIT has an important role in AR, especially in PAR and in mold-induced AR [142] and in cases not otherwise controllable.

Prevention

The absolute importance of environmental allergen avoidance will never be sufficiently emphasized [20]. A meta-analysis shows that exclusive breast feeding during the first 3 months after birth protects against AR in children, both with and without FHA. The summary OR for the protective effect of breast feeding was 0.74 (95% CI, 0.54–1.01). The effect estimate in studies of children with a FHA was 0.87 (95% CI, 0.48–1.58) [103].

Quality of Life

As in asthma, there is an aspect of the disease that affects the quality of life. In a study conducted on 83 youths 12–17 years of age with seasonal rhinoconjunctivitis, where the use of antihistamines alone or associated with other preparations was required in 73.1% of cases, serious limitations emerged (Table 12.20) [74]. In this study, a questionnaire was drafted, specifically focusing on everyday problems of children and adolescents, which was demonstrated to be specific to this age group, bypassing the divergences from similar questionnaires prepared for adults [74]. In the ISAAC study (Chap. 5), limitations of activities were present only in 3.7%–6.2%

Table 12.20. Limitations caused by pediatric problems related to quality of life

Limitation	%
Systemic symptoms	
Irritability	86.7
Poor concentration	86.7
Tiredness	86.7
Agitation	79.5
Exhoustion	78.3
Headache	74.7
Frustration	74.7
Impatience	69.9
Embarrassed by symptoms	68.7
Embarrassed by aspect	67.5
Embarrassment in general	62.7
Preoccupations	60.2
Nervousness more or less evident	53
Tension/depression	48.2–55.4
Specific symptoms	
Lack of good sleep	63.9–78.3
Nose symptoms	69.9–92.8
Eye symptoms	74.7–88
Practical problems	
Need to rub nose/eyes	94
Need to blow nose repeatedly	86.7
Need to have tissues/handkerchief always at hand	81.9
Limitations of social activities	20.5–44.5
Girls: problems with make-up	25.3
School and/or work	
Lesser efficiency	78.3
Poor concentration	74.7
Reduced capacity in general	69.9
Limitations related to leisure activities/sports	
Entertainment in general	81.9
Playing sports	65.1
Bicycling	61.4
Swimming	55.4

Adapted from [74].

of children aged 6–7 years and in 6.5%–14.2% of those aged 13–14 years. Symptomatic relief and a tolerability profile of cetirizine syrup daily converted into improvements in the HRQL of children with SAR [63]. In 57 teenagers with PAR, symptoms, practical problems, emotions, limited activities were all reduced 2 weeks after start of treatment with either loratadine or BDP, positively evaluating HRQL reproducibility [111].

Long-Term Avenues

Anti-IgE (*omalizumab*), a humanized monoclonal anti-IgE antibody, has successfully conferred a protective effect independent of the type of allergen, thus proving to be useful for the treatment of SAR, particularly for polysensitized children and adolescents [83]. In addition, anti-IgE therapy reduces LT release of peripheral leukocytes stimulated with allergen in children with SAR undergoing SIT, independent of the type of SIT allergen used: during both pollen seasons, the scores for daily medication use, daily nose symptoms, and daily eye symptoms were significantly lower in children receiving anti-IgE treatment compared with children of the placebo group [81]. Omalizumab treatment and concomitant SIT of 49 children with SAR resulted in *a reduction in the number of circulating myeloid DCs* (MDC) compared with control children during the grass pollen season. The MDC increase seen in the control children was paralleled by a dramatic increase in the severity score. Anti-IgE treatment might decrease both the amount of mast cell-derived IL_4 during the pollen season and the number of MDCs, known primers of Th2 cell differentiation, thus the observed effect of normal numbers of MDCs during the pollen season might provide an additional explanation for the clinical effects of anti-IgE treatment [55].

The studies by Terada et al [168] suggest that by using anti-CD49d/CD29 it would be possible to prevent the accumulation and activation of eosinophils in nasal mucosa, or monoclonal anti-IL_5 antibodies could be used to inhibit (in laboratory animals) eosinophilia and NHR. Otherwise it is possible to resort to anti-IL_4 to effectively control sIgE during the pollen season [163]. We wonder what actual, concrete applications can be drawn from this. Shorter-term prospects concern antihistamines, such as mizolastine and ebastine, epinastine, mequitamium, noberastine, rupatadine, and temelastine, which, however, are not yet marketed everywhere.

A novel approach to AR therapy is the application of antisense oligodeoxynucleotides (ODNs) to block proinflammatory IL production [54] by DCs [56] and increase the production of the Th1-related ILs [56]. PS (phosphorothioate-modified) ODNs had inhibitory effects on allergen-induced germline transcript RNA expression and mucosal eotaxin immunoreactivity, whereas PS-ODNs increased the amount of IFN-γ immunoreactivity, suggesting a combined mechanism of reduced synthesis of IgE and eotaxin. In conclusion, the IL_4 antisense PS-ODN effectively inhibits IL_4, IgE synthesis, and eotaxin 1, principal mediators of allergic inflammation, suggesting that mucosal PDCs may offer

a possible topical treatment for AR [56]. Plasmacytoid DCs (PDCs) stimulated allergen-dependent T-cell proliferation and Th2 IL production as efficiently as CD11c+ DCs. However, CpG-activated PDCs inhibited allergen-dependent proliferation of Th2 memory cells and markedly increased IFN-γ production in PDC/T-cell cocultures interestingly, PDCs efficiently drive allergen-dependent Th2 memory responses, thus suggesting that they play an active role in the allergic reaction. However, in the presence of CpG, PDCs produced high levels of Th1-related IFN-α/β and IFN-γ, indicating that mucosal PS-ODNs may be targets for CpG-based SIT strategies against airway allergy [54].

Pediatricians and Allergic Rhinitis

SAR is a highly prevalent chronic disease in childhood. In PAR children, the persistence of symptoms causes limitations in daily activities, not only because of the discomfort originated by the nasal symptoms and the associated symptoms such as migraine, disinclination, reduction in the capacity of to concentrate, etc. The limitations to social conviviality, sometimes erroneously interpreted as indifference, apathy, inattention, mainly at school age, rebound negatively on the emotional welfare of these children. A disease with a prolonged course deprives the individual of a great deal of sources of personal pleasure, as it interferes with self-estime, control of one's own body and in interpersonal relationships. The repercussions of a chronic disease in children and adolescents also affect their family as a whole, and the consequent long-term problems may further damage the image of the whole group. A certainly striking phenomenon is that AR is often *underdiagnosed*, with the prevalent concern of families being over the asthma symptoms, without taking into account the fact that for asthmatic children, AR is a triggering and aggravating factor, to the point that 75% of these children suffer from it; consequently, the impact as a cause of morbidity is also often underestimated [171]. In modern homes, various environmental factors, in addition to external ones, have contributed to increasing its prevalence. Pediatricians will certainly feel the evident need to suggest, where there is a greater concentration of pollutants and irritants, the preventive measures appropriate for concretely eliminating these factors [171]. The hygiene hypothesis [164] suggests that cross-infections might be protective against rhinitis. This is a provocative hypothesis as a wealth of studies have implicated viral infections in the pathogenesis of both rhinitis and asthma. Neonates spending their first night in a nursery are at risk of developing AR and more likely to experience low-dose and short-duration exposure to microorganisms [105]. In individuals >14 years of age with ≥2 siblings, the odds of suffering from SAR (but not from PAR) are less than the odds for people with no siblings [95]. However, AR prevalence is in a crescendo of striking data in children <14 years, and several studies referred to in Chap. 4 have linked AR to twelve different chromosomes and to several HLA molecules. Is it bad hygiene to inhale dust (Chap. 24) or pollens in early life? Should we refrain from inhaling pollens? On practical grounds, we can trust the positive influence of new studies on AR diagnosis and therapy, which will ensure a definite improvement in the quality of life, including *girls embarrassed with their make-up.*

Specific Immunotherapy

Specific Therapy for Pediatric Asthma and Rhinitis

Although specific immunotherapy (SIT) or specific desensitization therapy was first introduced into allergy practice in 1911, only during the last 50 years have controlled trials been conducted [200]. Noon [166] and then Freeman [82] treated some patients affected with hay fever, which was the name of allergic rhinitis (AR), a term that still survives in the Anglo-American literature, by immunizing patients to a so-called toxin existing in certain pollens; whence the term "vaccine", which remained in current use. Before beginning any treatment, Noon [166] took notes about the dilutions of allergen extracts, which when instilled into his conjunctiva, produced an immediate local reaction, thus showing that the conjunctival reaction could be provoked only by instilling ever more concentrated allergen solutions. The treated patients manifested a marked reduction in symptoms and Noon consequently stated that they had acquired a growing immunity to such a toxin [166].

The term "immunotherapy" is justified since *SIT corrects the immunoregulatory dysfunction at the basis of atopy:* the major purpose is that of reducing the patient's hypersensitivity to aeroallergens, thus achieving the phenotypic modulation of immune responses to specific allergens. Currently it is the only available means to transform the immune response to allergic agents in a clinically helpful way. SIT is therefore the therapeutic option of the greatest benefit to children, whose use should be combined with a high level of consensus on its effectiveness based on the severity and duration of the underlying disease [44]. However, SIT has limitations in addition to benefits, since its undoubted validity based on yearly reports stressing the clinical improvement and fading of more or less severe symptoms in allergic children is matched by several questions on the exact mechanisms of action responsible for its effectiveness. Answers to these questions have remained elusive, even if the never-ending progress in the scientific field in the last few years has led to a better understanding of some of the principal immunological changes, both humoral and cell-mediated, induced by SIT [54]. Additional important aspects are the persistent necessity of disposing of standardized allergen extracts and of clarifying the duration of injection cycles. The search for a gold standard treatment for allergic disease continues to offer outstanding acquisitions. Outcomes in adult asthma may be determined primarily in early childhood [218]. Two risk factors for development of asthma in children and adolescents have been demonstrated, the 88.8% increased prevalence of pediatric asthma in 2003 compared to 2001 [47], and the wheezing that persisted from childhood to adulthood or that relapsed after remission in 26.9% of the study members. At 21 years 77.5% were sensitized to HDM (house dust mite) and 53.8% to cat allergen [218]. In addition, we first report the oral desensitization of food allergy (FA) [187]. *In children SIT is more effective* compared to adults [44] and *it positively influences the natural history of respiratory allergy* [40, 122]. SIT has also been suggested to inhibit progression from AR to asthma [118, 158], and even more reassuring, *adverse reactions are very uncommon and fatal reactions are statistically nonexistent.*

SIT methods of use and safety are often controversial. Some authors suggest that SIT should be routinely given to all patients with respiratory allergy, others that the associated risks do not justify SIT use at all, also considering the availability of newer medications [18, 30, 83]. This philosophy is reviewed by a BSACI (British Society of Allergy and Clinical Immunology) Position Paper [33], which practically restricted the use of SIT to cases of rhinoconjunctivitis and allergy to insect stings, specifying *on the basis of adult studies* that there is no justification to use SIT in infantile asthma [33]. Similar concepts are expressed by the WHO/IUIS Working Group [237], with the notable exception of the EAACI (European Academy of Allergy and Clinical Immunology) [115]. However, both the BSACI [33] and EAACI [115] advised against SIT utilization in children <5 years of age, and raised doubts in particular for the treatment of pediatric asthma. The WHO may focus on SIT and ask for an international consensus with *specialists on adult asthma* [267], which is clearly surprising since the *different results currently found in children being cared for by pediatricians are being methodically neglected* [8, 45, 46]. Abramson et al [2] conducted a meta-analysis of randomized controlled trials using SIT in allergic asthma, and they found only two pediatric studies [69, 264]. It is worth mentioning that at the 11th International Congress of Immunology (Stockholm, 22–27 July 2001), we were invited to deliver a lecture on pediatric SIT.

Table 13.1. Reasons for initiating specific immunotherapy in children

Presence of IgE-mediated disease proven to benefit from immunotherapy
a. Allergic rhinitis
b. Allergic asthma
c. Anaphylaxis following Hymenoptera stings
Documentation of sensitivity to allergens associated with symptoms

Symptoms of sufficient duration and severity
a. Seasonal symptoms despite avoidance measures and pharmacological therapy
b. Perennial symptoms failing trials of avoidance measures and chronic pharmacological therapy
c. Anaphylaxis following Hymenoptera sting except children with non-life-threatening anaphylaxis

Availability of allergenic extract of allergen responsible for sensitivity
Other considerations
a. Discussion of long-term nature of treatment and need for compliance
b. Discussion of risk vs benefit of treatment
c. Accessibility of facilities and personnel capable of administering treatment and evaluating and treating anaphylaxis
d. Emphasis on avoidance as treatment of choice

Adapted from [36].

In this chapter, we illustrate the SIT immunological bases, evaluating its effectiveness in the natural history of respiratory allergy and its safety in children, and analyzing indications, counter-indications, and limits (Table 13.1) [36]:

- Is SIT effective in children with respiratory allergic diseases?
- Does SIT prevent allergic inflammation?
- Does SIT decrease nonspecific bronchial hyperreactivity?
- Is SIT safe in allergic children?
- What is the best age to start SIT?

Definition

SIT, as it is known, is *the only pediatric allergen-specific treatment for respiratory allergy and hypersensitivity to Hymenoptera venom syndromes*, which positively interfere with their underlying immune mechanisms. IgE-mediated disease proven to benefit from SIT is prerequisite, including AR, allergic asthma, and anaphylaxis following Hymenoptera stings. The immunologist says that the shift from Th2 to Th1-type interleukin (IL) predominance redirects the lymphocyte response toward the Th1 T cells and can change the ILs produced by Th2 cells in the respiratory tract [71, 155, 193, 203, 253]. The clinician says that at variance with drugs, SIT is a preventive treatment that has been shown to have long-term efficacy even several years after withdrawal [70], and modifies the natural history of respiratory allergy by *preventing new allergic sensitization* [60, 158, 179], or even *asthma onset* and exacerbations of disease [44, 118]. SIT has also been suggested to inhibit the *progression from AR to asthma* [16, 158]. SIT consists in the administration by subcutaneous (SC) injection of gradually increasing graded doses of the allergen to which the child is sensitized, which will certainly cause clinical manifestations, in order to modify the immune response and reduce the sensitization to the given allergen [37]. Despite its use in clinical practice, more personalized and safer allergy preparations are required to desensitize infants, children, and adolescents [43, 44].

Indications

SIT finds an elective indication in children, as shown by 44 studies (Table 13.2) [1, 7, 23, 26, 38, 40, 43–48, 60, 69, 90, 93, 98, 99, 103, 118, 122, 127, 130–133, 140, 154, 156, 158, 161, 174, 175, 179, 198, 207, 212, 222, 236, 240, 246–248, 268, 264]:

1. SIT is indicated in *allergic respiratory disease* (asthma and/or allergic rhinoconjunctivitis) [115] when the diagnosis is well documented, by skin prick tests (SPTs) and/or specific IgE (sIgE) positivity and, in certain cases, by the response to specific provocation test (PT), and when *the correlation between offending allergens, history and clinical symptoms is well proven.* In our opinion, SIT use should be instituted in the early course of disease [115, 265], *before both morbidity and duration of symptoms are aggravated in young sensitized children*, due to the widespread atopic march (Tables 5.18, 5.19) and more so in all children in whom allergic manifestations are so severe as to provoke school absences and/or poor progress in school as well as problems related to the *quality of life.* Independently of these prerequisites, SIT should be used when both allergen avoidance and drug treatment are inadequate and/or insufficient, or when children are sensitive to allergens that cannot be effectively avoided and need daily treatment for longer periods [115]. SIT is instituted when standardized extracts of true effectiveness of the allergen in question and specialists to perform it are available. Clinicians must also take into account the willingness of parents or responsible persons to accept SIT, their compliance to treatment as well as their socioeconomic status. Arguments have been put forward that suggest that early SIT institution provides a better opportunity for preventing rather than reducing chronic inflammation, and the protection achieved within months or years should be weighed against the increased likelihood of adverse reactions [115]. For perennial asthma, the treatment is also widely accepted even though only one controlled trial [3] was unconvincing (see below).

Der p/f allergy is more frequent in children, and SIT is able to efficaciously control the related symptoms [1, 7,

Kjellman and Lanner matched the children treated with purified pollen extracts (*S*) with those treated with crude pollen extract (*C*). Kuhn et al [133] compared those treated with pollen extracts or allergoids and Businco et al [38] with those treated with Der p extract. Sandin et al, Lilja et al [141] and Hedlin et al [99] evaluated the results of the same cohort after 1, 2, and 3 years: the positive results for Fel d were paralleled by those for Can f, even if at lower statistical levels. Shim et al [222] compared the final results with the basal data. Calvo et al [40] evaluated quality of life that was significantly better in the SIT-treated children. Gruber et al [93] performed cold dry air challenges. The children reported by Van Bever et al [248] come from the study by Cools et al [53]. In the study by Kuehr et al [132], 114 children received SIT + anti-IgE (omalizumab) and experienced even more favorable results. Milgrom et al [154] found IgE levels reduced by 95%–99% at the end of the treatment.
A active, *P* placebo, *Rand*, *R* randomization, *S* single, *D* double, *Eval* evaluation, *Clin* clinical, *BR* bronchial reactivity, *CPT* conjunctival provocation test, *DS* drug scores, *DU* drug use, *PE* physical examination, *HD* house dust, *PFT* pulmonary function tests, *NT* not tested, *SD* symptom diary, *SS* symptom scores, *SPT* skin prick tests, * median age, – no reduction.

38, 40, 44, 60, 93, 99, 130, 154, 164, 174, 175, 179, 194, 198, 222, 236, 240, 247, 248, 268, 264], reducing reactivity to nasal or bronchial provocation, increasing specific IgG (sIgG) serum levels and reducing serum IgE levels. Therefore it is not documented that SIT with Der p is less effective than SIT with pollens [18, 83, 164].

Pollen allergy is a SIT classic and well-documented indication both for AR and asthma [23, 38, 40, 43, 44–48, 99, 103, 118, 127, 131–133, 154, 156, 158]. We suggest that SIT use is justified in seasonal rhinitis (SAR) caused by grass in Europe and ragweed in the USA, recognizing that repeated allergen contact during successive seasons may lead to ever-increasing sensitization and to onset of more severe symptoms. SIT effectiveness is demonstrated with other pollens such as olive and *Parietaria*, although results of controlled clinical trials with these allergens in typically pediatric case reports are lacking. We have successfully treated several such children.

Mold allergy responds well to SIT only in cases of IgE-mediated monosensitization to *Alternaria alternata* [46]: its principal allergen (Alt a 1) is well characterized (Table 1.74) and extracts of good quality are available [46]. SIT for *Cladosporium herbarum* reduced medication use in asthmatic children, but not symptom score [69].

In *animal dander* (Can d 1 and 2, Fel d 1) [26, 98, 140, 154, 228, 246], SIT is warranted not only for the spread of related allergies (Tables 5.11, 5.18), but also in specific cases, including ineffective allergen avoidance, psychological shock for the child in case of animal removal, offspring of veterinarians, laboratory technicians, animal dealers, etc. However, while SIT with cat dander extract reduces the reactivity to bronchial PT and increases IgG_4 serum levels after 9 months [26, 98, 204], SIT with dog dander extracts was positive in five studies [26, 98, 140, 154, 246] and induces cat allergen tolerance [98]. These results could depend on a lesser potency of dog compared to cat allergen extracts [96] and on the only recent isolation of Can f 1 and 2 allergens (Table 1.74).

2. *Hypersensitivity to Hymenoptera venom* syndromes represents an elective application of SIT, especially when the history is positive for severe and life-threatening systemic reactions (SRs) to insect stings, and venom sIgE has been demonstrated. SIT should be given following specific schedules and with great caution (rush SIT) and performed in the hospital under observation, in a unit staffed to undertake emergency measures and with personnel capable of administering treatment and evaluating and treating anaphylaxis, especially in the initial

stages. However, the high effectiveness (>90% of cases) in preventing anaphylactic reactions from insect stings justifies the risk [83, 160]. In children, reactions localized solely or extensively to skin do not require SIT, since the prognosis is very favorable [184].

The allergies (almost always pseudoallergies) to drugs and chemical substances usually are not an indication for SIT, especially when IgE-mediated mechanisms do not predominate (exercise-induced asthma, hypersensitivity pneumonia, pulmonary infiltrates with eosinophilia, etc.) [37]. Allergy to foods [187] and to latex [186] can be desensitized.

Child Selection

SIT prescription should be the result of:

- Careful clinical examination (type, severity and frequency of symptoms) (Table 11.34)
- Allergy diagnosis (SPT, sIgE, spirometry, BPTs)
- Respiratory status
- Availability of allergen extract of allergen responsible for sensitivity
- A favorable risk-benefit ratio

Child Age

Although there are no sound and definitive data in the literature indicating the minimal age to begin SIT in children (Table 13.3) [1, 38, 43–48], 10% of pediatricians believe that SIT should be started at 2–3 years, 32%–42% at 5 years and 38%–42% at 10 years of age [207]. However, the most widely held opinion is that children should be at least 2 or 3 years of age [115], the age of several children in a number of studies [1, 38, 43–48] and in sublingual SIT (SLIT) [62, 209]. Although there is no appropriate age, age-related limits should be established [265], to take advantage of SIT's preventive potential [118], especially in children with AR, to prevent the risk of getting pollen asthma [130], but these children are not quickly diagnosed as such [208]. Carefully following both counter-indications and security measures specified in "Adverse Reactions", SIT

Table 13.3. SIT age at start

Data in favor of early treatment with SIT:
The most severe cases with asthma have an early onset of the disease
The allergic component of asthma is most pronounced in children and adolescents
SIT of children with rhinitis reduces the risk of developing asthma
Even slight asthma is accompanied by desquamation of bronchial epithelium, probably due to the ongoing allergic inflammation in the bronchial mucosa
Elastic fibers in the bronchial wall are destroyed in cases with long-standing asthma

Data from [1, 38, 43–48].

can be administered to children of all ages [60, 61, 118, 130, 208], when considering the early onset of more severe cases of asthma (Table 5.5) and the substantial allergic background of pediatric asthma. Above all, SIT can begin at a very early age, in children aged 3–5 [61, 182]. SIT might be a means of preventing asthma completely in such a situation [208]. When an irreversible deterioration in lung function has occurred in the child, and less severe forms are accompanied by bronchial epithelium desquamation caused by ongoing inflammation, or when the bronchial wall elastic fibers are disrupted in long-term asthma, it is too late to start (Fig. 13.1) [265]. Eosinophilic inflammation and even some early signs of airway remodelling might be present in children with developing asthma *before a reliable diagnosis of asthma could be made* based on clinical features [196]. Adult asthma severity is associated with childhood disease severity and indices of atopy, suggesting that adult outcomes are decided *at a very young age*. By the time a child requires medical treatment, the course of disease may already be established *demonstrating that no early intervention may lead to optimal outcomes* [141]. During early childhood the asthma persistence and severity predict disease presistence into later childhood and adulthood *in a least 25% of children* [218]. These are valuable clues to desensitize children as soon as possible. When treating young children with

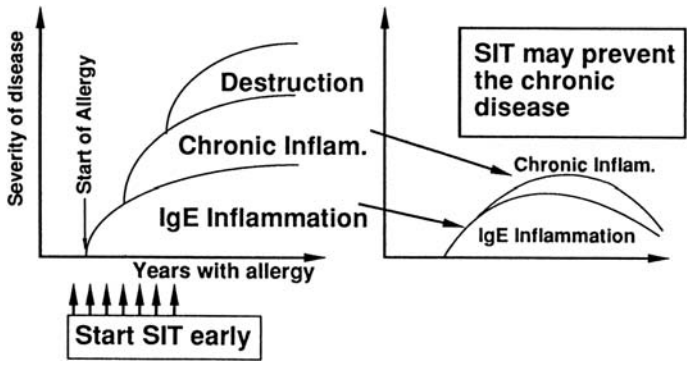

Fig. 13.1. Early start of specific immunotherapy (*SIT*) may change the natural history of respiratory allergy in children

SIT, physicians should know how to evaluate and treat SRs as well as have a well-equipped office [115]. The limiting recommendations made by several experts in adult asthma [78, 237], who report many SRs and the rare fatal cases, *are based on statistically nonexistent results in children.* The implications of SRs related to children stem from the *continuing extrapolation to children,* with these as well in other conditions, of results related to studies in adults.

Counter-Indications

Potential counter-indications may be absolute [38, 115]:

- Severe immunodeficiencies, primary or secondary
- Autoimmune and lymphoproliferative diseases
- Severe chronic and debilitating diseases
- Severe infectious diseases, ongoing or recent
- Other significant medical conditions
- Diseases in which epinephrine use would be contraindicated when necessary due to onset of anaphylactic shock
- Extremely severe sensitization such as that triggered by anaphylactic reactions to SPT
- History of severe reactions during past treatments with SIT (except cases of anaphylaxis to Hymenoptera venom)
- Absolute absence of compliance from children and their parents

Allergen Extracts

Allergen extracts used for SIT are of different types:

- *Aqueous extracts* with rapid absorption are heterogeneous mixtures of allergenic and nonallergenic materials; however, these vaccines can be standardized and used in special conditions such as rush or cluster SIT [267]. In traditional SIT, a greater number of shots is necessary before the maintenance dose is achieved [7].
- *Alum-precipitated* extracts, with stable, delayed and uniform absorption, therefore requiring fewer total injections before benefits are manifested [45]. Adsorbed extracts may be preferable in childhood because of efficacy, safety, tolerability and fewer shots. Lesser adverse reactions are produced and usually limited to the first injections, eliciting good clinical responses together with very good IgG antibody responses [7].
- *Allergen standardization* (Chap. 1) to obtain a complete suppression of IgE synthesis is permitted by a more precise characterization of the allergenic components of available extracts. The advantages of allergen standardization are well known; thus SIT performance with standardized extracts as well as alum-absorbed extracts ensures beneficial effects, and reproducibility and comparability, on condition that the extracts are expressed in International Units (IU), such as BU (biological units), BAU (Chap. 1), and subject to ongoing progress in the field of recombinant allergens (RA) (Tables 1.70, 1.71). It is certain that SIT with pollen extracts is effective when the extracts are lyophilized, of high potency, standardized, and correspond to international standards [115].

SIT Efficacy: Clinical Effects

To best appreciate the significant importance of clinical trial results, it is necessary to understand that allergen-specific IgG, or blocking antibody concentrations, are very low in both serum and secretions of atopic subjects. By administering the same sensitizing allergens, by gradually increasing doses and for a sufficient time span, SIT can increase a child's ability to produce blocking IgG antibodies that are necessary when children come into contact with offending allergens. Consequently, IgG levels rise progressively and unceasingly at the start of treatment and are correlated with administered allergen extract dose: actually *SIT efficacy is dose-dependent, compared to total delivered cumulative dose and not to treatment duration* [54, 96]. No statistically significant effect for ragweed below the maintenance dose of 2 µg Amb a 1/injection was demonstrated, although at a threshold dose for ragweed SIT protective effects begin to progress on both clinical and immunological components [85, 148]. In patients treated for 3 years with the highest immunizing dose, the eosinophil migration was distinctly dampened compared to control subjects, with a significant statistical difference; in addition, the clinical improvement is correlated with the maximal dosage received [85, 148]. In children <5 years, asthma attacks decreased significantly during the 1st year of treatment [61], and those treated for >1 year showed a decrease in the number of yearly acute exacerbations, in hospital admissions and in drug requirements for bronchial asthma [182].

Table 13.2 shows that 40/44 (90%) clinical trials based on a total of 2,909 out of 2,941 children and 592 children seen by us between 2000 and 2003 [47] were positive, with a total of 3,533 children and approximately the same number of control subjects (Fisher, p=0.0000), 1,933 from our studies (54.7%), have incontrovertibly established SIT efficacy in the treatment of respiratory allergy, *positively influencing its natural history in children*. There are four negative trials (9.1%): in one the sample was restricted in absolute and there was a second sensitization to pollens in 11 out of 13 children [161], another treated slightly older children with preseasonal SIT and highly variable doses [103], and the third [90] treated children for 0.6 months. In a further study with supposedly negative results [3], 61 children and 60 control subjects received a mixture of *up to seven aeroallergen extracts* (were they multisensitized?) or placebo for 2 years only, stressing that they suffered

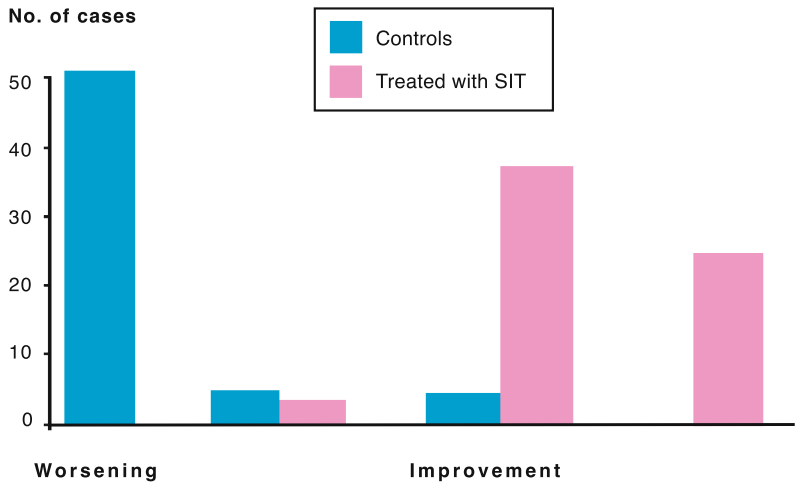

Fig. 13.2. Final results in 124 children with grass-induced asthma 67 treated with specific immunotherapy (SIT) and 57 control subjects treated with pharmacotherapy. Follow-up, 3 years, p=0.0001. (Data from [43])

from severe asthma requiring daily medications, but reporting a significant rise in IgG levels and a reduction in SPT diameter [3].

Six studies are especially noteworthy, two [40, 174] followed children over 10 years, one [157] confirming at most SIT efficacy, at re-evaluation after 5–10 years of SIT injections, the risk of frequent asthmatic symptoms was 3-fold higher in the controls than in the SIT-treated group; the rates of decrease in levels of sIgE and IL_4 were correlated with the rates of decrease in symptom scores after 5 and 10 years of treatment [174]. In another study, the frequent use of antiasthmatic medication was less statistically significant than in the control group even 12 years after SIT termination [40]. Also reduced were the number of days and nights free of asthma [45, 47] as well as the bronchial hyperreactivity (BHR) [99]. In asthmatic children monosensitized to HDM (house dust mite SIT has been shown to prevent onset of new sensitizations [163]. In a 3-year course of SIT there is evidence that SIT may hinder progression from allergic rhinoconjunctivitis to asthma [142]. Anti-IgE grass SIT (omalizumab) significantly reduced daily medication use, eye symptoms, and symptom load, whereas birch SIT significantly reduced nasal symptoms and symptom load [116]. Effectiveness was rated excellent or good for 31.5% and 44.7% of the omalizumab group vs 16.3% and 32.7% of the placebo group [139].

A study in 210 asthmatic children followed for 14 years has demonstrated that during adolescence 72% of SIT-treated patients outgrew their asthma for at least 1 year, while only 22% of control children were asymptomatic [122]. As early as 1968, this study demonstrated that SIT is able to modify the natural history of allergic disease, despite criticism raised because of its methodological limitations. These results were matched by a study reporting that SIT-treated children had fewer new sensitivities to inhalant allergens than those who did not receive SIT [60], by results on 688 children, 75% of whom outgrew asthma in the adult age [200], and confirmed by recent studies [44, 60, 118, 158]. Asthmatic symptoms faded after 5 years of therapy in 66% of SIT-treated pollen-allergic children, and increased by 16% in placebo-treated control subjects [121]. Several trials have been criticized because they were not double-blind (DB) studies using nonstandardized extracts, were not placebo-controlled (PC) and did not take into account that spontaneous improvement in asthma is commonly seen during childhood [18], although this is certainly not true in children with persistent asthma (Table 5.15). Table 13.2 shows that there are only 4 out of 44 (9.1%) pediatric studies that were not PC over 39 years. Several authors have demonstrated in long-term studies that a substantial proportion of non-SIT-treated children continued to present with asthma in their adolescence, thus establishing SIT efficacy in actively treated children with respiratory allergy [51].

In a study conducted in 87 children with pollen-induced asthma and/or rhinitis [43], treated for 3 years with SIT using a base of pyridine-adsorbed and alum-precipitated allergen extracts, we found very good results in 39% of cases and good results in 55% of cases. In 10% of control subjects, the improvements varied from good to poor (p=0.0033–0.0001) Figs. 13.2 and 13.3 show that the result is practically identical in children with pollen asthma or rhinitis [43]. Figure 13.4 [43] shows that *the clinical result is dose-dependent.* In a further study in 39 children with monoallergy to *Alternaria alternata* treated with SIT for 3 years and evaluated as above, we observed very good results in 80% and good results in 20% of cases (and in 0% and 2.5% of control subjects) (p=0.0001) (Fig. 13.5) [46]. In 300 Der p- or pollen-sensitized children, we again found significant differences between SIT-treated and control children and a reduction in the number of days with asthma (Fig. 13.6) [43]. In a trial on 28 children, we measured the mean daily grass-pollen counts (Fig. 13.7) [48] and among the clinical results we found a decrease in antihistamine use (Fig. 13.8) [48]. In the most recent trials

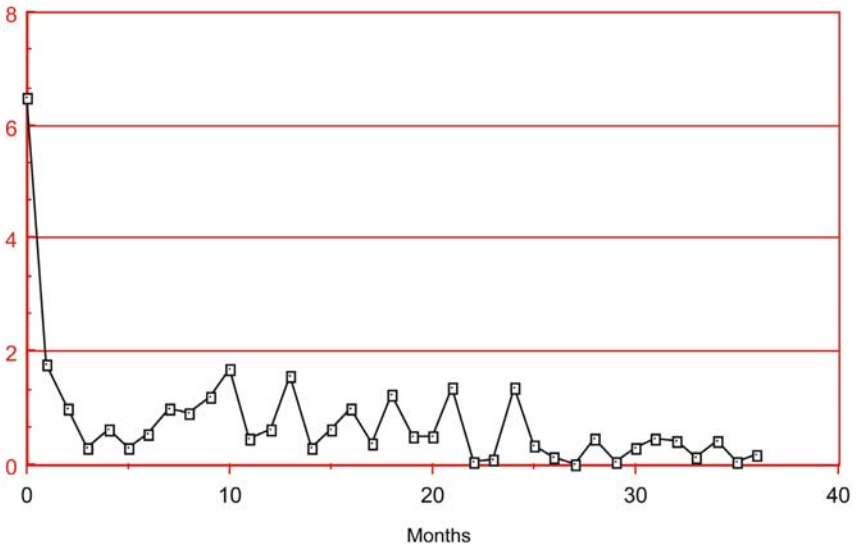

Fig. 13.6. Significant decrease in number of days with asthma after 40 months with asthma plotted in 151 children. (Data from [43])

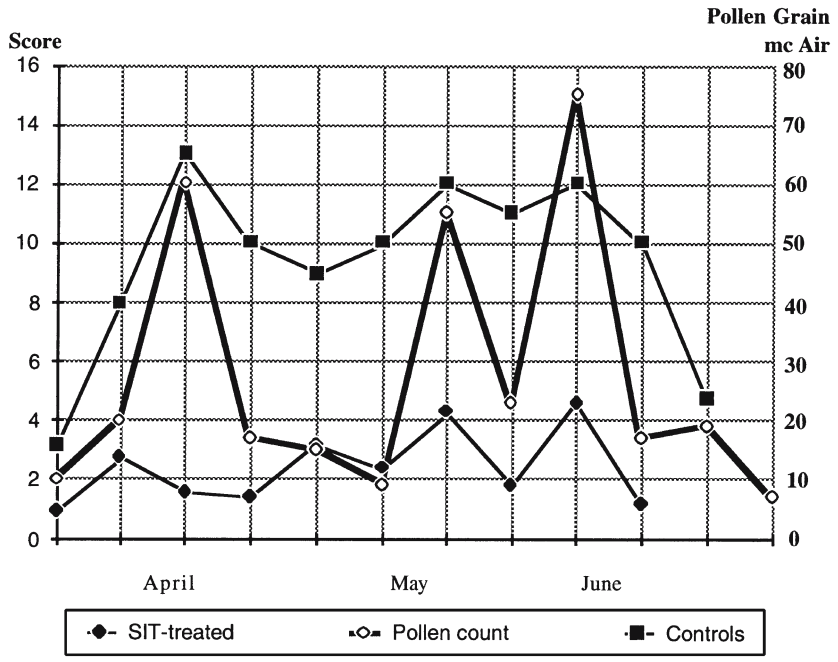

Fig. 13.7. Symptom rate (week mean) during grass pollen season in 28 children aged between 3 and 6 years with respiratory allergy treated with SIT and control subjects. Follow-up, 3 years. (Data from [48])

[43, 47] we have demonstrated the effect of asthma desensitization. As in the other trials, the control group formed by a sample comparable for all parameters to the study children was treated with all available medications. Results were evaluated based on a differentiated score of asthmatic and rhinitis symptoms. At the second yearly control the study children had a significantly greater reduction as regards the number of nights with asthma, school absences and the amount of rescue medication used as compared with drug-treated children [49]. In addition, AR draws a great benefit from SIT [43, 118], as demonstrated by statistically significant increases in symptoms and asthma development in drug-treated control subjects [118]. SIT for Hymenoptera stings was particularly effective both in adults [129] and in children: 9% of untreated subjects underwent SRs compared to 1% of those undergoing SIT [216]. DB, PC (DBPC) trials in children raise notable ethical problems [45] and very few parents would agree to give informed consent [45]. Recently a new problem has emerged, that pollen-treated children, with no asthma before commencement, developed asthma after *SIT*, in a dramatic number of cases [170] in contrast with a 6-year study [179]. In the PAT study the proportion of pollen-treated children developing asthma was 24.7% in the study group vs 39.7% in the controls [158]. In a *pre-seasonal* trial *23% of children* developed new sensitization to perennial allergens after a 13-week treatment, *and 61% 8 years* after start of SIT [72]. Notably, the percentage of children who had asthma after 3 years of

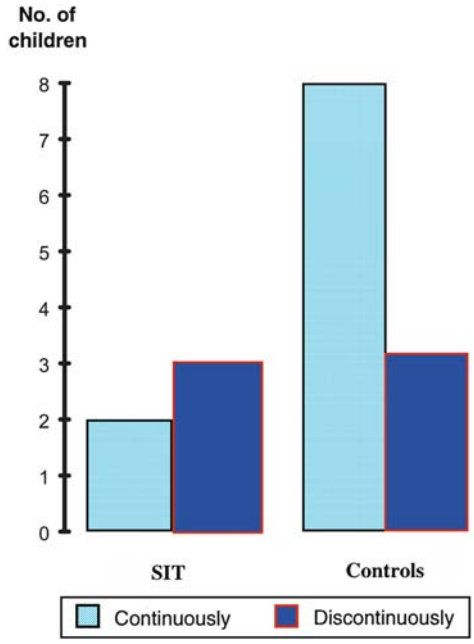

Fig. 13.8. Number of children aged between 3 and 6 years with respiratory allergy treated continuously or discontinuously with antihistamines in the study group and control group (Fisher = 0.0219). Follow-up, 3 years. (Data from [48])

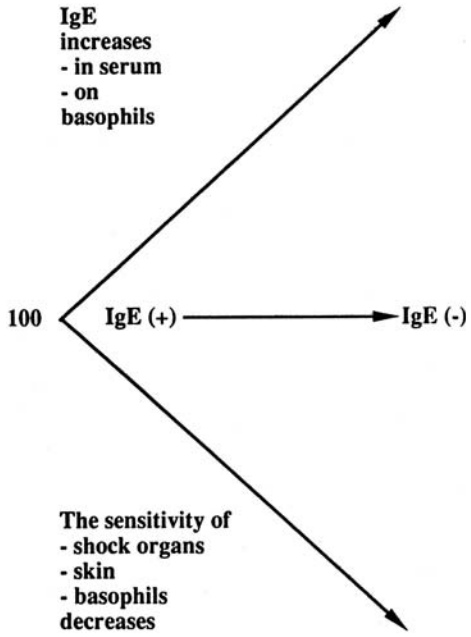

Fig. 13.9. In vivo results from clinical trials conducted with patients undergoing SIT with an effective improvement, controlled with in vitro investigations. These data correspond well to the hypothesis that the SIT mechanism works on a switch from IgE (+) to IgE (–)

SLIT *varied from 10% to 63%* [170]. We have treated hundreds of children with pollen-rhinitis, who never developed asthma, as seen in the frequent controls as detailed before [38, 44, 45, 47]. An investigation on SIT between Italian pediatricians showed that those who administered SIT evaluated SIT efficacy in 92% of cases and those who did not administer SIT in 78% of cases [207]. A recent study on the quality of life has found high ORs when assessing 27 children 6 months after SIT treatment, in pruritus (OR = 6.8), nasal obstruction (OR = 5.9), and also in runny eyes and nose (OR = 7), nose blowing (OR = 4.8), irrtability (OR = 6.2), and ocular pruritus (OR = 3.1) [159].

SIT Efficacy: Immunological Effects

SIT elicits immunological modifications, both humoral and cell-mediated [70, 94, 164]:

Humoral modulations

1. Regulation of IgE synthesis (Fig. 13.9) [68]
a. Long-term decline in antigen-specific IgE [54]
b. Decrease in seasonal IgE boost [54]
2. Increase in allergen-specific IgG [86]
3. Production of anti-idiotype antibodies [50]

Cell-mediated modulations

4. Reduced mediator release by sensitized cells
a. Decreases in human blood basophil reactivity to antigen-specific histamine [94]
b. Decreases in production of chemotactic factors for eosinophils and neutrophils [163, 202] and eosinophil adhesion [95]
c. Reduced mast cell numbers in the skin and respiratory tract
5. Reduction/inhibition of effector cell activity and tissue responsiveness
a. Decreased antigen-specific cutaneous response [164]
b. Decreased BHR [1, 93]
c. Decreased nasal responses to mediators
6. Decreased cutaneous late-phase response to specific allergens (LAR) [264]
7. Production and/or stimulation of lymphocyte populations and subpopulations [231]
8. Possible switching from Th2 to Th1 with ensuing down-regulation of Th2 and up-regulation of Th1 responses [253]
9. Induction of IL_{10}-producing regulatory T cells [79, 169]
10. Reduced expression of CD23 on peripheral B cells [123]
11. Increase in associated IFN-ɣ production [71, 149]
12. Reduction of adhesion molecules [113]
13. Increased antiendotoxin antibody [215]
14. Other IL effects

Taken together, these studies suggest that SIT may act by modulating T-lymphocyte responses to allergen exposure, compatible with the induction of T-lymphocyte tolerance in vitro. Future strategies directed at development of peptides that induce T-lymphocyte tolerance

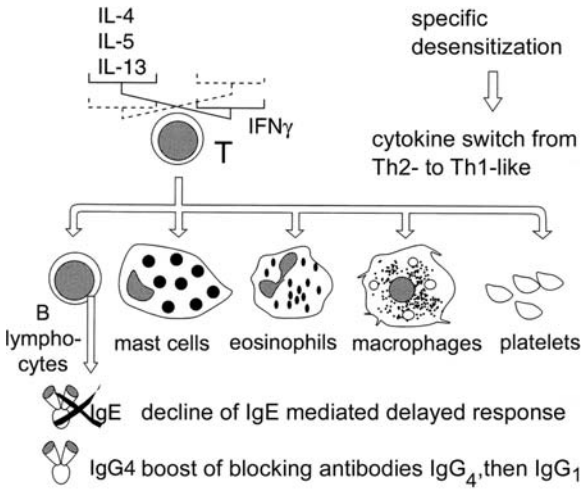

Fig. 13.10. Immunological effects of SIT

but do not interact with antibodies may improve the efficacy and the safety of immunotherapy, minimizing the risks of anaphylaxis [45]. Figure 13.10 outlines SIT immunological effects.

Humoral Modulations (Fig. 13.11)

Regulation of IgE Synthesis

Suppression of Allergen-Specific IgE Response

Initially in response to treatment, for some months a significant increase in IgE is observed, if SIT is continued for years, followed by a gradual lessening of seasonal increment and the further decrease in allergen-specific IgE synthesis after 5 years of SIT [174]. Alternatively, total serum IgE levels decrease after 4 months of SIT and increase 9 months after SIT starts. Since there is no correlation between IgE decline and clinical improvement, IgE monitoring during SIT is usually of no value, also because the response to SIT of a given patient may be highly variable [249]. SIT-induced sIgE reduction can acknowledge several mechanisms, among which the most fitting is the preferential induction of IgE- and allergen-specific CD4 or CD8 T lymphocytes [231], and production of ILs capable of modulating IgE synthesis, including IFN-α, IFN-γ and TGF-β (Fig. 1.58). The initial, rapid IgE increase is not accompanied by a matched increase in allergen-specific IgG, which occurs in a significant way only subsequently, as IgE response is evoked by low doses of allergen extracts, whereas for IgG antibody higher doses are necessary and hence a prolonged period of SIT injections. This discrepancy can explain the exacerbations of respiratory symptoms occasionally present in the first months of therapy, which therefore would always necessitate pharmacological prevention [45]. The bulk of evidence shows the need for receiving SIT for long periods and with adequate doses to obtain a firm and significant IgE reduction; however, IgE levels may increase a year after stopping SIT [70]. Surprisingly, in 225 children treated with anti-IgE, median free IgE ranged from 133 to 790 IU/ml at baseline and was in the range of 6–9 IU/ml at week 24 of the treatment period. This corresponded to a reduction in free serum IgE ranging from 95% to 99% related to subgroups. Omalizumab binds to free IgE at the same site as the high-affinity (FcεRI) receptor. Although it attaches to free IgE, it does not bind to cell-bound IgE, nor does it induce cross-linking of cell-bound IgE that would lead to the release of allergic mediators [154]. In conclusion, the reduction in IgE levels never corresponds to the levels found in control subjects: it is known that minimal ng levels of serum IgE are sufficient to induce mast cell degranulation. In a recent study [48] (Fig. 13.11) in children allergic to aeroallergens treated for 3 years, there was an inverse correlation between IgE and IgG antibodies, with highly significant differences [48], data confirmed by an adult trial [270].

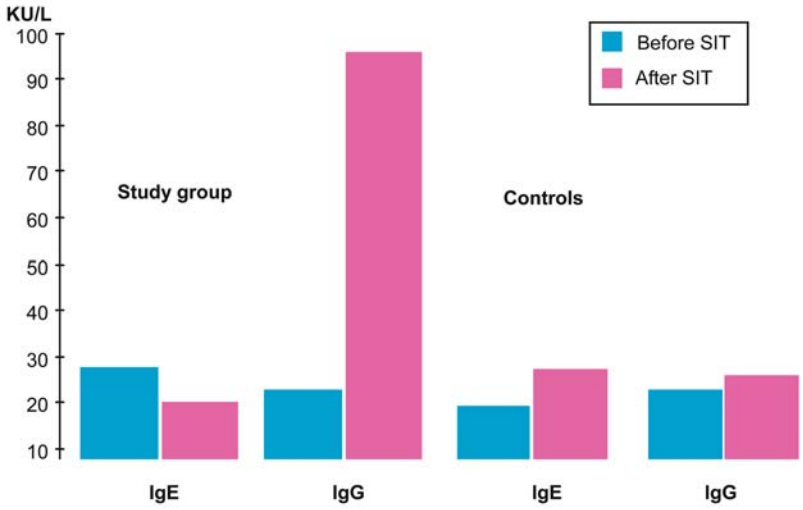

Fig. 13.11. Decrease in IgE and increase in IgG antibody levels before and after SIT in 28 children and 28 control subjects aged between 3 and 6 years with respiratory allergy. Follow-up, 3 years. IgE and IgG levels before vs after SIT; p=0.00001. (Data from [48])

Decrease in Seasonal IgE Increase

In pollen-allergic subjects, SIT significantly reduces the common seasonal increment of allergen-specific IgE with time. Only rarely will these levels disappear [48].

Production of Allergen-Specific IgG Antibodies

IgGs are identified with IgG_4, found in very low concentrations in serum and secretions of atopic subjects. IgG_4, equipped with receptors for metachromatic cells, are called *blocking antibody* (thus protective) because following the administration of allergen extract they do not trigger histamine and other mediator release but, on the contrary, compete with IgE for allergen binding. As a consequence, mast cell degranulation and mediator release is halted, with the ultimate result of intercepting specific allergens before reaching mucosal surfaces in the respiratory tract. Actually, the studies reported above suggest that these could be anti-IgE IgG antibodies complexed with sIgE (erroneously interpreted by RAST as IgG, see Chap. 6), provided with higher levels than supposedly free anti-IgE antibodies that are similar to sIgG, and that they might be at the basis of some negative results [120]. In addition, 25% of children could be deficient in one or more subclasses, or may be due to the use inadequate devices (Chap. 22). IgG, by competing with IgE, can therefore alter RAST results, by disguising and thus misrepresenting the true IgE concentration. IgG increase progressively and constantly at the start of treatment and are correlated with immunizing doses of administered allergen extract [174]. After 2 years of SIT, a mean 8.8-fold increase in the level of IgG allergen antibodies was noted [3]. Elevated serum levels are obtained only by high doses, whereas when discontinuing the treatment, IgG titers decrease rapidly. Among SIT-induced immunological changes this is understandably the most convincing and significant, strictly correlated with clinical efficacy (Fig. 13.11). The hypothesis that IgG may block an IgE-mediated condition is not decisively proven, there being cases with an evident clinical improvement preceding IgG rise [48] and inversely cases of negative clinical results associated with an IgG net increase [51]. It has been recently confirmed that SIT induces blocking IgG antibodies that inhibit IgE-facilitated allergen binding by B cells and presentation to T cells [257]. Moreover, mite-specific IgG_4 and IgA increased significantly in asthmatic children after SIT and is thus a marker of effective treatment [84]. Thus, IgG production (and production of IgA) may be a marker of effective treatment, even more so when allergens are diffused by blood, as is the case of SIT with Hymenoptera venom, but also seen in inhalant allergy. Increased titers of Der p-specific IgG_4 during SIT have reached a highly significant correlation with serum antibody levels and the clinical improvement in 96% of children after 2–3 years of injections [240]. Mite-specific IgG_4 and IgA increased significantly in asthmatic children after SIT and is thus a marker of effective treatment [84]. Similarly, after 1–2 years of oral SIT, IgE levels were decreased and IgG_4 levels were increased [187]. However, it is also true that follow-up studies of SIT-treated patients has shown that the SIT success persists, whereas allergen-specific IgG have returned to the starting point [120].

The role played by *IgG subclasses* has been studied over several years by many authors: in the first SIT stage, IgG_1 (mean half-life, 29 months) predominate and, after about 1 year there is an IgG_1 switch to IgG_4 [191], which does not influence clinical manifestations; thereafter IgG_4 (half-life, 9 months) prevail [191]. IgG_4 selective rise, in case of long-term SIT, for example with pollens, is significantly correlated with clinical improvement [11, 86, 233]. Other authors are not convinced that this rise depends on the production of antibodies directed against epitopes or antigens unrelated to IgE response [51]. Further data [225] show that the early appearance of IgG_1 (at 12 weeks) is inversely correlated with IgE immune response to certain antigens, whereas this response appears for additional antigens when the early IgG_1 rise is lacking. Moreover, in the reaction to certain antigens the IgE increase corresponds to a drop in IgG_4 values, and in other cases the contrary occurs. It is surprising that with unchanged IgE levels, the increase in IL_{13} titers is positively reflected on both IgG_4 titers and the improvement of Der p-allergic children [144]. There should be a common regulatory mechanism between IgE synthesis and either IgG_1 or IgG_4 [225], with a significant proof of a correlation between IgG and IgE after 2 years of SIT [191]. Among the immunological changes more recently described in association with grass pollen SIT are the allergen-specific IgG antibodies that can inhibit IgE-facilitated allergen binding by B cells and presentation to T cells and disrupt formation of allergen–IgE complexes that bind to APC (antigen-presenting cells) [257]. Bet v 1-specific IgG_4 levels were significantly increased after SIT. None of these changes were observed in the placebo group. When the sera were tested for their ability to induce serum IgE-facilitated allergen presentation, a complete abrogation of this effect was noted in the sera from patients receiving active treatment [250]. In particular, following SIT peripheral T cells cultured in the presence of grass pollen extract produced IL_{10} [169]. Post-SIT serum exhibited inhibitory activity, which co-eluted with IgG_4 and inhibited IgE-facilitated binding of allergen-IgE complexes to B cells [169] and presentation to T cells [257]. Both the increases in IgG and the IgG blocking activity correlated with the patients' overall assessment of improvement. Thus, grass pollen SIT may induce allergen-specific, IL_{10}-dependent protective IgG_4 responses [169]. In thinking about some antigens binding to IgE and expressing major allergens to which patients frequently react [46], IgG antibodies could be essential in preventing the start of side effects during SIT, thus decreasing patient reactivity to *progressively increasing doses of*

allergen extract. Recent data show that the capacity of IgG to counteract IgE is probably the central mechanism behind successful allergen desensitization. If the Fc fragment of IgG in the immune complex produced by allergen-specific IgGs in response to immunization bind to the inhibitory receptor FRcεIIb, this, in turn, inhibits the activation pathways activated by FcεRI. Classic desensitization may fail in a subgroup of patients because activating FcεRIIa prevails over inhibitory FcεRIIb [126, 275].

Production of Anti-Idiotype Antibodies

Idiotype–anti-idiotype interactions play a qualitative and quantitative role in regulating IgE production: concentrations of anti-idiotype antibodies were much higher in the serum of patients treated with SIT compared to control subjects [50]. However, an inverse correlation was found between titers of both IgE and anti-idiotype antibodies characterized by reduced IgE and elevated anti-idiotype antibodies in SPT-negative and RAST-negative nonatopic patients and by an inverse result in atopic subjects [50]. In complex, anti-idiotype antibodies increase in SIT-treated atopic subjects, whereas IgE decrease. Hence, SIT could stimulate an active production of anti-idiotype antibodies capable of inducing a complete and persisting suppression in sIgE [50, 244], functioning in atopics as antigens of the network [244], therefore in practice mimicking the structure of antigens that are apparently not correlated (Fig. 1.21). It seems, moreover, that further studies are necessary to correlate the development of anti-idiotype antibodies to SIT clinical efficacy, therefore clarifying the mechanisms that regulate this production.

Cell-Mediated Modulations

Reduced Mediator Release by Sensitized Cells

Reduced Histamine Antigen-Specific Release by Basophils

According to several investigators, SIT protracted for years and at high doses, modulates target cell function and number by reducing histamine release by basophils despite allergen–IgE interaction on their molecules, possibly depending on a synergistic action of other aspecific stimuli that contribute to a reduced histamine release. More precisely, basophils are the target of chemokines that, interacting with sIgE on basophil membrane, induce their releasability [30, 97] and hence histamine release [94]. Thus, basophils have the potential to play an outstanding role in decreased IgE-mediated histamine releasability during SIT [222]. Changes in cytokine production induced by venom SIT may also affect effector cells such as basophils and inhibit antigen-induced basophil histamine release [193]. HRF spontaneous production occurring in patients following histamine challenge, causing a ≥20 % drop in FEV_1 (PC_{20}), has demonstrated a significant correlation between HRF-induced histamine release by basophils (found only in atopic asthmatic subjects) and symptom severity during late reaction [114]. The clinical relevance of these results has been documented in pollen-allergic patients treated with SIT for 2 years (but not in control subjects) by an outstanding reduction in HRF spontaneous activity, correlated with an equivalent FEV_1 improvement [135]. Thus SIT can inhibit HRF seasonal increase by ragweed-stimulated mononuclear cells, as well as seasonal activation of nasal monochromatic cells. The elucidation of the mechanisms at the base of SIT and the clinical results require further suitable investigations, taking into account that a clear-cut likeness between histamine release and effects on IgE concentrations or on IgG production has not yet been recognized [35].

Reduction of Eosinophil Chemotactic Activity and Neutrophil Chemotactic Activity and Eosinophil Adhesion

ECA and NCA reduction can be correlated with eosinophil and neutrophil reduced attraction to the airways with evident clinical benefits. In patients with SAR treated for 3 years by the highest immunizing dose, eosinophil rates were clearly lower than in the control subjects, with a statistically very significant difference: by analyzing BALF (bronchoalveolar lavage fluid) it was demonstrated that SIT blocks eosinophil recruitment and ECP (eosinophil cationic protein), ECA and NCA accumulation in both nasal and respiratory mucosa, but *only in patients treated with elevated doses*, that is a maintenance of 10^5 BU [202, 203], likely for switching from Th2 to Th1. In 20 asthmatic children aged 5–17 years, half SIT treated and half not, only in SIT-treated patients was a significant reduction in eosinophils clearly shown [155]. The demonstration that SIT blocks eosinophil influx to the target organ, combined with inhibition of ECA generation [163, 202], a very sensitive marker of allergen exposure, could lead to the identification of etiopathogenetic mechanism of SIT [202]. This study has measured in the BALF cells and proteins the levels before and during two succeeding pollen seasons, demonstrating that *inhibition of eosinophil traffic is determined by the parallel inhibition of ILs released by peripheral blood mononuclear cells* (PBMCs) [202]. SIT prevents eosinophil adhesion to CD54 and CD106 molecules, but only in patients with pollen asthma, but neutrophil adhesion continued to progress, another event correlated with the switching from Th2 to Th1 [95].

Reduction/Inhibition of Effector Cell Activity and Tissue Responsiveness

Reduced Antigen-Specific Cutaneous Response

The reduced antigen-specific response is in part correlated with the reduction of late responses [165], due to raised IgG levels, as demonstrated in untreated atopics by low antibody levels and a 94% incidence of late responses, while in SIT-treated patients, IgG concentrations were elevated and the incidence of late responses dropped to <50% [94].

Reduction in BHR

Specific challenges given during a check-up done after a prolonged SIT cycle demonstrated a rise in the BHR threshold to the responsible allergen, an evident clinical improvement [1]. As a whole, these modifications speak for a general attenuation of effector cells actively involved in allergic reactions [30]. BHR reduction was recorded in adults with Der p-induced asthma without remarkable side effects [147]. In a placebo-controlled study, no significant change in BHR to histamine was found after 1 year of SIT with a standardized HDM extract [224]. Others observed an insignificant increase in BHR to histamine after HDM-SIT, while BHR decreased in subjects without SIT [161]. In a subsequent study [93], 2 years of SIT caused a significant reduction in BHR in HDM-allergic pediatric asthma patients. The difference in outcome [93] could suggest that a SIT course of 1 year [161, 248] might be too short to bring about a significant therapeutic effect on BHR. A 3-year course of SIT in children with allergic rhinoconjunctivitis significantly improved BHR [158].

Decreased Nasal Responses to Mediators

In the nasal lavage fluid of SIT-treated pollen-allergic adults, a significant reduction in histamine level and a reduction in immediate and late kinins and TAME-esterase reactions was observed after pollen challenge, always more evident as SIT progressed from the lowest to the highest tolerated immunizing dose [114]. Similarly to the cell-mediated field, eosinophil migration into the nasal cavity is inhibited with reference to dosage increase, by reaching reduced levels with increasing doses, as pointed out above [85]. This reaction can also be demonstrated in the skin [54]. SIT inhibits eosinophil infiltration in the nasal mucosa and activation, as well as a significantly increased expression of IFN-γ, unlike *control subjects who experienced highly significant increases in IL_4 and IL_5* [71]. Parallel results have been found during nasal SIT by an evident reduction in both eosinophils and patients' reactivity to the challenge [183]. Moreover, since PAF (platelet-activating factor) levels were remarkably increased during asthmatic attacks in children and as much decreased after SIT, this treatment may have interfered at the level of the metabolic pathway with the production or secretion of inflammatory mediators [111].

Decreased Cutaneous Late-Phase Response (LPR) to Specific Allergens

The decreased cutaneous LPR is responsible for chronic and aspecific hyperreactivity frequently seen in asthma and AR, hence the SIT potential for positively influencing the LAR is a very significant result, due to the known interconnection with symptom severity. Studies in cedar-allergic adults [77, 165, 252] have demonstrated a very significant reduction in cutaneous LPR, of $CD3^+$, $CD4^+$, activated eosinophils and switching from Th2 to Th1, which correlated with clinical improvement (Fig. 13.12) [252]. Three studies on exclusively pediatric entrants have evidenced a positive effect on the LAR after 1 year of injections: the classic study by the Soothill school [264], which was the first to show a SIT selective effect on the LAR, noted LAR suppression in 54.5% of children; the second in 33.3% vs none of the control children [247]. In a further study, the LAR was reduced in 88.8% of children, who fared far better in the 2nd year [248].

Production and/or Stimulation of Lymphocyte Populations and Subpopulations

SIT efficacy on regulatory T cells has been documented in several trials and not in others. According to the prevalent philosophy, SIT corrects CD8 depression (which does not respond to IL_2) in allergic subjects: thus SIT positive results can be associated with an *increasing T suppressor activity* [231]. T cells generated during SIT are activated by antigens, thus leading to the in vitro *suppression of sIgE synthesis, an event not seen in patients not undergoing SIT* [231]. In Der p-sensitized asthmatic children, SIT inhibited T-cell activation, and not only proliferative responses, but also T lymphocyte sensitivity to IL_2R (they are CD4 Th2) but not in the non-hyposensitized children [155]. Two studies in pollen-allergic subjects have instead reported a highly significant increase in $CD3^+$ and $CD4^+$ in BALF compared to control subjects, contrasting with nonsignificant variations in CD8 T cells [203]. On the contrary there was a significant decrease in $CD3^+$ and $CD4^+$ and an increase in $CD8^+$ in the skin compared to control subjects [253]. These data should be revised in light of T-cell switch.

Possible Switching from Th2 to Th1

In situ hybridization studies have shown at the cutaneous level an increased number of ILs, both Th2-like (IL_4 and IL_5) and Th1-like (IL_2 and IFN-γ), compared to control subjects, Th1-like ILs only in SIT-treated patients, without differences in IL_4 and IL_5 expression [253]. This DBPC trial, based on the new pathogenetic immune mechanisms of allergic disease, that is a Th2-to-Th1 shift that down-regulates IgE production, thus

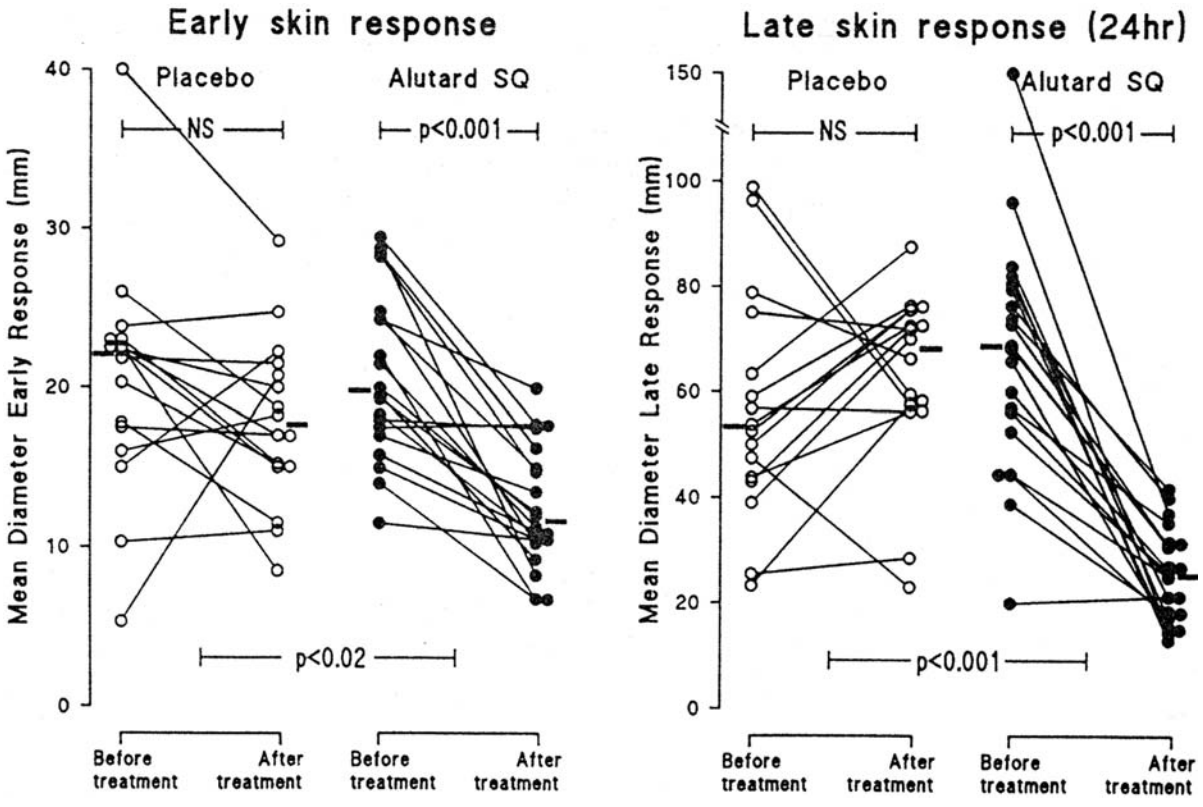

Fig. 13.12. Effectiveness of grass pollen SIT in reducing both early (*left*) and late (*right*) cutaneous responses to grass pollen SPT after 9 months of treatment
