matching the results from Jujo et al (Chap. 7), has confirmed SIT efficacy in severe SAR [253], in severe pollen [95], and mite [84] asthma and in venom SIT [193]. This study has been confirmed, since both IL_4 expressing $CD4^+$ and $CD8^+$ T cells were significantly lower in asthmatic children after SIT compared with those before treatment and the normal control subjects. Thus significant decrease of mite-specific Th2 cells might be closely correlated with the SIT regulatory mechanisms [84]. Studies on skin biopsies using immunohistochemical methods have detected in SIT-treated patients a parallel decrease in cutaneous LPR mediators, $CD4^+$ and eosinophils and additionally a significant increase in $CD25^+$ cells, the α chain of IL_2R, HLA-DR and mRNA for IFN-γ [253]. Since IL_2 and IFN-γ are part of only the Th1 secretive model (Table 1.10) and IFN-γ is produced during SIT [71], already after the dose-increase phase and a further rise after 1 year of treatment [149], a possible *shifting of Th2* (that dominate LAR) *to Th1-IFN*-γ ensues with *inhibition of IgE production* (Fig. 13.13) [70]. Opposing evidence can be found in pollen-allergic subjects successfully treated with SIT: the down-regulated Th2-dominated late response is accompanied by increased IL_{12} levels compared to control subjects, by an IFN-γ correlated increase (Fig. 13.14) [70] and an IL_{10} increase in venom SIT [193]. Examining the pattern of T-cell-produced ILs by atopic adults, their clinical improvement was correlated with an allergen-specific IL_4 reduced generation up to the levels seen in nonatopic subjects, but there were no discernible effects on IFN-γ production being CD8-dependent [220] between untreated and SIT-treated groups [84]. Importantly, rates of decrease in IL_4 levels correlated well with rates of decrease in sIgE [174]. We may conclude that SIT modifies both allergen responsiveness and presentation, steering it to IL_{12}-producing cells, which inhibit IgE synthesis and promote the differentiation of Th1-type cells [70]. Thus SIT may arouse a state of immune tolerance by modulating the IL local outline [70] and sIgE production [48, 174].

Induction of IL10-Producing Regulatory T Cells

Among the immunological changes recently described in association with SIT, it has been shown that following SIT, peripheral T cells cultured in the presence of grass pollen extract produce IL_{10} [169], an anti-inflammatory IL produced by T cells and dendritic cells, which down-regulates both Thl- and Th2-type responses [169]. The presence of peripheral blood T cells that produce IL_{10} in response to allergen stimulation after SIT has, however, emerged as a consistent finding from studies of venom SIT [21, 193]. An increase in IL_{10} production after venom SIT was superimposed on a suppression of T-cell ILs and proliferative responses [5]. More specifically,

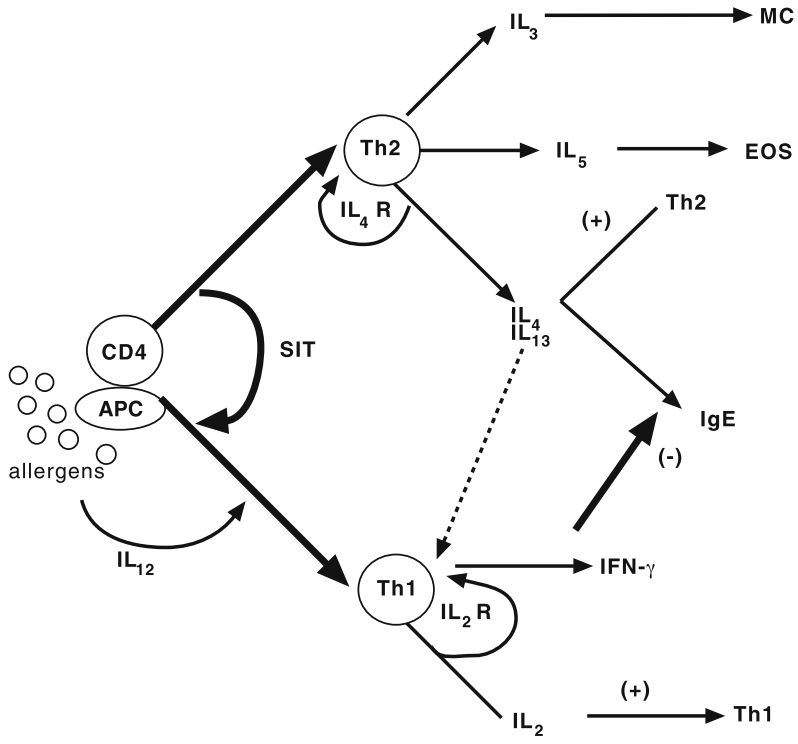

Fig. 13.13. Mechanisms of SIT: schematized encounter between allergen (*Ag*) and T lymphocytes, with a probable shift from Th2 to Th1 T cells. *MC* mast cells, *EOS* eosinophils. (Modified from [70])

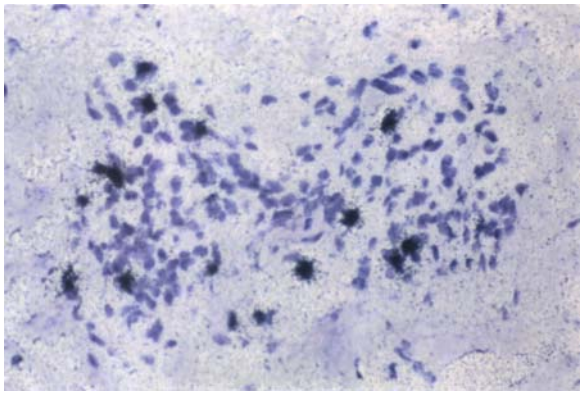

Fig. 13.14. Autoradiograph showing IL_{12} mRNA in a skin window 24 h after allergen provocation in a patient subjected to SIT

patients undergoing SIT produced significantly more IL_{10} than atopic control subjects, and exogenous recombinant IL_{10} did inhibit grass pollen-stimulated T-cell responses. Only T cells from patients undergoing SIT were positive for intracellular IL_{10}, and these were almost exclusively $CD4^+CD25^+$ cells, thus the number of $CD4^+CD25^+$ cells identified after allergen stimulation was greater in the SIT group than in the control subjects [80]. As a consequence, grass pollen SIT results in a population of circulating T cells that express the $IL_{10}(^+)$ $CD4^+$ $CD25^+$ phenotype in response to allergen re-stimulation [80]. The rapidness of allergen-specific IL_{10} mRNA expression in PBMCs is essential for the early and beneficial outcome of SIT [169] There is evidence that IL_{10}-induced tolerance could be a key phenomenon in SIT [5, 21].

Reduced Expression of CD23 on Peripheral B Cells

SIT leads to an inhibition of the CD23-mediated serum IgE-facilitated allergen presentation needed to obtain optimal T cell activation at the low allergen concentrations present in vivo [250].

Der p-sensitive asthmatic subjects have shown a significantly increased number of CD23-expressing B cells compared with healthy children, which were significantly reduced by SIT; however, no significant change was found in clinical improvement [164]. FcεRII/CD23 expression on peripheral B cells in grass pollen-sensitive patients was not found to be altered by successful SIT, but when grass pollen-induced *FcεRII/CD23 expression was correlated,* it was found to be *suppressed by SIT.* Severity of allergen-induced manifestations and drug requirement were reduced in the next pollen season, and correlated closely with a SIT-induced reduction in the percentage of FcεRII/CD23 B cells [123]. A subsequent study has found that CD23 levels were reduced when SIT duration was >36 months compared with a duration >3 to ≤36 months. In the first group, the CD23 mean value was 1.59 (1.0–1.9, 25th and 75th percentile), but in the group with shorter SIT duration, the corresponding values were 2.31 (0.5–1.7, 25th and 75th percentile) [6].

Increased IFN-γ Production

In other treated subjects, SIT increases the number of cells expressing messenger RNA for IFN-γ activity [71], which is also deduced, since it inhibits CD23 expression as compared to control subjects and thus IL_4 or IgE expression [123]. These results may be apparently discordant, but they attest to IL synthesis by CD4 memory cells that can be modulated by in vivo treatments [148, 220]. IFN-γ increased from 224.6±153.9 pg/ml before venom SIT vs 531.1±479.9 pg/ml after the initiation of venom SIT [193].

Reduction in Adhesion Molecules

Recruitment of leukocytes from the peripheral blood into tissue requires a series of cell-adhesion molecule-mediated interactions between the surface of the vascular endothelium and leukocytes. We demonstrated in Chap. 1 that several adhesion molecules play a critical role in the recruitment and migration of leukocytes to sites of inflammation in various diseases. Important adhesion molecules expressed on leukocytes or endothelial cells include CD54 and CD62L. A recent study has demonstrated that with long-term SIT, the percentages of $CD54^+$ T lymphocytes, $CD69^+$, an early marker of T-cell activation, and serum CD62L were significantly lower in children with a good response to SIT. Thus the decreased expression of adhesion molecules on T lymphocytes and the number of activated T lymphocytes in asthmatic children receiving treatment with SIT may decrease the recruitment of the activated T lymphocytes into the airways, resulting in a decreased airway inflammation [113].

Increased Anti-endotoxin Antibody

Endotoxin is a ubiquitous and potent proinflammatory agent (Chap. 11). Anti-LPS-antibodies of IgA, IgM, and IgG classes were investigated by ELISA in 22 bronchial asthma patients and 98 healthy control subjects. On the 70th day of SIT, higher levels of IgA antibodies to endotoxin of *Escherichia coli* (*E. coli*) K 30 were noted than before SIT, significantly greater than in the normal control subjects. A positive clinical effect of SIT in patients with bronchial asthma may be associated with an elevation in anti-endotoxin antibody, including an increase in IgA to endotoxin of *E. coli* K 30, suggesting an increase in Th1 responsivity [22].

Additional ILs and Chemokine Receptors

During specific pollen SIT, there is a mucosal shift from Th2- to Th1-type IL predominance, and IL_{12} plays a major role in this shift [169]. Moreover ovalbumin-IL_{12} can convert immune responses characterized by high IL_4 and high IgE synthesis into Th1-dominated responses in an antigen-specific manner [125]. In intermediate samples, taken in PBMCs of AR patients when the maintenance dose was reached, the peak expression of allergen-induced IL_{18} mRNA was associated with the most favorable outcome of SIT. Thus IL_{18} is an important IL in the SIT of pollen AR patients [214]. Chemokine receptors play an important role in the migration of leukocytes to sites of allergic inflammation in humans. An increased expression of the chemokine receptor CXCR1 was found on $CD4^+$ T lymphocytes obtained from patients with atopic disease. The expression of CXCR1 was dramatically decreased in patients undergoing successful treatment of AR by SIT [79].

In conclusion, the clinical improvement of symptoms cannot explicitly be correlated with any of these immunological modifications considered individually, but is likewise the result of a variable mixture of the aforementioned factors, and tentatively of other as yet unknown, but perhaps not less intriguing factors. Actually, in ragweed-allergic patients treated for 3 years with the highest immunizing dose, the rates of eosinophils were definitely lower than those found in subjects either not treated or treated with lower than threshold doses [85]. Likewise, IL_4 levels were correlated with SIT duration [220].

Considerations Before Initiating SIT

- Presence of IgE-mediated disease proven to benefit from immunotherapy
- Allergic rhinitis
- Allergic asthma
- Sound documentation of sensitivity to allergens associated with symptoms
- Symptoms of sufficient duration and severity
- Seasonal symptoms despite avoidance measures and pharmacological therapy
- Perennial symptoms failing trials of avoidance measures and chronic pharmacological therapy
- Anaphylaxis following Hymenoptera sting, except children with non-life-threatening anaphylaxis
- Availability of standardized allergen extracts of allergen responsible for sensitivity

General Criteria of SIT Execution

Before writing a prescription for SIT, pediatricians or allergists should inform the parents, in an adequate, complete and intelligible way, of the following points [37]:

- Duration of treatment

– Discussion of long-term nature of treatment and need for compliance

• Necessity of associating a pharmacological prevention with SIT to control symptoms completely
• Possible risks associated with SIT's overwhelming benefits
– Accessibility of facilities and personnel capable of administering treatment and evaluating and treating anaphylaxis
• Monitoring children to ensure they are waiting in the facility where they receive SIT for a time interval of 30 min, also during maintenance treatment
– Emphasis on avoidance as treatment of choice
• Inefficacy of SIT in a certain percentage of treated children

Tinkelmann et al have studied both chronology and type of reactions: *within 30 min of waiting* after each shot they observed 71.4% of overall reactions, 76.4% of respiratory reactions, 72% of cutaneous reactions and mostly important, 100% of cases of shock [239].

In conclusion, pediatricians or allergists must ask parents for their informed consent, adapting the proposal shown in Appendix 6.7 to SIT.

Technique of Administration

The elective way of SIT administration is the SC route. Within the practical principles of treatment, we describe the traditional technique as it is widely used, and then rush SIT.

Before administering SIT it is necessary to [37]:
• Ask whether the child had side effects after the previous injection.
• Attentively examine the clinical conditions of the child and carry out the physical examination, excluding the child from SIT if symptomatic and/or with intercurrent infections [8].
• Check whether name and surname of the child, batch number, allergen extract vial, concentration, and expiry date are correct: usually on the vial both batch number and expiration date are shown, because the child's name and the type of allergen extract may be specified on the box and not on the vial.

During the injection [115]:
• Before administering injections, make sure that epinephrine is readily available, and antihistamine and corticosteroids (CSs) are within reach to permit an immediate intervention if necessary.
• Any injection should be made with a single dose 1-ml graduated tuberculin syringe with incorporated needle, not an insulin syringe; however, if this type is available and for contingent reasons it is impossible to use the recommended syringe, in a 1-ml insulin syringe, scale 40, 0.10 ml corresponds to four marks.
• Lyophilized extracts should be accurately reconstituted with a suitable diluted dose, avoiding air bubbles, clots, etc., according to the manufacturer's instructions.
• Clean the area with an alcohol swab before injection.
• Accurately and gently roll and shake the vial before the injection.
• Carefully withdraw the proper amount from the appropriate vial with the syringe.
• Take care to avoid intracutaneous, intramuscular (IM), or IV injections.
• Inject subcutaneously in the middle third of the forearm, dorsal aspect; either arm may be used or the arms may be alternated, and when concurrently administering two allergen extracts use only one extract for each arm. The choice of forearm is dictated by the likelihood of placing a tourniquet upstream of the point of injection in case of severe local or systemic reactions.
• The needle should be introduced subcutaneously, with an angle inclination of about 40°; in this manner an intradermal inoculation is avoided; otherwise granuloma formation is caused along with a possible unsuitable absorption and reactions to the subsequent administrations.
• Before injecting the dose, gently draw the plunger, and repeat the aspiration once or twice depending on the volume to be sure that the needle has not inadvertently penetrated a vessel, then repeat carefully the aspiration during the gradual injection.
• If the needle accidentally penetrates a vessel, withdraw the needle and select a new injection site.
• Withdraw the needle at the end without stroking the inoculation site, to avoid a quicker absorption, which could increase the risk of SRs, apply pressure over the injection site for 15–20 s.
• After every injection, record the date of administration, hour, place (if different from the doctor's office), dose injected, the arm (right or left or both) and side effects (nature, timing, severity and treatment given).
• It is mandatory for children to wait in the doctor's office for at least 30 min after each shot, because the more severe reactions take place during this time [8, 101, 239];
• After 30 min, the injection site is inspected and the child may leave the office, after being instructed to avoid intense physical exercise such as running and climbing, and more importantly hot bathing, sauna, etc. on the day of injection: such activities may induce vasodilation with consequent accelerated absorption of allergen extracts.
• Allergen extracts in solution or lyophilized should be kept at a stable temperature between +2 °C and +4 °C at all times except when actually in use, absolutely avoiding both freezing and heat exposure.
• Exposure at ambient temperature (T) for short times does not disprove extract validity.
• When the extracts are not employed routinely, it is timely to change them after 4–5 months, even if the expiration date is still valid, since the proteins may denature, especially those in watery solution, and stick to vial walls (wall effect), with a consequent reduction in potency of the extracts.

- Beginning a new maintenance vial, we suggest reducing by 30%–50% the next administration dose, increasing the dose gradually, since the just opened vial may have a greater allergen potency than the vial in use [115].

Administration Schedules

As a general rule, doctors can follow the manufacturer's schedule enclosed in every box of allergen extracts prepared by specialized laboratories according to the results of specific allergy tests. Of course, a standard schedule cannot be used, since each subject differs, notably in the reaction to injections. Thus, to counter the impossibility of establishing a standard schedule valid for all patients, Appendix 13.1 shows a SIT average schedule, which should be used as a general guide. Pediatricians or allergists can modify the schedule according to age and the child's reactivity and allergen nature, to reach the highest tolerated dose, in other words the optimal dose, by personalized increments.

Generally each preparation of allergen extract contains three vials with increasing allergen concentration (build-up phase). The build-up phase involves the administration of incremental doses of allergen extract at 1- to 1.5-week intervals, up to the maintenance phase based on the *highest tolerated dose* that does not elicit side effects [45]. Initial doses should be reduced in children who are very sensitive to the allergen in question, and subsequent doses are regulated based on the first injection results; however, when no reaction is provoked, or no more than a mild local reaction, the dose may be increased by 50% or even doubled based on the doctor's judgment. Additional guidelines for dose modifications are as follows:

- No increment of allergen dose in case of local reactions of diameter >3 cm or in case of large local reactions >8 cm, delayed or lasting >24 h, or causing inconvenience to the child. In practice the dose of allergen extract should not be increased, repeating the last previously tolerated dose.
- The dose should be reduced in relation to the preceding dose, for example, in case of increased environmental exposure to allergens (grass pollination during seasonal SIT) or changing to a new vial of allergen extract.

Different guidelines may apply regarding immediate, local or large reactions, with a diameter >5 cm, which may warn of future immediate SR, therefore:

- If SR (wheezing, urticaria, shock, etc.) occurs SIT should be re-evaluated (see below).
- If the child does not receive the injection in due time for foreseeable or health reasons, that is if the child is within 2 weeks of being overdue, the prior dose should be repeated, but if the child is 1 month overdue the dose should be reduced by one step. If the child is 5–6 weeks overdue the dose should be reduced by two steps. Any lapse >6 weeks should result in a consultation with the physician [115].

The injection should be postponed contingent upon the following:

- Respiratory tract infections within the last week
- Intercurrent pathological situations within the last 3–4 days
- Exacerbations of atopic dermatitis (AD) (SIT administration may exacerbate cutaneous symptoms)
- Urticaria in the symptomatic phase (for the same reasons)
- Acute respiratory symptoms with evident functional impairment: namely, FEV_1 reduction with <70% of predicted value despite adequate treatment

The magnitude of dose reduction depends on severity of the reaction [115].

In SIT for Hymenoptera, the rush method is used (see "Rush SIT") [217]. We suggest that the doctor not exceed the maximal dose shown in the manufacturer's standard schedule. The units adopted by the single manufacturer are valid in relation to the extract used (Chap. 1) and do not allow interchangeability of extracts of different manufacturers in the same patient, even if titrated by the same method.

Particular precautions should be adopted in patients with *multiple sensitizations*: SIT should be undertaken in this case with two distinct hyposensitizing extracts, each to be injected on a different lower arm [161]. Also in multiple sensitizations only to pollens, no mixtures of allergens belonging to different families should be employed because of potential cross-reactivity, a possible cause of unsuccessful SIT [3]. In mold allergy, SIT should be proposed only to patients allergic to *Alternaria alternata* [44].

Treatment Chronology

SIT is done according to three procedures:

- Preseasonal
- Continuous or perennial
- Rush therapy

In pollen allergy, it is possible to provide either a preseasonal treatment with progressively increasing doses, to be completed before the start of the pollination period, or a continuous treatment, without interruptions during the injection schedule. SIT for perennial allergens can be started in any year period by following a continuous schedule. In both cases, the continuous treatment is the most effective and widespread method. SIT for Hymenoptera venom is begun in fall or winter to desensitize patients before spring, the insect season; in case SIT is started late or in high-risk patients a rush SIT may be instituted [68].

Preseasonal SIT

This unusual type of SIT may be suggested to patients with pollen sensitization, limited to the months of October to May or September to June. The goal is to reach, by scalar doses, the patient's maximal tolerated dose before plants begin to bloom and produce pollens to which the patient is sensitized. At this point, treatment is rescheduled to restart injections in the subsequent period, for several years straight. When SIT is started ahead of time, and its cycle is concluded 1–2 months before the expected onset of clinical symptoms, an advisable measure is to continue the maximal tolerated dose every 3 weeks, up to the pollination period. Eight years after commencement of preseasonal SIT, 61% of the initially pollen-monosensitized children had developed new sensitization to perennial allergens compared to 100% in the control group [72]; thus the long-term results are positive in only 39% of the treated children.

Continuous or Perennial SIT

Continuous or perennial SIT, a more common type of SIT, requires a larger consensus and is the SIT method that we recommend. This is prescribed to pollen-allergic children, particularly to those sensitized to *Parietaria* (with almost perennial blooming), and to children allergic to aeroallergens. The child is initially administered allergen extracts SC by scalar weekly doses up to the maximal tolerated dose (build-up phase), continuing subsequently by biweekly intervals for 1 year, then gradually extending to monthly intervals. This type of SIT is never stopped for the entire treatment. Clinical studies and scientific evidence indicate that a continuous treatment allows children to tolerate a higher cumulative dose, which ensures a greater protection than the preseasonal schedule. In SIT perennial for pollens, as discussed in the preceding section, it is advisable to begin 5–6 months before plants bloom. The dose may be reduced only in children in whom SRs develop presumably to seasonal and injected allergens to which children are sensitized, and then to return gradually, as the subsequent season approaches, to the previous maximal dose. Children sensitized to other aeroallergens, for example, Der p/b, can start SIT at any period deemed appropriate.

Each of these two types has advantages and disadvantages, apart from the possibility of personalizing SIT. The patient is more motivated with preseasonal treatment, since SIT begins before the pollination period, when disturbances peak, and ends after a relatively short time. With a perennial treatment, the total number of injections is in the end substantially lower, with the added advantage of spacing doses. *Neither in our studies nor in our daily practice have we suggested a preseasonal schedule.*

Rush SIT

Rush SIT is a method applied almost exclusively to children allergic to Hymenoptera venom, when a rapid immunization is necessary [70]. Rush SIT is done exclusively *in the hospital or under observation* in a unit staffed to undertake emergency measures and with personnel capable of administering treatment and evaluating and treating anaphylaxis.

Two methods are suggested:

- Normal rush (rush IT) with doses every week and the maximal dose at the 7th and last week in the hospital and under continuous control
- Modified rush (modified rapid means clustered SIT), which includes a first accelerated session (repeated injections at 30-min intervals), followed by another six injections (one every week) with conventional chronology (see Appendix 13.1) [160, 184 and Chap. 17]
- Accelerated in 3–5 days and semi-rush in 2–8 weeks [204]
- Ultra-rush for Hymenoptera-allergic adults and children over 3.5 h by administration of six increasing doses at 30-min intervals up to a total dose of 100 µg (Appendix 13.2) [27, 116, 160, 184 and JO Steiß, pers. comm., 2005]

Some authors distribute the first series of injections over 2–4 days [100, 101]. We deem that with the rush protocol the reactions are more frequent in absolute, resulting in a SR risk, especially in children [197, 204], which are prevented with adequate premedication [197, 236] and making admissions necessary or at least appropriate [101, 197]. Moderate adverse reactions (28.6%) [100], anaphylaxis (15.3%), serious reactions (37.3%) and strong reactions (34%) occurred in children [204]. Premedication reduces SR incidence up to 27% [197]. *Without premedication* SRs become significantly more frequent in children 3–5 years old [100] and in PC-treated subjects 6–18 years of age [197]. The SIT maintenance interval is usually 4 weeks. Lengthening the maintenance interval for children up to 6–8 or even to 8–12 weeks in case of Hymenoptera allergy [129] is likely to decrease SR prevalence.

SIT Duration

No ideal duration has been ascertained or established; however, Table 13.2 offers 44 studies related to pediatric cohorts: in our studies [38, 43–48] and in another 22 studies SIT duration was ≥3 years, so we estimate that SIT should be administered for at least 3–5 consecutive years of maintenance, or until a satisfactory remission of symptoms is noted over at least a 1- to 2-year period [43–46]. SIT for perennial allergens should be discontinued after 5 years [48], yet for seasonal allergens a shorter maintenance could be sufficient to achieve long-term results. We have decided to continue SIT for 5 years in either case, especially in children with initially severe

symptoms, obtaining definitive results in 97% of cases [47].

There is no consensus to define guidelines regarding the optimal duration of SIT for Hymenoptera hypersensitivity. In adult trials, 5 years would be adequate to ensure prolonged tolerance [91], provided that cases of severe anaphylaxis or other symptoms are not experienced [88]. The 5-year limit ensures the reduction of clinical sensitivity and, above all, that no SR will follow subsequent insect stings [91]. The likelihood of discontinuing SIT before the usual term remains to be evaluated [216] as well as the option of whether or not to extend the procedure to children, provided the intentional stings are done in a hospital environment to control the tolerance state and thereby determine the SIT duration (Chap. 17). Children who have experienced no previous life-threatening and/or exclusively cutaneous reactions are not necessarily subjected to SIT [216]. SIT-treated children at 9±3 years reported no SR at 26±5 years, while SRs occurred in 14% of untreated children, thus suggesting that over the long term children benefit from venom SIT [85].

When SIT-treated children do not respond with a clinical improvement within 2–3 years after receiving appropriate allergens, a diagnostic re-evaluation is indicated. If children switch to placebo after receiving 1 year of active treatment with Der p SIT the allergy relapses within months, whereas continued active treatment ensures ongoing improvement [264]. When clinical symptoms relapse, with heavy interference on school life and/or *quality of life,* SIT may be resumed subsequently, after a new diagnostic assessment.

Anti-IgE SIT has revolutionized the treatment duration: 3 [131, 131] to 6 [154] months has provided a 90%–95% reduction.

Possible Association of Medications with SIT

SIT association with levo-cetirizine, cromones, or long-acting theophylline may be necessary for complete symptom control. In particular, the association with oral cromones has been shown to be remarkably valid in preventing symptoms. Levo-cetirizine, antihistamine a new-generation is helpful because of its antihistamine activity. CSs and bronchodilators should instead be employed only in the treatment of clinical manifestations of a certain magnitude, and not as preventive drugs, since they could disguise the mild reactions that are useful signals for regulating the therapeutic schedule. Remarkably, a significantly greater proportion of children treated with omalizumab reduced the inhaled CS dose compared with children in the placebo group [154].

Monitoring SIT Efficacy

The tests proposed to monitor SIT-induced improvements, including total and specific IgE evaluation, SPT modifications and increases in both IgG and subclasses are not always correlated with clinical results. Specific challenges (reduction of nasal and bronchial reactivity to allergens) and variations in in vitro release of histamine or mediators released by basophils in response to specific allergens, are procedures that are not easily performed in children and are also not standardized. It is trivial to measure IgG periodically to monitor both dosing and frequency of administrations [115], as is the case in Hymenoptera allergy, although it was recurrently proposed [88], since there is no correlation with clinical symptoms [91]. Varney et al have shown the decrease in cutaneous immediate allergic reaction (PAR) and even more of LAR as possible markers of SIT efficacy [253]; the clinical results remain to be demonstrated. Therefore, sound clinical observation of children and the quantification of subjective and objective clinical parameters are the only reliable means to appraise SIT progress and the ensuing benefit. This assessment is based solely on the improvement of respiratory symptoms, which can be achieved, for example, by the daily recording of objective parameters such as PEFR [115] and mean daily drug usage, or of subjective parameters such as surveying daily scores of symptom severity [43–48]. The values of related subjective and objective parameters should be compared from time to time.

Causes of SIT Failure

As a general principle, the causes of SIT failure (Table 13.4) [37] are manifold, often a result of the child's or the family's lack of cooperation or unreasonable expectations, the premature conclusion that SIT has failed, which is often related to insufficient avoidance of allergen, resulting in an ongoing and overwhelming exposure to that allergen. More rarely, SIT failure may stem from the administration of inactive or expired extracts, or inadequate dosing (SIT efficacy is always dose-dependent), or on an inexact etiological diagnosis. Other explanations include poor concordance of in vitro results with clinical manifestations [1], the expression of new sensitizations or other triggering allergens, and SIT ineffectiveness in itself. Causes of SIT failure can be found in significant titers of microbial allergens that bind highly to IgE, instead of Der p, or in Eur m 1 homology to Der p 1 and Der f 1 (Table 1.73) in conventionally assembled extracts from cutaneous scaling. Pollen extracts could deteriorate if inappropriately stored at a T >4 °C [115]. Allergen mixtures may also be a cause of failure, because some allergens possess enzymatic activity that can alter the proteins of other pollens, thus reducing extract potency [267]: the employment of therapeutic extracts containing mixtures of up

Table 13.4. Potential causes of SIT failure

1.	No compliance from parents
2.	No compliance from children
3.	Incorrect SIT administration
4.	Administration of inaccurately prepared extracts
5.	Administration of inactive/expired extracts also because of long-term storage
6.	Administration of inappropriate doses
7.	Interventions for allergen avoidance inaccurately performed, with continuous and massive exposure to allergens
8.	Unreasonable expectations by children leading to a premature conclusion of SIT failure
9.	Mistaken etiological diagnosis or no clarification of all the allergens actually responsible forthe ongoing disorder
10.	Subsequent new sensitization of the child by additional allergens or intervention of additional triggering factors
11.	SIT inefficacy in a given child
12.	SIT inefficacy in itself
13.	Possible false-negative results of laboratory investigations

Modified from [37].

Table 13.5. Causes of a possible erroneous evaluation of SIT results

A.	Different pollen concentration in the atmosphere due to climatic influences, resulting in greater or lesser variations in clinical manifestations, in terms of both duration and severity
B.	Modification of patient reactivity, which may underlie a greater or lesser variability of disease severity, also independently of treatment
C.	Changes in the patient's habits, possibly inducing changes in the course of the disease
D.	Difficulty in the objectiveness and/or quantification of symptoms, also related to diverse therapeutic steps carried out in the time considered
E.	Complications related to the method of study and/or in balancing the patient cohorts

to seven unrelated allergens (pollen, molds, and HDM) may explain some negative results [3]. It is not surprising to find that mixtures containing variable doses of potent allergens elicit negative results [164], since both cross-reactions and/or administration of low concentrations of primary allergens are foreseeable [115, 267]. Dilution of multiple allergens may result in suboptimal doses of single allergens, and the potency of individual allergens may be reduced more rapidly when diluted or mixed with other extracts [258]. SIT is definitely *ineffective in multisensitized patients treated for a single allergy* [267] *or for seven allergies* in *the same extract* [3], or sensitized to *Plantago*, generally associated with grasses, but easily differentiated by the atypical calendar (Chap. 12). Therefore, apparent SIT failure may stem from imprecise scientific planning, without considering the variables that can influence an exact final evaluation (Table 13.5).

Adverse Reactions

The prevalence of adverse reactions has been analyzed at 99% in adults [232]. SRs occurred in 0.1%–1.7% of injections and in 1%–50% of patients treated with non-standardized extracts, with a greater frequency for these patients, the rush method and some types of polymerized extracts or allergen mixtures [252]. A comparison with the data in the literature shows that anaphylactic shock has an incidence of 0.01% of patients and 0.0013% of injections. Some experts not familiar with pediatric allergy [78, 237] ascribe a great number of severe or even fatal reactions to children without specifying they were reporting on adults [78]. As a consequence, the CSM "has eliminated SIT entirely as a therapeutic option," because it was believed that the risks would be higher than the potential positive effects. However, in most of these cases adequate cardiorespiratory equipment necessary for resuscitation was not available [78]. Several authors maintain that "SIT is dangerous in children and a cause of anaphylactic shock" [30, 178], since they quote the study by Hejjaoui et al [100], without pointing out that 30 of 105 children aged 3–15 years experienced SRs *in a rush study*, which should be done in hospital facilities [46] because it carries a risk for SRs [28], *especially with no premedication* (Table 13.6) [100]. As a rule, it is intriguing to extrapolate the results of rush studies and compare them with a normal SIT; however, in other children, when applying the due precautions, *no SRs were recorded* [47, 247, 248], and several trials *demonstrate the exact contrary of the CSM* in terms of SIT danger in children and in the time span considered here [38, 45–48]. To date we have treated thousands of children with SC SIT and have recorded only one case of anaphylactic shock in a multicenter trial [38] plus some cases of mild skin reactions.

- In a multicentric study, mild symptoms such as asthma and urticaria were observed in 0.08% of injections, and only one case of shock in 0.002% of injections; such reactions occurred in children with Der p allergy, giving a much more significant statistical difference than in children with pollinosis (Table 13.7) [38].
- In another prospective and controlled study lasting 3 years and including 300 asthmatic children, *we recorded no cases of shock*, and only mild reactions in 2.5% of cases and in 0.066% of treatments [44].

Table 13.6. Pediatric study by Hejjaoui et al

1. The children were subjected to a rush protocol, which is known to provoke more reactions
2. The children had neither premedication nor preventive measures; the authors were conscious of the risks, therefore the patients were hospitalized for the first night of treatment
3. The authors hypothesized that the hospitalization increased the rate of SR because of its psychological impact

Data from [100].

Table 13.7. Systemic reactions in 1,056 children

Extract	No. of cases	(%)	No. of injections	(%)
Mite	29/689	(4)	29/29,091	(0.09)
Pollens	9/291	(3)	9/12,286	(0.07)
Parietaria	3/109	(3)	3/4,602	(0.06)

Data from [38].
p (mite vs pollen) = 0.0001.

- In a cohort of 42,457 entrants undergoing SIT between 1957 and 1992, 3,187 SRs to SIT occurred with traditional allergens (7.5% of patients), 139 with modified allergens causing 8 SRs (8.4%), and 2,422 during rush procedures causing 393 SRs (16.2%). It is notable that in the USA $\approx 10^7$ injections are given annually and neither systemic nor fatal reactions were observed in children undergoing the conventional protocols [227].
- In another trial, nonfatal SRs were observed in 3 out of 374 children aged 2–9 (0.8%) and 37 out of 1,097 aged 10–19 (3.37%), a total of 139 cases with 513,368 injections (0.027%); pollen prevalence (50% grasses and 21% ragweed) in comparison to 1% attributed to dust (Der p is not named) [142].

The incidence of SRs in children is summarized in Tables 13.8 [38, 142] and 13.9 [4, 38, 177].

- In patients with a premedication regimen, over a 4-year period with 22,250 injections, an edema <5 cm in 1.9% of patients and >5 cm in 0.17% of cases and a mild SR in 0.023% of cases were reported [262].
- Of a total of 108,000 injections given over 4 years, only three children aged 7–15 years experienced reactions (rhinitis, conjunctivitis, urticaria), with a 0.0027% incidence, with only five injections responsible for symptoms in 0.0046% of cases [66].
- Tinkelman et al [239] concluded that SRs occurred in 2.14% of patients and in 0.06% of injections: taking into account only subjects between 1 and 20 years, the figures are reduced to 0.5% and 0.014%, respectively.
- In a SIT trial for sting allergy, only 1/62 children (1.6%) experienced a severe SR, explained by the fact that he had discontinued treatment 7.5 years earlier, after undergoing SIT for a total of 2.5 years [92].
- In a SIT trial for mold allergy after several months on maintenance therapy, following an earlier tolerable allergen injection, 3/106 children (2.9%) suddenly developed severe, nearly fatal anaphylactic reactions to Cla h, Alt a and Phl p for which ICU treatment with IV theophylline and epinephrine was required (all recovered without sequelae), and another three severe anaphylactic reactions also successfully treated with epinephrine [177]. In children treated with SIT for Cla h [69] and Alt a [46], *no such reactions were provoked.*
- In a retrospective trial for Der p and Der f allergy, SRs occurred in 12 children, successfully treated with epinephrine or clemastine, while one child also required intubation [4] (Table 13.9).
- Concerning the discussed issue of fatal cases, between 1945 and 1992 there were 45 cases throughout the USA [143, 227]. In 24 cases that were reported with sufficient data [143] and 17 from 1985 to 1989 [206], including 7 children aged 7–18, five cases can be related to specific errors, especially the delay in epinephrine administration, leaving the doctor's office too soon after the injection, and wheezing in progress and in the preceding 24–48 h (Tables 13.10, 13.11) [9, 143, 206]. In the remaining two children, there were no known errors: by introducing statistical corrections including SIT execution in a site different from the doctor's office (40% of cases), administration during the pollen season (33%) [227], insufficient experience on the part of the physician [263] and the number of injections per year [227], the FR incidence approximates 0% (Tables 13.9, 13.11). The shock onset was within 20 min in 29 cases, between 20 and 30 min in 2 cases and after 30 min in 4 cases, with no specific information regarding the other cases [143, 206]. The case record was updated in 2001 [9]. Recently, a 12-year survey of fatal reactions to SIT injections was conducted between 1990 and 2001, showing that the rate of fatalities per SIT injection has not changed much over the last 15 years. Fatal reactions were estimated to occur at a rate of 1×2.5^6 injections, with an average

Table 13.8. Systemic reactions (*SR*) in children during SIT

Authors and references	Year	No. of SR	Age (years)	No. of injections
Lin et al [142]	1993	3/374 (0.8%)	2–9	NS
		37/1,097 (3.37%)	10–19	139/513,368 (2.9%)
Businco et al [38]	1995	41/1,443 (3.7%)	2–14	41/45,979 (0.08%)

Table 13.9. Anaphylactic shock in children during SIT

Authors and references	Year	Age of children (years)	(%)	Injections (%)	Treatment
Akçakaya [4]	2000	8.5	1.1%	0.017%	Epinephrine, ICU, full recovery
Businco et al [38][a]	1995	8	0.09%	0.0016%	Epinephrine, hydrocortisone, no hospitalization
Ostergaard et al [177][b]	1986	7–13	2.8%	NS	Epinephrine, theophylline, ICU, full recovery

NS not specified.
[a] Additional data: cases of shock=0.089% of 1,119 treatments.
[b] See notes in the text.

Table 13.10. Fatal reactions (*FR*) in 7 children aged 7–18 years during SIT (1945–1989), updated to 2001 [9]

Cases	Cause
1.	Known error of SIT administration and an incorrect dose of epinephrine
2.	Probable dosage error and delay in the treatment
3.	Did not wait in the doctor's office
4.	Did not wait in the doctor's office
5.	Wheezing at time of injection and during the previous 24–48 h
6.	No known error
7.	No known error
8.	Epinephrine timing of administration not clear
9.	Left by father early before end of waiting period

Conclusion: 2/9 FRs not related to doctor during SIT from 1945 to 1989, plus 2 children aged 5 and 12, cases 8, 9 (1990–2001) (Bernstein, pers. comm., Apr 8, 2005).
Data from [9, 143, 206].

Table 13.11. Doctor-unrelated FRs in 9 children aged 5–18 years during SIT (1945–1989) updated to 2005

	Based on years considered	Based on injections
1 case	22.5 years	12×10^{18}

Data from [9, 143, 206, cases 8, 9 (1990–2001) (Bernstein, pers. comm., Apr 8, 2005)].

Table 13.12. Risk factors for systemic reactions to SIT

Related to children:
History of previous systemic reactions
Respiratory tract infections within the last week
Intercurrent disease, presence of symptomatic asthma within the last week
High degree of allergen sensitivity
Related to environment:
High allergen exposure
Related to extracts:
Passage to subsequent dose
Injections from a new vial
Rush SIT
Related to doctor:
Change of vials
Incorrect technique
Errors in dosage or administration
Mistaken clinical evaluation
Inadvertent intravenous injection of dose
Injections made during seasonal exacerbations

Moreover unchanged doses at the moment of switching to a vial with extracts of greater potency or with the new vial with maintenance doses; early months of injection course in very sensitized children; unchanged doses during pollen season; excessive increase in doses; excessive shortness of the intervals between administrations, excessive extension of these intervals, no concern for transient or permanent contraindications; disregarded prerequisite of not performing vigorous exercise before injection.
Data from [38, 115, 267].

of 3.4 deaths per year. Interestingly, 3 of these reactions occurred at times >30 min after the injections. There was either a substantial delay in starting epinephrine or that epinephrine was not administered at all in many of the fatalities [24]. Two children aged 5 and 12 were included (D Bernstein, pers. comm., Apr 8, 2005). Thus the pediatric rate is 0.16 deaths/year.

Conclusions that can be drawn from the data analyzed to date are as follows:

- Children do not have coronary heart disease and thus *tolerate epinephrine well*: CSM [78] and WHO-IUIS [237] guidelines for SIT are based on adults.
- We stress that in *analyzing the CSM's fatal cases* [78] *no children were found!*

- The rare SRs in children aged <18 years were *restricted to rush SIT and to Hymenoptera SIT* [227].
- Even fatal reactions may occur following administration of antibiotics, anesthetics, iodized contrast media, muscle relaxants, and foods (Chaps. 19 and 20).

The lesser prevalence of these reactions in children, apart from the hypothesis that children are less exposed compared with adults for age-related reasons, speaks in favor of the particular attention and supervision parents give to their children, more than to themselves. If properly instructed on the model of allergic diary charts, parents will clearly report any reaction to SIT such as potential intercurrent infections, massive allergen exposure, allergic symptoms, although temporary, and SIT contraindications. Moreover, children tolerate a possible antishock therapy better than adults, who, in addition to a greater statistical risk of coronary heart disease, can react unfavorably to epinephrine, because of increased numbers of mast cells lining the walls of their coronary arteries. Upon allergen challenge, these mast cells release mediators into the myocardium [68]. Severe adverse reactions with no apparent cause sometimes develop in children who have tolerated the long-term maintenance dose well; these SRs, although rare, can occur in any SIT stage, including administration of preparations with relatively low biological activity. Such reactions usually appear within 30 min [239]; commonly less severe delayed reactions complete the picture [51]. *Several risk factors,* well identified as causes of reactions to SIT and whose knowledge is vital to bring about an effective prevention, are summarized in Table 13.12 [38, 115, 267].

Clinical Reactions During SIT

Clinical reactions during SIT may be [37, 46, 115] mild local reactions or systemic and are thus schematized as follows:

- *Mild local reactions* include burning, warmth, bruising, redness, rashes, wheals of discrete entity, edema 5 cm in diameter, often accompanied by intense itching and tension in the injection site. These reactions occurred in 37.5% omalizumab- and 36.6% placebo-treated patients; the frequency and severity of local reaction tended to decrease over the course of the study [154]. These reactions usually resolve within a few hours (immediate reactions) or at the most within 24–48 h (delayed reactions). The immunological basis is unclear, but the reactions are considered within normal parameters and are not a reason to interrupt treatment; however, their monitoring for subsequent doses is useful.
- *Large local reactions* can be >5 cm in diameter within 30 min, a local swelling of part of the forearm, or a large swelling, but limited to the area of injection. These reactions commonly do not predict subsequent future SRs because they fall within the limits of normality. In this case no increment of allergen dose is suggested, unless the lesions cause a disturbance in the child. If the reactions recur it is necessary to check whether the injection was appropriate, since the extract can occasionally be injected in the hypoderm instead of SC tissue.
- *Moderate SRs,* usually sporadic and of short duration, localized to the target organ: urticaria, rhinitis and wheezing indicate that the tolerability threshold has been surpassed. A maintenance therapy should be reduced in relation to the preceding injection.
- *Severe SRs* (statistically less frequent) are acute, persistent, with the onset of manifestations localized to different organs and tissues, indicating that the tolerability threshold has been surpassed.
- *Immediate SRs* (very rare) are complicated by glottis edema and anaphylactic shock (statistically exceptional occurrence). They are almost always caused by errors in dosage. The early signs and symptoms of anaphylactic shock may include pruritus of the palms, soles and scalp, conjunctival injection, mild edema, cough, etc., which are the alarms invariably followed by systemic symptoms. Immediate reactions appearing within 30 min and with size >5–10 cm could be a premonition of impending SRs [37].

Also, in case of SRs (immediate or late), the dose should be reduced in relation to the preceding injection. Anaphylactic shock may be a SIT counter-indication and it is advisable to reduce the dose in case of uncertainty. Guidelines suggest decreasing the dose by 50%. If the reduced dose is tolerated, increase the dose by 0.05–0.1 ml weekly and resume the previous schedule. If reactions occur again the schedule should be re-evaluated [115].

Treatment of Local and Systemic Reactions

Even if SRs are severe and usually nonexistent in children, doctors should have all the recommended equipment necessary to protect children if such an occurrence should arise.

Equipment Recommended for SR Treatment

The medical office where SIT is administered should be supplied with appropriate equipment for treating SRs and medications required for resuscitative measures with proper expiration dates noted (Table 13.13) [8, 115].

It is of crucial importance that epinephrine, antihistamines and CSs be ready in syringes before beginning SIT procedures, in order to accelerate treatment in case of need. The periodic verification of the equipment and its maintenance or replacement as components or medications expire is recommended, making note in an appropriate registry.

Table 13.13. Equipment and drugs needed for office treatment of severe reactions

Stethoscope and sphygmomanometer
Equipment for administering O_2 with availability of a mask
Ambu bag with masks
Oral airways of the appropriate size
Tourniquets
Syringes and disposable needles
Tongue depressors
Endotracheal tube
Intravenous setup with large-bore catheter
Aqueous 1:1,000 epinephrine 1-ml vials for both injection and inhalation to be preserved at about 5 °C (expiration no later than 6 months) and/or Epi-pen
Equipment for administering IV fluids
Antishock solutions
Nebulizer for aerosoltherapy
Normal saline 10-ml vial for epinephrine dilution
Additional medications:
Antihistamines, anti-H_1 and anti-H_2, oral/injectable
β_2-mimetics, aerosol/injectable
Diphenhydramine injectable
Corticosteroids for IV and IM injection with rapid action

Data from [8, 115].

Treatment of Adverse Reactions

Ready recognition of SR and *immediate epinephrine administration* are the cardinal points of therapy [8]. The immediate therapeutic approach is as follows [115]:

1. *Mild local reactions:* most require no specific therapy. Oral antihistamine or topical CSs may be sufficient.
2. *Large local reactions:* in addition, a venous tourniquet applied above the injection site may decrease absorption of the injected allergen, and epinephrine administration. Observe for 60 min.
3. *Rhinitis:* oral antihistamines. Observe for 60 min.
4. *Mild urticaria:* oral or IM antihistamines, observe for minimum of 60 min;
5. *SRs* (asthma, ocular rhinitis, angioedema or generalized urticaria):

– Apply a venous tourniquet above the injection site and give 1:1,000 epinephrine immediately .
– Children should remain in observation under regular surveillance for clinical parameters until symptoms subside.

6. *Severe SR* – anaphylaxis (see Chap. 20).
7. When the clinical response to treatment is not immediate, *additional measures* should be taken before and after admission to a first aid station. The recent AAAAI (American Academy of Allergy, Asthma and Immunology) Position Statement suggests that specialists in these procedures should be immediately available [8]. If needed, the child should be hospitalized immediately in a pediatric emergency department or other suitable unit for at least 24 h to monitor anaphylaxis progression, because of the risk of a delayed shock [115], and to start an appropriate therapeutic approach.

Recommendations on Proper SIT Administration

Several guidelines and WHO [52, 115, 237, 267] have cautioned that risks and/or burdens to patients may evolve from SIT prescription and/or execution, as outlined below:

- *SIT prescription*
  – Superficial or mistaken indications
  – Specific contraindications
- *SIT execution*
  – Superficial, insufficient or absent evaluation (history and clinical examination) of the degree of child sensitivity to the allergens to be administered
  – Insufficient identification of a child at risk for severe reactions
  – Omitted, superficial or insufficient clinical monitoring of a child, in particular with high degree of skin reactivity to allergen inoculations, in which case adequate dosing of allergen extract is necessary
  – Inadequate equipment in the doctor's office regarding instruments, or the availability of medication necessary to deliver first aid, or the omitted or insufficient control of both validity and expiration of drug used, etc.
- *Risks associated with allergen extract*
  – Inadequate storing
  – Excessive potency
- *Risks relative to each individual child*
  – Temporary contraindications, apart from adverse unforeseeable reactions

In clinical practice, problems can arise when an injury, objectively demonstrable, results from negligence, inexperience, imprudence, and where a cause–effect rate between action, blamable omission and harmful accident exists. Jurisprudence with regard to a physician usually considers blamable error in the following issues:

- Examples of *negligence*
  – Inadvertent exchange of allergen extract vials
  – Insufficient alacrity in delivering treatments
  – Inadequate evaluation of the clinical status of each child before SIT administration
  – Incomplete and/or inaccurate clinical and personal history
- Examples of *inexperience*
  – Errors in administration of extract
  – Errors in dosage
  – Delay in carrying out emergency treatments

- Examples of *imprudence*

– Inadequate resuscitative instrumentation as detailed above

– Dose increase despite the child reporting large local reactions and/or SRs at the last SIT injection

– Improper SIT supervision by the administering physician

The attending physician should act with care, foresight, and experience in having all necessary equipment at hand, as well as complete, efficient, and precise knowledge as to the preventive measures which must be taken to avoid any risk factor and of course a complete understanding of all the therapeutic approaches. It is always preferable to take ten more precautions than one less to limit the number of unexpected situations or emergencies that any doctor should be able to handle. A study conducted on Italian pediatricians has shown that 79% of them were informed of the recommendations set forth on the proper SIT administrations that should be followed in their offices [207].

We underline the suggestion forwarded to minimize the risks and improve SIT efficacy [8]: 1. SIT prescription by specialists only; 2. SIT administration by physicians to cope with SR including anaphylactic episodes.

Comparison Between SIT and Pharmacotherapy

Disregarding the above-mentioned contraindications, we examine the SIT cost–benefit ratio, taking into account the main advantages and disadvantages, notably in children compared to adults (Table 13.14) [30, 267].

Cost–Benefit Ratio

The major problems that need to be addressed are symptom severity and frequency on the one hand, and costs and risks of SIT on the other. For proper evaluation one should compare SIT with the other available therapeutic options, taking into consideration several elements:

- Potential severity of the disease to be treated with SIT
- Relative effectiveness of available treatments
- Cost and duration of each type of treatment
- Risks of the disease and related treatment

SIT Advantages

- Specificity of effect
- Monthly frequency of administration (after the maintenance dose is started)
- Less medication usage
- Duration reduced to a few weeks with omalizumab [132, 154]
- Conventional SIT abates symptoms
- Anti-IgE treatment abates IgE levels
- Positive influence on the natural history of respiratory allergy

SIT Disadvantages

- High cost
- Administration only by physicians
- Costly instruments and continuing controls by physicians

Table 13.14. Advantages and disadvantages of SIT and pharmacotherapy in the treatment of respiratory allergy

Items	SIT	Pharmacotherapy
Specific cause	++	–
IgE synthesis	Decreased	–
Effect duration	Long-term	Short
Effect localization	Systemic	Local
Administration	Medical doctor	Patient
Frequency	Weekly/monthly	Daily (2–4 doses or more)
Duration	5 years	Lifelong
Mechanism of action	++	+ (?)
Side effects		
Short-term	±	±
Long-term	–	– (?)
Effectiveness	90%–95%	[a]
Materials used	Defined/undefined	Defined
Cost[b]	High	Moderate/high

[a] Effectiveness requires lifelong treatment.

[b] The SIT cost is divided between 5 years, the cost of medication may be reduced, but must be multiplied for each year of life.

Data from [30, 267].

- Time availability by parents/escorts (missed hours/days from work) and child (missed hours/days from school/study)
- Invasiveness
- Questionable availability of purified and standardized extracts
- Potential risks of SRs, in children statistically nonexistent severe reactions (Tables 13.10, 13.11)

Advantages of Pharmacotherapy

- Less invasiveness
- Substantially lesser cost in the European Union; in the USA SIT cost represents 32.1% of the cost of medications [25]
- Physician presence unnecessary
- Instruments and particular controls almost nonexistent

Disadvantages of Pharmacotherapy

- Aspecific effects mostly localized and of short duration
- Effect cessation when discontinuing treatment [256]
- Administration one or more times a day and often by different routes
- Risk of adverse reactions also in children
- Even early therapeutic intervention after the onset of symptoms may be too late to alter the natural progression of the changes in the airway wall [196].

In children with AR, SIT was substantially more effective in the long term compared to control subjects treated with cromolyn [174]. In our studies [38, 43–48] SIT-treated children fared much better than pharmacologically cured control children. The disappearance of symptoms after long-term SIT implies one more economic advantage [25]. Therefore, effectiveness can be evaluated, even in single cases, including the duration of pharmacotherapy that may last a lifetime [30], whereas SIT duration most often lasts 5 years [43–46]. The two treatments are not antithetic, each having particular characteristics that may act in a synergic and complementary way. However, no studies have demonstrated that pharmacological treatment alone with CSs, modifies the natural history of childhood asthma. Yet after 5 years, medication alone would be effective in controlling symptoms but not in modifying the underlying allergic disease, the major advantage of SIT [25, 44]. In contrast with pharmacotherapy, SIT offers the chance of addressing the fundamental pathophysiological process of allergy, mast cells and eosinophil mediator release upon contact with specific allergens up to a switch from Th2 to Th1 type immune response. In children who were not treated with SIT, CSs may reduce Th2 lymphocytes but not augment Th1 responses [70], nor abate IgE antibodies as in SIT [48, 256]. Several trials have instead concluded that 75% of pharmacologically cured children continue to suffer from asthma in their adult life [115, 121, 122, 200] and that discontinuing treatment makes the symptoms reappear [256]. Several authors failed to evaluate this issue, in particular those employing multiallergen extracts [3]. Compliance is improved in SIT , increasing with age (monthly injections that accustom to regularity), whereas the daily dependence on medications could have a negative impact on the quality of life, when noncompliance can lead to undertreatment in allergic children [115].

A recent study addressing the *sustained effect of SIT after 5, 10, and 16 years* (Table 13.2) re-evaluated 48 patients who had been treated with SIT in their childhood after a mean cessation 9.3±2.76 years. SIT-treated patients had fewer asthmatic features and needed fewer antiasthmatic medications than the non-SIT-treated control subjects (OR, 6.14–6.67); *the risk of frequent asthmatic symptoms was three times higher in the control group than in the SIT-treated group* [53]. This confirms that once established, SIT will give long-lasting relief of allergic symptoms, whereas the benefits of drugs only last as long as they are continued [83]. However, an analysis of the economic advantages of SIT would be incomplete without taking into account issues pertaining to *quality of life*, which may be important references for assessing the impact of disease morbidity on daily life activities [25]. The issue of quality of life was assessed in children treated with anti-IgE. In 54 children aged 7–17 years, a high OR was found when assessing children 6 months after SIT treatment, especially in nasal pruritus (OR, 6.8) and obstruction (OR, 5.9) and for carving eyes and nose (OR, 7.0), nose blowing (OR, 4.8), carrying disposable tissues (OR, 4.7), throat itch (OR, 4.0), irritability (OR, 6.2), and ocular pruritus (OR, 3.1). Patients without SIT were likely to use more drugs (OR, 6.4) than those receiving SIT [159].

Present and Future Perspectives

In the last few years, SIT has been the object of stimulating revisions, expressed in the formulation of several consensus documents, though only one for the pediatric age groups, as demonstrated by several recent studies and by the attention shown by scientific societies [37]. The points that deserve more consideration appear to be the following:

- SIT represents *the only allergen-specific treatment* of IgE-mediated respiratory allergies.
- The *hyposensitizing allergen extracts* available so far are much better purified and standardized and certainly in the near future there will be further innovations in this respect, especially concerning the titration in international units (Chap. 1).
- *Severe side effects* are wholly negligible in the pediatric field between 0% and one case of shock, equal to 0.0016% of injections and to 0.089% of treatments [38] and seem to stem not so much from a treatment that is dangerous in itself as from errors in execution, apart from unforeseeable reactions [46].

- *The cost-benefit ratio* is in favor of benefit, as documented.
- *The major progress* may originate from *current perspectives* such as new forms of therapy or from *future perspectives:* well-characterized and standardized allergens and new approaches to the modulation of IgE response.

Present Perspectives

The innovations include oral, sublingual, conjunctival and nasal or bronchial inhalatory and ID SIT. The idea of using the oral route for SIT is more or less as old as SIT itself.

Oral SIT (allergen immediately swallowed) was experimented in 1900 [56], does not elicit anaphylactic reactions, and avoids the inconvenience and unpleasantness of SC SIT while ensuring greater compliance. Oral administration of allergens leads to gastrointestinal lymphocytes and to GALT (gut-associated lymphoid tissue) [68], equipped with specific sites that fit to receptors on distant mucous membranes and glands by an intense cell exchange. It is known that orally absorbed medications reach systemic levels more rapidly than those parenterally administered. Lymphocytes stimulated in the oral or gut mucosa, or in regional lymph nodes, are then homing to the respiratory mucosa where they might induce favorable immune responses; however, the exact mechanism remains uncertain [108]. There is also an objective difficulty in overcoming the modifications that extracts undergo in the enteric environment, related to their breakdown, absorption procedures and contact with the immune system [178]. Positive results have been demonstrated mainly for birch [68], while for grasses the efficacy is unquestionably less than that of SC SIT [242], probably because of rapid enzymatic degradation of allergens in the gut [68]. Several DBPC studies have confirmed oral SIT efficacy and found it to be the most reliable route of administration (keratinized capsule or watery solution), including administration rate and doses to be reached. Adverse reactions reported up to now and typical of this method are principally gastrointestinal (diarrhea, dyspepsia, etc.), related to the overall necessity of achieving a clinically significant effect with doses as much as 100- to 400-fold higher than in SC SIT, typical of this method. For this reason the cost-benefit ratio is 4,000 times more costly than the benefit [115]. Positive results have been found in a Der p study in 18 children 3–13 years old, DBPC after 12 months of treatment revealed no local or systemic adverse effects [87]. A clinical improvement of rhinitis was seen only after 2 years of treatment, and of asthma symptoms only at the third year [87]. Allergen-specific IgG antibodies, especially IgG_1 and IgG_4 subclasses, increase, and the seasonal and postseasonal rises in sIgE antibodies are blunted [87], as in SC SIT (Fig. 13.11). The sIgA antibodies were studied in a cohort of ten children, but no significant differences were found between treated patients and control subjects [235]. In young adults, a comparison with local IT, though only in SC, SIT results were positive, with significant statistical differences as and clinical results [192]. The good compliance and the lack of severe adverse reactions of the oral route could favor, in the near future, this as the preferred route in the treatment of infantile respiratory allergies, especially if three conditions are satisfied:

1. It substantially reduces the cost.
2. It clearly defines the degree of risk. The results obtained to date are insufficient, because they are too inconsistent, even with enteric coated tablets, in terms of the rate of allergen release and because allergen denaturation makes the calculation of absorbed allergen difficult.
3. It makes safe home administration possible [115].

However, oral immunization of allergic children requires large quantities of protein, and for many allergens it would not be feasible to provide sufficient quantities of native allergen to immunize children. Moreover, the pharmakokinetics of allergens is in general still controversial [74].

Another possible oral route [187] is the *desensitization to natural foods diluted in H_2O,* starting with incrementing doses of the prepared solutions and continuing with purified foods: cow's milk (CM), egg, and fish (Appendix 13.4) [187]. Entrants were 34 patients, ten of whom were aged <12 years; the administrations were preceded by cromolyn medications. Twenty-seven of 34 patients (79.4%) completed the 4-month therapy (mean), which was positive in 25 of 27 (92.6%). Complications included abdominal pain, pruritus and urticaria treated in the doctor's office. In 32 children, the success rate was as high as 84.8%. A similar method was used for a *rush desensitization to CM* in a 13-year-old girl (Appendix 13.5) [20]. This desensitization route could meet with very good compliance in children with food allergy. The duration is similar to anti-IgE, but wholly noninvasive.

Sublingual IT (SLIT) is available in solutions of allergen extracts, and administrable in drops and soluble tablets [180]. The concept is promising, because of a consistent supply of lymphoid tissue in both the throat and neck, partly related to NALT: we can hypothesize that allergen extracts via the sublingual mucosa link to Langerhans cells (LCs) draining into regional lymph nodes. The rationale could be that LCs releasing IL_{12} modulate Th0 switching to the Th1 phenotype. However, we deem that the drainage of the allergen into regional lymph nodes is difficult to test in humans. In a DBPC study in 47 children aged 5–12 and 39 control subjects with monosensitivity to Der p, no variation in CD40 and ACTH, but a significant decrease in ECP, IL_{13} and prolactin were observed after 6 months of successful therapy [117]. In 24 children aged 4–16 monosensitized to Der p, SLIT was able to avoid the spontaneous increase in both nasal sIgE antibodies and in local aller-

gic inflammation in basal conditions [151]. An open study in ten children confirmed that SLIT was able to reduce CD54 expression on nasal epithelial cells and to decrease methacholine responsiveness [223]. No change in the mucosal level of tryptase and ECP was detected in pollen-allergic children [152], but tryptase levels were significantly increased in untreated children as well as nasal IgE [151]. Table 13.15 shows the results of 20 pediatric studies including 820 children [12, 13, 16, 34, 59, 62, 64, 105, 117, 136, 151, 152, 170, 180, 181, 209, 223, 233, 266, 269]. In two DBPC studies in 5–12 years olds, with monosensitivity to Der p, a significant reduction in asthmatic episodes was observed [223, 233] along with urticaria and asthma in some children [233]. Studies on children aged 8–12 with Der p asthma have demonstrated a statistically significant reduction of clinical symptoms and a very significant increase in IgG_4 antibodies [199]. Positive results were reported in 80% of 288 children aged 3–14, after 3 years of SLIT [59], and in children aged 4–16 either with allergic rhinoconjunctivitis to Par j [136] or to mites [12, 13, 16, 59, 62, 105, 117, 151, 180, 232]. SLIT performed poorly in two studies [104, 105] or the clinical efficacy of SLIT combined with fluticasone was equal to that of fluticasone alone [181]. In a DBPC study in 161 children after 1 year of SLIT, no significant difference between treatment and placebo was observed [34]. Additional DBPC trials were conducted in mite-sensitized [16, 151] and grass-sensitized [39, 209, 269] children, in whom SLIT was well tolerated and significantly reduced drug consumption during the 2nd [269] and 3rd [170] year of treatment. Importantly, SLIT is effective in children and maintains the clinical efficacy for 4–5 years after discontinuation: 8.6% of children were taking medications after 10 years vs 96% of control subjects [64]. SLIT was effective only in children with severe clinical symptoms and after 3 years of therapy [34]. Two studies involved treatment for 2 years [180, 266], 3 for 1 year [105, 151, 181] and 6 for <1 year [12, 13, 16, 39, 117, 136, 152].

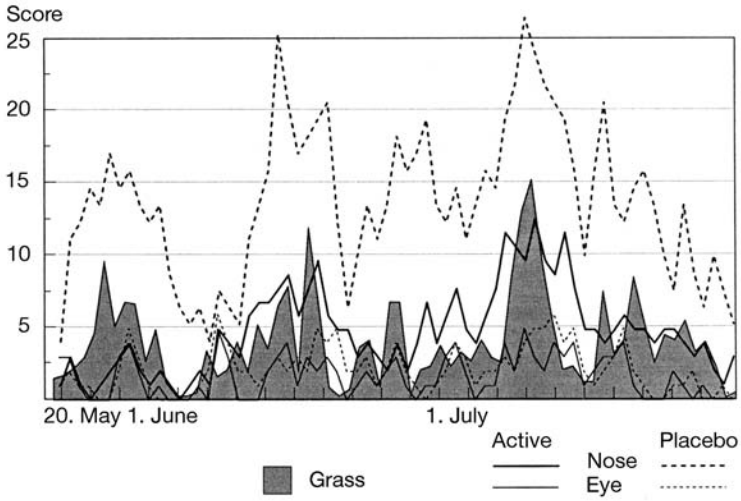

Fig. 13.15. Local nasal SIT: symptoms during the first season

Some studies are relatively small (8–15 children) [16, 105, 151, 180, 181, 223, 269] (as are 14/44 [31.8%] studies in Table 13.2) and about 18%–25% of the patients dropped out of the study or were lost to follow-up [34, 136]. Doses of allergens used in SLIT are usually fivefold to 20-fold greater than the doses required for traditional SIT [195]. Moreover, the cumulative dose of allergen used was fivefold [94] to 20-fold [41], and up to 375-fold [136], the doses given in conventional SIT, with a significant rate of gastrointestinal complaints [136].

The extract is usually kept under the tongue for 1–2 min [180]; then swallowed (sublingual swallow). The dose, especially in young children, is absorbed mainly by the gastrointestinal tract, thus making an objective evaluation of SLIT effects somewhat difficult. If the allergen is not absorbed in the mouth, the allergen contact with the oral mucosa is critical [15]; thus an almost complete degradation of the allergen should occur in the duodenum in humans [41]. The adverse reactions so far observed, in addition to more or less intense oral pruritus, are related to the digestive, respiratory and cutaneous systems [68]. However, 115 systemic reactions (5.2% of patients and 0.06% of injections) were observed [201] and 45 children (22.5%) had side effects: 20 oral itching or burning, 15 gastrointestinal symptoms and ten cases of rhinitis [81]. All side effects were successfully managed [81, 201]. A postmarketing study in 268 children aged between 2 and 15 years and receiving SLIT for up to 3 years showed that the overall incidence of systemic side effects was 3% of the children and 1 of 12,000 doses [63]. Thus more conclusive data are required [68]. In Appendix 13.6 we show a *4-day SLIT protocol to desensitize latex-allergic patients.* The desensitization was so successful that after 3 months all patients could wear latex gloves without any symptoms [186]. A Cochrane review has found that there was no significant reduction in symptoms and medication scores in four studies involving only children, but total numbers of participants were small, casting doubt on the validity of the conclusion [255].

Conjunctival IT, which refers to original experiments [166], has been experimented with good clinical results in adults with allergic conjunctivitis; however, a daily intraocular instillation of a given allergen in scalar doses for 8–30 months [137] does not meet childhood compliance, since this method has no effects on lacrimal IgE and SPT [137]. This kind of IT should be adapted for use in older children and adolescents.

Local IT includes nasal or bronchial inhalation of allergens: the rationale is to restrict the allergen immunological impact and the resulting immune responses to mucosal sites and to distant sites via MALT (mucosa-associated lymphoid tissue).

Nasal inhalatory IT utilizes treatment when symptoms are manifested. The allergens can be absorbed through the nasal mucosa and reach the bloodstream [72]. Treatment should start prior to the pollen season, to avoid allergen sensitization in the nose provoking symptom worsening that could be protracted beyond the season. The proposed hypothesis that the patient self-manages treatment appears unwise, because a nasal spray may trigger a psychological mechanism as seen in asthma therapy, that is an incentive to augment or increase the dose frequency: a new sensitization can produce symptom worsening secondary to a *priming effect.* To bypass the problem inherent in molecules that are too large to be absorbed through the mucosa, PEG (polyethylene glycol) modified allergens can be used to penetrate the nasal mucosal barrier better than unmodified allergens. They combine efficacy and reduced allergenicity; however, their results have been contrary to expectations [68]. A new technique is to incorporate allergens in granulometrically controlled powder form, which has shown encouraging results [108]. The predosed micronized allergen powder contained in capsules is sprayed in the mouth and applied to the nostrils by insufflators. The efficacy of this technique was demonstrated for grasses [108] (Fig. 13.15), *Parietaria* [10, 183], Der p and birch [267] and with DBPC studies. Only two studies were done in children with grass

Data from reference [49].

pollen [17] and Der p AR [150]. The efficacy is limited to nasal symptoms [10, 183], but no effect was seen on the eye or on lower airways, often associated symptoms [108, 192]. Incidentally, a discrepancy between nasal and eye symptoms should be noted: nasal lymphocytes could actually induce a tangible switch or modification also at the eye level (and cutaneous via the links between NALT and SIS). A significant increase in sIgA antibodies was observed in nasal secretions but not in serum and not correlated to the clinical picture [192]. An important result is the reduced response to nasal challenge, despite exposure to pollens and absence of treatment and CD54 presence within 30 min [183], most likely deriving from previous deposits. An original study has indirectly demonstrated the validity of this type of IT by inhibiting an immune response to Der p in mice [110].

Bronchial inhalatory IT: in a DBPC study in adults, the available positive results show a decrease in the clinical symptom score and a significant increase in bronchial tolerance to allergens and IgG levels. Before subjecting patients to treatment, it is necessary to perform respiratory function and bronchial provocation tests with the allergen, to ascertain the provocation threshold and the protective effect of associated cromolyn [115]. Further studies are required to adapt this method to children.

In both cases, the administration should be preceded by a premedication with cromolyn to prevent the onset of undesired effects produced by the inhalation of allergen vaccine.

Enzyme potentiated desensitization (EPD) consists in applying on scarified skin a very low dose of allergen premixed with a small amount of the enzyme β-glucuronidase, which, pretreated with other chemical substances, would gain a configuration able to ensure in a given subject a non-response or a tolerance to administered allergens; the hyaluronidase added to EPD would allow better transcutaneous diffusion of the formulation. Since a technical period of about 30–60 days is predicted to obtain the greatest level of immunological non-response, each pediatrician allergist should check, in case of need, the pollination period of the locality. The first controlled study in adults has given not very significant differences between actively treated subjects and controls [75]. Instead, significant results were noted in a pediatric DBPC study [49] in 20 children with Der p allergy and a median age of 8.5 years. The children were randomized to receive either two ID placebo injections or the active material with an 8-week interval. The ID injection of EPD (0.05 ml) contains 0.01 ml of β-glucuronidase (40 Fishman units) and 0.04 ml of a mixture of inhalant allergens (1 Noon unit). The EPD-treated children had significantly fewer days with asthma. In addition, the EPD-treated children used significantly less medication for the management of asthma attacks (p=0.0000 for both) [49], a greatly significant result of the conjunctival provocation test (CPT Table 13.16) [49] and of clinical evaluation by the investigators (Fisher = 0.0349) (Table 13.17) [49]. No significant local or systemic side effects were reported. The results of this study provide further data on the effectiveness and safety of EPD in patients with asthma.

Comparison of Traditional (SC) SIT and Other Routes

Even if these methods have been investigated in DBPC studies, at present there is no study that has compared the efficacy of these alternative SIT methods on a large scale and with the same methodological and statistical characteristics as traditional SIT by the SC route *in pediatric populations exclusively*. Various studies have examined the advantages and disadvantages of oral and local IT [58]. Oral IT yielded positive results only in the studies carried out over an average of 12 months, but in only one pediatric study [157], and negative results in the shorter trials, again in only one pediatric study [242]. In SLIT several studies found positive results, including 19 pediatric studies plus one covering a 10-year period [62]. For nasal SIT, there were several positive studies, including two pediatric studies [17, 150] with different types of extract; especially those employing dried-powder extracts appear devoid of side effects [58]. Unless the contrary is demonstrated, SIT is supported by better clinical and experimental evidence and still remains the most valid course of treatment for infantile allergies.

The crucial issue on the most effective route for SIT, speculative motivations appear to be subordinated to clinical results, which may favor the administration of SC or SLIT routes. SC SIT is asthma desensitizing [44, 118], whereas SLIT favors the asthma development in 15%–63% of nonasthmatic children [180]. Nonetheless, elucidation of factors influencing the shift between subsets of Th cells favoring Th1 migration to particular tissue sites and the influence of the microenvironment on Th1 polarization will be critical when making this decision. However, the induction of high levels of IFN-γ in the milieu of injected allergen, for example, offer interesting alternative approaches limited to SC SIT. The relative significance of generating IFN-γ-producing regulatory Th1 cells must also be evaluated, supported by the evidence that current SC SIT regimes associated with increased IFN-γ production may correct the IFN-γ defect in atopic children (Chap. 4). Thus, application of new SIT strategies should be proportional to careful consideration of actual immunological data.

Future Perspectives

The future is likely to bring increased focus on new developments: perhaps SIT, as it is practiced today, represents one of the first uncertain steps on the manipulation of immune responses. Advances in the knowledge of the cellular and molecular basis of immunity have greatly increased in the last few years and can prove very useful for therapeutic purposes in a more or less near future. The hallmarks are preparation of more standardized extracts and different approaches to the manipulation of T-lymphocyte functions and suppression of IgE response. In brief, future therapeutic options may feature novel vaccine delivery systems and modifications of allergens to reduce allergenicity (Table 13.18) [145, 154, 195].

Table 13.18. Future directions of specific immunotherapy (*SIT*)

SIT with native proteins
Crude extracts
Purified proteins
Recombinant allergens
Modified allergens
Allergoids
Urea denatured
Formaldehyde or glutaraldehyde
Polyethylene-glycol
Peptides
Short: up to 26 amino acids can be synthesized
Longer: produced as recombinant peptides
Recombinant proteins expressed in bacterial or yeast vectors
Natural sequence including isoforms
Altered proteins
Disulfide bonds causing misfolding of the molecule
Amino acid substitutions in epitopes producing subtle changes
DNA vaccines
Boost antibody and depending on DNA sequences can alter response
Controlled expression, site and continuity
Oligonucleotide immunomodulatory sequences
Anti-IgE
Decrease in serum IgE levels
Immunization early in life[a]
Unaltered antigen
Antigen linked to a Th1 adjuvant such as IL_{12} or bacterial proteins
Antigen incorporated into a plant (e.g., transgenic bananas) for oral IT

Data from [145, 154, 195].

[a] We suggested starting SIT as soon as possible (see text).

Necessity for More Standardized Extracts

As is logical, convincing advantages will evolve from allergen standardization and characterization and their titration in the more diffused BU, or IU and from application of techniques of molecular biology and genetic engineering (recombinant DNA [rDNA] technology). Extract manipulations facilitate the research on extracts with reduced allergenicity.

Allergoids

Modified extracts constituted by allergoids are allergens polymerized through a treatment that partially modifies their characteristics. The major benefit of allergoids

is to produce an immune response with less risk of anaphylaxis. However, these molecules in which formaldehyde has caused cross-linking both within proteins and between proteins induce IgG antibodies and have T-cell epitopes. Therefore they may not represent a major benefit for these patients [195]. Urea denaturation was therefore proposed as a method of preserving T-cell responses while reducing the risk of anaphylaxis. In mice, glutaraldehyde-polymerized allergens can down-regulate IgE antibody production through a mechanism that involves increased IFN-γ secretion. However, differences were observed in the availability of T-cell epitopes between allergoids and unmodified allergens, which are most likely due to structural changes within the allergen molecule [65]. The characteristic features of these chemically modified allergens are their strongly reduced IgE-binding activity compared with the native form and the retained immunogenicity [124]. These molecules have a greater MW (molecular weight) and are released more slowly from the injection site, circulate over a longer time, are not excreted by urine as are aqueous extracts, but are stored in the reticuloendothelial system (RES) of various organs. The well-known advantage is that of administering reduced doses, especially with delayed vaccines. Allergoid-based studies resulted in the reduction of allergic symptoms [185], especially when using high-MW allergoids [185], which, however, may be a shortcoming if these allergoids are administered in such a way as to induce their passing via the mucosal barrier. Several similar trials followed, with good clinical results. In an open, multicenter study of 90 children and adolescents 6–17 years old, short-term SIT using four injections of pollen allergoids adsorbed to L-tyrosine and adjuvanted by monophosphoryl lipid A adjuvant was shown to induce *significant reductions in symptom scores and medication use* compared with the previous pollen seasons. Pollen-specific IgG was significantly increased, whereas little change was apparent in pollen-specific IgE [67]. Two DBPC studies on the *Parietaria* pollen allergoid extract resulted in an IgE decrease and an IgG_4 increase [11] or was limited to IgG_4 antibodies [234]. Recently, it has been shown that using dendritic cells (DCs) and macrophages as APCs, allergoids exhibited a pronounced and reproducible T cell-stimulating capacity. Responses were superior to those with PBMCs, and isolated B cells failed to present allergoids. Considerable IL_{12} production was observed only when using the DCs as APCs of both allergens and allergoids. The amount of IL_{10} was dependent on the phenotype of the respective T cell clone. High IL_{10} production was associated with suppressed IL_{12} production from DCs in most cases. So the adoption of the allergoid principle in the development of genetically modified allergens with reduced IgE reactivity by retaining T-cell reactivity will provide a promising basis for the development of newer therapeutic vaccines for SIT [124]. Allergoid particularity is revealed also in the manipulation of B and T lymphocytes.

Liposomes

New approaches to SIT, designed to increase efficacy and safety, include encapsulation in liposomes and conjugation of allergens to immunostimulatory sequences (ISSs), short base-pair segments of DNA with a basic sequence of purine-purine-cytosine-guanosine-pyrimidine-pyrimidine. Stimulating perspectives are opened up by using allergen extracts incorporated into *liposomes,* which may be a vehicle for safe and effective SIT, as multiple injections of liposome-entrapped allergen have been shown to reduce sIgE response and induce specific IgG response in mice [219], even with allergen doses that were not too high. These are small, biodegradable phospholipid vesicles that shift the immune response toward Th1 and induce IgE-selective unresponsiveness [241]. Liposomes are formed by phospholipids disposed within compartments found between membrane-like lipid bilayers that fold concentrically; uni- and multi-lamellar liposomes alternate and water- or lipid-soluble molecules are within their interior. H_2O is able to entrap water-soluble substances, are biocompatible, biodegradable, stable and prolong the half-life of many drugs. The rationale behind the use of liposomes as allergen carriers is that since allergens are water-soluble, these will be sequestered inside the aqueous space and thus will not be capable of interacting with local IgE, whose levels will decrease by natural degradation processes. Moreover, liposomes are too voluminous to be absorbed by blood capillaries, so when they are SC injected they will follow the lymphatic route to lymph nodes, where the macrophages will phagocyte liposomes and process the antigens, thus minimizing the SR risk, since the protective bilayer inhibits interactions with antibodies [261]. This method seems to be promising, since it was demonstrated that in mice liposome treatment potentiates the specific IgG response rather than IgE and CD8 T cells [14], and IFN-γ more than IL_4, thus showing a Th1 dominance [219]. The problem is how to regulate and control the progressive release of allergens by liposomes to reach an effective therapeutic concentration [261]. Clinically, in a DBPC study asthmatic patients sensitized to mites were randomly assigned vaccination with Der p extract encapsulated in liposomes or empty liposomes for a period of 12 months. Asthma-free days increased from 10.5% to 64.5% in the active group and remained at 18% in the placebo group [19].

Recombinant Allergens

Using the rDNA technology combined with PCR (polymerase chain reaction), it has become possible to investigate the tertiary structure of allergens both by modeling based on sequences and because RAs can be produced in sufficient quantities for X-ray crystallography or nuclear magnetic resonance [215]. Therefore, the molecular cloning and sequencing of a striking number of well-defined RAs has made it possible to isolate the primary amino acid sequence of >60 different allergens (Table 1.70), although the identification of the complete

repertoire of allergenic epitopes may remain a critical task [164]. Concerning SIT, the use of RAs is promising, although the wealth of available allergens for SIT may never be transformed into practical results, considering the complexity of allergen extracts, and the incomplete characterization of the major allergen repertoire and the possible incomplete availability of RAs [215]. RAs can be produced on a large scale and with the assurance of purity compared to the traditional ones, which often contain additional allergens or histamine-releasing compounds, suggesting that children avoid receiving these proteins and allergens because they may increase their sensitivity [215]. Moreover, a widespread use of RAs will avoid untoward effects, new allergies and cross-reactivity, since RA extracts are prepared specifically for the exact number of potential allergens to which a given patient is effectively sensitized. In addition, it is now possible to produce commercial quantities of these RAs and in many cases to assemble molecules that are immunologically very similar to the native molecules [195], so that RA derivatives with greatly reduced allergen activity can be produced. Hypoallergenic RA derivatives can then be used for patient-tailored therapy, and, given their reduced anaphylactic activity, they hold the promise that patients can be treated with fewer injections of high-allergen doses and with a lower risk of side effects. RAs have undergone exhaustive clinical trials to become available for clinical use [215]. Recently, recombinant Fel d 1 (rFel d 1) chains have been successfully co-expressed as mature proteins with comparable immunoreactivities to natural Fel d 1. The rFel d 1 can be targeted to APCs through CD64. These constructs will facilitate structural studies of Fel d 1 and the development of improved allergy diagnostics and therapeutics. In particular, these allergens will also provide essential tools for basic and clinical studies of the immune response to cat allergens [243]. Similarly, the rBet v 1 derivatives exhibited a reduced capacity to activate basophils and mast cells by cross-linking of Bet v 1-specific IgE, and genetically engineered hypoallergenic rBet v 1 derivatives induced significantly lower activation of eosinophils by means of surface expression of CD69 and ECP release (and levels of GM-CSF and IL_4) compared with rBet v 1 wild type. The derivatives may therefore be candidate molecules for SIT of birch pollen allergy with reduced risk of inducing allergenic or inflammatory side effects [167]. Zhu et al [275] engineered a chimeric molecule in which the truncated human IgG Fcγ1 is fused to the rFel d1. This fusion molecule binds both FcεRIIb and the IgE specific for Fel d1 thus inducing dose-dependent inhibition of Fel d1-driven IgE-mediated histamine release from cat-allergic donors' basophils and sensitized human cord blood-derived mast cells. Such inhibition was associated with altered Syk and ERK (extracellular signal-regulated kinase) signaling. Similar fusion molecules could be designed to counter other types of allergy with an even stronger effect on countering allergy if they are used to ablate IgE-producing B cells, the source of immunoglobulins which also express FcεRIIb. This approach would induce true desensitization for example, by replacing Fel d1 with the major peanut allergen [126].

Plasmid or DNA Vaccines

Plasmids expressing allergens referred to as naked DNA could also be used for SIT. These plasmids are circular DNA molecules found in an assortment of bacteria, which rely on enzymes and other proteins in the host cell for replication and transcription. DNA can be inoculated as "naked" DNA or coating some sort of microparticle that facilitates cellular uptake. Plasmid vectors encoding specific proteins may be IM injected, where they are taken up by APCs and expressed, preferentially activating a Th1 response, probably because the antigen produced from the inoculated DNA is processed as an intercellular antigen presented on HLA class I molecules. When introduced into an animal, they can bring about a source for functional genes in addition to those on the chromosomes and can provide a novel form of immunization for allergic disease. Plasmids encoding Hev b 5, Ara h 2, and Der p 2 have already been tested in experimental animals [35, 112], and more food allergens are being identified and cloned. In DNA-primed mice with a plasmid DNA, encoding the protein β-galactosidase could not only switch off an ongoing IgE antibody response to the coded protein, but also produce a 66%–75% reduction in sIgE antibodies in 6 weeks [205]. However, the amount of protein produced is very small, and it appears that a major problem will be scaling up DNA vaccine from mice to humans. In addition, it appears that most plasmids will only continue to express proteins for a few weeks. Thus, it is still difficult to assess the potential role of gene vaccination for treating allergic disease; however, the primary goal is to switch T cells toward a Th1 profile. DNA plasmids can achieve the same effect, inducing a Th1-dominant response over the Th2 response [195]. Studies in mice have demonstrated that the immune response to plasmid-DNA SIT is strain-dependent [139]. Vaccination of mice with plasmid DNA encoding Der f 11 induced Th1 responses characterized by $IgG_{2\alpha}$ responses, and spleen-cell secretion of IFN-γ prevented the induction of IgE responses and could inhibit ongoing IgE responses [189]. Similarly, the lowest IgE and highest $IgG_{2\alpha}$ levels were found in mice vaccinated with the combination of plasmid IFN-γ and IL_{12} as an adjuvant [134]. If DNA vaccines could also change pre-existing immune responses, the inhibition of specific IgE antibody formation [188] is dependent on the specific ISSs in plasmid DNA, which suppress IgE synthesis and promote IgG and IFN-γ production [210]. Moreover, in a mouse, a substantially lower dosage (50 μg) of grass allergens, when administered along with a plasmid DNA IL adjuvant, can induce effective immune deviation and *a protective airway response* in comparison with allergens alone [134]. A combination of CpG (cytosine-phosphate guanine) + plasmid

DNA immunization may be effective in antagonizing Th2 responses. The effect of CpG motifs in vivo depends on a variety of parameters such as the nature of the antigen and the immunization modality [106].

Immunostimulatory Sequences

Studies have shown that ISS CpG motif DNA sequences can redirect an anti-allergen Th2 response toward a nonallergic Th1 response both in animal models of asthma and allergic diseases and in allergic patients [226]. ISS CpG oligodeoxynucleotides (ODNs) including unmethylated palindromic motifs have been shown to decrease airway hyperreactivity, lung eosinophilia (IL_5), and as effectively as 7 days of CSs and sIgE production if administered during allergen sensitization. This was associated with induction of a Th1 and inhibition of a Th2-like IL response [32]. CpG ODNs were capable of redirecting the Th2 to a Th1 response to allergen in mice inhibiting airway eosinophilia and BHR. CpG ODN led to induction of antigen-induced Th1-like ILs and of RANTES and suppression of eotaxin. An established atopic eosinophilic airway disease can be effectively overcome by a combination of CpG ODN and allergen [128]. Administration of CpG-ODN with antigen through the skin may provide the basis for a novel form of SIT of both allergic asthma and AD since treatment elicited an antigen-specific, Th1-predominant immune response and enhanced the production of IFN-γ and drastically suppressed Th2-like IL_4. IL_4-regulated IgE production was also suppressed [116]. However, while 61.5% of NC/Nga mice did not exhibit dermatitis after CpG ODN was administered intraperitoneally every 2 weeks for a total of five times, 38.5% of mice treated with CpG ODN exhibited an *exacerbation of dermatitis* accompanied by the hyperproduction of IFN-γ, although Th2-like ILs were suppressed in both spleen and lymph node cells and culminated in a decrease in the serum IgE level [230]. ISS conjugates to allergen (such as Amb a 1) are being developed as SIT for allergic asthma and AR [109, 213]. They have therefore been tested as immunoadjuvants for various vaccines including T-cell independent antigens. Using liposomes as a carrier for CpG ODN to improve the immune response to biotinylated liposomes and incorporating PEG-modified lipid in liposomes enhanced the immune response. In conclusion, liposomes are a useful delivery vehicle for CpG ODN as an immune adjuvant for T cell-independent antigens [138]. It is significant that, probably owing to steric interference by the attached ISS-ODN with the reaction of antigen with IgE, allergenicity is decreased, defined by decreased binding to IgE. Using ISSs as Th1-inducing adjuvants is conceptually derived from unmethylated CpG motifs in bacterial DNA. ISS conjugates to allergen (Amb a 1) are being developed as SIT for allergic asthma and AR [109, 213]. Recently, ISS–allergen conjugates were shown to induce stronger antibody and Th1-type immune responses, while reducing mast cell degranulation, anaphylactogenic potential, and delayed Arthus-type reactions than either allergen alone or allergen mixed with ISSs but not conjugated [109]. In this context, by exploring the relative immunogenicity and allergenicity of allergen/ISS–ODN conjugates of varying ratios in mice, an important result was that allergenicity and, in particular, anaphylactic potential were reduced significantly, although higher levels of ISS–ODN conjugation might reduce the immunogenicity of allergen conjugates slightly. Thus, *ISS–ODN is being explored as a safer and more effective approach to SIT* [109]. The chemical conjugation of ISS–ODN to Amb a 1 confers on the allergen a new property that makes it an excellent candidate for human SIT. Amb a 1–ISS conjugate induces strong Th1 and high IgG responses, even in the face of an ongoing Th2 response [213].

Manipulation of T and B Lymphocyte Functions

- *Manipulation of T Epitopes*

A suggestive hypothesis speculates that inhibiting interactions between TcR and HLA class II molecules by *synthetic peptides* could offer an alternative treatment to conventional SIT with allergen extracts. The rationale for using T cell-reactive peptides of this kind is that they would be loaded onto HLA class II molecules in vivo and presented to T cells in such a way that they would alter the T-cell responses in vivo. The assumption of a potential peptide vaccine is based on present acquisitions on CD4 recognition of antigens previously processed by macrophages or other cells with a specific task (APCs) and their transformation into peptide fragments. TcR triggering by peptide-HLA class II molecule complexes on APC surface establishes the activation of T lymphocytes along with B cell cognate help for the production of IgE antibodies, thus a point of attack could exemplify either the TcR or HLA molecules (Fig. 1.66). A possible use of synthetic peptides to block IgE binding to mast cells, and as a consequence the release of mediator and the development of anaphylactic shock is intriguing [251, 265]. These could be the starting base to make T cells tolerogenic in vivo in human beings [273]. The possible reasons why peptides reacting with T cells in vitro do not produce a clinical response in vivo include a) that chosen peptides covered too few of the relevant T-cell epitopes, b) that peptides are so rapidly decayed or removed in vivo that they cannot interact with the immune system, and c) that these peptides are presented to T cells in vivo in a form that fails to produce the solicited response [195].

- *T cell anergy or clonal deletion* [273]

Figure 1.22b illustrates T-cell anergy due to the absence of the second signal, which is obtained in the animal model by employing immunogenic peptides provided in particular of immunodominant T epitopes. Stimulating results have come out of this research, but so far they have not provided insight into the immunological

events that occur in human subjects. In rodents, tolerance was induced by delivering sequential doses of a peptide with T epitopes and subsequently the same peptide with an adjuvant. Conversely mice receiving saline continued to mount significant T-cell responses accompanied by significant antibody responses [221]. Very demonstrative studies have shown that sensitized animals in a first phase with Fel d 1 elicited similar results [31], and in the other phase intranasal inhalation of low levels of peptide containing a dominant T-cell epitope inhibited ongoing immune responses in mice sensitized to Der p 1 allergen [110]. If a T-cell peptide is able to induce peripheral T-cell tolerance in rodents to a subsequent challenge with allergenic proteins, peptides provided with T cell-dominant epitopes appear to be much more effective tolerogens than those with only minor epitopes, since in the first case a single exposure is all that is necessary instead of three exposures [221]. The potential use of a peptide-induced T-cell non-response is facilitated by the demonstration in animal experiments that peptides without B-cell epitopes are able to suppress immune responses [153]. However, using immunodominant peptides may have negative effects on the human immune system [172]. These effects include stimulation of peptide-specific Th1 T cells with the possible onset of fever, skin rashes, and/or delayed but not *systemic or anaphylactic reactions,* since Th1 cannot link IgE because it is sequential [57]. Similar peptides able to block a wide spectrum of different HLA molecules have not yet been identified, also because the studies on restriction have not been concluded exhaustively. To respond to practical applications, one should consider that in peptides provided with T-cell epitopes, one or two are immunodominant: therefore the functional regions of several allergens have been mapped, relative to such epitopes, thus identifying the peptides with an amino acid sequence identical to the allergenic one and able to stimulate T lymphocytes by making them unresponsive [171]. Perennial and seasonal allergens have been determined as well as others with T-cell epitopes (Table 1.76), also including Fel d 1, egg lysozyme, myeline basic protein, type II collagen, pollens, mites and Api m 1 [31, 215, 260]. The key point in preparing a peptide vaccine is that usually the single allergens possess several B- and T-cell epitopes. Thus peptides could be fragmented to utilize only the immunodominant regions, for example, small fragments with a few amino acids [260], thus avoiding the larger ones, which could activate both IgE and metachromatic cells; while inhibiting Th2 T cells IgE responses were eliminated or minimized [251]. Small peptides may equally bind IgE, activate basophils and platelets, and T cells can produce chemokines and related mediators, thus priming basophils and mast cells [57]. *Therefore T-cell immunodominant epitopes may act as potent inducers of Th2 unresponsiveness in humans* [260] *by activating Th1 and/or suppressor CD8 T cells* [215]. This is a very promising prospective, since it is easily understandable that peptides provided only with Th1 epitopes can effectively contribute to a therapeutic strategy that provides for the induction of a Th2 sound anergy without stimulating mast cells, which would result in nearly or entirely absent side effects [57]. However, clonal anergy is not the only mechanism involved in down-regulating T-cell responses, since anergy should presumably only affect T cells specific for the epitope used for treatment [221].

In keeping with that, it has been demonstrated that an analogical peptide was able to inhibit in vitro the proliferation of T-cell clones specific for Der p allergens, avoiding T lymphocytes both the interaction with HLA class II molecules and their recognition [171]: the concrete result is that DPB1*0401-restricted T-cell clones become unresponsive and are therefore no longer capable of secreting IL_4 and instead *produce IFN-*γ [172]: this is the switch from Th2 to Th1 that precludes IgE synthesis. The functional T-cell inactivation, made tolerant by use of such peptides, would be translated into a therapeutic potential in atopic disease, where Der p-reactive T cells are restricted by HLA-DP molecules [102]. By inactivating both HLA-DP- and HLA-DR-restricted T cells, SIT with allergen peptides may provide a therapeutic potential, also independent of whether it is associated with HLA class II molecules [102]. A practical question to be resolved is the more frequent immunogenicity of Der p 2, such that polypeptide fragments should be made ready in B-cell sites that have been inactivated along with peptide residues provided with a sIgE anti-Der p 2-linking epitope [173]. However, in applying this method we must recognize the impossibility of unmasking all relevant epitopes in allergen molecules [251]. Even if we could do so, we should point out that the antigen-specific T-cell epitopes are different from those recognized by IgE [274]. Thus, an IgE cross-linking to injected allergens should not occur in theory. Moreover, T-dependent IgE synthesis is reduced during SIT (Fig. 13.13). In addition, we must emphasize the necessity of mapping the T-cell epitopes of a given patient and typing HLA molecules [273]. A possible complication stems from the 85% homology between Eur m 1 and Der p (Table 1.74), while it is significant for SIT efficacy when using T-specific peptides derived from Fel d 1 in patients with this allergy [164]. In contrast, modifying the allergen and stimulating the priming of naive T cells results in a selective turn to the Th1 phenotype: for example by using glutaraldehyde, a high-MW compound is obtained, thereby increasing 20-fold the connection of IFN-γ with IL_4 and IL_{10} [271]. Reprogramming the Th2 response of allergic subjects to a Th1 response, thereby intervening in the signals that modulate naive T-cell differentiation is considered even more critical.

Further strategies include utilizing isolated, purified and mixed IgG antibodies with Der p allergen: thus autologous circulating immune complexes (CIC), possessing a potentially low allergenicity, would elicit a minimal SR, and in addition the greater part of the aller-

gen's biological activity would be neutralized by excess antibodies. This method would appear to be useful in eliminating the production of neutralizing antibodies, even evident after repeated administrations of recombinant cytokines or monoclonal antibodies [172].

A novel form of SIT that makes use of T-cell peptides derived from Fel d 1 has been developed for patients with asthma who are allergic to cats and are injected IT with short, overlapping, T-cell peptides derived from Fel d 1. The patients received either Fel d 1 peptides (90 µg in increasing divided doses) or placebo. Four of the 16 patients on Fel d 1 peptides had initial late asthmatic reactions, but could be desensitized to the higher dose of peptide [176]. Two studies [168, 188] first attempted to treat cat-allergic subjects by SC injection of two peptides (called IPC1 and IPC2), which spanned a large proportion of chain 1 of Fel d 1. However, IPC1 and IPC2 were 27 residues long and associated with immediate and late allergic symptoms that occurred between 10 min and 6 h after SC injections, which may have been the result of cross-linking of allergen-specific IgE. Therefore the Fel d 1 peptides in a subsequent study were of relatively small size (16/17 residues) and had a linear configuration to enable them to be presented to T cells [176]. To investigate the possibility of a peptide epitope-induced switch from a Th2 to a Th1 cytokine profile, the primary proliferative responses and cytokine production of PBMCs to both the individual peptides and whole cat dander was assessed. A single 5-µg ID injection of Fel d 1 peptides was associated with a reduction in both proliferation and production of *IFN-γ* and of IL_4 and IL_{13}, and the amount of proliferation *significantly decreased* between baseline and second follow-up, and the concentration of IL_{10} was significantly higher in patients on peptides [175, 176]. A hybrid peptide comprising seven T-cell peptides has been shown to possess the capacity of inducing T-cell proliferative responses that is superior to the potential of a mixture of the T-cell peptides and comparable with that of Cry j 1 and Cry j 2. Cry j (*Cryptomeria japonica*) the hybrid peptide will be of use in SIT as a potential therapeutic agent for pollinosis [104]. Instead of covering the entire length of several major allergens in a combination treatment, a DBPC phase I clinical trial was developed for patients hypersensitive to bee venom, a novel strategy of venom SIT based on three long synthetic peptides (LSP) mapping the entire 140 amino acids of PLA_2 (phospholipase A_2), a major Api m allergen. SIT with LSPs derived from PLA_2 was able to induce T-cell anergy and immune deviation toward a Th1-type T-cell IL response and enhanced IL_{10} secretion and specific IgG_4 production [76]. These results may thus represent a novel and safe approach to SIT [76]. LSPs offer the advantage of covering all possible T-cell epitopes for any HLA genotype, and can be considered candidates for a novel and safe approach to SIT [76].

- *Manipulation of B epitopes*

Extending the technique to B epitopes, the whole amino acid identification of the allergens via the technique of rDNA has surprisingly disclosed only limited information on the partial sequences necessary for IgE binding [195]. Although IgE antibody binding is severely hampered by the lack of monoclonal IgE antibodies, some B epitopes on allergens have reacted to monoclonal antibodies [215]. This result could be explained at least in part by the probability that special conformational peptides are necessary for IgE binding; thus certain allergens may even constitute an entire epitope. This was demonstrated for Der p 2 and seemingly also for Bet v 1. Subjecting a complementary DNA (cDNA) clone coding the latter allergen, via techniques of cross-hybridization and cloning, the resulting fragments had no IgE-binding peptide; likewise the allergen binding site was abolished by trypsin or thrombin treatment [245]. Weighing these results globally, we should point out that data raising uncertainty on the short term employed by such techniques should be taken into consideration.

Manipulation of IgE Responses

Studies related to IgE response show that if glutaraldehyde-modified allergens push the balance to the Th1 phenotype, they regulate IgE antibodies negatively. Various restrictions are predictable: since they are epitopes recognized by B cells they are conformational so that peptides representing small linear epitopes may not be able to trigger IgE-mediated responses. If peptides are recognized by allergen-specific IgE sequentially distinct from T-cell peptides, this enables the dissection of an allergen that respects the protein sequences, but abrogating the structural integrity of the molecule necessary for IgE-binding [57]. The discussion centers on the class-specific and antigen-specific suppression of IgE responses. In the first case, evidence is emerging that implies IL_4 inhibition by monoclonal antibodies, mutant proteins, etc., while IFN treatment results (Chap. 7) are controversial.

Antigen-specific suppression, as Fig. 1.66 indicates, may include:

- *Functional inactivation of T-cell clones* or subpopulations with different specificity, but with commonly characterized TcR
- *Replacement of epitopes* related to the disease by "inert"peptides via peptide-HLA molecules combinatory SITS;
- *Switching from Th2 to Th1* that down-regulates IgE synthesis
- *Idiotype manipulation of IgE*-specific responses
- *Engagement of antigen-antibody CICs* to functionally inactivated B cells, and to stimulate production of anti-idiotype antibodies to suppress IgE-specific responses

In the first case, a human $CD8^+$ regulatory subpopulation induced by CDR2 peptide modulates $CD4^+$ activity, as demonstrated that in depressing $CD8^+$, not only this modulatory capacity is terminated, but it additionally increases peptide responses [119]. Interestingly, the anergy of selected components of the T lymphocyte-specific repertoire, realized by a TcR peptide, based on the sequence of the *CDR2 region of TcR-Vβ3* gene segment inhibits human T-cell polyclonal responses to Der p [119]. In another trial, TcR expression (as measured by CD3) is reduced on anergic cell surface similarly to observations on activated cells. However, the TcR modulation is not capable of inducing a non-response since CD3 reappears on the surface within 60 h, while T-cell anergy persists. The effect of peptide-mediated anergy on T phenotype was studied on membrane proteins. In this context, CD25 expression was raised in tolerant cells, that of CD28 appeared to be down-regulated and not equally widespread [172]. CD25 increment is in line with the Th2-to-Th1 switch [253]. Thus, peptide-mediated tolerance results potentially from the signaling alteration via TcR/CD3, independently of whether this complex is expressed on the cell surface [251].

Especially stimulating are the experimental studies done on idiotype regulation of IgE response, which have demonstrated that anti-idiotype antibodies have the capacity of controlling IgE-mediated immune responses. In humans, important observations have been reported. Effects stimulating immune responses, such as the result in allergic subjects of markedly reduced titers of anti-idiotype antibodies and increased during SIT, and in other cases a suppression of this response, have been reported. Preliminary data appear to indicate that anti-idiotype antibodies recognizing idiotypes within the paratope are able to replace an antigen in certain experimental conditions, thus potentiating the immune response. Instead, when idiotypes were not associated with paratope, anti-idiotype antibodies appear to induce preferentially suppressive signals. However, an idiotype manipulation of IgE response contrasts with practical obstacles, while the question remains unsolved whether and which side effects follow a treatment based on these antibodies, even if no SRs were noted in the animals studied [195].

A randomized DBPC study was conducted in pollen-allergic adults, who, beginning a month before the season, were treated for 13 weeks with autologous allergen-IgG complexes. The allergen incrementing doses (containing the 12 most frequent European pollens) were on average 100- to 350-fold lower than the doses normally employed in SC SIT. What appears intriguing is that after a few injections the effects were notable: abolition of sIgE increase that was either transitory (present at the start of conventional SIT) or took place during the pollen season. Clinically, drug use as well as eye and bronchial, and to a lesser extent nose symptoms were significantly reduced [146]. In Der p-allergic children, good tolerance to the injections has been shown, thus suggesting that allergen-antibody complexes might be worth considering in mite-sensitized children, with the advantage of long-term improvement after SIT administration and a significant influence on nonspecific inflammatory changes both in the airways and skin [211]. In conclusion, it is suggested that:

- In addition to the rapid and sharp reduction in the levels of specific anti-Der p antibodies, there is a clear correlation between a decrease in IgG levels and clinical improvement.
- Treatment with allergen–antibody complexes boosts the production of corresponding anti-idiotype antibodies, with a loose correlation, however, between levels of anti-idiotype antibodies and clinical improvement, indicating a potential positive role for this therapeutic mechanism; an unsatisfactory explanation of the mechanism of action persist's.
- Suppression of anti-allergen antibody production may be the result of an epitope-specific mechanism; therefore antibodies experiencing a down-regulated production are of the same specificity as those administered in the form of complexes.
- To bypass this obstacle, anti-allergen antibodies of the polyclonal type should be produced, or antibodies to B-cell epitopes of Der p allergen may be envisaged: however, B epitopes are conformational, which renders their proper identification difficult [211].

Anti-IgE

A new concept of SIT to treat allergic disease has been developed to inhibit IgE function. The monoclonal *anti-IgE antibody, omalizumab,* lowers levels of serum-free IgE in human beings and reduces IgE-mediated symptoms, regardless of the allergen specificity and biological role of the IgE involved [154]. It binds to free IgE at the same site as the high-affinity receptor. Although it attaches to free IgE, it does not bind to IgA, IgG, or cell-bound IgE. It therefore does not induce cross-linking of cell-bound IgE, which would lead to the release of allergic mediators. It has been reported to decrease serum IgE levels in a dose-dependent manner, inhibit PAR and LAR, and cause a down-regulation of FcεRI receptors on basophils, as well as blocking the mechanisms responsible for the release of the cascade of mediators involved in early-phase and late-phase asthmatic responses to allergen aggression. Efficacy of anti-IgE vs placebo in reducing the severity of symptoms of SAR and in improving rhinoconjunctivitis-specific *quality of life* has been reported. Efficacy in patients with allergic asthma has also been reported, anti-IgE being used as an IV-administered formulation [30]. In 225 children aged 6–12 [154] and in 221 aged 6–17 [132] with inhalant allergy, treatment with monoclonal omalizumab and SIT was more effective than SIT alone and was well tolerated [132]. The proportion of days with allergy symptoms was also significantly lower in the SIT + anti-IgE group vs placebo (median percent of days of the entire pollen season, 58.5 vs 79.3 [132]). Treatment with omalizumab

allowed children with moderate to severe asthma who required CS therapy to reduce the need for inhaled and oral CSs. Median free IgE ranged from 133 to 790 IU/ml at baseline and was in the range of 6–9 IU/ml during the treatment period [154]. An increase noted in total IgE represents the persistence in circulation of biologically inactive omalizumab–IgE complexes. These low MW complexes lack the biological activity of IgE because the Fc portion of the molecule is blocked [154]. The anti-IgE therapy might be a novel strategy for further reducing symptoms and additional rhinitis medication requirements in patients for whom SIT is indicated. The lack of dependence on allergen specificity makes anti-IgE especially suitable for use in multiplesensitized allergic patients as well [132, 154].

Long-Term Perspectives

Further studies could explore*IL complete or partial inhibition* via anti-cytokines or tolerogen allergens capable of priming IgE response, by intervening on IgE synthesis [226]. IL_4 and IL_{13} inhibition by an IL_4 mutant protein (Chap. 1), as well as similar experimental results may eventually make it possible to augment the IgG_4 antibody levels by IL_{13} [144]. In effect, IgG_4 inhibits IgE antibodies, and therefore the ultimate benefit to patients would be the selective induction of IgG_4 antibodies [254]. To monitor SIT efficacy, it is very helpful to establish a correlation between modifications of T-cell function or IL generation and clinical symptoms. The induction of a rapid and strong allergen-specific IFN-γ release, as well as the IgG antibody formation to injections of low doses of allergen, are both desired properties that would enhance the beneficial response to an immunotherapeutic agent [238]. Other adjuvants that induce deviation of antigen-specific Th2-to-Th1 responses and include antigen-linked ILs, such as IL_{12} and IL_{18} [214], the latter expressing IFN-γ, or heat-killed *Listeria monocytogenes* [272].

Holt has proposed an immunization for young infants [107], in line with data from Varney et al [253], to include a protein extract provided with Th1-like ILs in a vaccine, to stimulate a Th2-to-Th1 switch, or allergens in bacterial or viral carriers, which induce Th1 responses [251]. It is a surprise that an edible, inexpensive transgenic plant could be used as an antigen vehicle for SIT. This technique would be best utilized by using a fruit or vegetable that is eaten raw, such as *transgenic bananas* expressing the major Der p allergens, which could be a very simple approach to inducing immunological tolerance in children [145]. Recent results demonstrate that oral immunization of transgenic rice to express and orally deliver specific peptide epitopes of tree pollen allergens expressing A1aB1b-Crp-1 and -2 protein resulted in the generation of systemic unresponsiveness with the inhibition of IgE-associated Th2 ILs, including IL_4, IL_5 and IL_{13} and of allergen-specific Th2-mediated IgE responses and histamine release. Inhibition of Th2 responses can occur without anaphylaxis [229]. Oral immunotherapy with transgenic lupin seeds expressing sunflower seed albumin dramatically *suppressed the developement of experimental asthma* by suppressing the production of Th2-type Abs, a response critically dependent on the development of the CD4+ $CD45R^{Blow}$ suppressor T cell population and the production of IFNγ [224]. In conclusion, since the future is this very moment, we can refer to the therapeutic perspectives presented in Chap. 1, which demonstrate stimulating long-term progress for SIT.

From a clinical point of view, we summarize in Table 13.19 the results of an epidemiological study of our Division centered on the SIT crisis, an alarming prospective since we have demonstrated that only 5% of children with allergic respiratory disease will undergo

Table 13.19. Epidemiology of allergic disease in Italian children. SIT in 323 asthmatic children

SIT	Children (%)
Traditional SIT	5
Oral SIT	1

Personal data.

Table 13.20. Conclusions on SIT efficacy

Efficacy in 93% of trials (Table 13.2) in the treatment of respiratory allergy as demonstrated by:
Improvement of clinical symptoms
Significant reduction of medication use
Improvement of spirometry results
Threshold raising of provocation tests
Opportunity to prescribe SIT to children with allergic rhinitis despite correct medication
Early reduction of asthmatic symptoms during SIT of children with pollinosis, *but not in chronic asthmatics*
Symptoms reduced in dose-dependent manner
Necessity of prescribing SIT early in the course of asthma, before permanent damage to the bronchi has developed
Reduction of allergic components of allergic rhinitis and asthma provided doses that are high enough are used
Several positive immunological changes
May induce allergic reactions, why proper monitoring is most important
Comparison SIT/pharmacotherapy: SIT effects persist after stopping injections, but medication effect is abrogated when medications are discontinued

Modified from [68].

SIT, stressing the significance of this result, since as analyzed in Table 5.16, 41.3 %–47.5 % of asthmatic children but 95 % of those with severe asthma continue to suffer from asthma when they reach adulthood. Not rarely have physicians stopped using SIT because they do not believe in the treatment [1], or fear (severe) side effects [1], in 5 % of cases [207], or because they consider the allergen avoidance and pharmacotherapy more effective [207]. This is a contradictory result because for 67 % of interested physicians, SIT positively modifies the long-term natural history of pediatric asthma [207]. However, we must point out that the very high number of reactions credited to SIT leads one to question the results presented in the 44 pediatric studies (Table 13.2). Table 13.20 [68] summarizes data on SIT as a conclusion of this chapter.

Pediatricians and SIT

A new page in the relationship between pediatrician and patient points to children in treatment with SIT and the pediatrician who cares for them. Given the long duration of SIT, over a period of years, it offers the pediatrician an exclusive occasion to set up good terms with young patients and their parents and/or relatives and/or escorts, which goes beyond a simple medical visit. The pediatrician is therefore a support figure for the child's entire family who lives the disease with comprehensible insecurity and fear. In other words, the pediatrician must explain the nature of the condition comprehensively, the positive SIT target, recovery from the disease, and the necessity of setting up an effective allergen avoidance regimen. This would be very helpful to the child thus able to accept the SIT course, in addition to parents who often transfer their anxiety into an overly protective attitude toward their child undergoing SIT. What worries us is that several authors have concluded that SIT results are controversial, whereas a thorough evaluation based on experience leads us to believe that SIT's critics are often supported by statements that are often clichés, including the controversial results of well-controlled studies, the limits of its efficacy, the improvement of drug therapy, and the potential danger. These clichés often resemble a repetition of the statements of various experts. Above all, pediatricians should be convinced and they should assure parents of *SIT efficacy, and safety,* which we have demonstrated, data in hand, in 99.9 % of cases (Tables 13.10, 13.11). Rhinitis symptoms are abated after a 5-year course, and are reduced in a dose dependent manner. Asthmatic symptoms are reduced early in the course of SIT in children with pollinosis, but not in chronic asthmatics when permanent damage to the bronchi has developed. Thus, SIT has the potential to provide a positive step forward in the treatment of respiratory allergic disease.

Eye Allergy and Immunology

Eye Disorders

The eye and the ocular membranes are frequently prone to allergic reactions in sensitized patients, because of the common ectodermal origins of the skin and several ocular structures, easy access for aeroallergens, and because of potential conjunctival immune reactivity. In this chapter we examine the various forms that involve the eye from an allergic-immunological viewpoint.

Pathophysiology

The eye surface having an area cavering several hundred square millimeters [139] is naturally exposed not only to microorganisms but also, and above all, to allergens for long periods, thus representing a relatively large collection window [139]. The eyelids defend the eyes from external attacks by closing, both in response to stimuli (blinking reflex) and automatically at short intervals (a few seconds) to avoid external substances, also allowing allergen removal and causes of inflammation due to the tear fluid layer. The tear film, which is continuously renewed, is most important for protecting the eyes and preserving tissue integrity [18]. Since the eye has a particular structure, the tissue most exposed to type 1 reactions is the conjunctiva. The eye is an immune *privileged site* since inflammatory reactions cannot normally occur in the cornea, the anterior chamber, the crystalline lens, or vitreous body, protected by their anatomical position, which makes the eye's interior inaccessible to external agents. The cornea in turn is protected by the conjunctiva from the immunological viewpoint [181]. This occurs because the optical axis needs only to cross transparent elements to ensure normal vision: therefore the privileged structures, to ensure protection from immune reactions that are potentially dangerous, have no blood vessels, no normal lymphatic drainage or inflammatory cells, which are instead numerous in the conjunctiva and the eyelids [67, 80]. The privileged immune sites are protected from invading pathogens and from infiltrating lymphatic cells by an active process that relies on the intraocular set-up of Fas/CD95 counter-receptor, Fas-L, capable of promoting apoptosis of activated ocular T cells [80]. The resident ocular dendritic cells (DCs) and macrophages cope with the immune privilege by producing interleukins (ILs) such as TGF-β [195].

Early DC activation by allergen within the conjunctiva is a very early step in disease pathogenesis [139]. The *conjunctiva* maintains a drainage system into the nose through the nasolacrimal duct, *thus representing the upper extremity of the respiratory system* [139]. The conjunctiva is a thin, transparent, vascular mucous membrane, which is divided into three portions: the bulbar conjunctiva, the palpebral conjunctiva, and the fornix, exposed to the external environment and protected by the tear film. It is endowed with a relatively limited capacity for inflammatory reactions. The eye normally appears reddened due to dilatation of conjunctival vessels, hence chemosis occurs, or conjunctival edema, due to fluid exudate across blood vessel walls; exudated cells, mucosal secretion and tears provide consistence to ocular discharge [167]. As the inflammation progresses, the palpebral conjunctiva develops follicles or papillae; subepithelial accumulations of lymphoid tissue, which cause papillary hypertrophy usually described as Roman cobblestones, typical of vernal keratoconjunctivitis (VKC) and atopic keratoconjunctivitis (AKC). Elongated microvilli with microplicae and medium-sized lymphocytes with no plasma cells are associated with papillary hypertrophy [16].

When inflamed, the *cornea,* which is normally clear and transparent, presents infiltrations in the stroma and granular opacities: these are initially marginal, forming close to the newly formed vessels and assuming a more central position as the inflammation progresses [36].

Another eye peculiarity is the accessory lymph node, represented by the *uveal tract:* the eye *in itself* has no lymphatic drainage and it is assumed that the external portion of the globe, including the conjunctiva, is richly supplied with lymphatics capable of responding to foreign antigens. The uveal tract (a continuous layer of iris, ciliary body, and choroid) constitutes the eye's vascular tunic and is the main deposit for lymphocytes; the limbus also accepts sensitized cells: repeated exposure to antigens, both at the ocular level and in other more distant sites, can set off local antibody reactions [67]. Lymphatics from the lateral conjunctiva drain into the preauricular nodes (parotid node) just anterior to the ear tragus. The nasal conjunctival lymphatics drain to the submandibular nodes and sensitized lymphocytes return to their original locations [14].

Table 14.2. Additional specific and aspecific agents in human tears that support ocular mucosal immunity

1. Lysozyme, among major tear components, possesses antibacterial activity.
2. Lactoferrin, another major tear component, may also prevent activation of the classic complement pathway by inhibiting C3 convertase.
3. A heat-stable antichlamydial factor prevents *Chlamydia* attachment.
4. Peroxidase may exert bactericidal, viricidal and fungicidal activity.
5. Plasminogen activator is chemotactic for leukocytes.
6. Specific tear prealbumin and transferrin may exert antibacterial activity.
7. Ceruloplasmin may reduce viral infectivity and act as a superoxide-dismutase.
8. A system producing superoxide radicals may also exert antibacterial activity.

Data from [166].

As with other organs and systems, there are natural defense factors for defending ocular immunity, schematized in Table 14.1 [166]. Furthermore, tears contain various specific and aspecific factors provided with antibacterial activity, which work together with the specific defense systems: these are illustrated in Fig. 14.1 [36, 166] and in Table 14.2 [166].

Ocular Immunology

Conjunctiva-Associated Lymphoid Tissue

The ocular immune system relies on the CALT (conjunctiva-associated lymphoid tissue), a structure which includes the conjunctiva and the lacrimal glands. The epithelial layer and the follicle-associated epithelium (FAE) overlying lymphoid follicles [77] demonstrate an intraepithelial pocket with the presence of $CD4^+$ cells

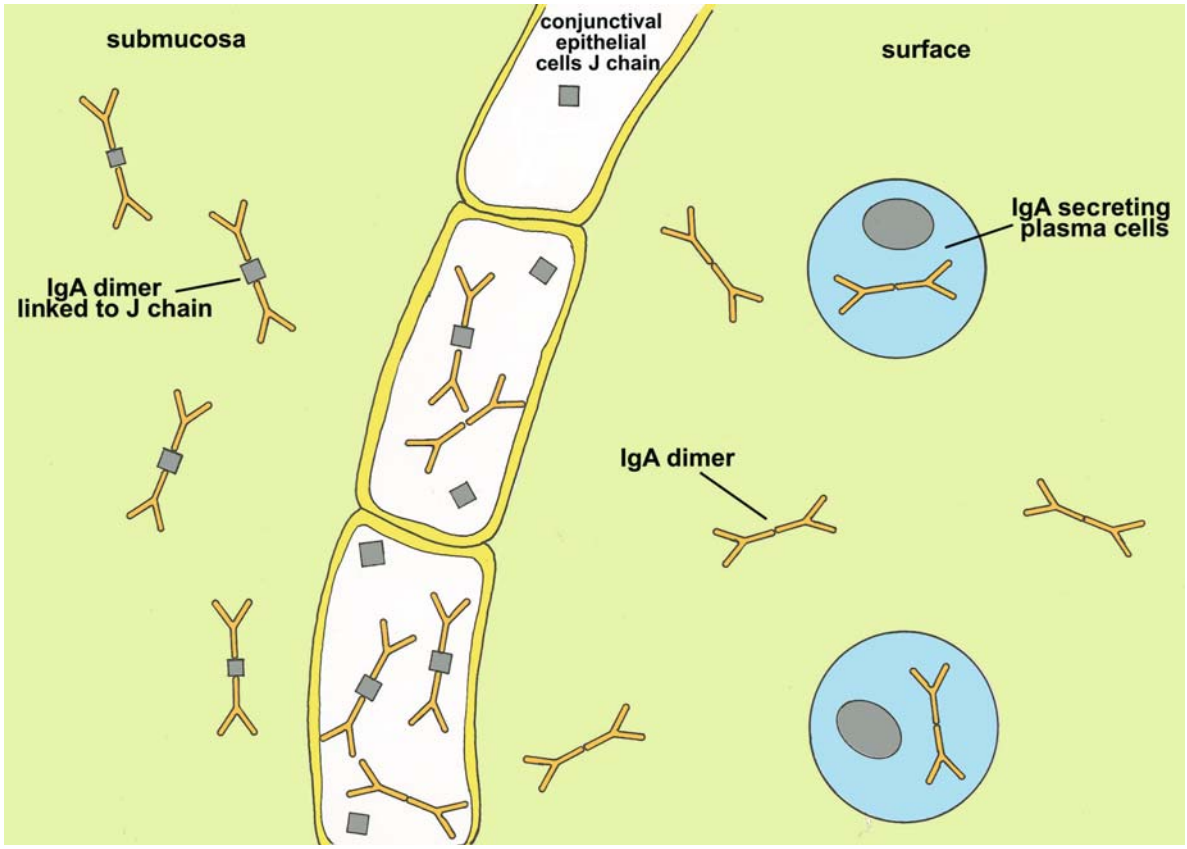

Fig. 14.3. Transportation of IgA antibodies across the conjunctival epithelium

[155]. In addition, the distribution of lymphoid follicles containing CD4, CD8 [155], B lymphocytes and a considerable number of IgA antibodies (Fig. 14.2) [170] shows morphological and functional features analogous to mucosal-associated lymphoid tissue (MALT), functionally linked to other structures such as BALT, NALT and GALT. In animals, CALT has a histological structure similar to Peyer's patches (PP), including the dome-shaped surface covering PPs, as well as for the significant proportion of B cells switching into B_{IgA} similarly to PP B cells [65]. The FAE overlying CALT demonstrates the morphological characteristic of M cells, including attenuated apical cell surface with blunted microvilli and microfolds [77]. DCs in the CALT follicular area were identified to be FDCs (follicular dendritic cells) [160]. The lymph nodes predominating in the CALT share several characteristics common to other MALT structures: 1. They are usually numerous and provided with small and medium-sized lymphocytes. 2. Frequently larger lymphocytes undergo mitosis. 3. The lymphocytes are also placed in adjacent lymphatic channels [36].

Lymphoid tissue with similar characteristics, including secondary follicles, was also observed inside the lacrimal drainage system [87]. Human plasma cells, most of which were IgA-positive, formed a thin layer in the lamina propria. The overlying epithelium produced *secretory component* (SC) [102]. Lymphoid tissue with similar characteristics, including secondary follicles, was also observed inside the lacrimal drainage system [77]. The sIgA (*secretory IgA*) antibodies, locally synthesized, prevent bacterial colonization, interfere with parasitic infestation, and defend the eye by reducing antigen changes to the membrane, while the remaining immunoglobulins (Igs) inhibit viral infection and internalization [57]. High endothelial venules (HEV) were present in all types of lymphoid tissue [102]. Thus the secretory immune system protects the eye from allergic, infective and inflammatory affections, ensuring ocular integrity and preserving visual acuity [118, 181].

Immunopathology

Tears contain high concentrations of proteins that are immunologically active and mediators such as lactoferrin, lysozyme, histamine, prostaglandins, complement and ILs, and also B and T lymphocytes, DCs and macrophages [76, 146]. Fifty-four percent of mononuclear cells in lacrimal glands are plasma cells [192], which mostly secrete IgA antibodies, with a subclass distribution generally corresponding to that of MALT [68]. Dimeric IgA, positioned in the glandular interstitium, after synthesizing the J chain and polymeric IgA,

Data from [166].

[a] The studies on sIgA and IgE antibodies are a meta-analysis of seven studies. In the six studies analyzing IgD levels the result was 0.

are transported across the epithelial cells where they bind to SC [27, 101], which facilitates IgA transportation into the tears and protects it from degradation by enzymes localized in the tears [36] (Fig. 14.3). Concentrations of IgG, IgM and IgD are rarely present [192]. Other cells are B lymphocytes (6%), organized in lymphoid aggregates at the center of primary follicles for 40% by T lymphocytes positioned in the follicle and parafollicular area, with a CD4/CD8 ratio of 0.56. CD8 T cells are more numerous than the CD4 T cells also at epithelial and interstitium levels [141, 192]. DC LCs and macrophages are present; the glands also express HLA-DR on B cells, DCs, and ductal epithelium [128]. In patients with allergic conjunctivitis (AC), IgE were positive in 56% of eyes compared with 21% and 25% of eyes with nonspecific conjunctivitis and dry eyes, respectively. IgE levels were significantly higher in the allergic group than in the other two groups [12] and in 64.7% of children with AC aged 10 months to 15 years. HLA-DR positivity in epithelial cells was negatively correlated with tear IgE [12]. Table 14.3 [166] indicates average Ig levels in the tears of normal patients. To a great extent, these levels depend on collection and processing methods and the measure of stimuli transmitted to tears [175]. Table 14.4 [166, 194] summarizes the effects of conjunctivitis on tear Ig levels.

The *conjunctiva,* the CALT's second component, which contains all components necessary for a complete immune response [102], plays an equally important role in the inductive and effector stages of the ocular immune system [170]. Unlike previous results [153], the presence of IgA plasma cells with the SC in conjunctival follicles (Fig. 14.2) confirms that the conjunctiva is part of MALT [170], hence of CALT (Figs. 14.4, 14.5) [36, 166]. Under normal conditions here too T and B lymphocytes are disposed in specialized lymphoid follicles, with IgA plasma cells outnumbering IgE plasma cells in a 6:1 ratio [117] and other Ig classes [5]. The connective tissue surrounding the eye provides an additional barrier with its large MALT supply [117]. The CD4/CD8 ratio is =0.75 and the CD3 T cells are 189±27/mm^3 [163]. There are higher numbers of leukocytes in the bulbar than in the tarsal area, highest for CD3$^+$ T cells and CD57$^+$ NK cells. In both bulbar and tarsal conjunctiva, B cells and neutrophils were seen in the epithelium and substantia propria, together with plasma cells, NK cells and mast cells.

Table 14.4. Effect of conjunctivitis on lacrimal immunoglobulin levels

Conjunctivitis	Lacrimal immune response
Allergic conjunctivitis (seasonal)	↑IgE

In comparison:	
Malnutrition (severe)	↓IgA, SC
Stevens-Johnson syndrome	↑IgG ≈ IgA, IgM

Data from [166, 194].

≈ Unmodified levels, *SC* secretory component.

[a] IgA levels were increased in one study out of five.

CD8$^+$ cells are more abundant than CD4$^+$ cells in the epithelium, but this was reversed in the substantia propria. Conjunctival intraepithelial lymphocytes (IELs), like gut IELs, are predominantly CD8$^+$, are found in the basal epithelium, are human mucosal lymphocytes-1 (HML-1$^+$) and have very high expression of CD45RO [83]. Significantly increased numbers of CD4$^+$ coexpress, CD45RO$^+$, CD45RA$^+$, and HLA-DR$^+$ T cells are found in the conjunctiva of patients with AKC, VKC and giant papillary conjunctivitis (GPC), whereas CD4$^+$ T cells in AKC are predominantly CD45RO$^+$ CD45RA$^-$ with a corresponding up-regulation of markers present on APCs (antigen-presenting cells). These findings suggest that like allergic conditions in the skin and lungs, CD4$^+$ memory T cells are involved in the regulation of the immunopathology of chronic allergic eye responses [126].

There is a large number of *T mast cells,* on average 9,342±3,472/mm^3 in the substantia propria (90% of the total) in normal patients aged between 1 and 25 years [88]; in mice these are more numerous in the palpebral rim [123], which produce LTC_4, similar to the BALT and GALT sister cells [167]. In the event that inflammatory processes should become chronic, TC mast cells will

increase [126]. Both the CALT and CLs are involved in the antigen presentation at the ocular level. The ocular CLs, situated in the epithelium [170] (85±16 CD1) [163], totally identical to the epidermic ones, seem to be more efficient than the macrophages: since they are antigen-activated, they are efficient APCs, taking the antigens up and migrating to draining submandibular and cervical lymph nodes [195]. If cell-mediated reactions also involve even simple haptens, this can result in important occasions for contact reactions [36]. Both T and B lymphocytes stimulated within regional lymph nodes migrate into the circulatory flow (Fig. 14.5), in which case T cells return to colonize submembranous conjunctival sites, while B cells localize in sites adjacent to the lacrimal epithelium and in accessory glands [65]. The presence of lymphatic glands in the two defensive structures allow local lymphocyte trafficking, thus avoiding their recirculation, although circulating lymphocytes may maintain contact both with other MALT structures such as the PPs and regional lymph nodes [192]. Some of the blood vessels associated with conjunctival follicles and lamina propria have HEV features and may play a significant role in lymphocyte homing to the conjunctiva, aided by the vascular adhesion protein-1 (VAP-1) [82]. In conclusion, the eye has unique immunological characteristics, reflected by *corneal avascularization,*

capable of receiving allogenic transplants with very little immunomodulation, producing antigens belonging to the HLA group, with a subsequent heterograft rejection [14].

In laboratory animals, the ocular secretory immune system is regulated by ILs. For example $IL_{1\alpha}$ and $IL_{1\beta}$ and TNF-α, but not IL_6 or IFN-γ, stimulate both SC synthesis and discharge [101]. IgA antibodies increase the production of TNF-α monocytes [52], while both IL_5 and IL_6 stimulate IgA synthesis in explants of lacrimal tissues, also increasing secondary responses of lacrimal IgA and pneumococcus antigens [143, 144].

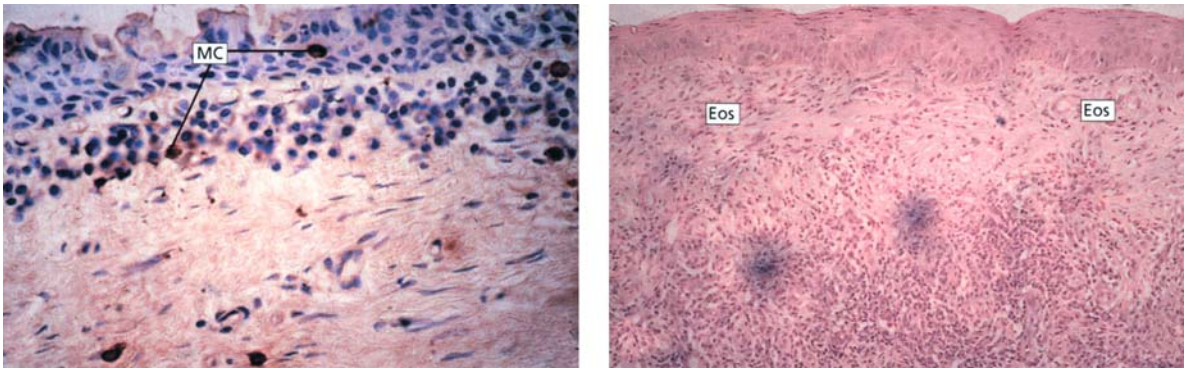
Immune Functions

Immediate Reactions

In the substantia propria of a normal conjunctiva there are once again inflammatory cells, such as mast cells, set out together with plasma cells, neutrophils and lymphocytes, these last ones also found in the epithelium, while basophils and eosinophils are characteristically absent. When a small dose of allergen comes into direct contact with an allergic child's conjunctiva, there is an encounter with the sIgE (specific IgE), which capture it and by cross-linking to mast cells, set off an immediate type I reaction with eosinophils and neutrophils in first position [14]. The quantity of allergen necessary for inducing a reaction is usually *10- to 100-fold higher than the amount needed for the skin*. Depending on the concentration of allergens the reaction can end within 1 h or persist for several hours (late reaction), with increasingly amplified symptoms when the dosage is 100- to 1,000-fold higher (320,000 BU/ml) [19]. Histopathology has been studied using the conjunctival provocation test (CPT) [34], both in conjunctival scrapings and in tears. After 20 min, there is a marked increase of neutrophils (from 4 to 21.5 on average), a more modest presence of eosinophils and lymphocytes (0.5 and 1.5, respectively), while monocytes are absent [18]; eosinophils predominate at all stages [21]. By instilling pollen in the conjunctival sac in atopic dogs, within 5 min conjunctival injection and edema appeared [68].

T Cells and Mediators

Th2 lymphocytes, with contribution from a few ILs, enhance IgE hyperproduction ($IL_{4)}$ and both mast cell (IL_3) and eosinophil (IL_5) differentiation and activation. In chronic cases, the numbers are higher, they are activated (CD25), and have a higher level of HLA-DR, CD1a (DC) and CD68 (macrophages) [126]. Unlike the skin, where Th1-induced delayed reactions are often prevalent, there is an *immune deviation priming Th2 T cells* [195]. *In situ* hybridization studies of ocular tissues have also shown Th2-like T-cell IL cluster (IL_3–IL_5) in subjects with VKC and GPC but a shift in IL profile toward a Th1-like pattern (IL_2) in subjects with AKC [127]. Tears from allergic donors contained significantly less IL_{10} and had significant increases in the ratios of TNF-α/IFN-γ, IL_5/IFN-γ and IL_5/IL_{10} [47]. Specifically, the tear IL_4 level in patients with AKC was significantly higher than those in VKC, SAC and controls [179], and a significant elevation compared to normal controls was shown in SAC, VKC and GPC [71]. Such findings suggest that all chronic ocular allergic disorders have a slight shift in mRNA expression to the Th2-like T-cell IL profile [127]: local lymphocytes express the Th2 phenotype and, to a lesser degree, the Th0 phenotype [113]. A subsequent study has found a greater localization to eosinophils for VKC and AKC than for GPC. RANTES, TGF-α, and TNF-α were localized to eosinophils in all disorders [84]. Tear TNF-α levels of VKC patients as well as TNF-α positive cells in VKC tissues were significantly increased compared to controls and significantly correlated with the severity of the disease. No differences were found between SAC and control tear samples [114]. Different patterns of eosinophil-IL localization were found to be prominent in VKC IL_3, IL_5, IL_6, and GM-CSF; in GPC IL_5; and in AKC IL_4, IL_8, and GM-CSF [84]. There are higher levels of *inflammatory mediators* including histamine, kinin, albumin, LTC_4, PGD_2 and TAME-esterase in tears immediately after CPT [146]. Histamine and PGD_2, at an average tear concentration of 5×10^{-7} and 5×10^{-8} mol/l, respectively, are directly responsible for the two cardinal symptoms: swelling and pruritus [146], also contributing to damaging the ocular structure [195]. There are also higher albumin and kinin levels, indicating the surprising rise in the ocular allergic reactions involving vasodilation and vascular permeability [143]. Histamine, when applied to the ocular surface, causes the typical clinical picture with a dose-dependent mechanism [18], and can be measured in high concentrations in the tear fluid of patients with VKC, but not in those affected by GPC [5]. The mediators released by metachromatic cells are involved either in immediate reactions or in delayed stages, recruiting inflammatory cells such as eosinophils, basophils, lymphocytes and platelets [3]. This action, up-regulated at the tissue level by *endothelial adhesive molecules* (ICAM-1 = intracellular adhesion molecule 1 = CD54, VCAM = vascular cell adhesion molecule = CD106, Fig. 1.59), results in the release of other mediators and the subsequent epithelial damage is worsened, together with other inflammatory products, causing fibroblast proliferation and collagen deposition [43]. IL_4 and IL_{13} increased production of collagen and modified the equilibrium between matrix metalloproteinase-1 and its inhibitor. These effects were partially opposed by IFN-γ and TNF-α [118]. In particular, CD54 expression on conjunctival epithelium was significantly more increased in 17 allergic children than in control children [138] after specific CPT [43] and during the pollen season [44]. CD54 seems to play a leading role in ocular inflammatory reactions, produc-



a b

Fig. 14.6. **a** Mast cells (*MC*) demonstrated immunohistochemically in the epithelium and submucosa in PAC. **b** Large numbers of eosinophils (*Eos*) present in the edematous submucosa of a patient with SAC

ing interactions between inflammatory cells and target organs [43]. A significant correlation between CD54 expression on conjunctival epithelium and ECP tear levels suggests that CD54 is locally up-regulated in inflammation, mediating eosinophil activation and migration to conjunctival epithelium [138].

Mast cells and *eosinophils* play a considerable role in ocular allergy (Fig. 14.6). In children's tears, both histamine and major basic protein (MBP) are present; ultramicroscopic studies have also documented mast cell degranulation [123]. Eosinophils are usually absent in conjunctival scrapings in healthy patients [5]; therefore *the presence of even only one cell is considered a diagnostic marker* in VKC and GPC, and in AC, where the absence of eosinophils on conjunctival scraping cannot rule out the diagnosis of AC because eosinophil infiltration may be deeper in conjunctival tissues [3], also the case if their numbers are lower because of intrinsic factors or environmental pollution [97].

In AKC the prominent IL_4, IL_8, and GM-CSF [84] are activated cells as proven by the presence of eosinophil cationic protein (ECP) also *in the tears* of patients with AC and VKC [66], significantly in the 17 children with AC but not in serum [138]. It is not the extent of eosinophil infiltration *per se* but the extent of eosinophil activation and the pattern of IL expression that is indicative of disease severity, as well as clinical variations such as involvement of the cornea [84]. Subjects with AKC and VKC had significantly higher tear ECP values than subjects with GPC and SAC, with a significant correlation between ECP values and disease severity in all disorders [131]. The release of IgE-induced eosinophil peroxidase (EPO) can be primed by incubating peripheral eosinophils of allergic patients along with specific allergens [66]. This process of activation/degranulation illustrates the concept of eosinophil releasability; furthermore tear MBP levels appear to be strictly associated with disease severity, especially in VKC and GPC [174]. Mast cells are not present in unaffected conjunctival epithelium [134], while in the bulbar and tarsal substantia propria either phenotype is found [134], 5% of T (tryptase) and 95% of TC (tryptase + chymase) [88]. TC mast cells are numerous in different types of conjunctivitis: in VKC epithelium they are as high as 96% and in GPC 100%, in the substantia propria they amount to 82% in VKC and to 98%–100% in others [88]. *Tear histamine* level (normal, 5 ng/ml) [9] varies on average between 3 and 4×16 ng/ml. The lowest levels are found in AC and in rigid-lens wearers; the highest levels are found in VKC. *Tryptase* concentrations (normal, ≤40 ng/ml) are high in tears, a marker of conjunctival mast-cell activation [66]. Mast cell activity is also well documented by histamine and tryptase high levels found in conjunctival epithelium, in AC and even more in VKC. This test is useful for diagnosis [73, 120]. Interesting contributions focus on a potential mast cell activation by *non-IgE-induced mechanisms* [17]. Approximately 50% of patients with VKC do not have a medical or family history of atopic diseases (FHA), and do not show IgE sensitization, suggesting that this disease is not solely IgE-mediated [25]. Moreover, it is possible an intervention of chemokine released by CPT stimulated lymphocytes and macrophages, not only by allergens but also by viruses, bacteria and unidentified antigens. These factors are equally capable of priming metachromatic cells to release mediators [17].

Late-Phase Reactions

Bonini et al [19] have provided the first evidence of a *conjunctival late-phase reaction* (LPR) in the eyes, although less accentuated than the immediate reaction, documented by *conjunctival eosinophilia 6 h after CPT.* Pertinent data on this LPR is summarized in Table 14.5 [18, 19, 109]. After allergen challenge, the conjunctival histological evaluation revealed a marked neutrophil influx, as was that of eosinophils and lymphocytes during the LPR (over 6–24 h), with a marked mediator release in tears collected after 20 min in patients affected by

Table 14.5. Features of the ocular LPRs

1. Persisting symptoms over 6 h (up to 24 h) after the immediate reaction
2. Continuous persistence and no biphasic aspect, or biphasic in 33%, multiphasic in 25% and monophasic in 41% of cases
3. Continuing recruitment of inflammatory cells, early neutrophil and lymphocyte accumulation and later increase of eosinophils, concomitant with symptoms
4. Mediators present in lacrimal fluid
5. Dose-dependence of clinical and histological changes (reduced with low allergen dose, higher with high allergen dose)

Data from [18, 19, 109].

conjunctivitis [18]. This pathogenic hypothesis correlates with experimental evidence from animal studies [109] and, indirectly, with an increase in vascular permeability after histamine challenge [41] and loratadine protective effects on CPT-induced LPR symptoms [42], extended by cetirizine to the immediate reaction [45]. Studies on IL involvement in the early and LPR of ocular allergy have given surprising results in knockout (KO) mice. IL_{12} KO mice and anti-IL_{12} antibody-treated wild-type animals failed to have a cellular infiltration into the conjunctiva. On the contrary, IFN-ɣ KO mice had a significantly stronger immediate hypersensitivity reaction and prolonged infiltration into the conjunctiva after ragweed challenge than control animals. The data suggest that the presence of IL_{12}, although predominantly implicated as a Th1-inducing IL, is important for the development and regulation of LPR pathological features in ocular allergy, whereas IFN-ɣ may have a protective effect on the LPR cellular infiltration of ocular allergy [121]. It is too early to reach definite conclusions from these studies, although the association of these two different ocular immune mechanisms (immediate and delayed hypersensitivity) is the most plausible hypothesis.

Conjunctival Hyperreactivity

An aspecific hyperreactivity to histamine recently identified in patients suffering from VKC may be helpful in characterizing some forms of VKC, and also in GPC, in which no elements of clinical sensitization were evidenced. An elegant study carried out on patients affected by VKC and asymptomatic AKC and in controls has reported this hyperreaction [20]. Injecting increasing histamine doses in one eye and normal saline in the other, widespread dose-dependent swelling appeared after a few minutes, but only in the eye treated with the mediator and more evident in patients than in controls; the quantity of histamine needed to elicit the reaction was considerably lower in VKC sufferers [20]. We suggest that this new pathogenic picture can explain symptom variability, which is not necessarily correlated with the allergen-induced changes. Equally, aspecific natural agents, such as the wind, dust and sunlight can contribute to an aspecific hypersensitivity.

Allergic Conjunctivitis

Definition

Although AC is the most common cause of ocular inflammations, ocular features deriving from immunological mechanisms have different characteristics in terms of severity and frequency of clinical manifestations. The causes can include IgE-induced as well as type III and IV reactions. The tissues involved in AC are summarized in Table 14.6 [30].

AC generally affects children and young adults and is the most widespread condition in ocular allergic pathologies, with a preponderance varying between 20% and 40%, with no distinction between males and females [16]. In a large sample, 32% of children presented ocular allergy as the only manifestation of atopy [189]. In our practice, children with AR (allergic rhinitis) also have AC in 80% of cases, dependent on sensitization to grasses. Inversely 12% of an unselected pediatric cohort were affected by AC. AC prevalence was 9.7%–10.1% in children aged 6–14, with no difference between highly or less polluted areas [182].

Table 14.6. Tissues involved in allergic conjunctivitis

	Tissues involved			
Conjunctivitis	Tarsal conjunctiva	Limbus	Cornea	Lid margin
Atopic keratoconjunctivitis	++	++	++	++
Giant papillary conjunctivitis	++	±	–	–
Perennial allergic conjunctivitis	+	–	–	–
Seasonal allergic conjunctivitis	+	–	–	–
Vernal keratoconjunctivitis	++	++	++	±

Modified from [30].

Classification

AC is caused by aeroallergens and is often seasonal (SAC) (pollens), but can also be a perennial condition (PAC) (dust mites, fungi, animal danders, rarely food), or present occasional peaks throughout the year depending on contact with the allergen (especially animal danders). In PAC exposure to Der p is far more frequent than SAC (42% vs 0%). The symptoms (conjunctival injection and itching) are more evident in SAC than in PAC [15]. Because of individual differences, some pollen-allergic patients report a prevalence of ocular symptoms, while the majority have a prevalence of nasal symptoms [35]. The association with AR is more frequent in PAC (72% vs 12%) [15]. In young adults, PAC is less common and does not depend on seasonal variations [15]. An association with ragweed is highly significant, but sensitization to fungal spores is diffused in 4.9%–9.9% of children with conjunctivitis: an aggravation that prompts these children to visit an emergency department (ED), where 8% were asthmatic. The risk could be sevenfold greater for fungal spores than for pollens [32]. Statistically significant risk factors for the development of pediatric AC may be FHA, negative antecedent of breast feeding, asthma or AR [33]. Secondhand tobacco smoke was present in 12.6%–36.2% of children's houses [182].

Fig. 14.7. **a** SAC in a child, with slight injection of the bulbar conjunctiva and **b** marked conjunctival edema. Despite the objectively mild manifestations, SAC may cause quite severe symptoms, with itching and profuse and persistent lacrimation, often affecting children's quality of life, especially girls

Pathogenesis

Since the eye is in direct contact with the outside environment, aeroallergens quickly melt in the tear film, provoking a type I immune reaction involving conjunctival mast cells [9] (Fig. 14.7a). In the tarsal conjunctiva mast cells can be found in increased numbers (15,380±2,830/mm^3 in the substantia propria = 100% of TC phenotype mast cells) [88] and widely degranulated, along with neutrophils and pollen granules [67]. Mast cell degranulation releases histamine, which can reach tear levels of >100 ng/ml [9], and other vasoactive mediators, preformed and newly formed, directly responsible for vasodilation and increased vascular permeability, with the addition of leukotrienes, kinin and PGD_2 and intensified symptoms [18]. The vasodilation causes conjunctival swelling, edema and pruritus (Fig. 14.6b), which are indistinguishable from the characteristic of the disease itself. Nasal irritation also causes conjunctival vasodilation that is transitory and without pruritus; lacrimation in turn can be stimulated in a reflected manner both by the conjunctival and the nasal mucosa. The *role played by the eosinophils* is remarkable: MBP levels are linked to disease severity [63]. These are found in the scrapings of 43% of patients with SAC and between 25% and 84% of those with PAC [15], as well as in tears together with ECP [138]. Recently the pathogenic role of the adhesive molecule CD106 [138] as well as the role of *chemokine eotaxin* has been emphasized [164]. IL_8 and the eosinophil chemoattractant RANTES (Tables 1.55, 1.56), are stimulated by TNF-α and IFN-γ in vitro, and upstream by NF-κB (nuclear factor of the κ chains of B cells) [74], which selectively recruit eosinophils via its chemotactic activity in IgE-mediated AC, also related to patient age and sex [90]. Moreover, IL_4-induced *eotaxin production in keratocytes* may play an important role in eosinophil recruitment to corneal ulcers in allergic ocular disease [75]. Following an experimental intraocular instillation of histamine, the allergic pathogenesis finds confirmation in the possible passive transportation of the disease and in the association with other allergic affections such as AR and asthma. AC is perhaps the only ocular pathology that can be considered an IgE-induced reaction [64].

Clinical Presentation

The clinical features are subject to even daily variations in relation to exposure to sensitizing substances. The objectivity is characteristic: red, swollen, itchy eyes and conjunctival edema (Fig. 14.7b). Itching is a distinctive

characteristic, also because there are very few ocular diseases linked to itching, which interferes with daily life and causes a great deal of inconvenience, as well as increased swelling and edema: without itching, a condition cannot be classified as ocular allergy [189]. This is caused not so much by the direct action of histamine as by a mechanical action of rubbing the eyes continuously, which frequently leads to increased susceptibility to infections and superinfections. Thus a *vicious circle* is created because the itching returns, acquiring greater drive [20]. Both eyes are involved, often asymmetrical in pollen allergies; unilateral in rare cases, for example when patients rub their eyes with hands to which animal hairs are stuck [18]. If the cause is pollens, the pruritus is mainly localized in the medial corner of the eye where the granules accumulate because of blinking [18]. Photophobia is absent and the mucus discharge scarce, and also microclimate variations causing symptom improvement when the weather is wet and cold and worsening in hot and dry climates [35].

Diagnosis

Diagnosis is based on positive results of a family and personal history. In children aged 6–14 years, FHA and personal history were positive in 58.9%–79.7% of cases [182], since the particular clinical symptoms are often negligible and *may go unnoticed.* Skin prick tests (SPTs) are positive in 67.7% of children: Der p in 52.9% and Der f in 47% of children [138], and if pollens are involved the botanical species are easily identifiable [57]. CPT is very useful: agreement between the two tests and the RAST (radio allergosorbent test) is positive in 71% of cases [110]. Eosinophils and sIgE are present in the serum in 59% of cases [138], and 89% of patients with PAC have sIgE for the Der p vs 43% of SAC sufferers [15]. In 50 children with SAR, SPTs were positive to Der p, Der f, Lol p, Atriplex bacteosa of the HDM group and pollens [33]. Thus PAC is more likely than SAC to be associated with AR, exposure to Der p is far more frequent compared to SAC (42% vs 0%) [19]. Additional triggers implicated in PAC that might elicit this reaction are animal dander and feathers [14]. Tear fluid presents high levels of total IgE, as well as sIgE to different aeroallergens [3], in 85% of patients with AC and in 10% of controls [86]. Tear IgE are mostly of local origin [85] and do not correlate with PRIST [17, 85, 86], for which in some cases there is no difference between allergic entrants and controls [86], while in others the correspondence was with tear IgE levels [175]. *Tear IgE levels* are reduced in normal cases (Table 14.3) [166], vs 0.25–25 IU/ml in allergic and therefore diagnostic [85], also stressing the difference between PAC and SAC regarding Der p: 78% vs 0% [15]. The *correlation of tear IgE and symptoms* is highly significant [86]. Tear eosinophil and ECP levels are diagnostic in children [138].

Fig. 14.8. Upper tarsal conjunctiva in a patient with SAC

The *ocular examination* takes place using a strong flashlight or a slit-lamp microscope that allows fine viewing of the smallest details that may be helpful to the doctor in making a diagnosis and following the AC course. The allergic conjunctiva appears inflamed and edematous: normally in tarsal conjunctiva moderate swelling and chemosis are observed (conjunctival edema), accompanied by small papillae (Fig. 14.8), symptoms that are less obvious in PAC [19]. Rather than intense redness and blood vessel prominence, there is a pinkish or milky coloring, caused by blood vessel vasodilation and chemosis; in acute and severe allergic reactions palpebral edema may also be observed [19]. Venous stasis produces bruising of the skin of the lower lids, called allergic shiners (Fig. 12.18). Unlike other forms of conjunctivitis, the cornea and the limbus are never affected [16].

In sum, the condition can be correctly diagnosed on the basis of five fundamental points:

- FHA and/or personal history
- Cause–effect relation with the pollen season in VKC
- Modest to intense pruritus
- Widespread conjunctival hyperemia from slight to modest
- Almost constant presence of sIgE

Differential Diagnosis

Differential diagnosis occurs with bacterial, viral or fungal infections (Gram stain for bacteria, and Giemsa stain for various organisms, bacterial and fungal culture). If a superinfection is present the bacterial culture may be positive (see Appendix 14.1 for examination of conjunctival discharges and their interpretation) [91].

Typical *bacterial conjunctivitis* is easily differentiated by the objectivity dominated by modest conjunctival swelling, chemosis and palpebral edema, the absence of pruritus, purulent mucus discharge and positive cultures (negative results do not exclude it). In bacterial

infections and in *Chlamydia* infections, leukocytes predominate, while lymphocytes are predominant in viral conjunctivitis (*Herpes simplex, Adenovirus*): the reaction is follicular in both cases. There is no evidence of IgE, nor of eosinophils [66]. In teenagers, sexually transmitted conjunctivitis should be ruled out [79].

Other causes must also be taken into consideration: irritation caused by toxic substances or *contact dermatitis* caused by drugs, cosmetics, and environmental pollutants, subpalpebral foreign body (left eyelid), *and the chemical conjunctivitis of neonates*.

Treatment

General Principles

No treatment is necessary if the disease is self-limiting and does not cause any particular discomfort. If necessary a conservative treatment can be applied for the first 3 or 4 days [13]. Treatment first of all must take the *hygienic aspects* into consideration. Primary treatment includes avoidance, cold compresses and lubrication. If the eyelids are encrusted with exudate or scaling, a bland liquid soap or also suitably diluted non-irritant pediatric fluid, applied using a tampon or a gauze can facilitate removal. Ocular washes are useful for mechanical allergen elimination, also using normal saline. Cold compresses reduce superficial vasodilation and provide notable relief from ocular pruritus [189].

Common eyewashes can be prescribed: medical eyewashes and decongestant/vasoconstrictors are useful aids if used in moderation. It is necessary to make the child understand the usefulness of eyewashes (young patients always have a negative reaction to the use of this form of treatment) instead of constantly rubbing their eyes: the eyewash must be used before rubbing, otherwise the drug will cause intense burning sensations caused by the preserving agents it contains [63].

Decongestants (vasoconstrictors) may be applied topically bid–qid as needed. We suggest oxymetazoline, which has a faster onset of action, longer duration of action, and a better decongestant effect than naphazoline and tetrahydrozoline.

Lubrication with artificial tears can be applied topically two to four times a day as needed (the solution should be refrigerated before application to improve symptomatic relief) [15].

Oral Medications

Cetirizine is used successfully for children with rhinoconjunctivitis [122], also for its capacity to modulate in vitro the eosinophil activity [158]. In 20 children with mite allergy, cetirizine was able to reduce nonspecific conjunctival hyperreactivity related to allergic inflammation compared to the placebo group [173]. We also prescribe levocetirizine to these children, with or without associated nedocromil eye drops, usually with optimal results.

Table 14.7. Topical treatment of pediatric allergic conjunctivitis

Topical medication	Daily dosing
Antihistamines	
Azelastine hydrochloride 0.05%	1 drop bid
Emedastine difumarate 0.05%	1 drop qid
Levocabastine hydrochloride 0.05%	1 drop bid qid
Antihistamine/mast cell stabilizers	
Ketotifen fumarate 0.025%	1 drop q8–q12 h
Olopatadine hydrochloride 0.1%	1 drop bid
Mast cell stabilizers	
Cromolyn sodium 4%	1–2 drops q4–q6 h
Lodoxamide tromethamine 0.1%	1–2 drops qid
Nedocromil sodium 2%	1–2 drops bid

Data as quoted in the text [191].

Eye Drops

Antihistamines in eye drops (Table 14.7 [191]) reduce pruritus locally and are usually associated with a vasoconstrictor to reduce hyperemia; by mouth they work after 20 min and the therapeutic effect persists, depending on patients, for 4–12 h. Antihistamines in eye drops are azelastine, emedastine and levocabastine, which reconfirm the properties illustrated in Chap. 12.

Azelastine eye drops in 20 children with mite allergy showed a significant reduction in nonspecific conjunctival hyperreactivity compared to the placebo group [46]. In 113 children aged 4–12 suffering from SAC or rhinoconjunctivitis, the mean response rate was significantly higher than in placebo children and comparable with levocabastine-treated children. Mainly local irritant effects were reported in 23% of placebo-treated, 35% of azelastine-treated and 38% of levocabastine-treated children [152].

Emedastine 0.05% and levocabastine eye drops are extremely selective H_1-receptor antagonists that are excellent for ocular pruritus. Emedastine administered twice daily is more effective than levocabastine 0.05% eye drops in the prevention and treatment of the signs and symptoms of AC in children ≥4 years. Both medications were well tolerated [185]. In other pediatric entrants, results confirm the potent and long-acting efficacy of emedastine, which was significantly superior to levocabastine for the relief of redness, itching, eyelid swelling, and physician's impression score [157]. Emedastine effectively decreased the extent of itching of

the eye and conjunctival hyperemia in 20 children; its effects were felt within minutes [62].

Levocabastine (0.5 mg/ml) can be used twice a day [186]; not associated with vasoconstrictors [4] it is effective for reducing hyperemia and pruritus in children aged 3–16, as confirmed on a total of 279 children [104, 130, 137, 150, 186, 193], proving to be effective in reducing pruritus, eye lacrimation and hyperemia, with good to excellent results in 83%–85% of cases. Its effectiveness was comparable [130, 137, 193], or better than that of cromolyn and placebo in CPTs [150] after 2 weeks, but matching after 4 weeks [186]. Levocabastine has a rapid onset of action in children with SAR and the topical application of medication does not irritate the conjunctival mucosa and nasal cavities [104]. In adults it proved to be significantly better than placebo [4] and cromolyn [7], especially for ocular pruritus, eye lacrimation and more severe eye symptoms [162].

Topical mast cell stabilizers include cromolyn and nedocromil, lodoxamide, and pemirolast. Ketotifen and olopatadine have H_1-receptor blocking activity as well as mast cell-stabilizing activity. These eye drops are suited for children with moderate to severe allergic eye conditions that in the past only steroids would help [79].

Cromolyn 4% ophthalmic solution in eyewash is particularly effective because of the high number of T mast cells. Well known as a membrane stabilizer and significantly more effective than placebo, the drops should be used three or four times a day. Cromolyn is helpful as a preventive measure for long periods, as there are no side effects [93]; some patients fare better immediately, others after 2 [107] or 6 weeks [93]. We regularly prescribe cromolyn eye drops for preventive purposes in children with eye allergy, as in those with AR (Chap. 12).

Nedocromil sodium is equally valid, in 2% eye drops [106, 107, 124]. In the first pediatric trial [130], it was statistically better than placebo for pruritus, eye tearing and the total score of symptoms (p=0.0097), with the additional advantage of limiting its use to twice a day. In experiments its effectiveness appeared to be closely linked to its capacity to reduce IgE levels, eosinophil infiltration, and mast cell numbers, also in degranulation and the subsequent IL release [125]. In adults with ocular allergies, headaches are reported and ocular burning, while in 7.4% of children [130], the effects were only light and passing.

Ketotifen (KF) fumarate has a dual mechanism, being a histamine H_1-receptor antagonist and mast cell stabilizer, as well as inhibiting eosinophil chemotaxis and activation and adhesion molecule [2]. In a double-masked, multicenter, placebo-controlled, CPT trial 133 children aged 8–16 with AC received KF 0.025% ophthalmic solution bid for 4 weeks. KF significantly inhibited ocular itching compared with placebo (p<0.001) and also significantly reduced hyperemia, chemosis, and lid swelling (p=0.031) in 79% of children. No KF-related systemic adverse events were reported, and ocular adverse events were comparable to placebo.

Lodoxamide at 0.1% concentration is a more potent mast cell stabilizer than cromolyn sodium in the prevention of histamine release, to be used qid, also for children aged <2 [165]. It is ≈2,500-fold more potent than cromolyn in the prevention of histamine release [15], and is effective in reducing tryptase levels and inflammatory cell recruitment (clusters of neutrophils, eosinophils and epithelial cells) in tear fluids after CPT [23].

Olopatadine is a recently introduced ophthalmic NSAID with mast cell stabilizing and antipruritic effects and has mast-cell stabilizing and antihistamine properties [79]. The 0.19% ophthalmic solution bid had a significantly greater effect on the ocular signs and symptoms compared with cromolyn 2% ophthalmic solution qid, but olopatadine had better local tolerability in children aged <11 [100]. Olopatadine relieves ocular itching and has a half-life of about 3 h. The dosage is one or two drops in each eye bid in children as young as 3 years [191].

Pemirolast potassium 0.1% is a more potent mast cell stabilizer than cromolyn sodium in the prevention of histamine release, inhibits eosinophil activation and chemotaxis [79]. It is effective and safe in preventing ocular itching in patients with AC during the allergy season [1].

Topical corticosteroids (CSs) are highly effective in the symptomatic treatment of acute and chronic forms of AC and are required for control of some of the more severe variants of conjunctivitis, including AKC, VKC and GPC [15]. CSs must be used carefully [37], because they can worsen pre-existing affections [123], foster glaucoma and cataract development if chronically used [13], and mask ocular infections [189]. However short cycles as needed have proved to be without undesirable side effects [4, 15].

Specific immunotherapy (SIT) proved to be effective in forms caused by grass pollens (Fig. 13.3) and *Cladosporium*, in CPT-tested children [56], but SIT is not effective in PAC [92].

Vernal Keratoconjunctivitis

Definition

VKC is characterized by a bilateral, chronic and recurrent conjunctival inflammation, but can also persist over both summer and fall, especially in warm and dry climates worldwide [117]. VKC is a Th2 lymphocyte-driven chronic inflammatory and potentially blinding disease [25], and a challenge for ophthalmologists since the pathogenesis is unclear and antiallergic therapy often unsuccessful [108]. This is because VKC is a chronic disease that requires prolonged treatment to control the inflammatory process [19]. Palpebral and limbal VKC are considered to be expressions of the same disease and only occasional histopathological differences are described between the two forms [148].

Epidemiological and Genetic Aspects

VKC mainly affects children and adolescents (82% <10 years old) with an average age at onset of about 8 years, rarely after 20–25 years [29, 117]. VKC burns out spontaneously in most cases after 5–10 years and vanishes after the age of 30 [10]. Otherwise 60% of patients are between the ages of 11 and 20 and of 0.1%–1% of cases experience other ocular pathologies [15]. The mean age at onset was 7.83 years and 10.94 years at presentation [28]. In 110 children, the mean age was 8.3 years, range 3.2–18 [148]. In 10 children aged 9.12±2.45, the mean duration of disease before the enrollment was 3.96±1.96 years [187]. VKC is common in some Mediterranean countries, the Middle East, the Far East, and South America, where VKC is perennial and the association with atopy is less prevalent [117]. Children are males more often than females (85% vs 15%); 75% have a personal history of atopic disease, and 67% a FHA [28].

Pathogenesis

VKC is a Th2 lymphocyte-mediated disease [108]. $CD4^+$ T cells are found abundantly in conjunctival scrapings and biopsy specimens [108]. These $CD4^+$ cells had been cloned and were demonstrated to exhibit Th2 phenotypes [119]. Plasma cell, neutrophil, T-lymphocyte proliferation, and especially *eosinophil and mast cell* proliferation is evident in the conjunctival stroma (16,000/mm^3 of epithelium) (Fig. 14.9). CD4 clones from conjunctival infiltrations express Th2-like ILs, with a subsequent massive migration of lymphocytes to the conjunctival epithelium (Fig. 14.10). $CD4^+$ T cells are found abundantly in conjunctival scrapings and biopsy specimens [119]. These $CD4^+$ cells had been cloned and demonstrated to exhibit Th2 phenotypes that produce IL_4 [119], IL_3, IL_5 and IL_{13} when compared to normal tissue [17, 108]. Expression of $IL_1\beta$, IL_1 Rα, IL_4–IL_6, IL_8, TGF-β1, TGF-β2, TNF-α and INF-γ were positive in 3–6 cases out of 6. IL_2 and TNF-β were negative in all patients, thus proving that the Th2 ILs play more important roles than the Th1 ILs in VKC inflammation [133], T lymphocytes in VKC are activated and express several activation markers that might contribute to the pathogenesis of VKC, including *potent T-lymphocyte chemoattractants* such as PARC (pulmonary and activation regulated chemokine), with numbers higher than macrophage-derived chemokine (MDC) and I-309 [60]. The numbers of $CD25^+$ T lymphocytes were higher than the numbers of $CD26^+$, $CD62L^+$, $CD71^+$, and $CD30^+$ T lymphocytes [60]. The chemokine receptor CXCR3 has a predominant role in the regulation of lymphocyte recruitment within the conjunctiva of VKC patients [59]. Eosinophil chemoattractants such as RANTES [73] and eotaxins [116] are constitutively expressed. Tear eotaxin-1 and eotaxin-2,

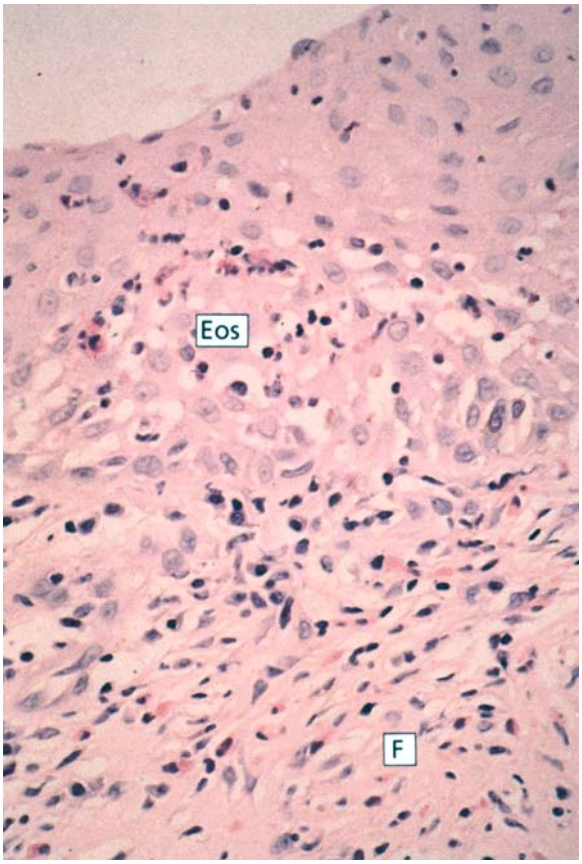


Fig. 14.9. Eosinophil (*Eos*) and mast cell infiltration in epithelium and increased fibroblast (*F*) activity in submucosa of a patient with VKC

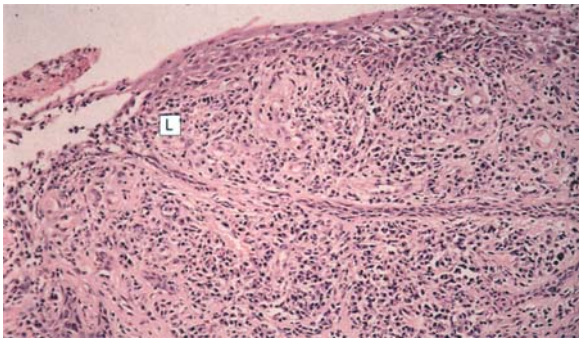

Fig. 14.10. Massive lymphoid infiltration (*L*) in a patient with VKC

potent eosinophil chemotactic and activating peptides, *correlated significantly with the eosinophil recruitment* in VKC and AKC patients compared with tears of normal patients [116]. A significant tear up-regulation of substance P (SP) a well-known neurotransmitter, was shown in patients with SAC and VKC compared to healthy controls and AD patients [72]. In concert with other changes, lacrimal CD54 levels appear to be higher in the severe limbal forms than in the palpebral forms

[48]. Eosinophils, serum IgE, ECP, and EDN are significantly higher in VKC than in control subjects [113]. Serum *ECP is a useful marker* of disease activity in tarsal and mixed forms [148]. Mast cells are mainly found in the substantia propria (24,689±7,748/mm^3, 82% of TCs), but also in the epithelium (7,994±2,120/mm^3, 96% of TCs) [88], 80% in degranulation [29]. There are high tear levels of IL_4 [71], total IgE and sIgE for aeroallergens, histamine and other vasoactive mediators, as well as MBP, Charcot-Leyden crystals, basophils and eosinophils (90% of cases) [180]. Therefore Th2 cells with IL_4 foster IgE production, mast cell and B lymphocyte accumulation and eosinophil activation [17]. The widespread polyclonal IgE activation even in the absence of IgE antibodies to common allergens have led to hypothesizing an IgE down-regulation, associated with up-regulation of the ILs of chromosome *5q*, which through its products (IL_3, IL_4, IL_5 and GMF (granulocyte/macrophage-colony-stimulating factor) regulates Th2 prevalence, IgE production and mast cell and eosinophil growth [22], thus suggesting that VKC may be *a Th2 rather than an IgE-induced form* [22]. Thus, IgE- and non-IgE-mediated immune mechanisms may coexist in the conjunctiva of VKC patients. Although high IgE antibody levels are found in tears, these IgE may stem from the local production by degranulated mast cells, and by low levels of plasma cells [14]. However, 57.8% of patients had a positive SPT and 52.2% had a positive RAST for common allergens [24]. On the one hand, interactions between specific (IgE- and Th2-mediated) and nonspecific triggers and mechanisms [108], and the percentage of Th2 lymphocytes are significantly correlated with the severity of the disease [113]. On the other hand, an overall eosinophilic response is present in VKC independently of IgE-sensitization. Tarsal and mixed forms, unlike bulbar forms, were associated with significantly high levels of total IgE: 10/16 VKC subjects showed evidence of IgE-sensitization [148]. Moreover, the amount of messenger RNA encoding ILs and inflammatory cell markers in VKC did not correlate with IgE-sensitization. [132].

Eosinophil levels, significantly high compared to controls, are present both in IgE- and non-IgE-mediated forms [17], regardless of positive or negative SPTs and RAST [22], and patients have tear and serum ECP levels [111] and tear MBP [111, 180] in the conjunctiva as well [174]. Tear histamine levels are fourfold higher than the levels found in GPC patients [3]. Recently high tryptase levels [120] have emphasized even more the pathogenic role played by mast cells. C3, C3a and high eosinophil levels (90% of cases) and plasma cells secreting IgA and IgE antibodies (with a 2:1 ratio) are characteristic of active stages; moreover, basophils, microvascular alterations of epithelial cells and deposits of fibrin are also found that prove the increased permeability [64, 111, 117]. Vast deposits of collagen drive the thickening of both conjunctival epithelium and stroma. Association with the hyper-IgE syndrome, characterized among other elements by a severe deficit of CD8 lymphocytes indicates a poor involvement of these lymphocytes in VKC etiopathogenesis [29]. In addition, histocytological examination demonstrated SP-positive cells in the conjunctiva of patients with VKC, but not in normal controls, thus suggesting that SP-increased tear levels may contribute to VKC pathogenesis and severity [72]. Structural cells such as epithelial cells and fibroblasts are involved both in the inflammatory process and in the tissue remodeling phase, eventually resulting in the formation of giant papillae [108]. Recently, the expression of toll-like receptors (TLRs) was investigated in healthy and active VKC conjunctiva in 9 patients with VKC and 10 healthy subjects. In VKC conjunctival epithelium and stroma, TLR-4 was up-regulated, TLR-9 was down-regulated, and TLR-2 was slightly decreased relative to normal tissues. TLR-4 was localized on CD4$^+$ lymphocytes, eosinophils, and mast cells, whereas lymphocytes and eosinophils, but not mast cells, expressed TLR-9. Thus the TLR up-regulated or down-regulated presence on inflammatory cells suggest their role in VKC [26].

Clinical Presentation

Children complain of conjunctival reddening, intense pruritus, tearing, abundant discharge of yellow-white dense and filamentous mucus, photophobia, burning and the annoying sensation of a foreign body [57] (Fig. 14.11). The intense and at times exasperating pruritus exacerbated by exposure to wind, dust, bright light, and hot weather [5] is the fundamental symptom, to the extent that its absence makes diagnosis difficult, the continuous eyelid rubbing while attempting to find relief amplifies hyperemia and burning [16]. Pruritus gets

Fig. 14.11. Photophobia is a common discomfort in a girl with VKC, especially on waking in the morning. She needs to wear a *hat with a brim* and spectacles with photochromic lenses

worse in the evening and also if exposed physical activities associated to hypertranspiration in addition to atmospheric disturbances [5]. In the mornings, patients are frequently totally unable to open their eyes [117].

Diagnosis

Allergic involvement in child VKC can only be assessed through a detailed evaluation, leading to specialized ophthalmic and allergic management [48]. Of the 10 children, 9 had concomitant AR and 2 asthma [187]. At the examination, conjunctival injection, epiphora, little mucus discharge, palpebral edema are seen, and in more severe cases also pseudogerontoxon and pseudoblepharoptosis (Fig. 14.12). Biomicroscopic examination emphasizes a very hyperemic conjunctiva, with a milky fibrinous discharge and many papillae at the lower tarsal level [16].

Two forms can be identified that depend on which conjunctival portion is mainly affected [16]:

- *Palpebral form* affecting the eyelid. One observes the giant papillae, reaching 7–8 mm in diameter, occurring at the upper tarsal plate with a polygonal shape and flat surface that are typically described as Roman cobblestones (Fig. 14.13), consisting of dense fibrous tissue with epithelium thickening and eosinophil infiltration, that by their weight can cause a mechanical type of ptosis; these cobblestones become extremely swollen during the active phase, commonly in the spring, and persisting during the quiescent phase of the disease [15].
- *Limbal form* at the upper sclerocorneal junction (the point of transition from corneal to conjunctival epithelium). *Trantas dots* can sometimes be observed (Fig. 14.14): gelatinous whitish or pale pink/grayish dots, collections of neutrophils and eosinophils, persisting for 2–7 days, more often seen in VKC and in black patients [3].

In the initial stages, the typical symptoms are not accompanied by giant papillae (acute forms). A biopsy, however, reveals these typical lesions [5].

In more severe cases, especially when the upper eyelid is everted and exposed to heat, pseudo-membranes (Maxwell-Lyon sign) punctate epithelial keratitis, and corneal lesions such as superficial ulcers, often close to the limbal papillae, may be seen. Keratitis is frequent, perhaps linked to MBP release, involves the upper half of the cornea and induces a reduction in visual acuity: the cornea becomes covered with a solid layer of mucus, fibrin and epithelial cells. Should the ulcer persist, with time the lesion will form scar tissue, neovascularization and a subsequent reduction in visual acuity up to 20/200 [5].

About two-thirds of patients display SPTs positive for aeroallergens, normally for pollens [63], and 50% have positive sIgE to more allergens [22]. SPTs were positive in 9/10 children (Der p 7, acacia 2, cat 1, cockroach

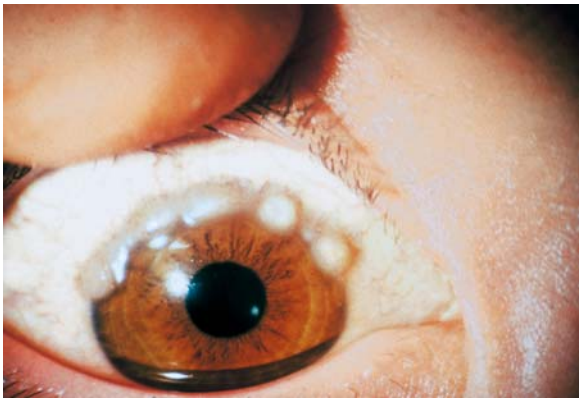

Fig. 14.14. Trantas dots at the limbus in VKC

1, and grass pollen 1) [187]. Eosinophils are diagnostic as mentioned above, since they are absent in normal eyes [5]. Serum and tear IgE levels are high. In acute stages tear tryptase levels are also high (14.5±13 µg/l), but not in late reactions [120]. For the examination of conjunctival discharges see Appendix 14.1.

The study of conjunctival hyperreactivity to histamine is useful for assessing either the pathogenesis of a number of clinical aspects or VKC outcome, and the hypersensitivity to natural agents observed in these patients [20].

Differential Diagnosis

For a differential diagnosis with atopic keratoconjunctivitis (AKC) and GPC, see Tables 14.8 [5] and 14.9 [3, 4, 31], respectively. Note that phenotype T mast cells are found only in VKC, in the epithelium and in the substantia propria (4% and 18%, respectively) [88]. Serum CD106 can be used as a marker to differentiate VKC from nonproliferative ocular allergic diseases [178].

Treatment

A specific treatment should be established in children, possibly based on allergen eviction [48]. Treatment includes cold compresses, natural tears, avoidance of specific/nonspecific triggers, and application of topical ophthalmic preparations ranging from antihistamines to mast cell stabilizers [14]. Some children may fail to respond satisfactorily to sufficient trials of conventional VKC treatment [197]. Considering VKC's good prognosis and the spontaneous recovery within 5–10 years in most patients, treatment must be conservative and aimed at alleviating subjective symptoms, without the development of a reduction of visual acuity because of the disease or the treatment. Children should live, study, work or sleep in fresh or air-conditioned environments: a cold, humid climate is more suitable than a hot, dry one. Ideally, treatment of VKC should be targeted toward reduction of Th2 activity [25].

Montelukast treatment significantly decreased physician-rated hyperemia, secretion, and chemosis as well as patient-rated burning, tearing, photophobia, secretion, and redness. Effects persisted 15 days after discontinuation of treatment. Clinical changes were associated with a significant increase in LTB_4 in tears and a significant decrease in LTE_4 in urine after 15 days of treatment [105].

Cromolyn led to full control in 19% and to partial control in 65% of patients [112] and is as effective as nedocromil sodium; another mast-cell stabilizer is ketotifen [61].

Antihistamines are also indicated [19] but are used only with children with a positive allergic evaluation [48]. *Lodoxamide* 0.1% significantly reduces ECP tear levels and thus eosinophil activation, and is more effective than cromolyn in reducing clinical signs and symptoms [6, 112]. In 15 children, both symptom scores and clinical signs were significantly lower than in controls. *Loratadine* had a greater effect on the $CD4^+$ cells, thus directed against the $CD4^+$ cells, which play a pivotal role in the pathogenesis of VKC [6]. Lodoxamide and *levocabastine* 0.05% eye drops, instilled four times daily for 3 months, were effective, safe and well tolerated by patients with VKC, but lodoxamide was significantly superior to levocabastine [184]. The drug can also be used in children <2 years, and is more useful in VKC, AKC, and GPC [165].

We have prescribed *cetirizine* drops and *levocetirizine* tables to children with rhinoconjunctivitis with a high clinical effect. Among the NSAIDs, the preservative-free *diclofenac sodium* in 0.1% eye drops has demonstrated its efficacy and safety in controlling the signs and symptoms of VKC in prolonged treatment [49].

Topical CSs such as the above-mentioned fluorometholone are to be used in resistant cases, but for *short periods* the potential undesirable effects can be reduced by associating the drug with chromones, with a parallel dose reduction [68]. CS therapy may cause ocular hypertension or open-angle glaucoma [28, 51], as in a young girl who presented with raised intraocular pressure and headaches due to the prolonged administration of nasal and inhaled CSs [51]. Therefore, CSs should be doctor-prescribed, to verify localized effects.

Cyclosporine 2% eye drops were effective and safe for treating 25 children with severe VKC, without causing major side effects After 2 weeks, most of the therapeutic effect was achieved and was maintained for the next 3 months [147]. Ten children with VKC were treated with cyclosporine, lodoxamide, olopatadine and emedastine [187].

SIT can be used successfully in a certain percentage of patients [48, 68]. Excision of the giant papillae is not advised [29].

Atopic Keratoconjunctivitis

Definition

More frequent in males, appearing <3 years and in the late teens, AKC prevalence among ocular pathologies varies between 2.5% and 10% [16]. It is the ocular counterpart of AD. AKC is associated with a 95% prevalence of concomitant AD and an 87% prevalence of asthma, and occurs in 20%–40% of individuals with AD. This condition is more prevalent in men than in women [37]. Like VKC, AKC is characterized by pruritus, tearing and a more chronic course than PAC, which intensifies during the winter. Complications may appear with structural eyelid changes. It is a potentially severe form in which secondary infections and corneal vascularization are a threat for eyesight integrity [3].

Pathogenesis

AKC histopathologic findings are diagnostically specific. They include degranulating conjunctival mast cells with the release of vasoactive mediators, and a marked papillary infiltration of monocytes, eosinophils and lymphocytes in conjunctival scrapings. T cells (CD3, CD5) and activated Th1 cells (CD25), CD4, macrophages with CD11b/CD18 and CD14, and $CD1^+$ cells are found in the epithelium; in the substantia propria there is a greater presence of inflammatory cells, as well as CD8 T cells and B lymphocytes (CD22) [64]. Histologically, epithelial hyperplasia can be observed with an increase in calyciform cells, and inflammatory cell infiltration in the limbus, especially eosinophils, with subsequent vascularization. It has been recently reported that eosinophil-released ILs in delayed stages, and also in VKC, attack the ocular cells, later causing corneal involvement [195]. Consequently, along with IgE-induced mechanisms (elevated serum and tear IgE concentrations), changes to cell-mediated immunity (CMI) are observed [5]. The immune pathogenesis is confirmed by frequently positive FHA and the presence of other allergic disease in addition to AD (asthma, urticaria, and rhinitis).

Clinical Presentation

Only a few patients with AD present bilateral eye symptoms, including evident hyperemia, intense itching, burning, tearing, watery or purulent mucus discharge, the feeling of the presence of a foreign body, photophobia and eczematous lesions on the eyelids, sometimes exuding such as the basic disease [57]. Ocular symptoms present with little or no seasonal variation (as opposed to VKC, which is seen mostly in warm weather). In addition to edema, lids may show thickening and tylosis, crusting, fissures and ptosis [37]. The conjunctiva may show small or medium-sized papillae, hyperemia, edema, and excessive mucin [5]. Children complain more about the *intolerable external aspect* that makes the eyes so red due to palpebral edge involvement than about itching. Scratch marks are noted around the eyes, the forehead and the cheeks. There is often canthi maceration because of continuous hypertearing: inflammation can distance the eyelids from the optical globe to the point that the lacrimal point no longer corresponds to the lacrimal lake; consequently the tears do not drain through the nose and fall outside [5]. Both eyelashes and palpebral edges often exhibit chronic blepharitis (Fig. 14.15), often induced by *Staphylococcus aureus* [63].

Diagnosis

Ocular examination shows conjunctival inflammation, often associated with upper tarsal conjunctiva papillary hypertrophy (Fig. 14.16). Sometimes giant papillae may form, caused by the infiltration of inflammatory cells and the accompanying edema. The eyelids appear reddened and bruised with palpebral margin hardening and lichenification. Both conjunctiva and cornea may develop scarring in the later AKC stages. With more active symptoms, Trantas dots can be observed around the upper limbus, all the more common in VKC [176]. Conjunctival biopsy specimens reveal excessive eosinophils, mast cells and goblet cells [37].

Fig. 14.15. Blepharitis complicating AKC in a child; the risk of corneal involvement is great. Therefore the infection should be treated urgently

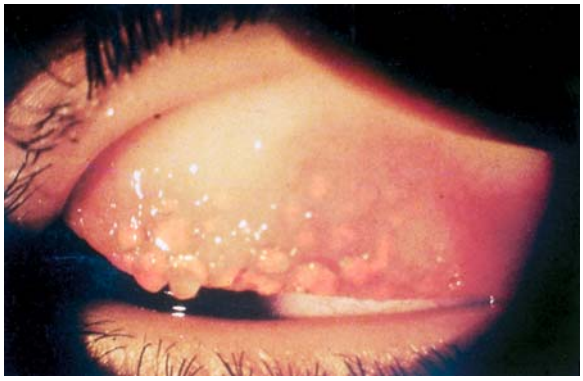

Fig. 14.16. Appearance of upper tarsal conjunctiva in AKC

SPTs are mainly positive to food, pollens, etc., but the meaning of these findings is as yet unclear. Total IgE levels are usually increased and eosinophils are frequently recognized [14].

Differential Diagnosis

Differentiation from AC is quite simple: in these patients the eyes are normal during intercritical periods, while in those with AKC the eyelids are thicker and harder, with scaling skin and scratch marks. Furthermore, there is the potential corneal involvement. Table 14.7 summarizes differential diagnosis with VKC.

Complications

Unlike patients with AC, progressive keratitis punctata with proliferation of the limbic vessels around the cornea may develop. If keratitis and neovascularization progress up to involving the visual axis, *eyesight is reduced and patients may go blind* [37]. About 10% of patients present opacity of the crystalline lens [5]: because of AKC persistence and excessive use of topical CSs, *a cataract* may appear extending to most of the anterior crystalline lens; the opacification can become complete within 6 months. Should it progress to prejudicing the eyesight, its extraction becomes necessary. Should a keratoconus also form, the cornea is highly astigmatic [181]. Correction of eyesight defects includes contact lenses: conservative treatment is insufficient over the long term in avoiding a cornea transplant. It is thought that the keratoconus is caused by the continuous eye rubbing because of itching and also perhaps by a congenital defect in collagen synthesis [176].

Treatment

Rinsing the palpebral rims twice a day with a saline solution and if necessary the application of antibiotic cream make up the usual treatment. Antibiotics will sometimes have to be prescribed systemically. Massaging the eyelids is useful, especially the lower one, which can be pulled externally to re-establish the connection between the lacrimal point and lake [5]. Often the severe clinical features require the use of topical CSs. Complications are seen more rarely with fluorometholone and rimexolone than with other CSs [15]. Some patients find cromolyn helpful, and it is certainly advisable for continuing treatment [3]. In the event of a relapse, the above-mentioned treatment should be continued for a long period of time [3]. Topical 2% cyclosporine has proven to be effective for exacerbations. Low-dose maintenance therapy (5 mg/kg q4d) may be required in refractory cases [37].

Giant Papillary Conjunctivitis

Definition

Originally described in contact lens wearers, both rigid and soft, more often with the soft lenses and in young females, GPC was found in patients with ocular prostheses, exposed corneoscleral sutures following surgery to the upper limbus, band keratopathy, etc. Probably these stimuli and/or the lens edges have a chronic microtraumatic effect on the upper tarsal conjunctiva. Between 10% and 15% of patients using soft lenses, and between 1% and 5% of those using hard ones were found to suffer from GPC [67, 145]. GPC is less serious than VKC or AKC, as corneal surface disease does not occur [127].

Pathogenesis

Although a great deal of data points to the coparticipation of an irritative mechanism activated by foreign bodies present on the outer ocular surface, associated

with the use of contact lenses, the current hypothesis most supported by data proposes a unifying immunological pathogenic mechanism underlying two different subtypes of a single category of conjunctival changes: VKC and GPC [29]. GPC has a risk factor that is fivefold higher than in healthy patients. FHA is frequently positive (67% of cases) as well as the presence of other atopic disease (AD, asthma, AR) in 75% of patients [29].

The immune pathogenesis is associated with markedly increased cells expressing HLA-DR antigen and LC infiltration [39] and with the presence of conjunctival infiltration, a mixture of plasma cells, mast cells and eosinophils, with participating basophils and lymphocytes [99]. The infiltration of eosinophils, neutrophils and granules is most prominent, with a lesser infiltration of mast cells [39]. Histologically, mast cells, basophils, eosinophils, neutrophils and a few lymphocytes are seen invading the conjunctival epithelium rich in papillae; the stroma shows only basophil and eosinophil infiltration, lower, however, than in VKC [53]. Mast cells are 17,313±3,801/mm^3 in the substantia propria and 3,814±2,052/mm^3 in the epithelium (100% of TCs): in asymptomatic patients, mast cells are only found in the first tissue, while in symptomatic patients or those with VKC, mast cells are found in both tissues [88]. Tear tryptase levels have provided further credit to GPC immune pathogenesis [31], proving that these might be an early diagnostic marker [73, 120]. Eosinophil infiltration in the conjunctiva, MBP and other cationic proteins are linked to the severity of clinical features and the presence of typical symptoms in young atopic people with SAR and who wear contact lenses [98]. Locally produced IgG, IgM and IgE antibodies are found in tears, but are absent in asymptomatic patients [53]. Excessive collagen formation leads to the flattening and movement of the micropapillae, resulting in conjunctival ulceration. Furthermore, contact lenses, like any foreign body, work as an abrasive surface that causes repeated trauma to the upper tarsal conjunctiva: the immune sensitivity of a traumatized conjunctiva is raised, allowing and promoting environmental antigens entering the conjunctiva, especially bacteria, which are normally avoided [53]. Reduced levels of lactoferrin in patient tears inhibited the formation of converted C3 (which splits the C3 into C3a and C3b) and therefore complement activation in the classic pathway [10]. In other studies these levels were increased [11, 53].

The condition is often set off or intensified by one of more of the following variables [5, 38, 54]:

- The use of thimerosal (Chap. 8) in fluids used for cleaning lenses (Fig. 14.17)
- The material accumulating on the lenses, especially if protein-like
- Edge design
- Surface properties
- Fitting characteristics
- Excessive lens use
- Individual sensitivity to a certain kind of lens

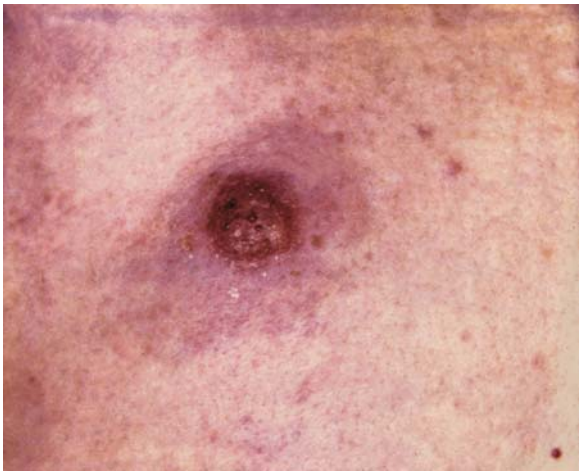

Fig. 14.17. Thimerosal hypersensitivity with vascularization of upper cornea

- Larger lenses providing a larger adhesive area for antigenic matter
- Genetic predisposition to an antigen linked to the lenses used

Other incriminated substances in addition to thimerosal in the solutions include sorbic acid, papain, benzethonium chloride, Hg phenylnitrated, etc.

Clinical Presentation

The symptoms are classic: pruritus especially after removing lenses, pain, burning, tearing, mucus discharge on awakening and the sensation of a foreign body.

Two more common forms of GPC are a localized form in which the papillae are confined to one or two areas of the tarsal conjunctiva, near the lid margin, and a generalized form similar to that seen with conventional soft contact lenses [54].

GPC course is divided into four stages, but individual variation is very common [5]:

- *Stages I and II* (preclinical, mild): symptoms are modest and can go unnoticed. If the lenses continue to be used, one enters the next stage.
- *Stage III* (moderate) consisting in abundant mucus formation and increased itching, to the extent that lenses cause intense annoyance because patients find it difficult to keep the lenses clean and they feel the sensation of a foreign body. Continuous lens movement on each blink results in fluctuating and blurred vision.
- *Stage IV* (advanced): the lenses are no longer tolerated, the mucus discharge increases to the point of covering the eyes, so that the patients' eyelids can stick together in the morning, the lenses are often decentered, the sensation of a foreign body becomes unbearable (Figs. 14.18, 14.19).

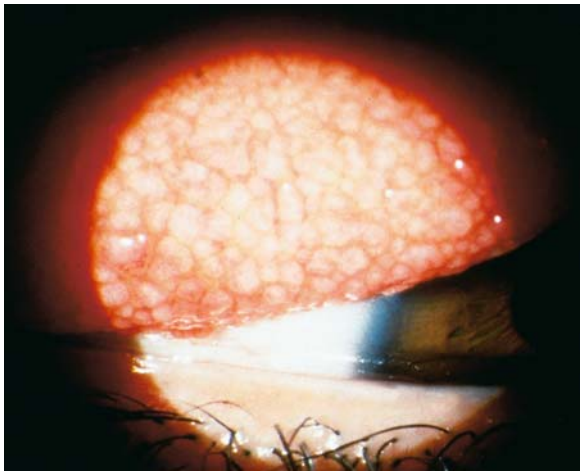

Fig. 14.18. Appearance of upper tarsal conjunctiva in CGP

Fig. 14.19. Limbal inflammation in CGP

Diagnosis

Biomicroscopic ocular examination makes it possible to follow how the alterations evolve [5]:

- In *stage I* the lesions are mild.
- In *stage II* micropapillae can be observed.
- In *stage III* giant papillae are seen (>1 mm), which increase in number, size and height, forming the Roman cobblestone effect (present in 5%–10% of those who wear soft lenses and in 3%–4% of those who use hard ones).
- In *stage IV* the apices of giant papillae look flattened and epithelial damage is visible. Punctate keratitis or erosive lesions may affect the cornea.

The micropapillae, with a diameter of 0.3–1 mm, are seen in 80% of GPC patients [5].

A patch test with thimerosal and the other indicated substances can be carried out [145].

Differential Diagnosis

Differential diagnosis of GPC and VK is schematized in Table 14.8. Although the histopathological picture recalls that of VKC, the cornea is not affected, and rear histamine and MBP levels are normal or only reduced [3] and those of tryptase are high [31].

Treatment

Treatment will only be effective if the diagnosis is made early. Changing the lenses, or if necessary, removing the prosthesis or eliminating the sutures, improves the situation surprisingly. If the patient cannot or will not give up wearing contact lenses, a type that does not prove troublesome should be chosen [34] and solutions *without thimerosal* should be used for cleaning them once a week.

Cromolyn eye drops has proved to be very effective. The drops should be used in the morning before putting in the lenses and in the evening after removing them. If necessary the lenses should be removed during the day for a few moments.

Loteprednol etabonate 0.5% ophthalmic suspension may be an appropriate treatment for GPC, by ensuring a rapid therapeutic response combined with the low incidence and transient nature of any intraocular pressure increase [69]. In case of documented hypersensitivity, children are advised not to use levocabastine, lodoxamide or olopatadine while wearing contact lenses [191].

Prevention

The Committee on Health Risks of Contact Lenses from the Health Council of the Netherlands has recommended that permanent-wear lenses should not be used, warning that a very serious complication of contact lens wear is infectious keratitis, caused by bacteria or fungi. This is most common in users of permanent-wear soft lenses (20×10^4 persons/year) and can lead to a severe loss of vision [156]. Young people can wear contact lenses safely only if monitoring takes place at least twice a year [100]. In patients who are at high risk for GPC, replacing lenses at intervals of 1 day to 2 weeks appears to offer a better strategy in avoiding GPC than incorporating enzymatic cleaning into their care system [55].

Ocular Contact Allergy

Definition

This is a typical form of conjunctivitis caused by xenobiotics, due to continuous and direct exposure to a variety of environmental stimuli, in particular to sub-

stances present in the surrounding atmosphere, with eye irritation despite the eyelid and tear protective action.

Pathogenesis

This late-type hypersensitivity is set off by whatever allergen or hapten comes into contact with the eye and periorbital area: eye drops and ocular drugs for topical use can be especially responsible [68]: in 62.5% of cases the culprit is phenylephrine [133]. Antibiotics are also on the top of the list, including neomycin, as are anesthetics, antiviral drugs, antimycotics, dilating agents such as atropine and its derivatives, etc., and also soap, various detergents, shampoo, cosmetics, hair spray, chemical substances, preservatives contained in solutions for contact lenses and eye cosmetics, eyelashes, etc. [68]. Some typical examples are rubbing the eyes with dirty hands, or after touching soap, detergents, cosmetics, etc., and the use of mascara, eyeliners, suntan lotion for the face, nail polish, etc. [68, 190] (Table 8.9).

Clinical Presentation

Symptoms can appear from within a few minutes to 24–72 h after allergen contact. Swelling of eyelids, which are inflamed and pruritic, is characteristic. Ocular symptoms vary from mild irritation to severe symptoms with marked hyperemia [3] and photophobia, sometimes so unbearable that the patient keeps the eyes obstinately closed, making the ophthalmologic examination impossible. In severe cases, caused for example by the continuous use of drops containing the sensitizing substance, corneal erosions also form. Some patients can develop psychological disorders stemming from the disease's effect on appearance.

Diagnosis

Diagnosis is made difficult because of photophobia. Irritation and variable hyperemia, tearing, papillary reaction, and chemosis are present, and in the most severe cases a thin punctate keratitis. The identification of sensitizing agents can be complicated, especially if it is a cosmetic or eyewash whose composition is not always specified. Benzalkonium chloride in nose drops is not inoffensive (see Chaps. 8, 20). Patch testing is useful in some cases [16].

Treatment

Treatment consists in the immediate elimination of contact agents. Both hot and cold compresses are often helpful and if necessary, topical CSs can be used in moderation, warning the patient that side effects of an increased use can be worse than the disease itself.

Acute Edematous Conjunctivitis

Acute edematous conjunctivitis is a form of angioedema localized in the conjunctival membrane, showing acute unilateral and bilateral chemosis, normally caused by direct contact of the conjunctiva with dust or vegetables and/or animal danders [57, 190].

Blepharitis

Most chronic blepharitis in children is of allergic origin. Initial symptoms consist in palpebral rim hyperemia, with thin scaling, becoming furfural near the eyelashes. It can be associated with Zeis gland hypersecretion with formation of yellow scales. Depending on the predominance of one or the other aspect, it is described as scaly or eczema-form blepharitis.

Pathogenesis

There are three main factors at the origin of eczema-like blepharitis: refraction defect and binocular vision, atopy and aeroallergens, especially animal danders.

Clinical Presentation

The features are classic for blepharitis: burning, tearing, photophobia, and sometimes blepharospasm. It evolves to tylosis (thickening of the palpebral rim), madarosis (loss of eyelashes), and sometimes trichiasis (inward growing of eyelashes).

Treatment

Eliminating the causes is fundamental, but not always easy. In the scaly forms, freeing the palpebral rims from the microcrusts with dry gauze is suggested. Local treatment involves the use of zinc oxide or antibiotic creams, limiting the use of topical CSs to the more resistant cases. Self-medication should be discouraged [57].

Keratitis

Allergic keratitis is more difficult to treat than AC because of differences in the corneal tissues, their fragility, the abundant innervation and transparency that may appear changed [66]. Because the cornea is avascularized, hypersensitive reactions may take place only in the limbal barrier, which is the sclerocorneal junction [66].

Lymphatic drainage is also absent, unless there is central cornea neovascularization. After penetrating the limbus, the allergens can spread to the cornea; this shows how the passage of macromolecules such as IgM is prevented, and all other Igs are present, mostly concentrated in the stroma [183]. The antigen–antibody reaction of the Arthus type, which damages the collagen fibrils, also occurs in the avascular cornea. In rabbits, by injecting the allergen into the cornea, within 3–5 days there is a reaction possibly of a delayed hypersensitivity type; after 7–14 days CIC (circulating immune complex) deposits follow, accompanied by a Wessely phenomenon [181]. Predominantly mononuclear cellular reactions are observed, although basophils, eosinophils and neutrophils are also seen, leading to the hypothesis that a reaction parallel with cutaneous reactions is also induced by basophils [67]. Lymphocytes and differentiated CLs are basically absent [159].

Allergic keratitis appears in inflammatory forms divided into superficial or subepithelial, deep or interstitial punctate.

In the first case, they etiology is led by aeroallergens, as in AKC, and mycetes come in second. Symptoms are bilateral, with photophobia, tearing and the sensation of a foreign body in the eye. It lasts for 1–2 weeks, characteristically receding to recur after 4–6 months [181]. The best-known forms of keratitis are AKC and VKC and those associated with GPC and contact conjunctivitis. Treatment is based on topical CSs, with careful use of contact lenses [57].

Interstitial keratitis appears in children after the age of 5 years, and is usually monolateral. Symptoms are milder than in the punctate forms and consist in photophobia and a more or less pronounced loss of visual acuity. With a biomicroscopic examination, one observes deep deposits that make the cornea look like frosted glass. The epithelium is intact and the stromal lesions can assume different appearances depending on the extension, causing nodular sectorial or total keratitis. In these forms, when they are persistent, there is a stromal vascularization starting from the limbus [57].

Uveitis

Definition

Uveitis is defined as an inflammation of the uveal tract, which encompasses the iris, ciliary body, and choroid. Uveitis is an entity most pediatricians and ophthalmologists rarely encounter and has been reported to cause increased rates of visual loss compared with adult patients [140]. An improved knowledge of disease patterns and associated morbidity will help in the care of children with uveitis [177]. Although its diagnosis and management present a distinct clinical challenge for the pediatrician, its early diagnosis and management are vital in the preservation of vision [177].

Epidemiology

The incidence of uveitis in district hospitals in children <16 years of age was 4.9×10^5 [58]. In a referral practice in south India, a total of 31 (6.29%) pediatric uveitis cases were seen among the 493 uveitic cases in the year 2000 [135]. Of 219 patients, 112 were girls, with a mean age of 7.4±4.2 years, and 107 were boys, with a mean age of 8.3±3.4 years. The mean follow-up time was 37±6.2 months [95]. In referral cohorts, the most frequent diagnosis was juvenile idiopathic arthritis-associated uveitis (67%) [58]. Uveitis in children represents only ≈5%–10% of all cases: uveitis associated with juvenile rheumatoid arthritis (JRA) was the largest group (41.5%), followed by idiopathic uveitis (21.5%) and pars planitis (15.3%) [177]. The most frequent type of uveitis in 0- to 7-year-olds was chronic anterior uveitis, posterior uveitis in 8- to 15-year-olds, and acute anterior uveitis in 16- to 19-year-olds [58].

Classification

Uveitis affects the iris, ciliary body, and choroid and represents an immune ocular disorder characterized by type III (CIC) and IV reactions [70]. The uveal tract commonly contains B and T lymphocytes, mast cells and fibroblasts [154]. In patients with uveitis, one can observe infiltrating T cells also in silent stages, unlike in controls, with a CD4:CD8 ratio >1:0, proving that there are CD4 linked to the inflammation, while when it is receding there are higher CD8 levels [154]. CDs of the posterior uvea look like veiled cells (Fig. 1.39). During a chronic choroidal inflammation, plasma cells, phagocytes and lymphocytes link up to form pseudo-lymphoid follicles or granulomas; inflammatory cells enter the anterior chamber and the aqueous humor [70]. No HLA antigens are in the uvea; however, IFN-α can induce both class I molecules and IFN-γ [81]. From an immunogenetic viewpoint, anterior uveitis is associated with HLA antigens like other immune pathologies with ocular symptoms; acute iritis is a classic symptom in this disease and is linked to the *HLA-B27* genotype. However, 45% of patients with acute anterior uveitis have this allele without the clinical or biological stigmata of other disorders [189] (Table 14.10) [78, 168, 171]. *HLA-B27* uveitis is associated with approximately 16% of pediatric cases of anterior uveitis [140]. *HLA-DR1*, absent in posterior uveitis, can be considered a protective factor, while 100% of patients with panuveitis (involvement of all three portions of the uveal tract) express *HLA-DR4* [169]. The anatomical classification of uveitis into four types [151] was confirmed by two recent papers. In one paper, anterior or iritis or *iridocyclitis* was seen in 56.9% intermediate or *cyclitis* or peripheral uveitis (20.8%), posterior or *chorioretinitis* (6.3%) and diffused or *panuveitis* was observed in 16% of cases depending on the area affected by inflammation.

Table 14.10. HLA alleles in disorders with ocular manifestations

Disorder	HLA allele	Relative risk [168, 171]	Relative risk [78]
Anterior uveitis	B27	10.4	8
Ankylosing spondylitis	B27	87.4	80
Reiter's syndrome	B27	37	40
Behçet's syndrome	B5/B51	6.1	
Multiple sclerosis	DR2	4.1	
Sjögren's syndrome	DR3	9.7	6
Pemphigus	DR4	14.4	

The most recent HLA nomenclature can be found in Appendix 1.1.

Nongranulomatous (77.6%) and noninfectious (85.7%) were the most frequent types of inflammation. The process was bilateral in 74.4% of patients [103]. In the other an equal number of children had anterior, intermediate and posterior uveitis and 4 children had panuveitis [135]. It is agreed that any uveitis lasting for >3 months should be considered as chronic.

Clinical Presentation

Clinically, uveitis is characterized by the more or less extended reduction in visual acuity, sometimes by conjunctival injection and ocular pain, by possible complications that are more frequent in children (cataracts, glaucoma, corneal calcification and globus atrophy), and the chronic and recurring course of uveitis [57, 188]. Moreover [140, 142]:

1. *Acute anterior uveitis* will frequently present with sudden onset of conjunctival injection, tearing, photophobia and a peculiar injection seen adjacent to the limbus, perilimbal flush (which can be confused with AC) [189]. Pain is temporofrontal and exacerbated by light; the pupil is myotic. In *chronic* forms, the symptoms are less evident. The loss of eyesight, to variable degrees, is reversible in the acute forms but can be aggressive in chronic forms, including ankylosing spondylitis, JRA, and Crohn's disease.
2. *Intermediate forms* are generally bilateral, presenting a chronic and insidious course. There are no or few symptoms until complications occur, consisting in black floaters (myodesopsia), occasional cloudy eyesight and transient myopia. Vitreal cells and cellular aggregates can be seen with direct ophthalmoscopy, while inflammatory cells in the anterior chamber, protein exudation in the aqueous humor (flare), keratic precipitate and exudates with membranes covering the ciliary body can be seen with indirect ophthalmoscopy and the split lamp.
3. *Posterior uveitis* is heralded by floaters. The humor darkens because of inflammation, causing loss of visual acuity and cloudy vision. There are inflammatory cells in the vitreous, retinal perivasculitis and papillary edema, with the option of evolving into optical atrophy. Chronic forms are associated with JRA.

In most cases, the allergic origin of uveitis is hard to prove; the cause is *idiopathic* in 29%–50% of cases [142]. A relapsing tendency following contact with a given allergen is clearly very attractive, but rarely demonstrated. Current research is orientated toward ocular immunopathology. However, uveitis onset in childhood can be insidious, without clear symptoms. Therefore knowledge of this potential complication and subsequent ophthalmologic tests are important for the prevention of severe consequences. Carrying out tests on children until the age of 15 is recommended [57].

Diagnosis

Table 14.11 [140, 142] gives a panorama of the different forms of uveitis in childhood. Although its diagnosis and management present a distinct clinical challenge for the pediatrician, its early diagnosis and management are vital in the preservation of vision [177]. Accurate diagnosis requires history from both children or adolescents and parents or caregivers, a complete ophthalmic examination that may require general anesthesia, and carefully selected investigations [161]. However, in 24.2% of cases, uveitis was idiopathic, since no etiological factor could be ascertained [95] or this was the most frequent diagnosis (78%) [58].

Complications

Uveitis in childhood is a potentially blinding disease, in the majority of patients characterized by a chronic course and a high complication rate: 26% of the eyes had <20/200 visual acuity at the time of first referral at ≤16 years of age [177]. Visual loss (any eye <6/12) occurred in 17% and was not associated with age [58]. Three patients (2%) with the onset of ocular disease <16 years became legally blind and an additional 20 out of 121 (17%) had one legally blind eye caused

Table 14.11. Different forms of uveitis in childhood

Anterior uveitis
Ankylosing spondylitis
Drugs
Herpes-associated uveitis
Heterochromic iridocyclitis (Fuchs)
Idiopathic
Juvenile rheumatoid arthritis (pauciarticular)
Kawasaki disease
Reiter syndrome
Sarcoidosis-associated uveitis
Spirochetal (syphilis, leptospiral)
Stevens-Johnson syndrome
Trauma-related uveitis
Tuberculosis
Ulcerative colitis
Intermediate uveitis
Behçet's syndrome
Lyme disease
Sympathetic ophthalmia (trauma to other eye)
Vogt-Koyanagi-Harada syndrome (uveo-otocutaneous syndrome: poliosis, vitiligo, deafness, tinnitus, uveitis, aseptic meningitis, retinitis)
Posterior uveitis
Idiopathic
Ocular toxocariasis
Sarcoidosis
Subacute sclerosing panencephalitis
Syphilis-associated uveitis
Toxoplasmosis-associated uveitis
Tuberculosis
Viral (rubella, herpes simplex, human immunodeficiency virus, cytomegalovirus)

Data from [140, 142].

by uveitis. The most frequent causes of blindness were chorioretinal scars in the macular area and glaucoma [50].

Treatment

Noninfectious anterior uveitis generally responds to topical CS and mydriatic therapy. Although used frequently in adults with posterior uveitis, systemic CSs may cause serious adverse effects, including growth retardation in some pediatric patients. Methotrexate is the most commonly used systemic immunosuppressive agent for pediatric uveitis. It is effective, generally well tolerated, easy to administer, and inexpensive. Cyclosporine has also been used successfully in children with uveitis, being associated with a low risk of renal toxicity when used at standard doses. Alkylating agents are generally contraindicated in children because of risks including secondary malignancy, sterility and bone marrow suppression [161].

New Therapeutic Perspectives

The antagonism of specific chemokines, their receptors, or both might be of value in the treatment of ocular allergy [132]. Therapeutic strategies that block CXCR3 may inhibit T lymphocyte recruitment and suppress adverse inflammatory reactions [59]. In parallel, antagonizing the MCP-1/CCR1 interaction or signaling from chemokine receptors holds promise for the treatment of both acute- and late-phase reactions [172]. In the murine model of ocular allergy, it has been shown that the antagonism of the receptor for eotaxin-1 (CCR3 = common to eotaxin-2) might inhibit both early- and late-phase inflammation [138]. A different way of neutralizing eotaxin-1 is by using the humanized anti-eotaxin-1 antibody (CAT-213) that can inhibit the activation of human conjunctival mast cells in an *in vitro* passive sensitization system [134]. Topical application of blocking antibodies to $IL_1R\alpha$ have a profound inhibitory effect on the recruitment of eosinophils and other inflammatory cells essential for the immunopathogenesis of ocular atopy in animal models [100].

Nonsteroidal ocular preparations have without doubt attracted great interest, among them cromolyn, nedocromil sodium, antihistamines such as levocabastine, effective and safe alternatives compared to the risks linked to CSs.

Tacrolimus (Table 7.21), a macrolide antibiotic that has potent immunomodulatory properties, was effective in several ocular immune-mediated disorders, including keratitis and uveitis [15]. Application of *tacrolimus 0.1 % ointment* on eyelid skin may be effective for treatment of severe AD of the eyelids, and may have secondary benefits for AKC and VKC [149]. The ointment was applied to the lower conjunctival sac of both eyes once a week then twice a week and also daily in one child with VKC without any significant side effects [187].

Recently, a novel anti-IgE antibody (omalizumab) was developed that is directed against the receptor-binding domain of IgE. This binding is specific toward free IgE, thereby preventing it from attaching to the mast cell and its subsequent activation. In adolescents and children with SAR, there was a significant reduction in the nasal and ocular symptoms, with a side effect profile no different from the placebo [8]. Recently the systemic or conjunctival administration of immunostimulatory sequence oligodeoxynucleotides (ISS-ODN) has

been shown to significantly inhibit both eosinophilia and neutrophilia in the late-phase reaction in a mouse model of ragweed-specific conjunctivitis. This indicates that ISS-ODN may be an effective novel approach that may be useful in the treatment of SAC and VKC [129].

Effective treatment of contact lens-associated GPC might be possible in the future by employing inhibitors of LT synthesis and action [89].

Pediatricians and Eye Allergy

The eye is often considered as an incompletely defined accessory during childhood, but when inflamed – and generally when it is reddened – it automatically becomes the recipient for creams, eyewashes, etc. (hardly ever prescribed by a doctor), commonly for esthetic reasons, with less concern for eyesight [189]. AC, VKC, and AKC usually affect the child's quality of life, also because the illness is clearly visible, and can become the cause of an inferiority complex in older children, but this aspect, as all the others emphasized here, is normally ignored. Limitations in normal, relational and emotional spheres of life emerged from investigations concerning the quality of life for children suffering from SAC due to symptoms [94]: a pediatrician knows how these problems are also important for adolescents and to what extent they affect their quality of life. The clinical manifestations are important; however, a correct consideration of the emotional aspects will reflect effectively on the symptoms. The treatment of ocular disorders has focused to date on symptomatic relief, but just as we have a better understanding of the mechanisms, we now have better therapeutic interventions. With further discovery in the basic understanding of these conditions, we may eventually develop even better preventative therapeutic strategies [15].

Allergy to the Venom of Hymenoptera and Other Insects

Historical Data

Hymenoptera, an order of bees and wasps, were known and written about by the early Latin and Greek scholars: Aristotle (384/383–322 B.C.) accurately reported on the bees, Aristophanes (445–385 B.C.) titled one of his comedies "The Wasps" and Virgil (70–19 B.C.) described them in the "Georgics," although they first appeared in a hieroglyphic of 2641 B.C., attributing the death of Pharaoh Menes to a wasp sting, and a note in the "Babylonian Talmud" reports an analogous fatality [15]. In France in 1765, the first reported case of mortal anaphylaxis in a 30-year-old who had twice suffered near fatal episodes was published [19]. In 1914, the anaphylactic shock induced by insects was identified with the anaphylaxis described by Portier and Richet [134]. From the scientific point of view in 1978, during a prospective study of the disease, the venom was recognized to be the causative agent responsible for Hymenoptera sting hypersensitivity [53]. As a result of a deeper understanding of the mechanisms of this illness, a radical change in both the identification of venom and allergen components and in the diagnosis and treatment has been reflected in a positive sense towards the practice of SIT (specific immunotherapy). Recently, interest in other insects by researchers looking at this study has broadened.

Definition

Allergy is an abnormal response to the bee sting, especially that of the order Hymenoptera. This abnormal response is not so much a consequence of the toxic effect of venom constituents in honeybee, yellow jacket, hornet, and wasp venoms, but rather is secondary to an IgE-mediated reaction to those constituents.

Epidemiology

The pediatric prevalence of insect allergy is reported in Chap. 5. Insect allergy is relatively more common during the pediatric age group up to about 20 years of age, with a male to female ratio of 2:1 and in those who are atopic, it is on the order of 33% [109]. The incidence in children of about 0.4%–0.8% [96]. Classical textbooks defined systemic reactions as uncommon in children: three studies by Settipane et al on 10,057 boy scouts and girl scouts demonstrated a prevalence of 0.4% (medical diagnosis) *compared to 1.9% of those questioned* [1, 116, 118], with a slight increase in the atopic population [118], while those in the general population revealed an increase of 3% [32]. In one study on 3,236 subjects who had an adverse reaction to insect bites, the prevalence during the pediatric age was 31.8%, with a net percentage of moderate or severe reactions of 56% [62]. In the Swiss Canton of Bern, the annual incidence of anaphylaxis ranged between 7.9 and 9.6×10^5 inhabitants per year. Hymenoptera stings (58.8%) were the most commonly identified culprits for anaphylaxis [46]. Among 229,422 children and adolescents with a median age of 12 years studied between March 1, 1991, and December 31, 1997 there were 30.8% of probable and 15.2% of possible cases of anaphylaxis to Hymenoptera stings and 2.8% of probable and 1.9% of possible cases of anaphylaxis to toxic effect of venom [7]. Ninety five episodes of anaphylaxis occurred in 76 Italian children and 36.4% were for bee, 36.4% for wasp and 27.2% for Polistes [77]. The lethal episodes at minimal levels are more frequent in adults [97] ($\times 10^6$): Switzerland 0.45, France 0.43, Denmark 0.25, Germany 0.18, USA 0.14–0.16, Great Britain 0.09 [70]; in total the rate does not exceed 50–100 cases per year, which translates into 40 in the USA, 20 in Europe [70], 37 in Japan [2], etc. In Australia the mean annual incidence rate was of 0.02 deaths $\times 10^6$ per year [67]. As regards the death incidence related to single insects, in Sweden, this is 0.95/year for wasps and 0.05/year for bees [56], in Denmark is 1.3/year for wasps and bees [69], in the US wasp and bee sting fatalities occur with approximately equal frequency [4]. As to the pediatric prevalence, in an average decade the number of fatal cases regarding children <10 years of age in the US was 1%, those 10–19 years was 0.5% [38], while in 163 autopsies performed, 1% referred to children who were 4–10 years old and 5% to those who were 11–25 years old with a male-to-female ratio of 5:1 [74]. Postmortem blood tests of a 10-year-old girl who collapsed on the street and died after a bee-sting revealed increased total IgE level as well as increased levels of sIgE (specific IgE) against bee and wasp venoms [75]. A retrospective study of a series of 94 suddenly deceased subjects in the absence of other determinant illness revealed that, in 23% of these (two of whom were 15 and

Table 17.1. Taxonomy of stinging Hymenoptera important in clinical allergy

Order	Hymenoptera						
Suborder	Apoides		Vespoidea				Formicidea

	Apis mellifera Honeybee	*Bombus pennsylvanicus* Bumblebee	*Vespa crabo* European hornet	*Vespula* spp. Yellow jacket	*Dolicho-vespula* Yellow hornet[a], white-faced wasp[b]	*Polistes* spp. Paper wasp	*Solenopsis* spp. Red fire ant[c], black fire ant[d]

There is a marked cross-allergenicity between the genera *Vespula* and *Vespa*, broad cross-reaction between *Vespula* and *Polistes*, and negligible cross-reaction between Vespidae and Apidae families.
[a,b]These are more properly the names of *V. arenaria* and *V. maculata*, respectively.
[c,d]These are more properly the names of for *S. invicta* and *S. richteri*.
Data from [82, 138].

20 years old) sIgE was present for at least one type of Hymenoptera venom [114], suggesting that *a number of cases remain misdiagnosed.* This is indirectly confirmed by significant reports of parents who were unaware whether their young children, aged 15–39 months, had had a previous allergic reaction to imported fire ant sting [3] and in 15% of 269 adults who presented with an unexpected positive skin prick tests (SPTs) [32]; therefore a few subjects who were bitten did not consult with a physician [32]. For these reasons, we can not offer complete epidemiological studies.

Characteristics of Hymenoptera

Taxonomy and Entomology

The order of *Hymenoptera* contains about 16,000 species in only North America [41], of various forms and dimensions endowed with a unifying characteristic, two pairs of membranous wings [41].

The diffuse species found in Europe are essentially part of the families of *bees and wasps* (Table 17.1) [82, 138] (Figs. 17.1–17.4), while those found in the US also include some formicids (ants) [124]. Only the females of the pointed Hymenoptera are equipped with stingers and venom sacs, which are formed following atrophy of the reproductive apparatus [82]. However, it has been disputed that the various venom components demonstrate a significant homology with proteins derived from the male reproductive system, suggesting that this derives from a separate venom apparatus (Fig. 17.5) and not from a modified ovipositor, as traditionally believed [54].

Bees (Figs. 17.3 and 17.4) in general are rarely aggressive towards man, because since ancient times the bee has been domesticated for honey and wax, thereby resulting in a close relationship with man [80]. The domestic bee is distinguished morphologically by its stout body, which is covered with fuzzy hair and a black-brown coat with brown-yellow transverse stripes [41]. The aggressive instinct changes according to the colony

and is habitually influenced by age (older bees are more aggressive), by adverse atmospheric conditions and also by periods of insufficient gathering of pollen [5]. The bees in fact have a particular activity that they perform known as pollination, in which they diffuse or spread the pollen of the flower chosen because of its nectar and in so doing they guarantee the reproduction of those particular flowers [80]. Bees are provoked or stimulated by brilliant colors, perfumes, vibrations, sharp movements, distinctive noises, etc. [10], but above all by traversing the corridors of flight or flight paths used by foragers to perform waggling dances containing information about the distance and direction to food sources [22]. The food-location information in the dance is presumably important when food sources are hard to find, variable in richness and ephemeral, whereas colonies with disoriented dances (lacking directional information) recruit less effectively than do colonies with oriented dances [106]. The bee is the only insect to leave the stinger (Fig. 17.6) embedded in the skin of the victim: in fact it does so because of the stinger's anatomical form of a serrated edge (Fig. 17.7). The stiner detaches and remains in the flesh together with the entire distal segment of the bee's abdomen, various muscles, and the venom sac, thereby causing evisceration of the insect and as a consequence its death [68, 80, 132]. The sting consisting of two lancets with curved barbs continues to inject venom after separation from the bee because the detached stinger is attached to a nerve ganglion that continues to coordinate its movement and in so doing, the barbs provide one-way traction and the sting continues to pump venom deeper into the flesh [132].

The *bumblebee* is distinguished by its larger dimensions, its black coat or alternating yellow or orange stripes and its layer of fuzzy hair. Allergy to bumblebee venom is a rare form of Hymenoptera venom allergy. Since this insect is increasingly utilized for the pollination of greenhouse plants, allergic reactions are increasing subsequent to its stings [41], especially when it attacks in order to defend its nest. The bumblebee moves

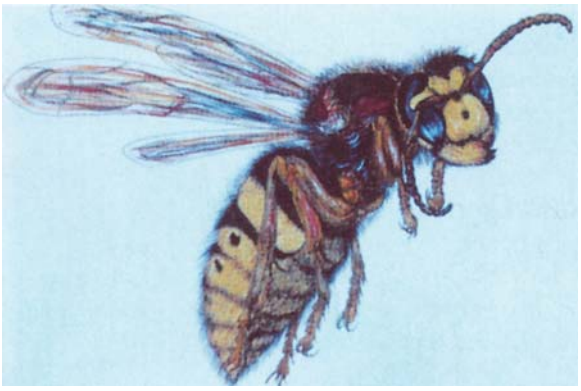

Fig. 17.9. Dolichovespula media

Fig. 17.10. Hornet

very slowly and in so doing man has time to make an escape long before the defender has left its nest [41]. Among the vespids (Figs. 17.1, 17.2) (yellow jacket, hornet and wasp), the genera *Vespula* and *Polistes* have a fusiform body and smooth coat, with black and yellow stripes (Figs. 17.8, 17.9) [68]; in addition, the *Vespula* has a distinct abdominal form, which is joined to the thorax by a thin stalk. These Hymenoptera nest underground, for example in the interior of caves that are not being used by other animals (mice, moles, etc.), or externally in hollow logs among the roots and debris of trees. They have a pugnacious attitude, especially in late summer or autumn, stinging even though not provoked; therefore they are responsible for numerous allergic reactions [10, 41, 68] The *Polistes* possess long legs characteristically distended during flight. In addition, the position of the nest is typically located above or around inhabited buildings, high wall cavities, roofs, windows or the branches of trees, in general of small dimensions and constructed of paper-like materials leading to the English denomination of paper-wasp [10, 68, 80]. In the vespids, the stinger lacks barbs (Fig. 17.6), which allows the extraction from the skin without further damage, providing that no traumatic events such as crushing are involved [80]. The formicids, especially the red imported fire ant (*Solenopsis invicta*), provoked a systemic allergic reaction in 94% of children (aged 15–39 months) and *Solenopsis richteri* in 100% of cases) [3] represent a serious allergic problem in the USA [124], less in Europe [115]. The potential for anaphylactic events caused by *S. invicta* is greater than for native ants because of its unusual venom [123].

The *hornet* (principal allergen Vesp c 1) (Fig. 17.10) is recognizable by its larger dimensions (>3 cm), builds its nests in the trunks of hollow trees, decaying logs, stumps or in wall cavities and may sting children of nursling age. It frequently flies at night and is attracted to light [41].

Hymenoptera Venom

The injected venom contains immunogenic proteins and nonallergenic substances, including biological amines and irritants (Table 17.2 [73, 82, 138] and Table 1.74 for the allergens). The most important, including those most studied, are Api m 1 and Api m 2, two enzymes that constitute 7%–15% and 0.5%–1.5% of the dry weight of the venom, respectively [51], and Api m 3 (melittin) corresponding to 50% [59]. Api m 1 is a very powerful allergen, even through inhalation, and 95% of patients with allergic reactions are sensitized to the bee sting [59]. We point out that all the allergens with the # 1 correspond to phospholipase A2/B, with the # 2 (Table 17.2) to hyaluronidase and with # 5 to progressive antigen 5. The numerous nonallergenic substances help to explain the prevalent vasoactive reactions and are responsible for the normal local reactions caused by the bite [70]. For example, bradykinin reinforces the inflammatory activity of the venom and contributes to the pain that it causes and hyaluronidase, constantly active (as Api m 2, Dol m 2), favors the intracutaneous penetration of the venom [84]. Many venoms contain histamine and some kinins; melittin has a potent histamine-releasing activity [54]. The presence of leukotrienes, above all LTC_4, accounts for the possible persistence of edematous reactions [17]. The cross-reactivity between the bee and wasp venoms seems to result from the presence of IgE anti-hyaluronidase [51]. Finally, the quantity of venom injected, from 2 to 100 µg (Table 17.3), with a single puncture varies in relationship to the species and age of the insect [10], although some wasps have been known to secrete as much as 330 µg [113].

Table 17.2. Venom nonallergenic substances

Apis mellifera	Bombus	Vespinae		Polistes	Solenopsis
Api m 1	Bom m 1	Dol m 1	Ves m 1	Pol a 1	Sol i 1

Genetic and Environmental Factors

The sensitization and the natural history of the illness are influenced by a composite interaction of genetic and environmental factors.

Genetic Factors

It has been seen that in 13.1% of families in which allergy to Hymenoptera is present there are subjects with the same type of sensitivity, vs 3.1% of the controls (p=0.0195) [30]. With the study of HLA alleles, analyzing the skin infiltrates of 23 Hymenoptera venom-allergic patients, the subcutaneous (SC) application of Hymenoptera allergens induced a perivascular and periadnexial cutaneous mononuclear cell infiltrate consisting mainly of $CD4^+$, $CD45RO^+$ and $HLA\text{-}DR^+$ cells [57]. Moreover, basophilic granulocytes in allergic subjects, compared with those in healthy persons, showed elevated expression of CD32, CD122, CD124, CD130, CD154 (Table 1.2), and HLA-DR [120].

The prevalence of atopy is considerable at all ages. In 688 boys with a family history of atopy (FHA) and positive SPTs, atopy was 32% [62], in 19 toddlers it was 63% and a history of atopic disease was elicited in 47% [3]. In one Italian study, a personal history of atopy was present in 22.7% of children [82]. *Serum sIgE to Hymenoptera* venom was *significantly associated with young age* (children vs adults, odd ratio (OR), 2.80 [104]). In one survey of 525 adults, atopy was present in 25% and serum IgE levels were ≤100 kU/l in 48% [94]. The analytical goal of four studies of non-beekeeping adults revealed the percentage of atopy: on the basis of personal case histories it found between 10.8% and 65.9%, while in three cases of beekeepers and their families the rate was between 29.6% and 47.1% [94]. An increased prevalence in families of non-beekeepers is anomalous, because a clearly increased risk is expected in a family of beekeepers, or may in general be expected with life in the country [82] or suburbs. FHA was negative in ten children with negative SPTs to Hymenoptera venom [76].

Environmental Factors

Not to be ignored are the risks associated with environmental factors, listed in Table 17.4 [63]. Besides the correlation between exposure and risk of sensitization, a peculiar aspect is represented by the chronology of the stings. The study of 120 patients who had demonstrated a systemic reaction for the first time to a Hymenoptera sting and of 100 healthy controls showed that the shortness of the interval of time (<2 months) between the last two punctures represented a significant risk factor for the development of allergic reactions [95].

Data from [63].

Natural History

The natural history demonstrates that babies and adolescents have *a risk = 10%–20% of reporting systemic reactions* after successive bites, therefore less than that of adults, who show a risk of 27%–57% [40, 110, 116–118, 121, 127, 129]. A much debated problem stems from the variability of the response: it is possible that some patients with progressive serious allergic reactions to the first puncture present no reactions to successive bites and are not in the desensitized state; in other subjects it is possible that a second puncture causes an increase in sIgE levels, thereby provoking more serious reactions [97, 99]. It has been observed that the risk of presenting with a serious reaction after a localized puncture is 5% [70, 99]; in addition, after a serious systemic reaction it is possible, at least in 40%–65% of cases, that a successive puncture is better tolerated and less consequential [53, 70]. This raises the question of whether in a baby serious reactions, after a cutaneous lesion, can be verified, even with a very favorable prognosis. Three pediatric studies (2–17 years) demonstrated that after localized reactions, the risk of systemic reactions, that is without acquiring characteristics of particular severity [129], as a consequence of successive stings is minimal [110], 2% [40] or 9.2% [110] of the cases. In another case report [98], the percentage of

reactions, independent from the period of time from successive punctures, was 46% in 112 children ≤16 years of age and 74% in adults. Usually, clinical features range from urticaria to anaphylaxis [96].

Etiopathogenesis

Bee and wasp venom extracts contain potent allergens able to induce severe clinical reactions [136]. The sequence of events in the allergic reaction of the immediate type is summarized in Fig. 17.11 [68]: the first contact with the allergen (preparatory) is not always followed by the second contact (provoked) [68]. The IgE-mediated pathogenesis is demonstrated by the presence, in subjects with Hymenoptera venom hypersensitivity, of a highly differentiated percentage of IgE^+, which is significantly greater than in nonatopics ($p<0.001$) [21]. After an extensive local reaction, such patients have SPT+ and, after a generalized reaction, venom-sIgE antibodies by interaction on mast cell surfaces [59]. However, there is the possibility, although rare, of non-IgE-mediated reactions caused by exogenous vasoactive amines delivered by the insect venom [97]. The contact with sIgE induces the liberation of histamine, leukotrienes, prostaglandins and other mediators from the metachromatic cells: in adults subjected to intentional challenge with insect venom [130], a notable increase has been demonstrated in the levels of histamine and tryptase (1.275±2.294 and 406±1.062 nmol, respectively), but not prostaglandin the level (specifically of PGD_2), an effect of Api m 1, which is also capable of interacting with specific lymphocyte clones with production of elevated titers of IL_4 and IFN-γ [20]. *Elevated levels of tryptase* have also been noted in the serum of recently deceased patients secondary to insect bites [138]. CD203c up-regulation on basophils activated by molecularly defined allergens was induced by defined Hymenoptera venom components in 35 of 39 patients with a diagnosed allergy to wasp and/or bee venom. Twenty-seven patients with wasp allergy showed *CD203c up-regulation in response to Ves v 5,* and 26 also reacted to Ves v 2 and 17 to Ves v 1 [7]. A recent trial observed that the lower the titers of angiotensin I and II the more severe the clinical symptoms in patients with a history of hymenoptera venom anaphylaxis [49].

From the events so far summarized, three phases can be discerned [70]:

- *Increased vascular permeability,* peripheral vasodilation, sequestration of fluids, therefore hypovolemic shock
- *Disseminated intravascular coagulation* with potential generalized hemorrhage and consequent aggravation of the hypovolemia
- *Hypoxia* induced by bronchoconstriction and cardiotoxicity secondary to the mediators from which the cardiac insufficiency and arrhythmias are derived, all contributing to shock

The IgE-mediated mechanisms are clearly evident when the symptoms are immediate. The allergic pathogenesis is more difficult when the reactions are localized, in so much as one cannot verify a progressive diffusion of the edema, which may not depend upon vasoactive amines whose half-life is too short to sustain such a manifestation but may imply instead an allergic mechanism. In addition, when the intensity of the reaction provoked by the sting increases dramatically, it is a sign that there is an IgE-mediated mechanism [70], which should set off alarm bells. Localized lesions at a distance from the initial puncture would have the ability to cause allergic processes [84]. Lacking allergenic stimulation, IgE levels diminish slowly, in variable measure from subject to subject, although they are capable of remaining high for years [99]. The release of secondary mediators from the inflammatory cells (eosinophils, neutrophils, macrophages, etc.) is probably responsible for the less common form of *protracted or biphasic delayed anaphylaxis* [80], whose incidence is about 3%–4%. The delayed reactions bring to light the intervention of other immune mechanisms, similar to type III reactions, which may appear within a few hours, or type IV reactions if the interval is 1 day [84], although they can also manifest themselves days or weeks after the puncture. A subject bitten many times within a short period of time may undergo a toxic reaction in which the symptoms are similar to IgE-mediated forms, but if the SPTs become positive the subject may be at risk of allergic reaction to a subsequent insect sting [97]. These venom-induced variants usually occur in nonatopic children [76].

Clinical Presentation

In normal subjects, the lesions consist of a localized reaction characterized by erythema, edema and pruritus, with a pain component of variable intensity. They regress spontaneously or with local therapy within a few hours, usually without leading to particular concerns in small children or relatives. In some cases the response is exaggerated with extension of the local reaction. The reactions are generally prevalent in the head and neck regions, although they may present to any other region of the body [70, 97].

The reactions are distinguished as *either immediate* (within 2–4 h of the sting) *or delayed* (>4 h); the immediate reactions are summarized in Table 17.5 [70, 72, 81, 97, 107] (Fig. 17.12). In 70%–80% of cases, the systemic reactions are not life-threatening [107].

The symptoms, for the most part, begin after 10–20 min *without any warning signs* [133]. The symptoms present either in isolation or grouped together. In the immediate type reactions, the rapidity of the insurgence is, in general, an indication of the severity of the clinical picture [80]. The most serious reaction caused by the puncture of the Hymenoptera is *anaphylactic shock* and

Table 17.5. Features of immediate reactions (local and systemic) to Hymenoptera stings

Immediate reactions [72, 81, 97, 107]	
Mild local reactions, with pain, localized to the sting site, transient erythema and swelling, usually last a few hours and involve 90% of children	
Large local reactions, with erythema and edema, extended up to half of the stung limb, type urticaria-angioedema, which peak within 24 h and last for up to 1 week (10% of children)	
True systemic reactions involve different organs and systems:	
Gastrointestinal: nausea, vomiting, abdominal pain, diarrhea	
Respiratory: laryngeal edema, rhinitis, dyspnea, bronchospasm	
Cardiovascular: hypotension, cardiovascular collapse and anaphylactic shock	
Toxic, nonallergic reactions, with onset after several stings, and include fever, nausea, vomiting, and other systemic symptoms	
Systemic reactions [70]	
Grade I	Generalized urticaria, itching, malaise, anxiety
Grade II	Any of the previous symptoms plus two or more of the following: nausea, abdominal pain, vomiting, diarrhea, generalized angioedema, bronchospasm, wheezing, dizziness or fainting
Grade III	Any of the previous symptoms plus two or more of the following: dysphagia, dyspnea, hoarseness, weakness, confusion, deep anxiety and sense of impending death
Grade IV	Any of the previous symptoms plus two or more of the following: cyanosis, hypotension, cardiovascular collapse, urine or stool incontinence, loss of consciousness

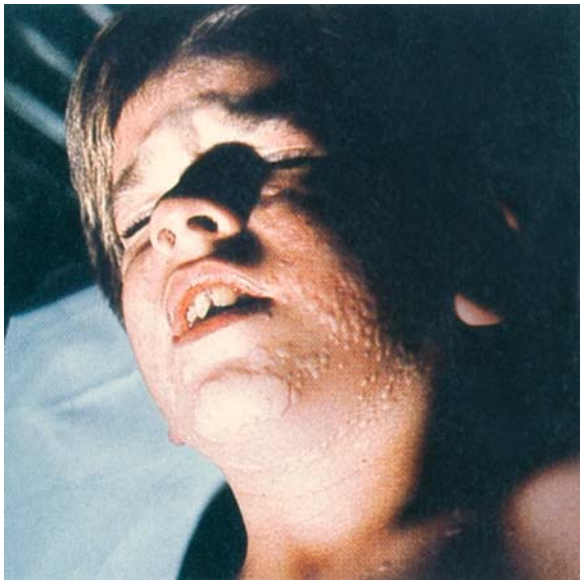

Fig. 17.12. Acute urticaria as part of a systemic anaphylactic reaction. In similar cases SIT for Hymenoptera is obligatory

it is not common to any particular age group [60, 61]; the symptoms have analogous characteristics to those observed in the reactions caused by other allergens: hypotension, bronchospasm, swelling of the epiglottis, gastroenteric symptoms, sphincteric incontinence and loss of consciousness [133]. This was the case of a 12-year-old boy who was stung by a swarm of yellow jackets. Immediately he developed severe pain at the site of sting and swelling all over the body. He complained of *constricting sensation in the chest within minutes.* His condition was so severe that he was *discharged after 30 days in the hospital* [126]. The delayed reactions may cause atypical reactions, including serum sickness accompanied by sIgE and IgG antibodies, renal complications, vasculitis and neuroencephalitis, transverse myelitis, myocarditis, vascular lesions which lead to vasculitis, nephrosis, etc., all of which are rarely fatal [100]. During the pediatric age, the following reactions present a notable risk, even though they are rarely observed after the sting of a wasp: collagenosis associated with arthritis, purpura, melena, terminal myocarditis, nodular pericarditis, nephritic syndrome or glomerulonephritis [84].

Imported fire ants defend their territory aggressively and make extensive use of pheromones or chemical signals to recruit other workers, synchronize attacks and initiate stinging. For this reason, multiple stings are the rule rather than the exception [123]. Imported black and red fire ants (Table 17.1) stings typically cause a pustule 24 h after the sting. *Red imported fire ants* (Fig. 17.13) are inconspicuous, reddish-brown ants with no distinguishing features visible to the naked eye. Superficially, they resemble many common native and exotic ant species present elsewhere. They range in size from 2 to 6 mm; their optimum habitats include grassed areas, gardens, sites near flowing and still water and recently disturbed soil [123]. The natural history of fire ant hypersensitivity in children who have only cutaneous manifestations has not been well elucidated. Because there is increased risk of fire ant stings in children who

live in areas where fire ants are prevalent, SIT may be recommended for such children [93].

Müller has differentiated the systemic reactions into *four degrees of increasing severity* (Table 17.5), which helps to distinguish the reactions that are less life-threatening, reactions limited to the skin and gastroenteric apparatus (grades I and II), and reactions involving the respiratory airways, cardiovascular apparatus and finally sensorium (grades III and IV), which are reactions leading to a more severe risk, especially those caused by Solenopsis [12]. Table 17.6 shows the prevalence of these reactions, whose average is on the order of 20.3%, 52.7% and 35.4% in four pediatric cohorts [39, 82, 98, 110], and which is less frequent with respect to adults 43% vs 56% (p=0.0019) [39]; 59.6% of the cases are not life-threatening, a number less than usual [107] and similar to the numbers derived from other selected cases. The *increased prevalence of severe life-threatening systemic reactions* in the 112 babies [98] suggests that there is a relationship with progressive episodes of anaphylaxis and with nonadmission to SIT. In 10 of 76 children aged 3–13 (12%), Hymenoptera venom caused 11 episodes of anaphylaxis; sIgE against Polistes were detected in 3 cases, against wasps in 4 cases, and against bees in 3 [76]. In 107 children, Hymenoptera venom was the second most frequent cause of anaphylaxis (29%). Most of the patients with Hymenoptera venom anaphylaxis were male (80%) and more frequently they had no history of atopy [13]. Among 1,175 children, 228 (19.4%) had a history of Hymenoptera sting reactions [34] or 19.06% local reactions and four 0.34% local and systemic reactions) [77]. Quite differently, in 91 children the clinical symptoms were anaphylaxis (15.3%), serious reaction (37.3%), strong reaction (34%), and mild reaction (7.6%) [96].

The prevalence of the clinical characteristics of the reactions seen in infancy is summarized in the second part of Table 17.6 [35]. Usually, the reactions in children are generally *limited to grades I and II*, with a more favorable clinical outcome and a mortality incidence clearly lower than that of adults.

Müller has, in addition, stated that patients developing side effects during SIT are exposed to a significant risk of relapse [71], and factors such as age and type of the reaction influence the natural history of anaphylaxis to Hymenoptera stings. Recent observations indicate that for the majority of patients the event is self-limiting [98].

Diagnosis

A detailed case history is of capital importance; the investigation assumes particular prominence when there is positivity within the personal and/or family histories,

or when there are family activities or environmental characteristics where the patient lives that can increase risk. Besides the clinical aspects of the reaction and its progression subsequent to another sting, it is opportune to be able to identify the Hymenoptera that is the cause of the reaction, even though there may be great difficulty in doing so, because of the child's or relatives' inability to describe the particular morphology of the insect in question or their inability to remove the stinger [127]. It would be useful if the health provider working in the area, even though it may be risky, could provide photographs or specimens preserved in formalin to show the patient and/or relatives, with the aim of having valid criteria or evidence beyond that of the diagnosis before subjecting prospective patients to SIT [127]. In 47.7% of cases, there is a correct identification of the insect responsible, primarily by families of beekeepers [82]. However, *young children* present special problems in diagnosis because they *are usually not able to identify the insect.* The presence of a stinger, which is left by bees, or the presence of a pustule as a result of a fire ant sting (up to 24 h later) may help in insect identification [93].

SPTs are preferably done with caution and in a hospital environment because of the possible risks. Because the insect that caused the sting often cannot be identified, testing is usually done with all of the commercially available venom extracts [93]. It is suggested to employ the purified venoms corresponding to the national entomological origin when considering the taxonomy (Table 17.1). Lyophilized venoms exist for mellifera bees, *Vespula* species and *Polistes* species [138]. There are reactions in the US, besides those to the *Solepnosis* spp., to the *Halictidae*, of the Apid family, which are difficult to diagnose [85]. In the case of suspected fire ant hypersensitivity, SPTs should be done with whole-body extract [93]. SPTs are the first tests to be done in children, but several studies were prudently based on concentrations of 1 µg/ml, which in case of negativity were continued with intradermal reactions (IDR) performed at 30-min intervals [84]. The maximum concentration of 1 µg/ml for the IDR was used [18]. However, this procedure has led to a decreased rate of positive SPTs. Using SPTs with standardized venom extracts at a concentration of 100 µg/ml, 3.66% of 1,175 children had positive SPTs to any given Hymenoptera extract, 2.98% to honeybee venom, 1.45% to wasp, and 1.02% to *Polistes* venom [77]. Proper SPT execution ensures a positivity in the range of 95% in the absence of any complications [84]. However, although SPTs may be able to identify the different sensitivities, there is not a good correlation between the degree of response, the severity of the progressive reactions and the probability of a reaction to another sting [107]. Müller [70] recommends performing SPTs between the 1st and 3rd month after the acute allergic manifestations in order to guarantee a sufficient amount of mast cell mediators.

The RAST was negative in 15.4% of 52 children with a positive SPT [82], and is therefore less credible as a screening method [61]. RAST testing may be considered for those patients who have a convincing history of anaphylaxis after an insect sting and who have negative SPT responses [93]. RAST is very useful in the immunological monitoring of subjects who were both treated and not treated with SIT [81] because of RAST sensitivity to *Vespula* and *Polistes* species, both seen in 101 children (17.8% SPT and 10.9% RAST positivity) [82]. In another pediatric study, the SPT results were 80.7% positive and 71.7% positive to RAST, with a high concordance for both cases [81]. It should be noted in the interpretation of both SPT and RAST results that the reactivity to Hymenoptera venom compared to common inhalants increased in atopic patients [81]. A partial analysis by Müller determined that *both tests distinguish between positive and negative patients* (p=0.0001 and 0.0036, respectively), while the predictive value with respect to a successive puncture is less significant [71]. Other results appear to contradict this, disregarding the value of these tests [131], or recognizing a good concordance between SPT and RAST results for bee venom and a very good SPT sensitivity to wasp venom [26]. CAP has both a rapid and a good sensitivity, correlates well with the history, the SPTs and the RAST with which it has an increased sensitivity [55]. A method based on RAST inhibition distinguishes between the various RASTs positive for the venom and is attributable to IgE cross-reactivity [42]. ELISA is well correlated with RAST and is less costly [92].

We face SPT-negative results in about 10% of people with elevated RAST and RAST-negative results in about 20% of subjects with positive SPT results [36] *when we need to treat a child at risk.* Several adult trials have concluded that it is a self-limited process for difficult cases, where history, SPTs and RAST do not allow a clear decision regarding the relevant insect species for VIT [37]. In cases with contradictory test results, additional tests are recommended such as a test based on basophil CD63 expression as marker of activation in comparison with the basophil histamine release test and the cellular antigen stimulation [23] and cellular tests for IgE-mediated reactivity [24], which may not be available everywhere [37]. It is also true that in a trial on 149 people, only five (3.35%) with severe insect sting anaphylaxis had negative SPT reactions up to a venom concentration of 0.1 µg/ml [60]. In parallel, only 0.9% of 208 insect-allergic patients had both venom SPTs and RAST negative and still reacted to a challenge sting [34]. In adults, intentional provocation tests for diagnostic purposes [130, 131] were given in a hospital environment with live insect punctures to the skin in order to test the state of tolerance to successive stings by the same Hymenoptera (and to determine the indications for SIT [99]). In fact up to 72% of the adults with a history of prior reactions, even severe, did not present with any symptoms to a successive sting [99], while a 10%–15% positivity was found in a stimulatory test on skin-negative subjects [131]. According to these results,

the test was not in fact true and proper proof of whether protection was reached or not [99]. It was also demonstrated that if venom emission during the procedure was in the form of a spray, it could reach the patient in a negligible measure, explaining why at times a single challenge is not sufficient [29]. In other studies, 21% of adults who were negative to the first test proved positive to the second test with systemic symptoms in 50% of cases; nor was it proven that patients negative to this test were completely free of reactions to successive stings [131]. Therefore, fixed rules need to be instituted regarding the clear ethical problems [97]. In contrast, it could be useful diagnostically in subjects who are SPT+ to avoid subsequent bites and live a normal life [31]. In 21 children (aged 4–15 years) with bee-sting allergies, sequential challenges done to establish the need for VIT provoked on the first challenge a normal local reaction in 33% of the children, a large local reaction in 29%, and a systemic reaction in 38%. On the second challenge, the reactions were 67%, 22%, and 11%, respectively, in 18 out of 21 children [45]. However, *in children sequential bee-sting challenges have a high negative predictive value of 94.6% for the risk of further systemic reactions* [112] and may be a powerful tool to determine the necessity for VIT in bee-venom-allergic children [111].

One study on 113 children between 2–17 years answered these questions positively [44]. In particular:

- While 84% of the subjects had a history of severe systemic reactions and 16% of extended local reactions after the two challenges had comparable results, in 76%–78% the reactions were normal local, in 1%–5% they were extended local and in 13%–17% systemic.
- VIT was prescribed to all subjects with a history of severe systemic reactions or who developed them after the challenges.
- In the subsequent period after the procedure (2 weeks to 35 months) 40% were once again stung. Of the six treated with VIT, one presented with urticaria, while of the 39 not treated only one developed moderate respiratory symptoms.
- In comparison with other diagnostic evaluations such as SPTs, determinations of specific IgE and IgG antibodies and single-sting exposure, the dual sting challenge scheme appears to be the best predictor of reactions to subsequent stings [44].

Following this study, 78 of 92 children fulfilled the current criteria for VIT [26], but only 13 received VIT based on challenge studies.

- Therefore 65 of 78 children (83.3%) would have undergone unnecessary therapeutic interventions using the above guidelines.
- Two of the 13 children (15.4%) developed systemic reactions 1 year after VIT of 5 years, of which one was mild and one was severe.
- Among the 48 re-stung children who were not treated with VIT, three (6.3%) experienced mild systemic reactions, whereas 45 reported no more than a local reaction.
- The long-term predictive value of sequential bee-sting challenge tests for systemic reactions in children who are not SIT-treated remained at a level of 93.8% over a period of >5 years [111].
- Sequential bee-sting challenges are thus critical to establish whether to start VIT in bee-venom-allergic children [111].

Adult data justify the recommendation that patients with a history of a systemic reaction but negative venom SPTs should be evaluated by RAST, and if still negative, by repeat SPT after 3–6 months [34].

Treatment

The treatment for the reactions that result from insect bites and VIT, including first aid, is as follows [72].

If the sting remains within the puncture site it must be extracted delicately without producing any kind of pressure that may risk emptying the contents of its venom sac into the lesion [113]. *It does not matter what method is used*, but time to remove the venom sting is important [132]. The venom sac breaks in 90% of cases emptying in <20 s, and on average after 2–7 s 53 µg are released, after 8–16 s 133 µg are released, and after >16 s 148 µg; therefore *the quicker the reaction the better the prognosis* [113]. If a limb is involved it is convenient to place a tourniquet proximal to the puncture site in order to retard venom diffusion, releasing the pressure every 3 min until the elective treatment is started [84]. If the local reactions are not extensive they can be treated with cold packs or with antihistamine ointment. Cold compresses may help to reduce local pain and swelling. Local anesthetic cream and oral antihistamines are useful to reduce the pain or itching associated with cutaneous reactions [93]. In cases where the reactions are extensive or with manifestations of urticaria-angioedema, a tourniquet should be applied as described above and epinephrine injected subcutaneously (Chap. 20). Therefore, the cornerstone of emergency treatment to avoid death, which may ensue within 1 h in the majority of cases, is epinephrine administration, whose action is *immediate if injected IV* or within a few seconds if injected SC or IM [124]. For the treatment of anaphylaxis, see Chap. 20. Tables 17.7 and 17.8 report the treatment schedules for cutaneous and respiratory reactions indicated in the Position Paper of the specific EAACI (European Academy of Allergology and Clinical Immunology) subcommittee. If the symptoms progress towards anaphylactic shock it is imperative that children be hospitalized [26].

With reference to the use of VIT, it was demonstrated in 1978 that employing the entire body the treatment results did not differ from those found in placebo patients, while utilizing the venom resulted in positive results in more than 95% of cases [53]. However, *since 1956 Dr. Loveless has proven the superiority of VIT* [64, 65], using extracts of venom sacs removed from vespids that she

Medical treatment	Additional treatment
Large local reaction	
Antihistamines H_1 oral (cetirizine, clemastine, loratadine, etc., dosage see Table 12.10)	Apply ice or cold compresses
Corticosteroids, oral (prednisolone 0.2 mg/kg bw)	Immobilization and elevation of the affected limb
Systemic reaction, urticaria-angioedema	
Antihistamines H_1 IV (clemastine) or subcutaneous adrenaline (Chap. 20)	Continued observation until the child improves for at least 1 h
Corticosteroids, IV (prednisolone 0.2 mg/kg bw)	

With protracted symptoms, readminister adrenaline every 10–20 min (Chap. 20).
Data from [26, 72].

Table 17.8. Pediatric emergency treatment of Hymenoptera sting. II: Respiratory reactions

Medical treatment	Additional treatment
Bronchial obstruction	
Epinephrine (Table 11.17)	Inhaled epinephrine
Albuterol or terbutaline to be repeated more times	O_2 supply by face mask, until full improvement
If severe, albuterol, IV (Chap. 20)	In severe cases hospital
Corticosteroids, IV (prednisolone 2 mg/kg bw)	Admission or intubation
Theophylline	
Laryngeal edema	
Epinephrine, SC or prednisolone/methyl-prednisone IV	

With protracted symptoms, readminister inhaled epinephrine every 10–20 min (Chap. 20).
Data from [26, 72].

had captured personally [65]. However, her studies were not taken into consideration because they were not conducted using double-blind controlled procedures [16], even though periodic deliberate stings were performed by Loveless [64], without convincing the medical community of the benefits of this approach [38]. Recently, her contributions have finally been recognized [14, 128] and nearly a quarter century after Dr. Loveless' pioneering publication, venom sac extracts were approved by the US FDA for the treatment of anaphylactically sensitive patients [128].

Normally during the pediatric age, the criteria for admission to a SIT treatment plan would include children with *life-threatening systemic, severe and strong reactions* (88.8% of 91 children) [96] and with positive SPTs, while excluding those cases with solely cutaneous reactions [83] (Table 17.9) [28, 80], with the aim of reducing the costs and avoiding the *possible toxic effects of long-term administration* [83]. In Chap. 13 we discuss the modality and the treatment schedules and examine the chronology of interrupting VIT [43, 58, 108]. It can be confirmed at this time that it is a completely decisive treatment, toward which children and their families can be directed without hesitation and/or concern and without necessity of modifying their normal routine [99]. As previously shown (Fig. 13.8), specific IgE levels initially increase and later decrease, as shown for wasp venom [135] and birch pollen VIT [48]. The follow-up

Table 17.9. Selection of children for VIT

Reaction to sting	Results of SPT/RAST	SIT?
Systemic, life-threatening (Müller stage IV)	Positive	Yes
	Negative	No[a]
Systemic, non-life-threatening (Müller stage III)	Positive or negative	No
Large local (Müller stage II)	Positive or negative	No
Normal (Müller stage I)	Positive or negative	No

SIT specific immunotherapy, *SPT* skin prick tests.
[a] Pastorello et al [80] suggest admitting to SIT children who are SPT+ but RAST-negative.
Data from [38, 80].

after 15–19 years of 1033 children, of whom 356 received VIT has shown that systemic reactions occurred in 3% of VIT-treated patients compared to 17% of untreated patients (p=0.007). Non-VIT-treated patients with a history of moderate to severe reactions had a 32% rate of reaction compared to 5% in the VIT-treated patients (p=0.007). VIT in children leads to a significantly lower risk of systemic reaction to stings even 10–20 years after treatment is stopped, and this prolonged benefit is greater than the benefit seen in adults [33]. Recently it has been shown that *VIT is able to protect insect venom-allergic children against life-threatening sting reactions* after a sting of the respective insect [111]. This effect is attributed to a shift from Th2 to Th1 (Chap. 13). Basophils in persons with wasp venom allergy are permanently activated, as illustrated by the expression of different activation markers, such as IL receptors and HLA-DR molecules. VIT immediately increases this activation, as shown by the rise in CD63 during VIT, which indicates a partial basophil degranulation with release of stored protein mediators. ILs released by T cells, which as a result of VIT change from a Th2 type to a more Th1 type, down-regulate the activation of the basophil granulocytes, which subsequently decreases to the normal levels seen in nonallergic persons. An initial rise in IgE may be caused by IL_4, which is released by the basophils during VIT. A significant decrease in the basophilic surface antigens CD11c, CD32, CD35, CD63, CD116, CD122, CD124, CD130, and CD132 was detected 1 week after the end of rush VIT [120]. Decreased large local reactions after long-term VIT was correlated with a significantly reduced recruitment of $CD4^+$ cells and $CD23^+$ cells as compared to large local reactions at the application site, whereas the number of $CD8^+$ cells, $CD11c^+$ cells, $NP57^+$ cells, and $CD25^+$ cells remained high [57]. The "rush" method is performed using diverse protocols and within a few hours [8]; because of the potential for systemic reactions, we recommend using a university or hospital center [11]. VIT is well reported, but protocols differ according to authors: ultra-rush in 3 h, accelerated in 2–5 days and semi-rush in 2–8 weeks [96, 125]. Venom-allergic patients underwent a modified ultra-rush desensitization protocol consisting in a *2.5-h ultra-rush desensitization by the SC route,* reaching the cumulative dose of 101.1 µg according to Table 17.10 [105]. The treatment caused a rapid variation of IgE and IgG_4 beginning the 15th day. SPT results became negative in 15 patients (27%) and decreased in 14 patients (25%). This *effective and safe ultra-rush desensitization can be adopted even for children and teenagers* [105]. A second protocol [125] reached a cumulative dose of 150.11 µg in 3 h plus a final dose of 100 µg on the 2nd day and was also effective in 14 children aged 6–18 (mean 9.7) (Table 7.10). A novel strategy of VIT based on long synthetic overlapping peptides (LSPs) mapping the whole sequence of PLA_2 (phospholipase A_2), a major bee venom allergen was safe and able to induce Th1-type immune deviation [27].

Biting Insect Allergy

Beyond the Hymenoptera there are numerous other stinging insects that bite, including common or domestic flies, fleas, fire ants, mosquitoes and bedbugs, whose most common species is the *Cimex Lectularius* (Table 17.11) [138]. Mosquitoes are overrepresented worldwide, encompassing >40 mosquito genera and more than 3,000 mosquito species [122].

Pathogenesis

Reactions to mosquito bites are immunological in nature, with the involvement of IgE-, IgG- and T lymphocyte-mediated hypersensitivities [88] and are caused by the proteins in the mosquito saliva [87]. These reactions consist of inflammation caused by the trauma inflicted on the skin and the act of sucking performed by the insect while simultaneously introducing irritating and antigenic substances in the host [50]. Various studies have demonstrated the necessity of a *phase of sensitization* before the development of a bite reaction: the pro-

Table 17.11. Biting insects reported to cause allergic reactions

Order	Family	Genus	Common name	% Of anaphylaxis cases[a]
Diptera	Cimicidae	*Cimex*	Bed bugs	
	Muscidae		House fly	15.5
	Culicidae	*Aedes* *Anopheles* *Culex*	Mosquito	10.3
	Simulidae	*Simulium*	Black fly	18.9
	Tabanidae	*Crysops*	Deerfly	13.8

[a] % Of reactions: see the AAAAI study [50] in the text.
Data from [138].

gression is schematized into *five stages* illustrated in Table 17.12 [50, 103]. A sensitizing bite is needed before a reaction can occur to a specific insect bite; a nonreactive period follows the first exposure. This type of reaction depends upon the number of bites, and time between initial sensitization and challenge leading to the acquisition of tolerance, which suggests the development of a protective mechanism [50, 103]. The role of the immune system in the pathogenesis is not clearly defined, despite the *evidence of IgE antibody involvement* in some reactions employing extracts from the insect salivary antigens [78, 89] or from insect saliva [102]. In the reactions to mosquito bites, IgE is involved *in the development of skin immediate reactions* in mosquito-allergic subjects [86]. Other studies on mosquito saliva have documented that 18% of North American healthy blood donors without any specific history of mosquito allergy had mosquito saliva-specific IgE levels >1 SD above the mean for mosquito bite test-negative subjects [91]. Although IgE does not cross the placenta, the IgE reactivity to the mosquito *Aedes aegypti* (Aed a) antigen is so strong that it was found in the cord blood probably because of a mixture of maternal and fetal blood during delivery [87]. In the saliva or salivary gland extracts from ten mosquito species, seven of which have worldwide distribution, 3–16 salivary allergens with molecular masses ranging from 16 to 95 kD were found in each species. *Species-shared and species-specific allergens that cause IgE responses* in subjects allergic to mosquitos are immunological in nature. Species-shared allergens are the most important for potential use in diagnosis and immunotherapy [87]. Recently, the gene encoding a 37-kD salivary gland protein of *Aedes aegypti* has been cloned and expressed, and using the antibody to the recombinant protein, the 37-kD *Aedes aegypti* saliva protein was found in *Aedes vexans* (Aed v) and *Culex quinquefaciatus* (Cul q) salivary gland extracts, confirming the existence of species-shared antigens in the three species, which may explain the cross-reactivity of skin reactions and IgE responses among different mosquito species [86]. In late reactions after 2 h, neutrophils and eosinophils are found, in addition to CD4 and CD8, which appear after 24 h and parallel other types of such reactions [103].

Table 17.12. Classification of cutaneous reactions to insects

Immunological stage	Reaction	
	Immediate: 15 min	Delayed: 24 h
Stage I (no sensitization)	–	–
Stage II	–	+
Stage III	+	+
Stage IV	+	–
Stage Y (tolerance)	–	–

Data from [50, 103].

Clinical Presentation

In addition to causing local and systemic reactions, biting insects serve as vectors for serious diseases [10]. Mosquitoes (order Diptera), including black flies, house flies, fruit flies, gnats, midges [50, 122, 138] (Table 17.11), and the tiger mosquito (*Aedes albopticus*) bite, which causes pruritus of variable intensity as well as swelling and blisters. Pediatric cases of yellow fever caused by the tiger mosquito have not been reported in Europe, but they have been reported in Southeast Asia where they originate [122].

The genus *Triatoma*, a night species found in illuminated homes, exclusively attacks vertebrates, although

Table 17.13. Clinical expression of mosquito bite reactions

Reaction types	Frequency
Immediate (up to 4 h after sting)	
Wheal and flare	Very common
Large edema	Not common
Anaphylaxis	Very rare
Delayed (>4 h after sting)	
Pruritic papules	Very frequent
Pustules or erythema surrounding hemorrhagic lesions	Quite common
Blister or tense bulla	Rare
Papular urticaria	Frequent in children
Erythema multiforme-like rash	Rare

Data from [103].

the bites are not painful and the victims are awakened by itching and respiratory distress, in contrast to the Tabanids whose bite is deep with notable bleeding [138]. The various types of clinical expression of mosquito bite reactions are summarized in Table 17.13 [103]. Anaphylaxis is, as a rule, a rare event [50, 66]: over 5 years of observation, the pertinent AAAAI committee has tested the serum of 132 patients who presented with 58 anaphylactic reactions, of which 36 out of 132 (27.3%) were RAST+ (Table 17.11), 47.2% were IgE-related and 29.3% were reactions to the bite of Triatoma [50]. In addition, there were 23 equivocal reactions in 14 patients, 6 of which to Triatome (26.1%) and 5 to deerfly (21.7%) [50].

Diagnosis

Diagnosis is made with nonstandardized whole-body extracts when salivary extracts are unavailable. SPT interpretation is compared to that of control subjects: the sensitization, specificity and positive or negative predictive values are not reported [66].

Both RAST and histamine release tests are useful. The frequent findings of *cross-reactions between insect and Hymenoptera stings* should be noted [50]. Up to 50% of patients with stinging-insect allergy have double-positive RAST results to honeybee and yellow jacket venom, and carbohydrate-specific IgE is a major cause for the double positivity seen in patients with Hymenoptera allergy. The *double sensitization and cross-reactivity* through venom hyaluronidases may be a logical explanation for this multiple reactivity [47]. Because of the lack of salivary preparations, allergic reactions to mosquito bites are *underdiagnosed and undertreated.* The diagnosis is also made difficult by the strong cross-reactive skin and IgE responses and species-shared antigens existing among the three mosquito species Aed a, Aed v, and Cul q [86]. However, the use of recombinant salivary mosquito allergens will greatly facilitate the diagnosis and, possibly, the SIT of mosquito allergy [90]. The tiger mosquito can be recognized by its black color, with white bands on its body and legs that give it its name.

Treatment

For local reactions, therapy is provided as detailed above with anti-inflammatory or antihistamine ointments; for anaphylactic reactions, refer to Chap. 20. Cetirizine has had a positive effect on the cutaneous reactions as well as on itching [101]. VIT is used with the *ultra-rush method* in cases of necessity with generally good results [66]. In a meta-analysis of ten studies, four of which studied 56 children aged 1–9 years, the results were positive in 41/56 (73.2%) cases [66]. VIT was also positive in children with severe skin inflammatory reactions to Aed a and Cul q mosquito bites [6]. The use of *repellents on clothes and skin* is suggested, especially for *infants and young children* [10]. However, one should select among currently available repellents those providing prolonged protection and those that can be relied on to provide effective protection in environments where mosquito-borne diseases are a substantial threat [28].

Prevention

Patients with hypersensitivity to Hymenoptera stings must, with precision, avoid all high-risk situations which include the summer season and during periods spent outdoors and in proximity to stimuli such as colors, perfumes or foods which attract the offender [10]. Bees are normally only aggressive and sting people only when alarm pheromone is released, while the Vespulae are particularly aggressive in the autumn when food is scarce [72]. Children at risk should wear a *MedicAlert bracelet or necklace,* and carry *Epi-Pen junior* for emergency self-treatment in case of future reactions caused by insect stings [93, 137]. These notes are expanded in Chap. 24 along with the proposed measures regarding other insects [10].

Pediatricians and Insect Allergy

The prevalence of Hymenoptera allergy has increased during the past decades. However, in the pediatric age group, insect allergy has a low prevalence, a propensity to elicit only mild clinical manifestations with a high assurance of definitive treatment. The vast majority of bites and stings cause little more than local pain and never require medical attention. We recommend that pediatricians who work in the emergency department

be prepared to treat the few children who present with anaphylactic reactions to Hymenoptera stings and recognize and treat those rare children who are severely bitten by poisonous snakes, spiders, or scorpions [52]. We also recommend that at-risk children always carry an Epi-Pen junior injector. Moreover, the prognosis of insect venom hypersensitivity in children is extremely favorable. Continuing our ideal conference, pediatricians should play down the importance of the condition by explaining to parents that both clinical characteristics and prognosis are different and even more favorable from those in adults. Although most insect stings produce only local discomfort, we stress that VIT may represent a definitive treatment. VIT is able to protect insect venom-allergic children against life-threatening sting reactions. Pediatricians can better provide information on the often self-limiting natural course in most of these children.

Allergic and Pseudoallergic Reactions to Drugs

Pediatric Drug-Induced Disorders

The rapid development of new drugs to cure or control human illness corresponds to an expanding spectrum of adverse reactions to such agents. Before the introduction of sulfonamides in the late 1930s, the incidence of adverse drug reaction (ADR) approximated 0.5%–1.5% of all patients. Currently, 15%–30% of hospitalized patients experience an ADR [120]. The zenith is found in nurslings and toddlers. Drugs cause allergic and pseudoallergic reactions (PAR), even though other researchers, especially the Anglo-Americans, seem to consider it more suitable to call them ADRs, obviously shaped on the definition of adverse reactions to food, thus foregoing a pathogenic classification [2].

Definition

Adverse drug reactions may be defined as undesired and unintended noxious consequences of an appropriate drug that is administered in standard doses by the proper route for the purpose of prevention, treatment or diagnosis, defining as a drug any substance used for this purpose [67].

Prevalence

Prevalence in children ranges from 1% to 7.3% [41, 61, 90, 110], whereas in the general population it is estimated at about 15%, with figures ranging from 14% to 17%. Allergic reactions correspond to about 6%–10% of the total [51]. The age group most affected has been investigated. Data from a case study of 163 patients including 8-month old babies show that while ADR prevalence appeared to be higher during the first four decades of life, the figures in absolute terms for the first 10 years reached the highest peak [98].

Incidence is 5% in newborn babies, 11% in children aged 1–2, and 9% for children aged 3–10 [61], or 76% for those aged <7 [66] and 59.5% if the age is 7–12 years [211]. Therefore, *neonates are by no means unaffected,* with an incidence that sometimes matches 24.5%, mostly involving erythematous maculopapular rashes (67.1%) [90]. The majority of reactions is to antibiotics [23, 104, 224, 228], with a clear predominance of β-lactams [49], which in children account for 67.7% and 53.3%–55.2% of ADRs, respectively [81, 167], followed by aminoglycosides, tetracyclines, vancomycin, nitrofurantoin (9.8%) and macrolides (9.5%) [81], to which 35.1% of children in another case study reacted positively [167]. In 46 out of 214 children (21.5%), antibiotics-associated ADR (50%) predominated, followed by corticosteroids (CSs) (16%), tuberculostatic (4%) and immunosuppressive agents (4%). In five cases, an ADR was responsible for prolongation of hospital stay, and in four children ADRs were responsible for hospitalization [224]. However, incidence decreased in very large groups: 152 ADRs affecting 150 children were documented in a cohort of 12,628 children (1.2%), 60% of these occurring within 3 days after treatment initiation: 47% of reports were related to antibiotics, 31% to immunizations, 11% to respiratory, and 4% to gastrointestinal agents [104]. Table 19.1 [33, 44, 144, 148] reports the prevalence of allergic and PAR to several drugs

Table 19.1. Prevalence of allergic and pseudoallergic reactions to some drugs (range of values of several statistics)

Drug	Prevalence (%)
Acetaminophen	2–7
Antibiotics in general	34
Anticonvulsants	7
ASA	15–21
B vitamins	4–5
Disinfectants (oral, cutaneous)	2
Erythromycin	1
Insulin	2
Iodinated compounds	3
Neuroleptics	6
NSAIDs	39
Penicillin	6–29
Propionic acid derivatives	2–8
Pyrazolone derivatives	1–40
Sulfonamides	3–14

Data from [33, 44, 144, 148].

Table 19.2. Prevalence of allergic and pseudoallergic reactions to some drugs that required hospitalization of infants/children

Drug	% Of reactions	
	Total (*n*=76)	Severe/moderate (*n*=27)
Analgesics	9.2	11.1
Antibiotics	19.8	3.7
Anticonvulsants	3.9	11.1
Bronchodilators	10.6	7.4
Cardiovascular	10.6	14.8
Muscle relaxants	7.9	–
Sedatives	15.8	37
Steroids	7.8	3.7
Others	11.8	3.7

Data from [61].
ASA acetylsalicylic acid, *NSAID* nonsteroidal anti-inflammatory drugs.

and Table 19.2 shows the prevalence in children aged 4 days to 16 years [61]. Confusing figures include a high rate of errors in prescriptions and dosage [204], in the use of drugs beyond their indications [61] and the inclusion in pediatric statistics of cases of poisoning and/or oncology patients [61]. Overall, the frequency of drug-related allergies in infancy is underestimated [152] or assimilated to allergic reactions in adults [215]. The true impact is therefore much greater, since 99 substances listed among drugs, vaccines and diagnostics can cause anaphylaxis, considering that some are included within their class, or by examining the 1,000 most prescribed drugs, it is possible to calculate that *at least 70 % provoke ADR* [152].

Classification

Adverse drug reactions can be divided into in four main types [47, 97, 214]:

- *Type A:* an *increase* in *predictable* but undesirable clinical and/or pharmacological effects depending on the intrinsic properties of drugs, occurring in otherwise normal children. This type is dose-dependent, common (80 % of adverse drug reactions), generally not severe: collateral and side effects of drugs, toxic reactions, and drug interaction.
- *Type B: an increase in bizarre and unpredictable* effects, independent of drug action and dose, relatively infrequent (20 %), often severe (in 1902 a case of shock was due to acetylsalicylic acid administration) [75], and individual response by predisposed subjects: allergic, pseudoallergic, intolerance-induced, and idiosyncrasies [47, 97].
- *Type C: chemical* reactions that could be predicted from the structure of the drug or its metabolites. Examples include acetaminophen, which is bioactivated in the liver to a hepatotoxic quinone imine and azathioprine, metabolized to myelotoxic 6-mercaptopurine and must be further converted by the enzyme thiopurine methyl transferase [60].
- *Type D: delayed reactions* from drugs including teratogenicity and carcinogenicity [60], rarely found in children.

This classification has been somewhat overlooked by immunopharmacology, a recent science that has revealed how a certain number of drugs can modulate the immune response [124]. In most cases, an ADR can fit into one of the four classic types of hypersensitivity (Table 19.3) [46, 120], to which autoimmune reactions must be added (Chap. 18). It is believed that 25 % of cases of drug reaction are of *immunological pathogenesis* and in 75 % of cases are an *extraimmunological pathogenesis*, further divided into pseudoallergic, idiosyncratic and toxic reactions [214]. A more useful classification is nosological [205], both for the frequent mixing of these four types [23] and for symptom identification caused by allergic and pseudoallergic reactions [221].

Etiopathogenesis

Genetic Factors

Genetic factors play a vital role in hypersensitivity to drugs, conditioning the specificity of sensitization to a given drug or chemical substance. Various experimental studies have aroused understandable interest, by showing that ADRs are conditioned by specific genetic factors linked to HLA. At present, there are relatively few examples of restrictions or associations of HLA with respect to various allergies to drugs: *HLA DQw2* in patients with asthma caused by ASA, *HLA B7*, *DR2*, *DR3* in allergy to insulin, *HLA DR2/DR3* in allergy to D-penicillamine, *HLA DR4* in hydralazine-induced SLE [205], *HLA A2*, and *DRw52*, in patients with delayed hypersensitivity to aminopenicillins with a relative risk (RR) of 6.76–9.28 [169] and HLA-DR in eosinophilic pneumonia [13]. The rapidly evolving field of immunopharmacology has already clarified that many individual variations in drug metabolism are *genetically determined* [124]. Genetic factors can therefore act at various levels in the biochemical route to sensitization such as formation of reactive metabolites or selectively inherited capacity to develop specific antibodies to a given chemical substance [45]. A strong association of hypersensitivity to the HIV-1 reverse-transcriptase inhibitor, abacavir, was found with the 57.1 ancestral haplotypes *HLA-B*5701*, *HLA DR7*, and *HLA-DQ3*, such that there was a positive predictive value of 100 % and negative predictive value of 97 % in the presence of this haplotype [112]. A later replication study showed much poorer predictive value

Table 19.3. Classification of drugs most frequently implicated in allergic drug reactions

Organ System	Manifestations	Gell and Coombs type	Examples
Generalized	Anaphylaxis	I	Allergy extracts, chymopapain, penicillin, polypeptides
	Serum sickness-like reactions	III, I?	Antilymphocyte globulin, hydralazine, penicillin, polypeptides, sulfonamides
	Drug fever	II?, IV?	Barbiturates, CAF, cephalosporins, penicillin, phenytoin, quinidine, sulfonamides
	Vasculitis	III, IV?	Allopurinol, hypoglycemic agents, iodide compounds, NSAIDs, penicillin, propylthiouracil, sulfonamides
	Systemic lupus erythematosus	III?	Hydralazine, isoniazid, phenytoin, procainamide
Dermatological	Urticaria-angioedema	I, III?	Allergen extracts, foreign antisera, insulin, neomycin, organ extracts, penicillin, sulfonamides, thiouracil
	Morbilliform/ maculopapular	?	Allopurinol, ampicillin, barbiturates, CAF, erythromycin, naproxen, phenytoin, quinidine, sulfonamides
	Fixed drug eruptions	IV?	Barbiturates, penicillin, phenolphthalein, tetracycline
	Allergic contact dermatitis	IV	Antihistamines, neomycin, parabens, penicillin, thimerosal
	Erythema multiforme	?	NSAIDs, penicillin, phenylbutazone, phenytoin, sulfonamides
	Toxic epidermal necrolysis (Lyell syndrome)	IV?	Barbiturates, hydantoin, phenylbutazone, isoniazid, penicillin, pyrazolones, sulfonamides
	Purpura	?	Antihistamines, barbiturates, phenylbutazone, sulfonamides
	Exfoliative dermatitis	?	Allopurinol, carbamazepine, penicillins, sulfonamides
	Photosensitive reactions	IV	Furocoumarins, griseofulvin, psoralens, sulfonamides
Cardiac	Myocarditis	?	Methyldopa, penicillin, sulfonamides
Hematological	Eosinophilia	?	Aminoglycosides, carbamazepine, gold, phenothiazine
	Coombs + hemolytic anemia	II	Cephalosporins, chlorpromazine, insulin, methyldopa, penicillin, phenacetin, quinidine, sulfonamides
	Thrombocytopenia	II	ASA, carbamazepine, heparin, hydantoin, imipramine, quinidine, quinine, ranitidine, stibophen, thiazides
	Neutropenia	II?	Analgesics, antithyroids, penicillin, ticlopidine
	Lymphadenopathy	?	Phenytoin
Respiratory	Asthma	NI	ASA, NSAIDs, indomethacin, timolol, propanolol, naproxen
	Pulmonary infiltrates	?	Penicillin, sulfonamides, carbamazepine, cromolyn sodium
	Pulmonary edema	?	Hydrochlorothiazide, nitrofurantoin, opiates
	Hypersensitivity pneumonia	IV?	Gold salts, hydrochlorothiazide, nitrofurantoin, procarbazine
Hepatic	Acute hepatitis	IV?	Halothane, isoniazid, methyldopa
	Cholestatic jaundice	?	Phenothiazines
	Chronic hepatitis	?	Methyldopa, nitrofurantoin
Renal	Acute interstitial nephritis	II?, IV?	Cephalosporins, methicillin, NSAIDs, penicillin, sulfonamides
	Chronic interstitial nephritis	?	ASA, phenacetin
	Nephrotic syndrome	?	Captopril, paramethadione, penicillamine, trimethadione
Neurologic	Myasthenic syndrome	II	Penicillamine
	Encephalomyelitis	IV?	Live virus vaccines

Modified from [46, 120].
ASA acetylsalicylic acid, *CAF* chloramphenicol, *NI* nonimmunological mechanism, *NSAIDs* nonsteroidal anti-inflammatory drugs.

in another population, highlighting the limitations of such studies [74]. However, administering a single pharmacologically active molecule can sometimes lead to the formation of antibodies directed against different epitopes; consequently the association with HLA antigens would continue, in a certain sense, to be masked, nor are there sufficiently sensitive immunochemical instruments to evaluate the specificity of synthesized antibodies and the correlation with HLA antigens in drug-allergic subjects [124].

Allergic Reactions

Allergic ADRs occur when the immune system recognizes and reacts to a drug-derived antigen, which can also be represented by neo-epitopes formed by virtue of drug-induced clinical changes, or the epitopes may not be recognized as self by adjacent structures eluding immunosuppression [205], as we have seen in another context in Chap. 18.

We all know that only a very small quantity of antigen or drug is needed to trigger an allergic ADR [23]. Therefore, since low-molecular-weight (MW) (<1,000 Da) substances and most drugs fall into this category, given that they are not immunogenic in their native state and have low MW (<1,000 Da), to become effective immunogens, they must be covalently bound to high-MW carrier proteins and they should bind to a carrier protein, a hapten in order to acquire this property [38]. Two different kinds of drugs can be differentiated (Fig. 19.1):

- *Low-MW* molecules act as haptens, and should be conjugated with a protein carrier to become antigenic and elicit immune responses.
- *High-MW* molecules (>5,000 Da) act as complete antigens (Table 19.4) [2, 46].

B cells recognize soluble antigens by IgM and IgD receptors, processing and presenting antigens associated with class II molecules. T lymphocytes cooperate with activated B cells with the help of IL_{4-6} (Chap. 1): this mechanism accounts for the *hapten–carrier* bond, also explaining why TcR recognizes the antigens in association with HLA molecules [124]. Hence, the hapten drug, to acquire antigenicity, must bind to a carrier protein *to form an epitope* that is recognized by B and T cells, one group independently of the other [38] (Fig. 19.2). Another characteristic is found in the particular kind of bond. Drugs that are capable, and most are, form covalent bonds with tissue proteins, which are far more immunogenic than those that are relatively less reactive. This kind of bond, however, is not indispensable: even if not covalent, there may be sufficient affinity for the drug–carrier unit to remain intact during both processing and presenting stages. Nor is it necessary for the drug to be highly reactive, since its hydrolysis or biotransformation in the organism can serve as haptens [221]. The fact that some haptens can be derived from these changes makes epitope identification difficult.

Data from [2, 46].
ACTH adrenocorticotropic hormone.

Alternatively, *neo-epitopes* may form, as for example in kinin-induced thrombocytopenia, with synthesis of specific IgGs for quinine bound to platelets, therefore an antigenic neo-epitope not cross-reacting with other hematic cells or other tissues [221]. Hapten–carrier interactions, with formation of stable bonds with acyclic, amide or sulfhydryl bridges (*haptenization*) [38, 48, 197] create immunogenic bonds, which can form depending on the different ways outlined in Fig. 19.3 [221]. A classic example of haptenization is that of sulfonamides [197]. In other cases, a single unbound molecule should link to an IgE molecule, and the consequent mediator release. In theory, this takes place with molecules having two or more identical or similar epitopes or involving different epitopes belonging to the same molecule. Local anesthetics are an example of the first type, while thiopental, trimethoprim-sulfamethoxazole (TMP-SMX) and β-lactam antibiotics all have more than one epitope binding to IgE [2]. Such small T epitopes, consisting of a few amino acids, being unable to bind to specific IgE (sIgE), or of causing histamine release, cannot elicit anaphylactic reactions, like monovalent haptens (those containing only one epitope) [44, 45], and unlike the bivalent or polyvalent forms (Fig. 19.4). Drugs that have a high MW and are complete antigens (Table 19.4) are directly immunogenic [2]. As seen in Table 19.3, drugs also cause *type II reactions* with complement participation (Fig. 19.5), *type III reactions* with CIC (circulating immune complex) formation and *type IV* or cell-mediated reactions. It appears that like haptenic contact allergens, other drug haptens are not recognizable by T lymphocytes unless they are conjugated with a protein carrier [38]. Thus APCs (antigen presenting cells) process the hapten-modified carrier protein, degrading it to peptides that are complexed with HLA molecules and presented to antigen-specific T cells [60]. If presentation occurs in the context of appropriate activation signals, an immune-initiated inflammatory cascade ensues that leads to the development of clinically relevant drug-induced disease [158].

Consequently, the offending drug *may both possess and acquire antigenic properties*, binding to organic proteins and denaturing them: when it is possible to identify drug-specific antibodies, these would have diagnostic value. Broader knowledge of roles played by allergic reactions is in line with recent findings on drug recognition by specific T lymphocytes, meaning that APC before protein-hapten uptake and processing is unnecessary, because T-cell activated clones can recognize drugs with the HLA–peptide complex in a noncovalent manner. This type of presentation presents several interesting similarities with that of superantigens (SAs), but the drugs are incapable of stimulating PBMCs (peripheral blood mononuclear cells) in unsensitized subjects [218]. In addition, drugs have a MW that is much lower than that of SAs and consequently a T-cell stimulation is not as strong as that of SA. So T cells maintain an intermediate position between SA and peptide stimulation [218].

The role of T cells in ADRs is controversial because T cells recognize peptide antigens and not the low-MW compounds of which drugs are an example [184]. However, T-cell phenotype and cytokine release may correlate with the type of immune response involved in cutaneous drug reactions. Increasing in vivo and in vitro data indicate that cell-mediated immunity (CMI) is particularly involved in some cutaneous reactions such as drug-induced maculopapular exanthems and sulfonamide-induced reactions [67]. The involvement of T cells in the pathogenesis was demonstrated by a child with X-linked agammaglobulinemia who experienced a maculopapular rash after therapy with ceftriaxone, and an additional dose provoked a recurrence of the rash with severe itching, flushing, and hyperthermia. The child had no B cells or detectable IgE and negative SPTs to penicillin reagents and ceftriaxone, but further studies revealed a positive patch test to ceftriaxone and infil-

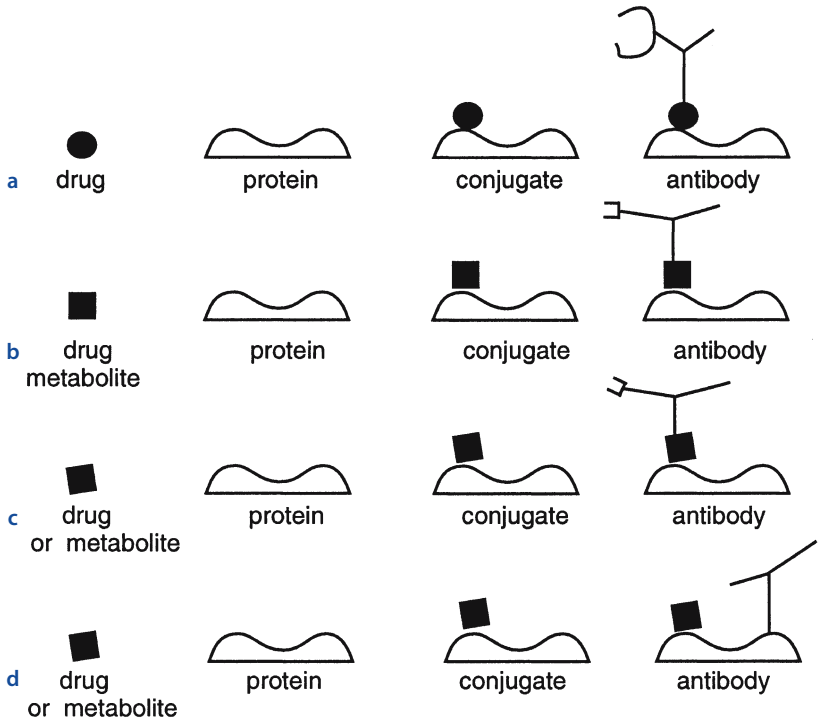

Fig. 19.3 a–d. The interaction drug-antigen may result in antibody formation (as shown) or T cells directed against epitopes (see text). The specific antibodies are directed against (**a**) the native molecule, (**b**) the drug biometabolites, (**c**) a new epitope formed by the interaction between the drug or its metabolites and the protein. **d** As a result, conjugation of the drug or its metabolites leads to a conformational change in the protein, which is then recognized as non-self by the immune system. (Modified from [221])

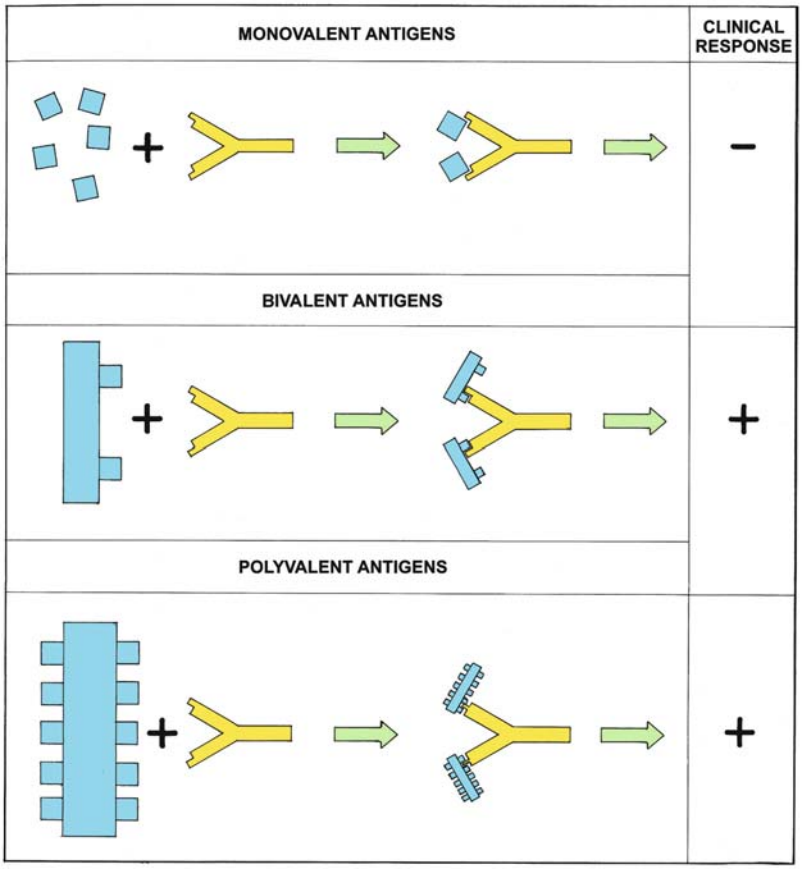

Fig. 19.4. Drug hypersensitivity: valency and antigenicity. Monovalent antigens including most drugs are incapable of eliciting an allergic reaction, which requires cross-linking of the antigen binding site on the Fab part of antibody molecules. To quickly cross-link, they must become bivalent or multivalent antigens, such as haptens attached to a carrier macromolecule, to becoming able to prime a reaction

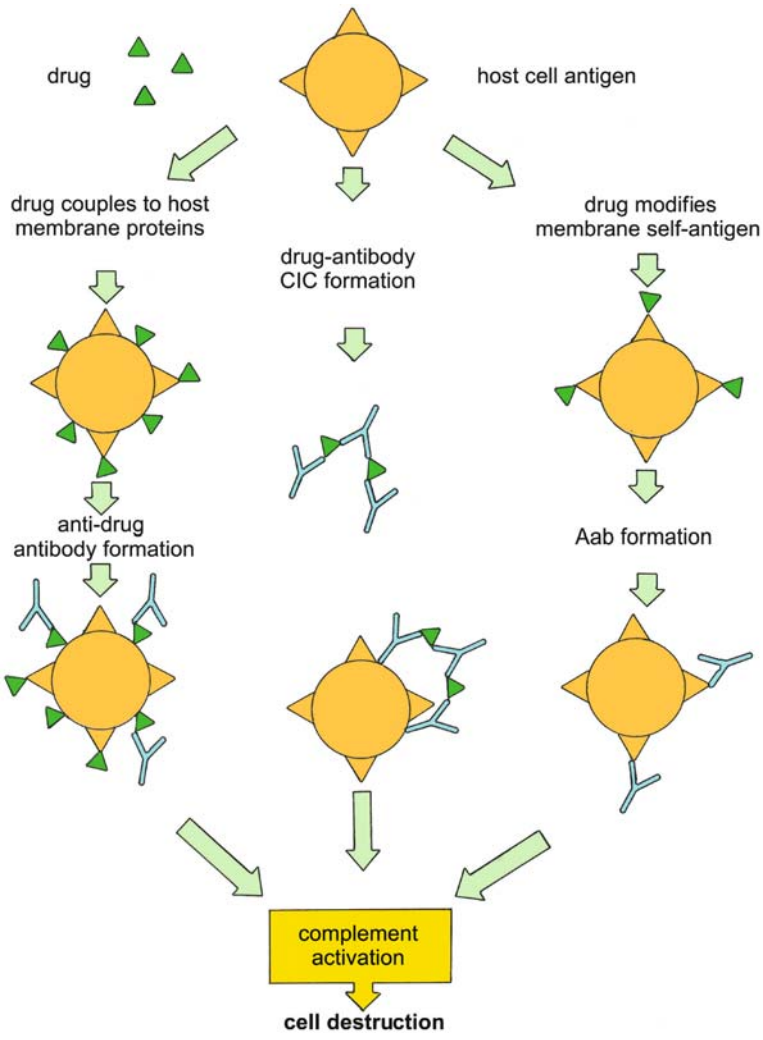

Fig. 19.5. Type II drug hypersensitivity. Complement-mediated cell destruction takes place in different ways. *Left*: Drugs covalently bind to host membrane proteins; anti-drug IgG antibodies bind to the drug and activate complement (such as, penicillin). *Middle*: Circulating drugs and IgG antibodies form CICs, which attach to cell membranes, thus activating complement cascade (such as cephalosporins). *Right*: Drugs bind to cell membranes, but immune responses are directed against the formerly altered host cells: Aabs are formed, also bind to the cell in drug absence, thus activating complement (such as α-methyl-dopa)

tration of the test site with $CD4^-$, $CD7^-$, and CD45RO-positive mononuclear cells, indicating that such rashes are T-cell mediated and occur in the absence of IgE [88]. The skin of patients with an exanthem may be infiltrated by T cells and show a marked enhancement of perforin and granzyme B immune staining, both expressed in T-cell $CD4^+$ and $CD8^+$ cells, partly located at the dermoepidermal junction and in the perivascular dermis [231]. In acute lesions, there was a large increase in TNF-α (9-fold), perforin (6-fold), and granzyme B (7-fold) with positive correlations with disease severity in patients with reactions to drugs in comparison with control subjects. FasL was expressed in PBMCs only in Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) [158]. In the blister fluid of a patient suffering from cotrimoxazole-induced TEN, blister fluid cells were evaluated. Blister fluid lymphocytes were predominantly $CD8^+$, DR^+, CLA^+, $CD56^+$ T lymphocytes, perforin-positive and expressing preferentially two Vβ chains of the TcR repertoire. These lymphocytes were cytotoxic to autologous cells only in the presence of cotrimoxazole and some related metabolites [126]. Most phenobarbital-specific T-cell clones and lines from patients with cutaneous and extracutaneous involvement exhibited a Th2 phenotype, but those with Th1 or Th0 phenotype also constituted minor populations [70]. Further, strong immune reactivity for IL_{12} and IFN-γ was observed in the PBMC infiltrate, indicating that these ILs may be crucial in activation of cytotoxic T cells (CTLs) [231]. *Drug-induced maculopapular exanthems* express significantly increased numbers of eosinophils and amounts of IL_5 and eotaxin and markedly lower amounts of IL_8 in comparison with controls [232]. An elegant study has reported on the IL profiles of PBMCs collected from patients with an ADR. The PBMCs of patients with immediate reactions (urticaria or anaphylaxis) displayed predominantly IL_4. Those from patients with nonimmediate reactions (exanthema or SJS) displayed predominantly IFN-γ, TNF-α, and IL_2, thus showing *the classic Th1/Th2 paradigm* in vivo [157]. A subsequent trial in patients with nonimmediate immunological reactions (severe or mild) to β-lactams (40%) and anticonvulsants (30%) has confirmed that there was a high increase of IL_2, IFN-γ, and TNF mRNA

Table 19.5. Characteristics of drug-related allergic reactions

Previous treatments without drug-related reactions
The reaction occurs after several days of treatment even with no history of a previous drug-related reaction
Reactions are not reduced by doses well below the therapeutic range
Symptoms induced may be dissimilar to other classic allergic reactions
Reactions are encountered only in a small number of patients receiving the drug
Reactions occur in a restricted number of syndromes defined as allergic
Antibodies or T lymphocytes react with the drug or related metabolites in a few cases
Reaction may be reproduced by other agents possessing similar and cross-reacting chemical structures
Reactions may be reproduced even by a minute dose of the suspected drug or other chemically related molecule
Reactions should resolve after drug discontinuation

Modified from [207].

expression in both groups at the acute stage, with a significant relation between IFN-γ and TNF-α only in severe reactions. Thus, ILs appear to play a closely related role in mild reactions, whereas cytotoxic markers appear more relevant in severe reactions. The complexity of the Th1 phenotype after drug intake is fairly evident [159].

In conclusion, the *essential characteristics of drug-related allergies* can be outlined as follows, differentiating them from reactions that recognize dissimilar mechanisms [47] (Table 19.5) [207]:

- The phenomenon is *species-characteristic* and can usually be reproduced experimentally in all members of the same species. ADRs are objectively rare, involving few exposed subjects.
- To elicit an ADR, *previous sensitization to a given drug* is generally necessary (even if hidden) [47]. When the drug is administered for the first time, the *allergic reaction appears 6 and 10 days after start* of treatment. In the event of prior sensitization, the reaction occurs within a few minutes or several hours.
- Although the drug's chemical structure and therapeutic or toxic nature are widely different, *the clinical symptoms they cause,* having the same pathogenesis, *are uniform* and generally reproduce the classic symptoms of atopic diseases: shock, urticaria, bronchospasm, etc.
- *ADRs abate or fade several days after treatment discontinuance* (3–5 days on average), but reappear each time the same treatment is resumed [66]. ADRs *are reproducible* with similar chemical substances and are dose- or pharmacologically independent: they can be provoked by minute doses or can occur by taking other drugs with a similar chemical structure expressing cross-reactivity [47] (Table 19.5). Even if an allergy-related syndrome is recognized, it is often difficult, if not impossible, to prove the existence of prior sensitization, and it is equally difficult to prove that a drug can acquire immunogenic properties.

Nonallergic Reactions

Nonallergic reactions (NARs) are classified as unpredictable reactions: they are divided into PARs; those caused by intolerance and idiosyncrasies by definition do not recognize immune-mediated mechanisms.

In PARs there are three basic mechanisms [45]:

1. *Activation of mast cell mediators* by drug metabolites, often patient-specific, with a mechanism of direct basophil histamine release, as for example in radiocontrast media reactions [28, 165]. ASA-induced asthma involves mediator release from mast cells, as shown by the increase in neutrophil chemotactic activity following ASA challenge [137].
2. *Complement classic and/or alternative pathway* activation, with formation of C3a and C5a anaphylotoxins.
3. *Cyclooxygenase (COX) inhibition,* as in the case of NSAIDs that cross-react with ASA. This inhibition boosts the peptide-leukotriene release that stimulates bronchial hyperreactivity, a highly critical mechanism in ASA-induced asthma (Fig. 19.6) [163]. Recent data show that COX-2 inhibitors are unlikely to cause reactions in NSAID-sensitive patients [184].

Intolerance reactions are due to individual threshold lowering of pharmacological action, with a quantitatively increased effect, for example tinnitus caused by small doses of salicylate or an undesired drug effect produced by therapeutic or subtherapeutic dosages of the drug.

Idiosyncratic reactions occur in patients with genetically determined metabolic or enzymatic defects, after taking specific drugs: a deficit of G6PD is paradigmatic or an uncharacteristic reaction not explicable by known pharmacological actions of the drug [1, 67].

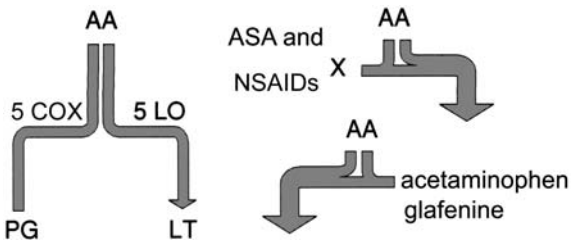

Fig. 19.6. Drug allergy/pseudoallergy: asthma induced by ASA and NSAIDs. *AA* arachidonic acid, *5 COX* 5-cycloxygenase, *LT* leukotrienes, *5 LO* 5-lipoxygenase, *PG* prostaglandins. Physiopathological hypothesis to explain ASA and NSAID-induced (pseudo)allergic reactions, as well as the reactions of intolerance to 5-LO inhibitors

ADRs that are considered predictable may depend on the following:

- *Overdoses* or toxicity. Examples include acetaminophen and toxic metabolite, aminoglycosides and nephropathies.
- *Drug interaction* from administration of two ≥2 drugs together with reciprocal modifications of their pharmacodynamic and pharmacological effects.
- *Undesired side effects* caused by pharmacological action directly linked to the therapeutic action such as first-generation antihistamines and sleepiness (Chap. 12).
- *Secondary effects* such as an indirect consequence of drug pharmacological action that often mimic a new pathology, for example oral candidosis by inhaled CSs (Chap. 11), alteration of oral and/or enteric flora by antibiotics [6, 46].

Predisposing Factors

Predisposing factors consist of atopy, age, sex, factors related to the drug itself and those related to concomitant infections or therapies [197] (Table 19.6) [20, 34, 77, 92, 97, 115, 145, 152, 164].

Atopy. It is not exact to state that atopic subjects are genetically predisposed to developing immediate ADRs [47]. The atopic phenotype relevance is inversely proportional to the sensitizing drug's immunogenic nature, while it is less decisive in strong immunogens [152]. Compared to nonatopic patients, there is no greater frequency in atopic patients of type I allergic reactions to injected allergens such as penicillin, Hymenoptera venom, or insulin compared to inhaled or ingested allergens [225]. The atopy prevalence in children is 16% [144], with much lower levels of 6% in adults [44]. Children of parents allergic to antibiotics have a 15-fold relative risk for histories of reaction to these drugs than controls with no positive history [9]. Confirmation comes from two studies on 1- to 15-year-old allergic to β-lactams with atopic heredity in 46%–60.3% of cases [66, 211] and 44.9%–45.2% with positive personal history [155, 211]. In addition, a questionnaire focused on family histories (FH) revealed cases of aspirin intolerance among parents, siblings, and children of ASA-intolerant probands [119]. In atopic children, systemic symptoms tend to be more severe compared to controls [155, 211].

Age. We have already noted that prevalence in newborns and in children is generally below the general population prevalence, indicating that they are less at risk than adults. This probably occurs because of the immaturity of immune responses or a lower exposure to drugs or smaller doses, in summary the necessary drug exposure for sensitization to occur [188]. Because drug pharmacokinetics and pharmacodynamics in children differ from those in adults, children are highly susceptible to ADRs. In a study in 278 children, the first episode occurred in *51.1% of children aged 0–4 years,* in 24.5% of those aged 5–8, in 16.9% of those aged 9–12, and in 7.6% of those aged 13–16, with no substantial differences between males and females (G. Patriarca, personal comunication). We found ADRs in 29.2% of 411 chil-

Sunscreens	
P-aminobenzoic acid (PABA)	

Data from [182].

dren, 220 males and 191 females, aged 7 to 13. ADRs affected children more than food allergy (21.7%). Since pharmacokinetics has not been studied on a large scale in newborns and nurslings, many ADRs caused by prenatal, perinatal and postnatal exposure, especially in maternity wards, remain undiagnosed [68]. Moreover, since drug doses are not regulated on the basis of body weight (bw) and age (Chaps. 5 and 11), it is likely that in younger children there are higher drug blood levels, and in premature babies even higher levels compared to full-term babies and adolescents [68]. Age at time of the first ADR was *26.1±26.3 months* [143]. In addition, children often receive higher mg/kg doses than do adults [4].

Sex. According to some authors, females are more often affected than males [144], while others feel the opposite [211], the male/female ratio being 1.2:1 [90]. Reactions to anesthetics, ampicillin and ASA are more common in females [152].

The *individual drug characteristics* are outlined in the following sections.

Drug Nature

It is difficult to predict a drug's sensitizing capacity prior to widespread clinical use (experimental data in animals or healthy volunteers does not always coincide with practice). Considering the large number of drugs in use, a certain period of study is needed to ascertain which are implicated in ADRs and if these ADRs are scientifically based [204]. Reference is often made to chemical structures and the example of rigid-structure muscle relaxants, which induce allergic reactions less readily than those with a flexible structure [215].

Table 19.1 shows that many classes of drugs are implicated, the number of patients claiming to have allergy to

Table 19.8. Cross-reacting drugs

Drugs	Cross-reacting agents (examples)
Aminoglycosides	Gentamycin, kanamycin, neomycin, streptomycin
Aminopenicillanic acid	Cephalosporins, penicillins, synthetic penicillins
Aspirin	Other NSAIDs
Benzoic acid esters	Benzocaine, pantethine, pontocaine, procaine
Cyclooxygenase inhibitors	Aspirin, fenoprofen, indomethacin, NSAIDs
Ethylenediamine	Antazoline, aminophylline, promethazine,
Glafenine	Antrafenine, floctafenine, NSAIDs
Heterologous antisera	Antisera from other species
Insulin	Bovine, swine, DNA-recombinant
Penicillin, methicillin	Amoxicillin and other semisynthetic penicillins, ampicillin, cephalosporins, penicillamine
Procaine	Benzocaine, pontocaine, procainamide, tetracaine
Quaternary ammonium ion	Antibiotics, antihypertensive drugs, antiseptic agents, cosmetics, muscle relaxant anesthetics
Radiocontrast media Sulfonamides	Hypoglycemic agents, diuretics related to sulfa group, carbonic anhydrase inhibitor (acetazolamide) depending on the component to which allergic: egg, chicken, duck, rabbit, antibiotics, gelatin
Viral vaccines	

Data from [207].

one drug is equally surprising [78]. It should be noted that group B vitamins, often prescribed for nurslings, and acetaminophen, which is commonly recommended as antipyretic, even to children allergic or intolerant to ASA and NSAIDs, cause reactions in 4%–5% and 2%–7% of patients, respectively. In addition to severe reactions caused by overdoses [203], Acetaminophen has caused anaphylaxis in a 9-year-old girl [106] and in adults [102]. Moreover, repeated episodes of urticaria and angioedema have been reported in a 7-year-old child [43] and in 25% of children with NSAID hypersensitivity (OFC-ascertained) (oral challenge test) [86]. Other drugs, especially antibiotics, prescribed for children with fever, are often accused of causing skin rashes, whereas viruses are more frequently responsible for these rashes [204].

Cross-Sensitization

Once sensitization to a drug has occurred, the chance exists of reactivity either to drugs with a close structural chemical relationship or to immunochemically similar metabolites. This occurs since an epitope may be common to different substances with the same chemical group, for example it may share a free amino group in the para position of a benzoic ring, the β-lactam and 6-amino-penicillanic acid ring, or the benzene ring with the SO_2NH group of sulfonamides and correlated compounds, or it may share similar pathogenetic mechanisms (NSAIDs and cyclooxygenase) [193, 237] (Tables 19.7 [182], 19.8 [207]). Within this framework, a patient sensitive to a drug having these groups must prudently avoid other substances with the same group. Multiple sensitization enters into play in penicillin-allergic patients with a risk that is tenfold greater for ADRs to antibacterials not correlated with any penicillin drug [197]. A similar event occurred in a population of 120 children who, during antibiotic treatment, totaled 337 ADRs: 18.3% were sensitive to three different antibiotics and 1.6% to >3 (19.9%) [81], corresponding to 19.7% of another pediatric survey [61], opening the route to multiple sensitization in this case as well.

Route of Administration

- *Topical application* of some drugs is associated with a high incidence of sensitization and should be avoided, especially in inflamed or band-aid irritated skin, as disrupted skin often provides a compromised barrier to absorption in babies [68]. Cutaneous alterations increase the penetration into the organism of creams, ointments, lotions, eyewashes and their fixation on macromolecules such as seralbumin and cutaneous proteins [152]; in particular penicillin and sulfonamides are implicated. Furthermore, in nurslings and toddlers, the involvement of a larger surface area relative to volume increases absorption of topically applied drugs per unit mass [68].

- *Oral administration* can instead contribute to reducing the reactions associated with other routes since it is linked to antigen endoluminal degradation in low-MW constituents and to sIgA's protective role [152].
- *Inhaled drugs* are normally less immunogenic, despite challenging conclusions [152].
- *Intravenous (IV)* use should be evaluated on a case-by-case basis, because the risk of sensitization is either objectively reduced or it can increase the risk of severe immediate allergic reactions, becoming responsible for severe episodes of anaphylaxis [23].

Degree and Duration of Exposure

Sensitization is more likely when using a high dosage over a long period of time; two frequent events must be borne in mind:

- *Alternate or intermittent cycles* with reduced dosage are in perspective more sensitizing than a single, prolonged, and uninterrupted cycle.
- *During a single treatment* cycle, there is greater risk in the first 2–3 weeks of therapy [197].

ADRs are often accompanied by other symptoms of the immune type, including fever, skin rashes (50% of cases), eosinophilia, and especially shock and/or generalized urticaria in 0.1%–0.2% of cases [47].

Other mechanisms (Table 19.6) are related to concomitant diseases: asthma, cystic fibrosis (CF) and especially viral infections, active above all during infancy, including HIV (human immunodeficiency virus) and EBV (Epstein-Barr virus). Among the factors linked to infection a pivotal role is played by:

- *General factors* such as endotoxins [34], SAs [115], proteins with cytokine-like immunoregulating activities [77], complement inhibitors [92], and molecules activating metachromatic cells [145].
- Specific factors such as the elevated ADR frequency in patients with EBV or HIV infections due to the immunoregulating impact of respective viruses and to suppression or exaggeration of effector functions vs ongoing therapies [77].

Clinical Presentation

Based on the aforementioned classification it is possible to distinguish four types of symptom causes [1, 204]:

Symptoms Caused by Allergic Reactions

Type I reactions: IgE-mediated

- General: anaphylaxis, if IgE-mediated (Table 19.4) is caused by enzymes, insulin and other hormones, polypeptides and antibiotics.
- Respiratory: bronchospasm, rhinitis, etc.
- Cutaneous: urticaria/angioedema, etc.

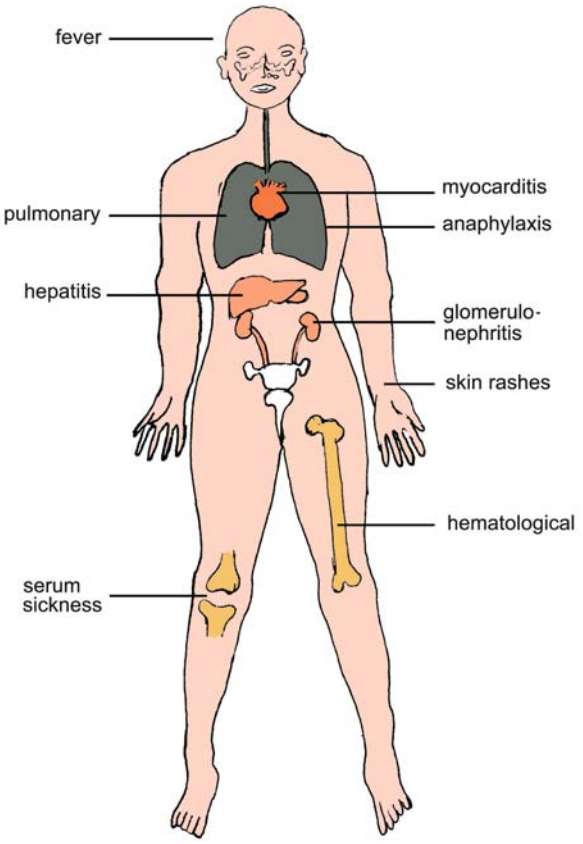

Fig. 19.7. Manifestations of drug allergy/pseudoallergy. Several organs are often involved, but in many instances the reactions are not confined to a single organ, the severity of the reaction can also vary

Type II reactions: cytotoxic IgG- and IgM-mediated

- Hematological: hemolytic anemia with a positive Coombs test, platelet disorder, agranulocytosis.
- Interstitial nephrites.

Type III reactions: caused by CIC

- Serum sickness (caused by any drug).
- Glomerulonephritis.
- Vasculitis.
- Drug induced SLE.

Type IV reactions: cell-mediated.

- Allergic contact dermatitis (ACD).
- Photodermatitis.
- Respiratory symptoms.

Table 19.3 and Fig. 19.7 summarize the clinical symptoms of allergic ADR divided according to organs and/or apparatus. The same drug may involve different mechanisms such as in the paradigmatic example of insulin: the 1st, 3rd and 4th type of immediate and systemic reactions are IgE-mediated and delayed reactions are Arthus-like dependent on IgG anti-insulin (Chap. 1). Antibiotics can cause immediate reactions (<1 h) or accelerated reactions (1–72 h), both belonging to type I and also delayed reactions (>72 h) of types II and IV [228]. Reactions can involve practically any organ or apparatus.

Symptoms Caused by Autoimmune Reactions

In some cases drugs induce auto-antibodies (Aab), often persisting at length even after treatment has been stopped (autoimmune hemolytic anemia, AIHA) (caused by α-methyldopa, pharmacological SLE, etc.).

Symptoms Caused by Reactions Probably Involving Immune Mechanisms

- *Cutaneous eruptions* (erythema, erythema multiform (EM), maculopapular rash, etc.)
- *Febrile mucocutaneous syndrome:* EM, SJS, TEN
- *Drug fever*
- *Eosinophil pneumonia*
- *Hepatitis and cholestasis*
- *Interstitial nephritis*
- *Lymphadenopathy*

Symptoms Caused by Pseudoallergic Reactions

- *Anaphylactoid reactions* (example: radiocontrast media)
- *Intolerance to salicylates* (in some cases caused by interference on production or mediator release)
- *Intolerance for various additives*
- *Rash caused by ampicillin*

Drugs causing anaphylactic or anaphylactoid reactions are summarized in Table 19.9 [207].

The *onset* of clinical symptoms after drug administration can be:

- *Immediate*, from a few minutes to 1 h, as in the case of anaphylaxis
- *Delayed* by a few days such as exanthematic rashes, or by a few weeks, as in the case of serum sickness

The *modalities of drug appearance* or related syndromes are:

- After the first administration: sensitization at first exposure
- After a later administration: successive, gradual sensitization [221]

Clinical Features

The data in Tables 19.3 and 19.10 [197] distinguish systemic and localized allergic reactions of individual organs or tracts, and Table 19.11 [33, 44, 107, 144, 167, 181] shows the frequency of different symptoms not yet identified and that most symptoms are cutaneous. In the 278 children, 75% of the reactions were cutaneous, 10% each were respiratory or gastrointestinal, and about 5% were unclassified.

Systemic or Mast Cell-Mediated Reactions (Table 19.10)

Generalized cutaneous reactions

The most frequent are *exanthematic rashes* and urticaria-angioedema [162]. Figures 19.8 and 19.9 show cases of allergic exanthema after taking phenolphthalein and delayed-release penicillin.

Iatrogenic urticaria (23% of cases), almost indistinguishable from forms of different etiologies, subsides in a few days when the drug is discontinued [57]. The purported drugs are summarized in Table 19.12 [213, 214]. Neomycin, which belongs to the aminoglycoside family, mostly causes urticaria, in >2% of treatments [213] and for this reason is involved in reactions to anti-measles vaccinations [31]. Of great concern are NSAIDs and ASA. The onset of penicillin-induced urticaria is the signal for oncoming immediate and generalized reactions, which rapidly turn into anaphylaxis [103]. Urticaria-angioedema reactions caused by β-lactams [66, 67, 121, 188] and by chemo-antibiotics in general are more frequent in children (72.1% of cases) [167]. In only two children could it be stated for sure that a medicament was the cause of urticaria (1.5%) [11].

Angioedema is caused by 1×10^4 treatments with penicillin, lethal in $1–5 \times 10^5$ cases. Incidence increased with the growth of prescriptions for ACE (angiotensin-converting enzyme) inhibitors, especially with delayed effect and in new patients during the first 3 weeks of therapy, equal to 2–10 cases $\times 10^4$, higher than penicillin incidence [172]. See also the subsection on sulfonamide.

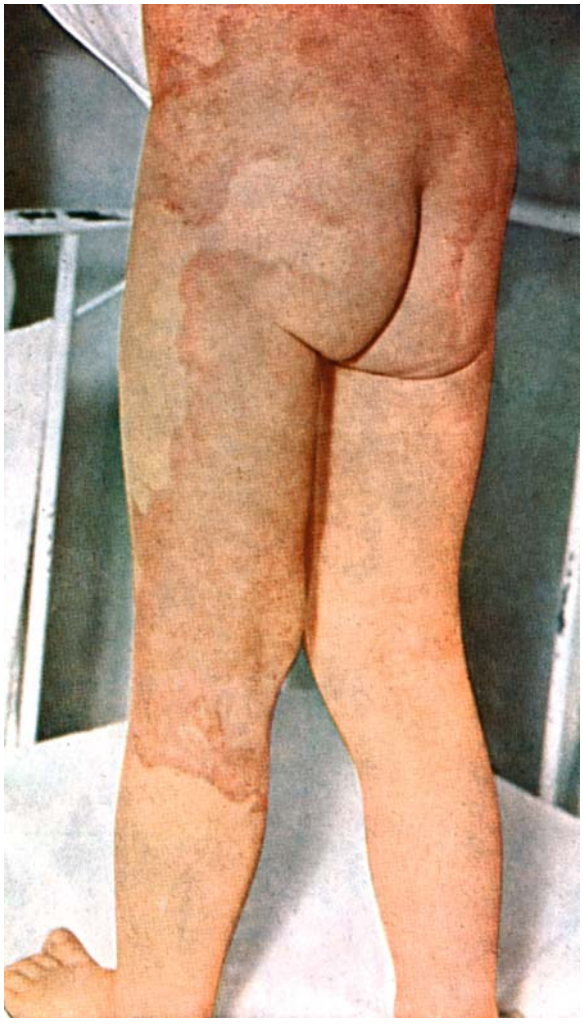

Fig. 19.8. Widespread allergic exanthem, partly scalloped, in a 2-year-old child, following administration of a phenolphthalein-based laxative, abated after drug discontinuation

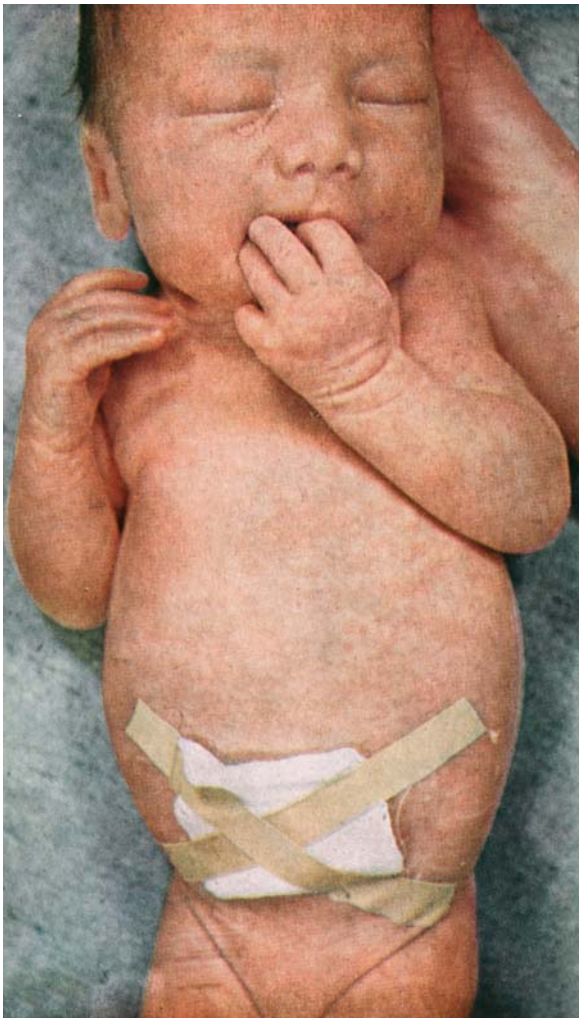

Fig. 19.9. Erythematous, roseoliform exanthem in an infant, 10 days after administration of slow-release penicillin

Serum sickness is a classic prototype of CIC-mediated ADR, with CICs diffusing into involved small vessels, activating complement and initiating inflammatory responses [172]. Currently the complete clinical expression has become rare since specific immunoglobulins (Igs) have replaced heterologous serum [47]. The cases reported are mostly caused by antithymocyte globulin (ATG) and antilymphocyte globulin [197]. Children may be as young as 0.8–0.9 years [84]. The primary form occurs 7–14 days (but also after 21) after the causative agents are administered; the latent period reflects the period of time necessary to synthesize a sufficient amount of antibodies and to elicit symptoms. Heralded by development of pruritus, fever and malaise are the cardinal manifestations (100% of cases), then urticaria-angioedema, morbilliform rashes and polymorphous exudative erythema in 90% of cases, arthralgias (50%–67%), glomerulonephritis (20%) and lymphadenopathy (13%), and at times edema [103]. A diagnosis is suggested, in addition to the typical clinical picture, by a marked fall in C3 and C4 levels. In 75% of patients treated with ATG for controlling transplant rejection, a serpiginous band of erythema was observed on their hands and feet at the margin or palmar or plantar skin, 12–48 h before a measles-like rash [46]. The drugs involved most often are summarized in Table 19.13 [116]. In children, the role played by antibiotics was ascertained, but the risk was modest, between 0.007 and 0.14% [71]. For cefaclor a prevalence of 0.02%–0.2% has been found, especially in children <5 [216], which may attain much higher levels [116]: up to 25% of all drug reactions [84]. A type III immune mechanism has been suggested, but there is no CIC evidence [73]. However, the symptoms and signs attributed to drugs may actually be caused by the disease itself, especially if the disease in question is viral [204]. Differential diagnosis as well as retrospective confirmation may be based on cefaclor cytotoxicity, via an in vitro lymphocyte-based cytotoxicity assay [84].

Drug Fever. Body temperature (T) is regulated in the anterior hypothalamus preoptical region. In normal circumstances, the thermoregulatory center keeps body T within restricted limits by controlling local heat production and preservation via autonomous and skeletal neuromotor pathways [205]. The T rises when macrophages are stimulated to produce IL_1, which in turn stimulates PGE generation from arachidonic acid (Fig. 1.57): the PGE increase influences the thermoregulatory center, leading to a rise in T. Numerous factors are

capable of stimulating the production of IL_1 [187]. The main inducers of nonimmunological fevers are the following:

1. Endogenous release of bacterial pyrogen
2. Administration of exogenous pyrogen
3. Secondary effects caused by an ADR producing toxic tissue injury
4. Increased tissue metabolism
5. Peripheral vasoconstriction and reduced heat loss
6. Central effect
7. Hormonal effect

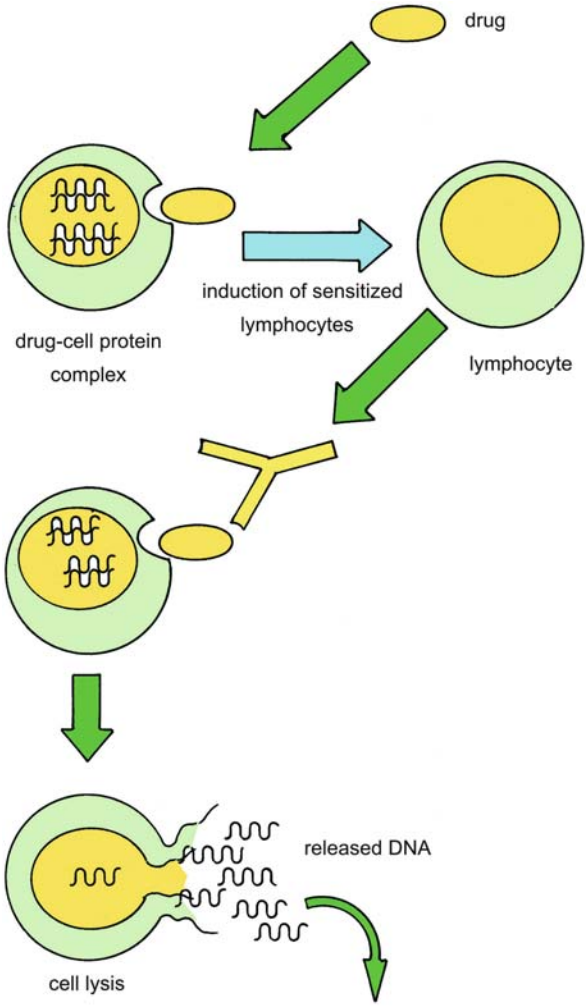

Fig. 19.10. Pathogenetic mechanism of drug-induced SLE

In children, epinephrine and norepinephrine are also involved [207]. A drug-induced fever and bone marrow suppression developed in a 12-year-old girl with CF [65]. Therapeutic progress comes with a price tag: the use of prostaglandins in treatment has led to feverish reactions: an example is alprostadil (PGE_1) to maintain the ductus arteriosus open in newborn babies with congenital heart disease, and with IFN-α to induce PGE_2 generation into the hypothalamus [205].

Fever may occur as the only manifestation of an ADR. In various cases the contrast with the patient's condition is peculiar. Table 19.14 [207] summarizes the drugs that most often cause a fever; the most involved among those are β-blockers, β-lactams and streptokinase [172].

SLE (systemic lupus erythematosus) (Chap. 18). In some children SLE is caused by an ADR (Fig. 19.10). The most incriminated among these are summarized in Table 19.15 [87]. In many cases SLE is self-limiting, clearing up after the offending drug is discontinued. The main symptoms, with a sudden onset a considerable

number of months after therapy has been started, include fever, cutaneous symptoms, arthritis and pleuropericarditis. Antibodies against double-stranded (ds) DNA and anti-Smith antibodies and especially positive ANA (antinuclear antibodies) with antihistone specificity are diagnostic (90% of patients, while complement levels are normal [87] (Tables 18.25, 18.26).

Other Drug-Induced Autoimmune Diseases. Aab incidence during therapies involving certain drugs is clearly higher in the presence of a real autoimmune disease: D-penicillamine is not only associated with SLE but also with cases of hemorrhagic alveolitis simulating Goodpasture syndrome, severe myasthenia, polymyositis and IgA deficiency; practolol with Sjögren syndrome; ethyldopa and penicillin with AIHA, and, together with oxyphenisatin and perhaps also halothane, with hepatitis; and methicillin with tubular nephropathy [47, 62].

Reactions Localized in Individual Organs or Apparatus

Cutaneous Manifestations

ACD is caused by topical or repeated application of low-MW haptenic drugs, outlined in Table 19.16 [195], in addition to sunscreens that almost without exception contain PABA, tars, balms, additives and bases for topical drugs and adhesive plasters [26] (Tables 8.8 and 8.9). Deflazacort for topical use is also involved, associated with betamethasone, budesonide and hydrocortisone in a case of type IV hypersensitivity [129], and emulsifiers, hexamidine, clotrimazole and prednisolone contained in a cream applied by a boy suffering from atopic dermatitis (AD) [26]. The prevalence of positive patch tests for CSs is between 0.2% and 5% [15]. Table 19.17 synthesizes the prevalence of cutaneous reactions caused by drugs [6].

Fixed drug eruptions (10% of cases) are virtually pathognomonic of ADR. The onset appears in the form of solitary, pruritic, bright red or dusky red patches, round or oval, which can evolve into a livid discoloration, with clear margins, and central hemorrhagic pigmentation. Later the lesions spread to the oral and genital mucosa, the extremities, face and genitalia, more rarely to the chest, and are characterized by frequent duplicity. They are termed fixed because they tend to affect identical sites each time the specific drug is taken [12] (Fig. 19.11). In 15 children, the genital lesions were associated with several drugs [133]. Once the drug is stopped, the lesions subside, leaving desquamation and erythema, which darkens to become deeply colored, reddish-purple or brownish-pink. An IL- [187] or CIC-mediated mechanism has been identified (the latter implying that it is a EM variant) (see "Reaction Potentially But Not Definitely Drug-Induced") or by T lymphocytes [12]. Sulfonamides account for 43.3% and NSAIDs for 30.7% of cases [178]. More drugs and additives could be responsible, and those commonly involved are listed in Table 19.18 [71], in addition to nimesulide, which provoked extensive lesions showing cross-sensitivity to sulfonamides in a 10-year-old boy [177].

Macular and/or exanthematic lesions and/or generalized eruptions occur frequently: erythematous, maculopapular, morbilliform, and scarlatiniform lesions, associated with itching, generally appear at a later stage in the course of therapy and appear to be practically in-

Table 19.16. Drugs causing allergic contact dermatitis

1. Local anesthetics

A. Potentially cross-reacting with benzocaine

- Butacaine

- Netilmicin
- Paromomycin
- Streptomycin
- Tobramycin

Data from [195].

distinguishable from common exanthema. Anticonvulsants such as phenytoin, carbamazepine and phenobarbitone were implicated in 41.6% of patients with maculopapular rashes [178]. Some pediatric morbilliform and maculopapular rashes could present a CMI pathogenesis [166]. Recently, drug-specific $CD3^+$, $CD4^+$ and $CD8^+$ T cells in the skin and the peripheral blood of a child with maculopapular drug eruptions have been

identified through use of immunohistochemistry analysis [88]. In addition, all penicillin G-, ampicillin-, and amoxicillin-specific short-term T-cell lines showed high intracellular expression of IL_4, IL_5, and IL_{13}, but poor or no expression of IFN-γ, thus exhibiting *a clear-cut Th2 profile* [27]. Other common damaging agents are ampicillin, incriminated in 3%–7% of pediatric cases, aminoglycoside antibiotics, benzodiazepine, gold salts, sulfonamides [205], penicillin (Fig. 19.12) and barbiturates (Fig. 19.13).

TEN or Lyell syndrome, the most severe of the SJS-TEN spectrum, has an incidence of $0.2–1.2 \times 10^6$ and is in more than 80% of cases ADR-caused (Table 19.19) [12, 103, 172]. TEN can be linked to a constitutional or inherited defect in the detoxification of culprit drug-reactive metabolites [230] and in rare cases caused by GvHD (graft vs host disease). Culprit metabolites develop a specific mechanism activating immunocompetent cutaneous lymphocyte-associated antigen-positive (*CLA*) *T cells*, which migrate toward the skin and contribute to TEN. ADR-induced TEN and SJS are weakly associated with HLA-B12. Among patients reacting to a given drug, the stronger links were especially to *HLA-A29, B12, DR7* and sulfonamides [172]. The ensuing mechanism for anticonvulsant-induced TEN is associated with an immunological reaction originating in skin enabling CLA^+ T cells to migrate by a multistep adhesion mechanism involving CLA-CD62E, very late activation antigen-4 (VLA-4)/VCAM-1 (CD106) and lymphocyte function-associated antigen-1 (LFA-1) CD54 interactions in parallel with the severity of clinical symptoms [105]. After activation by Langerhans cells in the skin, T cells can release TNF-α and IFN-γ, leading to the necrosis of epidermal cells [105]. The widespread keratinocyte apoptosis from TEN patients results from interaction between the death receptor Fas (CD95) and the lytically active FasL [217]. Subsequent results indicate that soluble FasL (sFasL) secreted by PBMCs, not keratinocytes, plays a crucial role in the apoptosis and pathomechanism of TEN [1]. Notably, there is no correlation between sFasL levels and the degree of skin detachment in both TEN and SJS [1]. TEN affects schoolchildren or also older ones, unlike etiologic streptococcal forms that appear during the first stages of life; it can also be set off

Fig. 19.11. Fixed erythema of the left thigh before (*left*) and during (*right*) exposure to sulfamethoxypyridazine: note the flushing of the previous reaction

Fig. 19.12. Widespread allergic exanthem, first morbilliform, then rapidly confluent, assuming a bullous aspect in a 7-month-old infant, treated for 14 days with penicillin because of meningitis

in newborn babies by viral or bacterial infections. Cutaneous lesions involve 20%–100% of surface and mucous membranes in 70% of cases, oral mucosa in 95% and conjunctival mucosa in 86% of cases. Over a 10-year period, mucous membrane involvement was documented in 61% of children. Ocular involvement was seen in 39%. Complications occurred in 21% cases, all of whom had SJS or TEN. Only one patient died as a result of their skin condition [59]. Sometimes preceded by burning sensation, skin tenderness, fever and malaise, within a few hours and up to 2 h a sudden widespread erythematous eruption appears, evolving into bullae formation characterized by raised flaccid blisters which, full blown within 12–24 h, sloughs off into large *sheet-like denudation,* revealing a raw oozing surface as in a second degree burn, similar to streptococcal scalded skin syndrome) (SSSS) [12, 103] (Fig. 19.14). The consequent dehydration, severe electrolyte imbalance, septic complications and eventually disseminated intravascular coagulation (DIC), concur in determining a fatal outcome in 20%–30% of those affected [103, 172]. Long-term CS therapy delays TEN onset without blocking its progression [67]. In children, TEN was managed successfully in a burn facility, using early debridement and wound coverage with allograft skin as a biological dressing. The most common long-term sequelae involve the skin (100%), the eyes (40%), and include diffuse itching early after wound healing (53%) [191]. Mucosal involvement and ocular involvement occurred in 10/11 children (91%).The most common long-term morbi-

dity involved eyes (3 children), nails (4 children), and variegated skin depigmentation (11 children) [183]. Since antibodies present in *human intravenous immunoglobulins* (IVIg) blocked Fas-mediated keratinocyte death in vitro, ten individuals with clinically and histologically confirmed TEN were treated with IVIg; disease progression was rapidly reversed and the outcome was favorable in all cases [217]. No new blisters developed in children with SJS and TEN within 24–48 h after IVIg administration and rapid recovery ensued [122]. The average time to arrest the progression of lesions was 2.1 days and to complete re-epithelialization 8.1 days after IVIg treatment in children [202].

SJS [192] is another fulminant form in which PBMCs secrete sFasL on stimulation with the causal drug. The induced apoptosis in cultured keratinocytes indicates that sFasL produced by PMBCs may contribute to the pathogenesis of SJS, as well of TEN [1]. SJS has an incidence of 0.4%–1.2%, equal to $1.2–6 \times 10^6$ patients per year, according to others 1–6 cases $\times 10^6$ [173] and $2.6–7.1 \times 10^6$ patients per year [196]. Among 42 children evaluated, 22 had EM (11 EM minor and 11 EM major), and 17 SJS, and there was a male predominance (28 boys and 14 girls), especially in the group of EM patients (16 boys and 6 girls, sex ratio 2.6:1). Mean age was 8.7 years (range, 8 months to 15 years). EM children were a mean 9.7 years old and SJS children 7.8 years [99]. In 25 years, 17 children had a diagnosis of SJS, in 64.7% of cases due to infectious agents [99]. Cutaneous lesions in SJS are preceded by fever, headache, prostra-

Fig. 19.15. **a** SJS with lip and oral mucosa ulcerations. The child also had widespread blistering lesions on the limbs and other mucosal sites. **b** Histological appearance of skin subepidermal separation and necrotic epidermis

Fig. 19.16. SJS with widespread lesions

tion and characterized by the abrupt onset of a polymorphous eruption of erythematous or purpuric macules on the face and trunk, which rapidly and variably develop a coalescing darker center to form vesicles, bullae, and skin detachment of less than 10% of the body's surface area. The *widespread small blisters* are accompanied by involvement of ≥2 mucosal surfaces, for example, the eyes, oral cavity, upper airway or esophagus, gastrointestinal tract, or anogenital mucosa. Children report a burning sensation, edema, and erythema of the lips and buccal mucosa, which precedes the development of bullae, ulceration, and hemorrhagic crusting [8, 172, 173] (Figs. 19.15, 19.16). The oral, rectal, vaginal or conjunctival mucous membranes are always involved, as well as the lungs, gut, kidneys, and joints. This condition is *overdiagnosed* because of a mistaken interpretation of clinical data, to the point that 31.2% of children admitted to hospital for a suspected diagnosis of EM or SJS were misdiagnosed [99]. The detachment of <10% of the epidermis is suggestive of SJS, detachment of 30% is suggestive of TEN [173], and detachment of 10%–30% of body surface area suggests overlap of the two syndromes [67]. Approximately 50% of cases are associated with drugs, especially barbiturates, long-acting sulfonamides, NSAIDs, and anticonvulsants responsible for 43.8% of life-threatening reactions in TEN and SJS [178]. Generally it is difficult to confirm or exclude, also because the cause may be different, such as in HSV infections (the most frequent), *Mycoplasma* or other pathogenic agents, connective tissue diseases, tumors and radiological therapy [207]. In some cases, an immunological pathogenesis has been proven [172]. Because in SJS the same TEN-linked drugs appear frequently, it is believed that both may be elements of a common pathological spectrum [172]. In both these diseases, the highest risk of reactions per year is linked to the use of sulfonamides (0.0234%) and of co-trimoxazole (0.0224%) [173] or sulfonamides and penicillins (26% each) [59].

Data from [213].

Diagnostic features include widespread blisters predominantly on the chest, presenting with erythematous or purpuric macules and one or more mucous membrane erosions. The mean duration was 18 days for SJS [99]. The serum sFasL level may be a good indicator for the early diagnosis of TEN and SJS [1]. Nursing should include meticulous skin and mucous membrane care, daily ophthalmological examination, and long-term follow-up when necessary [99].

Eosinophilia more frequently accompanies drug-induced diseases, but occasionally it is the sole manifestation, warning in this case of more severe complications to come. The drugs most commonly associated are outlined in Table 19.20 [213]: many of these can trigger mast cell degranulation (Table 10.13) or asthma and other conditions, albeit associated with eosinophilia, not, however, causing hypersensitive reactions such as digitalis, which if this case should not be discontinued. Differential diagnosis often includes many other diseases (Table 6.15).

Hematological Manifestations

Drug-induced AIHA (autoimmune hemolytic anemia) represents 16%–18% of all acquired forms. There are three different types depending on whether it is caused by haptenic reactions or is CIC-induced, or is caused by drug absorption or by autoimmunity. A lower number concerns nonimmunological mechanisms [62]. The most commonly cited causes of drug-induced AIHA are second- and third-generation cephalosporin antibiotics. The first case of cefuroxime-induced AIHA has recently been reported in a 4-year-old girl who 3 years later attends school and functions at her age-appropriate cognitive level [113].

Hapten-Cell Mechanism (Type II Immune Reaction). The most direct mechanism is via the drug or its reactive intermediate, binding to a cell membrane protein, thus typifying the hapten model. The prototypes are penicillin molecules incorporating into red blood cell (RBC) membrane by binding protein, thus forming a neoantigen. Anti-drug antibodies are formed of the IgG type, which react, more than with RBCs, with the membrane-fixed penicillin, which, adhering to the membrane, effectively has become a neoantigen. Additional drugs most commonly associated with hapten mechanism are ampicillin, carbenicillin, cephalosporin, tetracycline, and tolbutamide [109].

CIC-Induced Mechanism (Type III Immune Reaction)
Various stages develop:

- A tripartite antibody–drug–blood group antigen complex is formed (Kidd, Kell, Rh, I/i).
- To form a neoantigen, an antibody recognizes a drug only when it is associated with *a blood group antigen.*
- Antibody will not bind to RBCs deprived of the blood group antigen even if the putative drug is present.
- Then complement activation occurs.

It was previously believed that drug–antibody CICs linked to RBC membrane, either aspecifically, or via the C3b receptor, indicating that RBC acted as an innocent bystander during phagocytosis or cell lysis.

A further, severe variant involves second- and third-generation cephalosporin: the patient develops severe hemolysis with hypotension and DIC, but if re-exposed to cephalosporin the clinical manifestations worsen, with a possible fatal outcome [109].

Drug Absorption Mechanism. The drug absorption mechanism is proposed to explain the pathogenesis of penicillin-induced AIHA, and later extended to other compounds. The drug strongly binds via a covalent bond with the erythrocyte membrane, inducing later anti-drug IgGs that do not activate complement (Fig. 19.17). This reaction either induces a simple serological anomaly or hemolysis caused by extravascular removal of cells sensitized by IgG antibodies, by phagocytosis or, to a lesser extent, ADCC (antibody dependent cell-mediated cytotoxicity) by macrophages, especially if splenic, provided with the relative FcγR [109]. Hemolysis caused by penicillin is dose-dependent [62].

Autoimmune Mechanism. The paradigms for the autoimmune mechanism are α-methyldopa and mefenamic acid: the associated IgG-Aab are directed against RBC antigens with Rh specificity and inducing changes in the RBC surface membrane via a direct mechanism, with neoantigen formation, considered non-self by the immune system, and therefore capable of evoking an antibody response (Fig. 19.18). Simultaneously the drug,

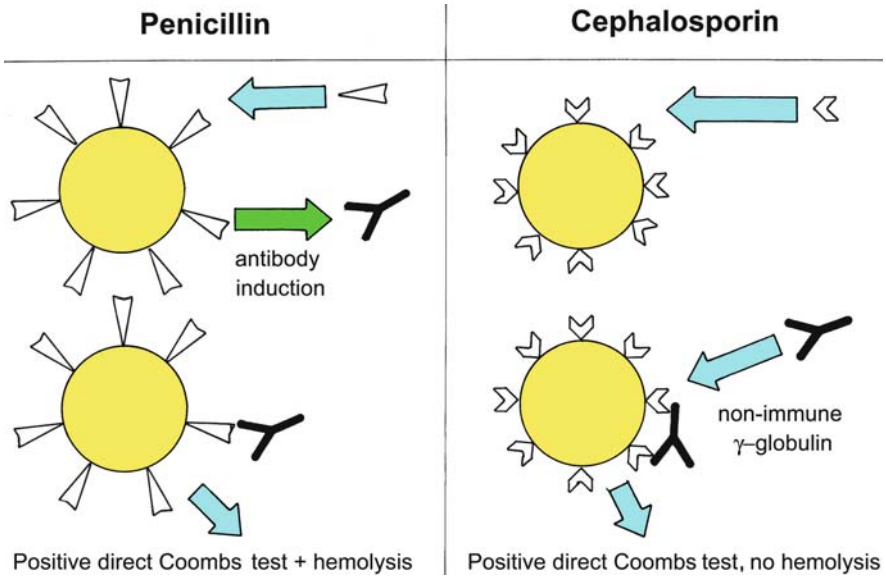

Fig. 19.17. Drug effects on circulating erythrocytes. *Left*: penicillin attaching to erythrocyte membrane causes specific antibodies to yield a positive direct Coombs test. *Right*: cephalosporin also yields a positive direct test but hemolysis does not occur, since the antibiotic induces erythrocyte membrane changes that expedite nonimmunological serum protein absorption

by increasing lymphocyte cAMP, inhibits the function of CD8 T cells, including those cells preventing uncontrolled Aab production, in this case directed against RBCs and not against the drug. Unlike the above mechanisms, these drug-induced Aab will react with normal RBCs even in the absence of the drug [109].

One further mechanism, present in <5% of patients is the *nonimmunological absorption of blood proteins* by nonspecific plasma protein absorption into the RBC membranes; cephalothin, the basis of this mechanism, does not cause hemolysis, even if it can cause it via the first mechanism [109].

Intravascular hemolysis occurs after complete complement cascade is activated: the often sudden onset is accompanied by hemoglobinemia and hemoglobinuria. Kidney failure can put the patient's life in danger. C3b-coated red cells are taken up by splenic and/or liver sequestration via C3b/C3bi receptors on macrophages. The drugs most involved in AIHA are recapitulated in Table 19.21 [62]. Two children aged 2 and 5 died from massive hemolysis 20–55 min after an IV injection of ceftriaxone, a third-generation cephalosporin [14, 96]. In one case, RBC cytolysis by a CIC mechanism was mediated by an anti-ceftriaxone-directed IgM antibody [14].

Thrombocytopenia type II was seen in 41.6% of children with ADR, and only in 0.46% of children without ADR. It is caused either by antigen–antibody interaction, especially of IgG [156]. Quinine antibodies are bound to platelet membrane glycoproteins (gp) GPIb/Ix and GPIIb/IIIa or V in association with the drug [62], thus generating a new epitope that does not cross-react with other cells or tissues [229]. The pathogenesis is best explained by the development of an antibody recognizing the *heparin* epitope bound to platelet factor 4 [109]. Heparin–IgG complexes bind to platelets and activate them via FcR recruitment; moreover this antibody causes platelet aggregation [103], and thromboxane (TX) biosynthesis and release [62]. Heparin is mostly responsible if IV injected (prevalence 5%). There are two different forms: early (before the 5th day) and delayed (between 6 and 25 days), associated in 30% of cases with skin necrosis and in 10% with thromboembolic complications. Within a few hours or days after the offending drug is administered, sensitized patients present fever, chills, widespread petechiae and ecchymoses, on occasion hemophtysis, hematuria, gastrointestinal and vaginal bleeding, and mucosal hemorrhages, while platelet counts fall but not to their nadir as in other drug-induced thrombocytopenia. Treatment must be stopped as in other ADR cases; diagnosis is often presumptive because platelet counts return to normal within 2 weeks [103]. Some cases of thrombocytopenia are induced by a type III immune mechanism. Table 19.22 lists the drugs that more commonly induce immunologically based forms: in pediatrics phenytoin, sulfonamides, TMP-SMX, valproic acid are most commonly used, heparin most rarely [62].

The rare *neonatal alloimmune thrombocytopenia purpura* is caused by development of maternal antibodies against allergens present in fetal platelets, shared with the mother and recognized as foreign by the maternal immune system. IgG alloantibodies are found against human platelet antigen (HPA)-1a in 75%–90%, HPA-1b in 3%–5%, HPA-3a in 4%–5%, HPA-5b in 6%–19% and against private platelet antigens in 3% of cases. Extensively testing children serologically is required to confirm the diagnosis, and their parents have to be typed for the important platelet-specific antigens, monoclonal antibody immobilization of platelet antigens and/or ELISA techniques [156].

Agranulocytosis appears 1–2 weeks after starting a new drug and is not dose-dependent. In patients previously sensitized the onset of neutropenia may occur within 24–48 h. Clinical characteristics include high

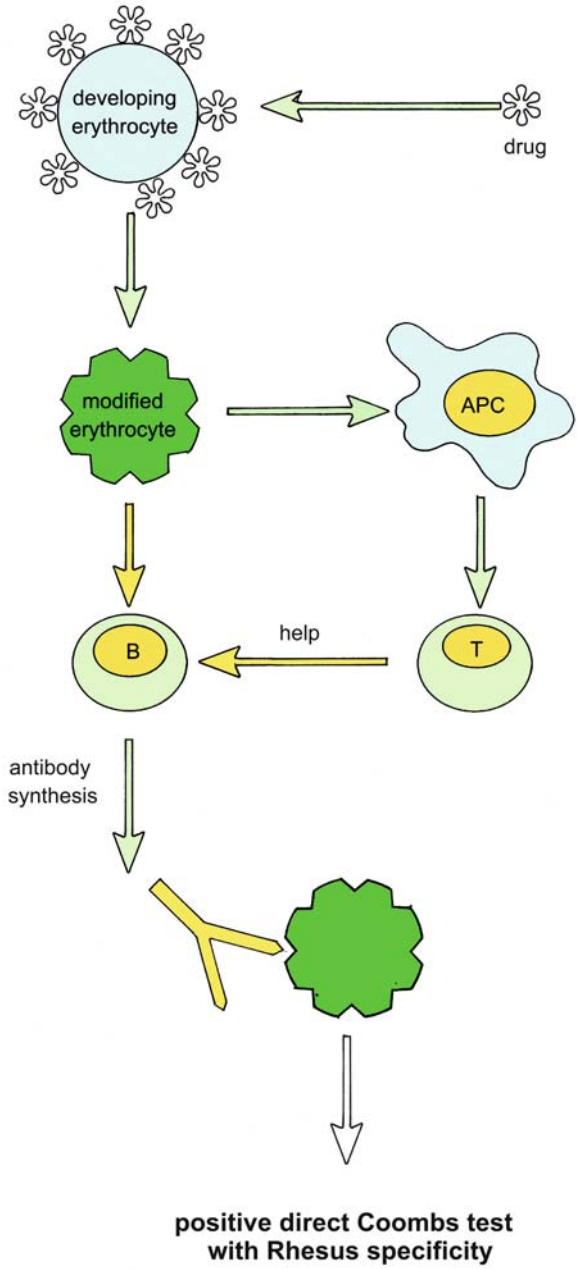

Fig. 19.18. Autoimmune hemolytic anemia

fever, acute chills, arthralgia, severe prostration, and neutropenia [235]. On the contrary, weeks to months after initial therapy with toxic effects, and readministration of even small doses may result in a fall in granulocytes [80]. Toxic or idiosyncratic forms caused by medullary depression may develop insidiously and are revealed by white blood cell count, requested for example to monitor a persistent infective form or in a child resistant to therapy. In an immune ADR in a 16-month-old male infant, there was no production of any type of granulocytes, and leukocytes began to increase from the 8th day after discontinuation of ethosuximide administration [80].

Data from [62].

The immune mechanisms are as follows [42]:

- *Type II:* the drug or one of its metabolites can bind to the granulocyte membrane acting as a hapten, to which the resulting antibody binds, thus eliciting neutrophil splenic sequestration.
- *Type III:* drug IC and anti-drug antibody bind to Fc or complement receptors on granulocytes.
- The drug antigenically modifies the neutrophil membrane, *to create neoantigens* that are not recognized as self by the immune system, evolving into an Aab-induced reaction.
- The drug *induces Aab against neutrophils,* without reacting with neutrophils.
- *Drug-induced immune mechanisms* may interfere with T-cell regulation of granulopoiesis [62].

Via immune mechanisms, a number of drugs potentially cause *immune neutropenia,* associated with potential granulopoiesis inhibition in mature circulating granulocytes (aminopyrine, ibuprofen, hydantoin, quinidine, clozapine and ticlopidine); others evoke anti-neutrophil drug-dependent antibodies, reacting directly with mature circulating neutrophils (β-lactam antibiotics, cephalosporin, phenytoin, flecainide, procainamide, propylthiouracil). Other drugs acting as drug-dependent antibodies against mature circulating granulocytes are summed up in Table 19.23 [42]. CAF (chloramphenicol) has been responsible for seven lethal cases of aplastic anemia [90].

Pulmonary Manifestations

Prevalence of hospital admissions amounts to 1%–5% [171], several cases are not diagnosed or reported [134]. *Hypersensitivity lung disease:* following sensitization, ADRs develop within 4–6 h of exposure including an acute or subacute onset, rapid recovery after drug withdrawal and symptom worsening when reintroduced. Laboratory tests and radiographic findings are nonspecific and compared to other illnesses in different organs, it is characterized by rapid recovery after drug discontinuation. Laboratory findings include peripheral eosinophilia, elevated IgE concentrations, and increased lymphocyte blastogenesis resulting from positive lymphocyte transformation test (LTT) [134].

Various problems encompass drug-induced asthma and pulmonary infiltrates [46]:

Asthma may often occur as part of a hypersensitive ADR and rarely is the only manifestation of a systemic allergic reaction. ASA and NSAIDs are among the most common drugs underlying asthma: prevalence in asthmatics is 10% (Table 19.24) [79, 100, 141, 207]. Moreover, 24 children reacted to ibuprofen (63%), acetaminophen (46%), diclofenac (25%) and other NSAIDs (9%) [84]. Drugs can structurally damage the respiratory system by four mechanisms:

Alveolocapillary endothelium direct cytotoxic lesions

Oxidative lesions

Intracellular deposition of phospholipids produced by amphophil drugs

Immune-mediated lesions [171]

Data from [42].
[a] Drugs most often quoted in epidemiological studies.

Asthma can be caused by various mechanisms:
Pharmacodynamic (parasympathomimetic, α and β-adrenergic)
Cycloxygenase inhibition (ASA and NSAIDs)
Hypersensitivity (ACTH, hydrocortisone, penicillin and other β-lactams, cimetidine, rarely aminophylline)
Local irritations (acetylcysteine, sulfites and sulfates) [79]

Pulmonary infiltrates characterize eosinophil pneumonia and infiltrative reactions (Table 19.25) [108, 141, 207].

Eosinophil pneumonia, rare in children, occurs with few clinical symptoms (mostly fever, dyspnea, wheezing), accompanied by a chest x-ray showing peripheral nodular infiltrates, marked eosinophilia, high IgE levels [108] and expression of HLA-DR molecules [13]. Two patterns have been systematized: in the acute pattern, in ≈90% of cases the reactions occur within 1 month; in the remaining cases with a chronic pattern the reactions occur within 2–5 months. In the acute form, resolution is usually the rule upon drug withdrawal; chronic cases, if complicated by interstitial fibrosis, which nosologically excludes them from eosinophil pneumopathology [152], are more difficult to deal with [108], especially if caused by antirheumatic [239] and chemotherapeutic drugs [234].

Infiltrative reactions normally develop 2–10 days after treatment is started, with acute symptoms characterized by cough, dyspnea, chills, fever and malaise, a maculopapular eruption is often also present; a few or basilar crepitant rales and, on occasion, a few focal rales and a harsh sound on lung bases may be appreciated. x-ray findings include widespread alveolar, reticulonodular, and focal migratory infiltrates. Sometimes patients present patterns similar to pulmonary edema, especially following treatment with nitrofurantoin [46].

Data from [108, 141, 207].

The atopic individual may develop IgE to these antigens, and upon exposure manifest bronchial asthma caused by the response outlined above. A delayed response may be mediated by CMI [46]. CMI mechanisms and lymphocyte subset imbalances have been proposed without reaching definite conclusions [207]. As stated in Table 19.25, there is a multitude of drugs involved, but before making a diagnosis, we should exclude other potential causes, especially infective ones [134].

Pulmonary infiltrates with eosinophilia are a group of heterogeneous disorders with the common findings of lung disease and eosinophilia in the peripheral blood, bronchoalveolar lavage fluid, or pulmonary interstitium. Among 11 retrospectively identified cases, there were 2 drug-induced cases, 3 cases of acute eosinophilic pneumonia, 2 of infant pulmonary eosinophilia, and 5 of other diseases. The disorder is associated with signif-

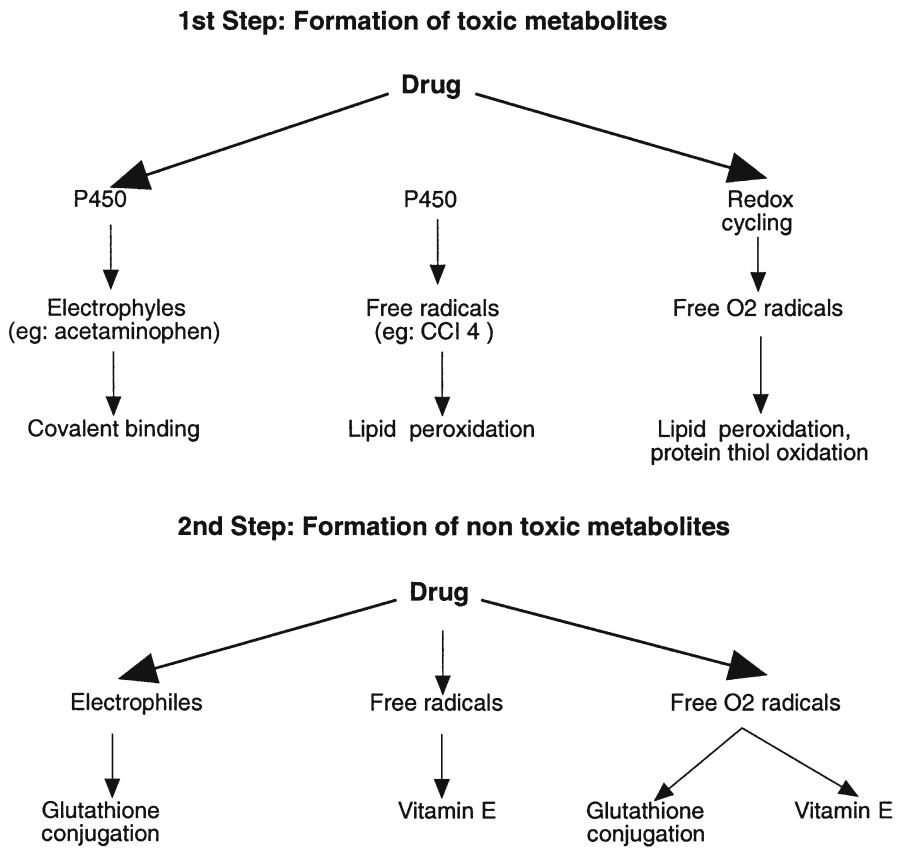

Fig. 19.19. Drug biotransformation up to detoxification (see text). Drug biotransformation is the conversion from a lipophilic to a hydrophilic compound to be filtrated by the glomerule or excreted by the bile. CCl4 C tetrachloride. (Modified from [229])

icant morbidity and mortality; therefore aggressive diagnostic evaluations are warranted, especially in children with respiratory failure of unknown etiology [135].

Hepatic Manifestations

The liver is the main organ concerned for drug metabolism and is specifically susceptible to drug injury as severe as liver failure [100]. Acetaminophen overdose was the most common apparent cause of acute liver failure, accounting for 39% of cases. Idiosyncratic drug reactions (isoniazid) were the presumptive cause in 13% of cases, viral hepatitis A and B combined were implicated in 12% of cases, and 17% of cases were of indeterminate cause [138]. The reactions are characterized by fever, cutaneous eruptions, eosinophilia and inflammatory infiltrates rich in eosinophils or granulomas in the hepatic parenchyma, with a sensitization period of 1–4 weeks and immediate exacerbation of hepatic function following readministration of even small doses of involved drugs [100]. Regarding liver injury, there was neither the ability to prove dose-related hepatic damage in laboratory animals, nor the presence of hepatitis-associated antigens, nor a correlation between drug dosage and cellular damage. We therefore wonder how a drug can be able to cause immune reactions, since most drugs are of low MW and nonimmunogenic [229]. To correctly classify this paradox, we must first confront a dilemma: most drugs provoking immune reactions are not reactive to the point of being capable of acting as *haptens*, forming drug–carrier conjugates that in turn interact with the host immune system [221]. Consequently it has been speculated that, via liver biotransformation products, various drugs may serve as *haptenic metabolites*, forming compound substances (step 1, Fig. 19.19) [229]. Having formed this conjugate, it becomes capable of acting as an immunogenic agent and activates a specific humoral or CMI response, or both. This acquisition, based on research on halothane-caused hepatitis, has stimulated the identification and characterization of such haptens involved in hypersensitive reactions. Currently these haptens have been purified and can be used as neoantigens for identifying at-risk individuals [229]. In the second step of Fig. 19.19, it is possible to observe how detoxification occurs (step 2): electrophiles are conjugated with glutathione, free radicals interact with vitamin E, while O_2 free radicals are eliminated by both mechanisms. These in turn lead to varying biochemical consequences, including covalent binding and lipid peroxidation. Different variables, endogenous and exogenous, modulate the delicate balance of hepatic drug metabolism in either direction, the main factors being genetic polymorphism, enzyme induction, nutrition, hepatic functional heterogeneity and enzyme polymorphism [223].

Data from [100, 141, 207].

A number of preparations are implicated in direct, allergic, toxic-allergic and idiosyncratic hepatic injury [100]. Histopathological studies show that hepatic lesions are of two kinds: either intrahepatic cholestasis or hepatocellular damage (Table 19.26) [100, 141, 207]. In the first case, a number of hepatic tissue components may become sensitized during treatment with phenothiazine and sulfonamides; the mechanism at the basis of hepatocellular reactions is even less clear. Histopathological studies document the microscopic lesions (Fig. 19.20). The prognosis is good and recovery is ensured by stopping treatment. Data on erythromycin shows that, with the exception of cases caused by estolate, rare cases of hepatic lesions based either on toxic metabolites or hypersensitivity reaction were reported [64].

Hepatocellular damage induced by halothane, isoniazid, methyldopa and oxyphenisatin can mimic chronic active hepatitis, but is different because after treatment discontinuation the hepatic picture returns to normal. Some hepatotoxic drugs instead cause a picture virtually indistinguishable from that of viral hepatitis, charac-

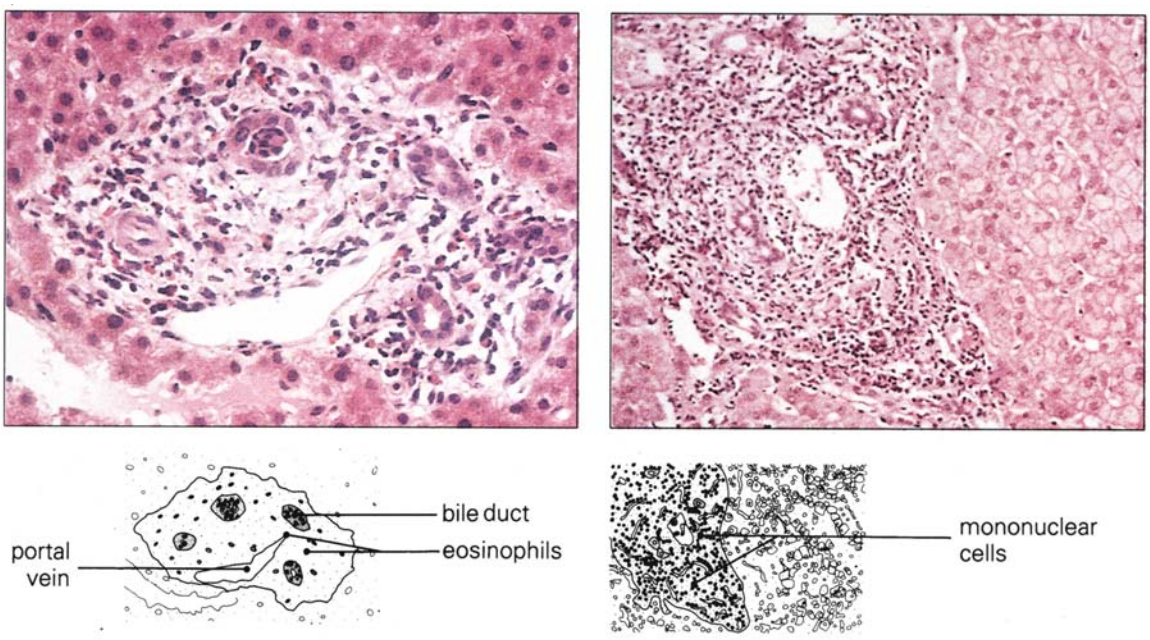

Fig. 19.20. Drug-induced hepatic disease with hepatic or cholestatic jaundice. *Left*: Chlorpromazine-induced cholestatic jaundice showing eosinophilic infiltrate in the portal tract. *Right*: Hepatic jaundice showing periportal mononuclear infiltrate

terized by a rapid onset of malaise and jaundice in association with elevated aminotransferase levels, fever, hepatomegaly, skin rashes and/or eosinophilia [100]: this is the reaction most often present in children treated with valproic acid. Recovery is good if liver injury is not severe [229]. Last, we mention Reye's syndrome, acute liver failure that may follow ASA intake during certain viral infections, particularly in children [63].

Renal Manifestations

The kidney is vulnerable to drugs because of its high blood flow and large capillary surface area, its role as the excretory route for many drugs and its detoxifying action, because any substance or drug present in the blood can easily come into contact with the glomerular endothelium and tubular epithelium [54]. Little is known about epidemiology of drug-induced disorders in the pediatric kidney [54]. Damage can be functional, as in the case of drugs acting on the pre- and postglomerular small arteries such as ACE inhibitors and NSAIDs, or organic with lesions that are more frequently interstitial [87] (Fig. 19.21).

Tubulointerstitial nephritis is most likely ADR-induced among renal manifestations; in 8% of cases this is the cause of renal failure [47]. The clinical picture, which appears 5–37 days (average 2 weeks) after starting penicillin, is marked by fever, maculopapular morbilliform rashes, arthralgia, eosinophilia and eosinophiluria, macro- or microhematuria, proteinuria, leukocyturia, pyuria and elevated IgE levels. Direct renal tubular toxicity has also been described with a number of new medications with unique effects on the epithelial cells of the kidney [153]. The drugs are listed in Table 19.27 [98] including the antiviral agents cidofovir, adefovir, and tenofovir as well as the biphosphate pamidronate [153]. Compared to adults, pediatric ADRs are more modest and do not last as long; regardless of the degree of severity, 90% of patients recover within 1 year. In acute immunological forms caused by penicillin and other drugs listed in the table, other symptoms have been identified such as eosinophilia, eosinophiluria, high total IgE levels and humoral and CMI mechanisms [46, 98]. In particular, the following have been identified: penicilloyl haptenic group of methicillin, antibodies to tubular basement membrane, complement (C3 bound to tubular basement membrane) and CICs; a positive LTT to methicillin, late reaction to a SPT for the drug and the interval necessary for the appearance of symptoms do indicate CMI [205]. Eosinophiluria is almost diagnostic [128].

ADR-induced *nephritic syndrome* (Fig. 19.22) can appear during treatment using anticonvulsants, heavy metals, penicillamine and puromycin. In some cases immunochemical data seem to indicate type III immune mechanisms [204].

In *glomerulonephritis* with the possible onset of serum sickness, cimetidine, D-penicillamine, dihydralazine, and NSAIDs, etc. are usually involved [87].

Hemodynamic renal failure may result from drugs that reduce renal PGs and thus renal blood flow and glomerular filtration rate [153]. An increase in the last 10 years in the involvement of drugs in acute renal failure has been observed in newborns [54].

Data from [98].

Enteric Symptoms

Pseudomembranous colitis is linked to broad-spectrum antibiotics (ampicillin-amoxicillin, CAF, clindamycin, lincomycin, penicillin, tetracycline), which by altering the enteric flora favor hyperproliferation of *Clostridium difficile*. This elaborates B toxins, causing mucosal cytopathy in low doses, and is potentially lethal in high doses [161].

Anticonvulsant hypersensitivity syndrome (AHS) is a rare syndrome that occurs with exposure of variable lengths to anticonvulsant medications, which have a high risk of triggering hypersensitivity syndrome in susceptible individuals and their first-degree relatives. AHS may be associated with severe morbidity and sometimes even mortality [179]. It is characterized by fever, rash, edema, conjunctivitis, oral ulcers [179] and generalized lymphadenopathy along with visceral organ involvement [212]. Liver damage, in particular, seems to be associated with fatal outcomes. The pathophysiology of AHS is still uncertain, but it may be linked to a genetically determined inability to detoxify reactive drug metabolites. AHS has also been described with carba-

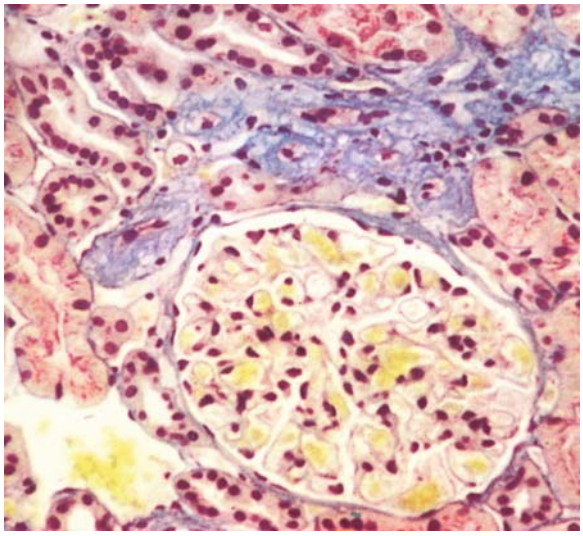

Fig. 19.22. Minimal change glomerular nephropathy. Histology usually shows normal glomeruli, but EM evidences fusion of epithelial foot processes in each glomerulus

mazepine, dapsone, phenobarbital, phenytoin, minocycline, and sulfonamides [212]. In addition to early withdrawal of the offending drug, treatment is mostly symptomatic. Recently, a 6-year-old boy showed a dramatic response to IVIg within 24–48 h, with an improvement in overall well-being and alleviation of AHS symptoms [179].

Reactions Potentially But Not Definitely Drug-Induced

Erythema multiforme is considered a variant of the pathogenetic process underlying urticaria. A minor acute form is known as well as a major form, which some have identified with TEN or SJS [172]. *EM minor* is perhaps the most common aspect of cutaneous allergic ADR (46%–94% of cases), with a usually benign course, rarely seen by doctors [227]. It is characterized by the abrupt onset of self-limiting cutaneous eruptions and by a wide range of symmetrical lesions with typical targets or raised edematous papules acrally distributed [12]. *EM major* exanthema is widespread, initially maculopapular, and later urticarious lesions involving one or more mucous membranes with blisters and bullae surrounded by a central elevated edematous ring in expanding erythematous macules or papules, spreading on dorsal surfaces of distal extremities [99]. EM lesions are fixed, and red papules, some of which evolve into plaques with central, dusky coloration and blister formation, called target or iris lesions, remaining in the same skin site for at least 7 days, are the hallmark of EM [227] (Fig. 19.23). Differential diagnosis with infections is indicated by finding rashes on both feet and hands in the first instance, while the lesions have an almost cyanotic aspect in the second instance. Furthermore, withdrawal of causative agents is followed by a quick recovery. Among the diverse etiological causes that have been purported, in 63.6% of 22 children were the infectious agents [99], the most reliable being HSV, mononucleosis, histoplasmosis and some drugs (Table 19.28) [12, 103], almost exclusively antibiotics and co-trimoxazole, often widely prescribed. Major EM, frequently used as a *synonym for SJS,* generally appears after HSV and *Mycoplasma* infections, and may be differentiated by one or more mucous membrane involvements [174]. The mean duration of EM disease was 12 days, 40% of children had recurrent disease. The mean disease duration was 16 days in ten children treated with steroids vs 15 days in ten non-steroid-treated children. A child with recurrent EM major was well controlled by thalidomide [99].

Fig. 19.23. Typical erythema multiforme lesions with target appearance

Exfoliative dermatitis or erythroderma is a potentially fatal cutaneous disease, characterized by macular (erythroderma) or maculopapular eruption over a period of 1–2 days and followed by an *extensive exfoliation* that progressively spreads to the whole body, accompanied by intense itching. If the affected areas are not quickly treated it may lead to edema and exudation, with severe dehydration. The lesions also provide a

fertile area for secondary infections. This could be a first stage of TEN or SSSS [103]. In infancy, a toxic reaction may be consequent to vitamin A poisoning following high-dose intake for some months [2]. About 10% of cases are attributed to drug-induced reactions (Table 19.29) [12, 207] (Fig. 19.24) or to cefoxitin therapy. From an immunological point of view, given the disease's eczematous nature, a mechanism mediated by T lymphocytes has been suggested [207].

Vasculitis (Table 8.19) – drug-induced forms mainly affect the small vessels and are subtypes of hypersensitive forms [12]. Some might be attributable to an immune pathogenesis most probably induced by CIC deposition. Other symptoms are systemic: fever, malaise, headache, arthralgia, myalgia, and abdominal pain [46]. Table 19.30 outlines the offending drugs more frequently purported in vasculitis [12, 172]. The overall picture that is most well-known in infancy is Schönlein-Henoch anaphylactoid purpura (Tables 8.20, 8.21 and Fig. 8.19). Drugs (antibiotics and thiazides), food, infections, vaccines, insect stings, etc. are usually incriminated. At the basis there is an immune Arthus-like mechanism (type III) with infiltration of polynucleates and the typical lesions of leukocytoclastic vasculitis. A high concentration of CIC-IgAs and serum IgA levels are reported while ANA is negative (Table 8.26).

Vaccines

Data from [206].

Pseudoallergic ADR

PARs involve several drugs (Table 19.31) [206], which cause symptoms suggesting allergy, but are rarely immune-mediated. As previously mentioned, the clinical similarity of these reactions to allergic responses is caused by the same effector cell involvement and the same mediators of allergic inflammation [221]. Some possible mechanisms are the following:

- Direct stimulation of metachromatic cell mediator released through nonspecific mechanisms (Table 10.13)
- Generation of C3a/C5a by alternate complement pathway
- Direct stimulation of platelets, involving the indirect mediator release through effector cells
- Plasma generation of bradykinin/quinine
- Nonimmunological stimulation of other effector cells (eosinophils, neutrophils, monocytes, lymphocytes)
- Release of inflammatory neuropeptides by neurons [45]

Differentiation from allergic reactions is shown in Table 19.5: PARs almost always appear after a first exposure, but only if the dose is sufficiently high, and often look similar to toxic reactions rather than an immune-mediated mechanism. It must be emphasized that, in addition to light reactions such as ampicillin-induced rashes, increased during viral upper respiratory tract infections (URTI) [184], there can also be severe reactions, sometimes fatal, because several drugs are capable of causing anaphylactic or anaphylactoid reactions (Table 19.9), also depending on prevalent widespread use. In particular, *anaphylactoid reactions*, caused by direct and nonspecific mast cell mediator release, are caused by iodized radiocontrast media, IV anesthetics, muscle relaxants, codeine, polymyxin, thiamine, tubocurarine, ASA and NSAIDs. The reactions are more severe if the offending substance is given rapidly and IV and/or high doses of drugs are promptly released into the circulation [206]. Prevalence is estimated at around 1 per 5000, with a rate of fatalities of 6 % among patients treated (Chap. 20).

Additional Drug-Induced Reactive Syndromes (Table 19.31)

Histamine-Releasing Substances [206]

Polybasic compounds

In humans, polybasic compounds release histamine only from skin mast cells and include:

- *Compound 48/80* is used by the pharmaceutical industry as a standard reagent to study the nonimmunological histamine release and mast cell heterogeneity.
- *Polymyxine B* is rarely used due to its nephrotoxicity.
- *Vancomycin* is an antibiotic that is highly effective against methicillin-resistant streptococcal infections and those caused by Gram-positive germs in penicillin-

allergic patients. It causes eosinophilia and the so-called *red man syndrome* similar to erythroderma. If too quickly IV-injected it may cause angioedema, pruritus and sometimes chest pain, dyspnea and hypotension.

- *Protamine* is IV-injected to counteract heparin anticoagulating effects and to treat overdoses of this hormone, with severe systemic reactions sometimes occurring [16]. There is also evidence of an allergic sensitization: in diabetics previously treated with insulin containing protamine, anti-protamine IgE and IgG antibodies increased risk to 95% and 38%, respectively. Very severe reactions were experienced by rechallenged patients, while 5/9 controls had only IgG. Protamine can potentiate in vitro basophil release of IgE-mediated histamine. In nondiabetic subjects, the presence of protamine IgG is significantly associated with an increased risk of acute protamine reactions, although many nondiabetic subjects had reactions but no IgG antibodies [226].
- *Somatostatin* is a compound that is no longer in use, and has been replaced by an analogous octa-peptide, provided with minimum effects on histamine.
- *Substance P* is provided with histamine-like activity.
- Neuropeptide Y is stored in noradrenergic neurons along with norepinephrine. The characteristics of histamine release are shared with those of substance P.

Other drugs [213]

- *Atracurium* and *d*-tubocurarine. The latter is the only muscle-relaxing agent triggering a clinically significant increased histamine release.
- *Codeine,* meperidine and morphine cause mediator direct release and cutaneous reactions to the same extent, the first two are also systemic.
- *Deferoxamine,* an iron-chelating agent elicits hypotension and anaphylactic shock if not slowly IV injected.
- *Phytonadione* (colloidal vitamin K), administered by IV, probably because of the effect of fatty acids used as emulsifiers, by releasing mediators and/or inducing vasodilation, may provoke shock, which should be a warning sign.
- *Pentamidine* causes 75% of IV-treated patients to manifest facial flush, pruritus, nausea, tachycardia, hypotension and syncope.
- *Thiopental* or thiopentone produces a noncytotoxic dose-related mast cell histamine release; the prevalence of reactions is estimated at between $1 \times 23{,}000$ and $1 \times 29{,}000$ administrations [213].

Complement Activation

Many substances can activate complement via nonimmunological mechanisms, including [213]:

- *Bacterial endotoxins* activate both pathways and zymosan only the alternative pathway if used for testing properdin.
- *Ig* activate the classic pathway generating anaphylotoxins. Previous use was limited due to a frequent onset of anaphylactoid reactions because of high-MW complexes. Reactions are more frequent in agammaglobulinemic patients, in particular with a selective IgA deficit (Chap. 22), or after fortuitous IV injections or repeated administrations.
- *Foreign proteins* such as peptone are used on laboratory animals.
- *Hemoderivates* and plasma substitutes are substances used as plasma substitutes. They are capable of direct mast cell activation.
- *Albumin* causes reactions due to aggregates formed during the polymerization process indispensable for preservation or stabilizing.
- *Dextrans* are available in three types with different MWs, which induce clinical symptoms in five stages, going from urticaria to a systemic reaction, and also cardiorespiratory arrest. The prevalence of severe effects is 0.008%–1% of administrations. They activate the complement alternative pathway, generating C2, C3 and C5. Compounds with lower MW are less immunogenic, but may react with anti-dextran antibodies belonging to IgG or IgM classes, formed in response to previous exposure to polysaccharides of bacterial or viral origin [213].
- *Protein fractions,* where rapid infusion determines a feeling of heat and a full head, constrictive chest pains, abdominal and back pains and hypotension are attributed to prekallikrein activators that stimulate the prekallikrein-kallikrein system during infusion [214].
- *Plasma expanders* such as fluid gelatins can be used as fillers in emergency situations and in measles vaccine [31]. Prevalence of reactions varies from 0.07% to 0.25% of infusions, while *severe reactions* range from 0.016% to 0.066%. From a pathogenetic point of view, histamine is released by metachromatic cells, mostly nonimmunological [85]. Clinical manifestations also are divided into five stages, with progressive worsening leading to death [213].

Enzyme Inhibitors

ACE inhibitors are practically used in managing hypertension. The first drug, captopril, produces maculopapular rashes in 50% of patients, attributed to kininase inhibition. New preparations have a lower effect, related to sensitivity of these molecules to sulfydryl groups. It has been ascertained that at least 10% of patients present at night a persistent, nonproductive cough, at times extremely irritating, and asthma worsening [206]. Anticholinesterase will be discussed in "Adrenergic and Cholinergic Substances."

Drugs Active on the Central Nervous System

Anaphylactic reactions caused by *general anesthetics* are better known [16, 20], while *local anesthetics* such as benzocaine can cause ACD immune type systemic reactions are very rare. Halothane, still used in the *induction stages in pediatrics,* causes reactions in 1 × 35,000 cases [141]. A 4-year-old child developed systemic anaphylactic reaction to lidocaine hydrochloride within 15 min after a dental procedure [35]. A 14-month-old boy developed anaphylaxis to propofol. The child was allergic to egg and peanut oil, and propofol formulation contains both foods [76]. Toxic reactions are more frequent, resulting from rapid drug absorption, inadvertent IV injection, or overdosage. Hence preservatives such as parabens and Na sulfite are blamed [214], more frequently during dental anesthesia or small surgical procedures [6]. Negative SPTs do not necessarily predict that a drug will be tolerated. Latex allergy (Chap. 8) should always be considered in the differential diagnosis of a perioperative reaction.

Additional muscle relaxants include reactions to *chymopapain* more frequent in atopic patients previously exposed to papain, for those who are candidates for chemonucleolysis, SPTs are extremely predictive [123]. *Suxamethonium* more often than other drugs causes IgE-mediated reaction, fourfold more frequently than with vecuronium and 2.5-fold more frequently than with atracurium, respectively inducing bronchospasm and hypotension [220]; others are discussed in Chap. 20.

Adrenergic and Cholinergic Substances [206]

- *Adrenergic β-blockers,* of which propanol causes or worsens asthma, 50% of asthmatics may experience bronchospasm, which does not improve with inhaled bronchodilators. There were reports in American asthmatics of 13 cases of deaths and 200 severe reactions to timolol maleate eye drops; β_1-blockers only partially avoid undesired effects [213]. Cases involving shock have been pathogenetically attributed to cAMP inhibition, by reducing its endocellular concentrations, and to the consequent lower threshold of mediator release by metachromatic cells. Moreover, these drugs decrease endogenous epinephrine secretion, both by blocking β_2-receptors at synapsis and inhibiting β_1 effects of endogenous and exogenous epinephrine on the heart [213]. All β-blockers increase in vitro the synthesis and release of anaphylactic mediators, as well as IgE levels [206]. They may be implicated in undesirable reactions that, albeit rarely (0.015% of cases), occur during SPT and SIT administration (specific immunotherapy) [72]. Definite data derive from a double-blind study on a statistically representative sample of patients. In the meantime, in collecting patient history in adult subjects, it is worth investigating any contingent use of β-blockers [69].
- *Other antihypertensive drugs,* for example, reserpine causes dose-related nasal obstruction and rhinorrhea and bronchospasm worsening at higher doses. Additional side effects are dry mouth and nasal mucosa from clonidine, asthma and nasal congestion from guanethidine, dyspnea from hydralazine, nasal obstruction and dry mouth from methyldopa [207].
- *Cholinergic agents* and *anticholinesterase.* The effects of methacholine are so predictable that it is used for bronchial provocation testing (Chap. 6). Another group, the *reversible inhibitors,* are used for managing paralytic ileus, urinary bladder atony, etc. These should be used by asthmatics with due care [206].

Characterization of Various Drugs and Categories of Drugs

Tables 19.32–19.34 [132, 186] summarize the best-known drugs containing sulfites and also rates of dye agents and aromas; those stemming from Na benzoate are shown in Fig. 10.3; sensitivity to tartrazine has been confirmed in Chap. 10, where we reported that of the 2%–35% the illustrative leaflets of several drugs did not specify the type of additive included. Not all oral preparations contain doses of sulfite capable of causing reactions: asthmatic reactions occur using injected products in very intolerant patients [186]. In Chap. 11, we analyzed side effects caused by CSs. Table 19.2 shows the rate of severe and moderate reactions. A meta-analysis reported approximately 100 published reports of immediate hypersensitivity reactions occurring after oral and parenteral administration of CSs [82]. Deflazacort, structurally similar to methylprednisolone, given to two 12-year-olds with severe rheumatic forms, with a dose of 1.5–2 mg/kg/day, caused a vertebral collapse [53]. Vaccines, in addition to the immunizing agent, can also contain small amounts of allergens, derived from production processes, such as egg albumin and other growth media for viruses, silk used for filters, antibiotics, preserving agents including phenol, mercurials, nystatin and gelatin, for example in the MMR (measles-mumps-rubella) vaccine [40] but no case of anaphylaxis [24]. A 28-month-old child experienced a severe anaphylactic shock following a testing dose of aprotinin during major orthopedic surgery [174a].

NSAIDs and ASA

NSAIDs and ASA inhibit cyclooxygenase, consequently blocking prostaglandin, prostacyclin and thromboxane synthesis from ASA, and the diversion down the 5-lypoxygenase pathway, finally producing leukotrienes [34]. NSAIDs, although possessing a chemical structure not remotely correlated to that of ASA, and also in the ab-

sence of cross-reactions, can cause the same symptoms in ASA-sensitive subjects [3]. Thus, the similarity between NSAIDs and ASA should be pharmacological, with shared COX-2 inhibition, although the mechanisms proposed are not exhaustive; otherwise all subjects treated with NSAIDs would have adverse reactions [193]. In a study of 60 aspirin-sensitive asthmatic patients [194] and other studies in patients with cutaneous (243 patients) or respiratory (40 patients) reactions to NSAIDS showed that only a single patient developed mild urticaria [117, 127, 139]. Generally speaking, these are adult subjects suffering from asthma and/or nonallergic rhinosinusitis, often with nasal polyps and eosinophilia, less frequently in adolescents or children. Most at risk are children suffering from asthma or allergic rhinitis complicated by chronic sinusitis and nasal obstruction.

ASA can cause:

- Urticaria, angioedema, other skin affections.
- Rhinoconjunctivitis and bronchospasm; the nasal provocation with ASA induced itching and sneezing in intolerant subjects.
- Rhinitis associated with reserpine treatment, maculopapular and pruriginous rashes and an irritating cough confused with asthma, related to treatment with captopril; worsening of asthma when using β-blockers [193].
- Symptoms may be limited to the respiratory tract, while methylated ASA appears to be responsible for cutaneous and gastroenteric forms [238].

In a cohort of asthmatic children aged 9–13.6 years, 14.8% were allergic to ASA [193], with ≈25% of patients experiencing asthma worsening. In a group of *atopic children* suffering from rhinoconjunctivitis (81%), AD (31%), food PA (19%), sinusitis (81%), with SPT and/or RAST positive to inhalants (88%), 15/16 tested positive to a provocation test (PT), with ASA presenting asthma and three also urticaria (20%); 11/15 (73%) were previously reactive to NSAIDs [50]. Thus, this infantile population appears to have a number of particular features that distinguish it from adults:

1. Absence of nasal polyps
2. Higher prevalence of urticaria
3. High atopic background
4. High incidence of sinusitis [50]

In a group of children aged 0–21, ASA was the most commonly reported NSAID, and less common were pyrazolone and ibuprofen, and 69% of them reported a facial angioedema NSAID reaction occurring once or more due to inadvertent exposure. The reactions most frequently occurred in the group aged 16–21, although NSAIDs are more often used in younger children [32]. In conclusion, cutaneous reactions [32, 50] and sinusitis [50] appear to be prevalent in children. Two percent of NSAID-induced facial angioedema developed in 0- to 5-year-old children, 3.8% in 6- to 10-year-olds, 8.2% in 11-to 15-year-olds, and 21.8% in 16- to 21-year-old *atopic children* [32]. The 24 children presented com-

plaints to NDAIDs such as periorbital angioedeme (88%), urticaria (50%), wheezing (33%), perioral angioedema (21%), rhinorrhea (13%), facial swelling (8%), and a maculopapular rash (4%), developing 30 min to 4 h after ingestion of the offending NSAID. An oral challenge test (OCT) resulted in periorbital angioedema (100%), frank wheezing (38%), urticaria (38%), rhinorrhea (23%) and respiratory symptoms of tachypnea, wheezing, and cough (35.5%) [86]. A positive FHA was present in 86% of the children [86].

What a number of authors have recommended is a prudent use of *hydrocortisone* in subjects suffering from ASA-related asthma, only in emergencies such as status asthmaticus or anaphylaxis, since it might start reactions that in prospective may be very severe and hard to control. This is because, by inhibiting arachidonic acid release by phospholipids, the drug deprives the airways of PGE_2 and prostacyclin bronchodilator effects [160]. Subsequently a preferential sensitization to hydrocortisone was excluded (only 1.9% of adults presented rhino-ocular symptoms), suggesting that succinate was the case [55], possibly causing a fatal case (Chap. 20). Therefore there is no valid reason to avoid the use of this drug in those emergencies in which it is indicated. Caution imposes the inclusion of sensitization to hydrocortisone in the history. In those who are ASA-sensitive, it is possible to administer CSs either by mouth or by spray during anesthesia or during surgery [130].

NSAIDs and ASA cross-react with numerous drugs (Table 19.35) [184, 193, 213]: the strong COX inhibitors of cyclooxygenase have a rate of cross-reactivity of 90%. A challenge with COX-2-specific inhibitors resulted in mild periorbital edema and mild generalized urticaria in 4 of 25 children [86]. Acetaminophen is not tolerated by 6% of ASA-sensitive patients [213]. Many people who are ASA-intolerant do, however, tolerate salicylates, structurally similar to ASA. Furthermore, in ASA-intolerant patients platelets interact with ASA, creating cytotoxic products [214]. Additional data is lacking [3]. In 3/17 adults, mast cell involvement has been shown, since tryptase and histamine levels appeared to be higher [25]: negative results in the other 14 required considering an underlying heterogeneity as a pathogenetic model of ASA intolerance.

Ionic Radiocontrast Media

Ionic radiocontrast media are almost exclusively of the PAR type, independent of specific sensitivity to iodine compounds as such or present in the diet. They consist of erythema, bronchospasm, angioedema, syncope and hypotension; effects are multiplied by occasional hyperosmolality and/or medium viscosity: for this reason preparations with a reduced osmolality and viscosity have been introduced [222]. Age is a major risk factor, with children aged 5–15 having the highest sIgE levels, which are lower at age 25, but always the highest level for that age, as compared with the lowest levels at age 65–75 [97]. Reactions during contrast tests in children <10 years were as frequent as 0.063%, using both ionic and nonionic compounds, suggesting that, unlike adults, reactions do not increase test safety in children [83]. In the urine of patients suffering from previous reactions, histamine levels were higher than in controls [28]: hypersensitivity to radiocontrast media may therefore depend on their concomitant influence upon metachromatic cells, effectively activated by tryptase [165]. Yet such agents appear unable to react with tissue proteins to form immunogens [28]. Complement activation, observed in severe reactions, is potentially caused by elevated concentrations, but it has not yet been clarified whether this mechanism is due to direct actions or more likely to protease activation, in turn resulting in bradykinin generation, an effect modulated by kininase, particularly by ACE [28]. Contrast media seem to have the capacity to interfere with bradykinin catabolism [97], of activating the prekallikrein–kallikrein complex, of inhibiting platelet aggregation, and damaging the vascular epithelium [165].

Penicillin and β-Lactam Antibiotics

Immune mechanisms involved in ADRs to aminopenicillins in vivo are related to genetic markers of immune response and confirm that the presentation of penicillin-hapten determinants to lymphocyte is HLA-restricted [169]. Data suggest that *Th2-like T-cell ILs play an important role* in all β-lactam-induced ADR, even when late clinical manifestations occur and an IgE-mediated mechanism cannot be demonstrated [27]. It has been shown that at least three different epitopes

Fig. 19.25. Same infant as Fig. 19.12. After 5 days the exanthem assumes this hemorrhagic aspect

exist in the penicilloyl groups. They consist in the new antigenic determinants resulting from the opening of the β-lactam ring and conjugation to endogenous proteins. Penicillins form part of the epitopes contacting the antigen receptors of β-lactam-specific T cells in allergic individuals, as demonstrated by a peptide sequence derived from a natural *DRB1*1101*-binding peptide modified in vitro with penicillin G, which acquired antigenic properties [140, 236]. sIgE for penicillin have been identified in cord blood (Table 3.2) and also during the neonatal period [52], following pertinent therapies for pregnant and breast-feeding women [213]. sIgE levels to cefuroxime were not detected at the moment of the reaction but became positive 1 day after, increasing to peak at day 51, and still positive after 115 days [175]. Most IgE-dependent sensitizations were diagnosed by means of SPTs (86.4%) [155]. A high proportion of IgE antibodies to both benzylpenicillin and cephalothin suggested the presence of a *cross-reacting epitope* on each molecule [237]. Moreover, IgE-type reactions after SPTs or OCTs in 34% of children in whom 32%–60% suspected penicillin, amoxicillin, and cephalosporin reactions were shown to be IgE-mediated [154]. *Antibiotics are a paradigm of immunological reactions,* including IgE-mediated anaphylaxis, urticaria-angioedema, bronchospasm (type I), immune-mediated cytopenia (type II), serum sickness, urticaria, rashes (type III), ACD and other eruptions (type IV) [211, 214, 228], with a prevalence of cutaneous symptoms of 87.3% [211] to 96.6% [66]. The likelihood of β-lactam allergy was significantly higher for anaphylaxis (42.9% vs 8.3% in late reactions) and *immediate reactions* (25% vs 10% in other reactions) [155]. The risk was significantly higher in children with anaphylaxis (26.7%) and in those reporting immediate reactions (33.3%) vs 8.5% and 7.5% of the children with late reactions) [155]. Previous data suggest that Th2-like T cell ILs play an important role in all β-lactam-induced ADRs, even when late clinical manifestations occur and an IgE-mediated mechanism is apparently indemonstrable [27]. Specific IgE levels to cefuroxime were not detected at the moment of the reaction but became positive 1 day after, increasing to peak at day 51, and still positive after 115 days [175]. Most IgE-dependent sensitizations were diagnosed by means of SPTs (86.4%) [155]. A high proportion of IgE antibodies to both benzylpenicillin and cephalothin suggested the presence of a cross-reacting epitope on each molecule [237]. Of 72 children tested, 32% described their past cutaneous eruption as hives and 68% had other rashes; 96% of rashes were generalized [93]. ADRs to five classes of antibiotic were noted in 3.1%, to four classes in 10.3%, to three classes in 47.4% and to two classes in 39.2%. Most *children (85.6%) experienced an ADR to a penicillin,* while *71.1% reacted to a cephalosporin, 80.4% to a sulfonamide* and *35.1% to a macrolide.* Clinical presentations of the ADRs included urticaria or pruritus, rash, serum sickness-like reaction, angioedema or anaphylaxis, EM or SJS [143]. Indiscriminate antibiotic use *in animal fodder* to prevent infections may start a primary immune response, so that when the child receives one of the myriad of antibiotic cures, the *secondary antibody response occurs upon re-exposure to the same antigen* [39]. Cutaneous reactions form a large body of evidence, the study of patients reactive to ampicillin (7.6% with a positive history) [199], with delayed reactions to SPTs, led to the hypothesis of a type IV hypersensitivity [168, 199, 208, 219]. Opening the tetra-atomic ring and the linkage to a protein carrier occasions the classic form of haptenization (as in all low-MW chemicals), facilitated by ultrafiltrable serum factors [48]. Penicilloyl represents 90% of hapten–protein complexes and plays a nodal role in 75% of type I reactions to penicillin: the rest are divided between type II, III and IV reactions [197, 213] (Figs. 19.9, 19.12). The molecular nucleus, 6-aminopenicillanic acid, is found in penicillin and 7-aminocephalosporanic acid in cephalosporins and in all semisynthetic penicillins (first-, second- and third-generation cephalosporins) [1]. Four different groups of antibiotics, all sharing a tetra-atomic β-lactam ring in their basic chemical structure are commonly referred to as β-lactams (Fig. 19.26). Penicillins share a five-membered thiazolidine ring, and a dihydrothiazolinic ring is common only among cephalosporins [1]. The β-lactam group encompasses penicillins, cephalosporins, carbapenems, monobactams, and β-lactamase inhibitors [151]. New synthetic cephalosporins such as imipenem have the same characteristics [228]. An Italian 7-year old girl died because of an anaphylactic shock after taking a tablespoon of cefaclor (G. Tripodi, pers. comm., 2004), and a 9-year-old

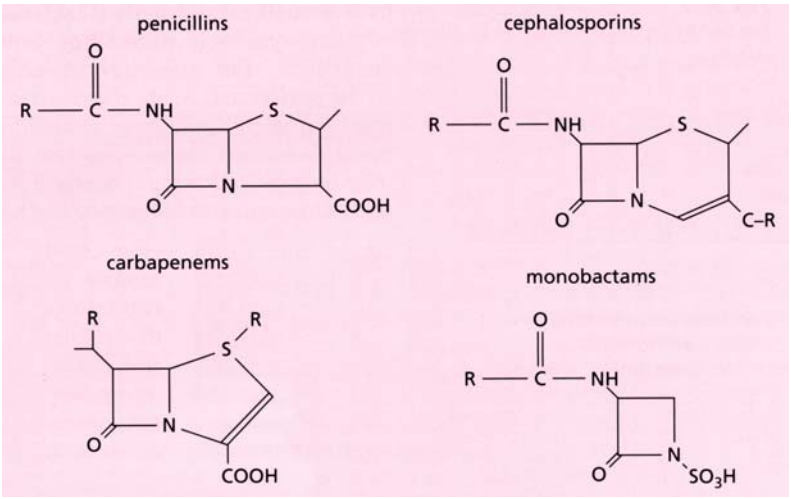

Fig. 19.26. Structure of 4 β-lactam antibiotics

boy after taking oral cefaclor presented with respiratory difficulty, throat tightness, and skin erythema, which required hospitalization. A dose of cefaclor taken 15 days earlier was uneventful (R. D'Ambra, pers. comm., 2005). A reaction was reported even in two 2-month-old babies [86, 111]. Aztreonam is a prototype of monocyclic β-lactams [20] with a production of IgE and IgG in 0%–3% of patients [23], but it is not tolerated by all β-lactam-allergic patients [209]. It follows that a patient who states to be allergic to penicillin can be allergic to all of them [49], as patients sensitive to NSAIDs are allergic to all drugs [149], while a patient reacting to one β-lactam can tolerate the others [114], also at a later administration [181]. Haptenization explains why some patients are allergic and others are not [48].

Several comments are necessary:

- Reactions that may be severe are caused by exposure to *hidden sources of penicillin,* nonmedically used penicillin (Table 19.36) [21, 136], or as an additive in cow's milk or in meat [21].
- Occasionally an allergic reaction may occur after a *first dose of penicillin:* this can also be explained by a prior exposure to antibiotic traces in food or vaccines that has remained unnoticed.
- Reactions can occur in subjects who have taken penicillin *up to a given moment,* an anomaly requiring investigation.
- It is absolutely imprudent *to prescribe penicillins and similar drugs,* as confirmed by various percentages, because the risk of severe and sometimes fatal anaphylaxis may be impending (Chap. 20) [189]:

– *Patients stating that they are allergic to penicillin* are 5%–20%; however, a meta-analysis on 295 articles, of which 30 fulfilled the inclusion criteria (15.6% of children) concluded that 33% of clinical history with SPT-positive patients had a vague penicillin allergy history; therefore such patients, like those with convincing histories, should undergo *penicillin skin testing prior to penicillin administration* [190].

Table 19.36. Hidden sources of penicillin or uncommon causes of exposure

Animal foods
Red meat Poultry Entrails, etc.
Dairy products: contamination during production
Cheese Yogurt
Dairy products: contamination during preparation
Cow's milk as such and powdered Cream Butter Additional dairy products
Penicillin added to foods as a preservative
Residue of animal foods
Surgical operation
Handling penicillin-containing capsules and syrups
Sexual contact
Use of contaminated glasses

We have not reviewed sensitizations by topical formulations. Data from [21, 136].

– *Subsequent treatment* causes a relapse in 6%–40% of subjects, but only in 6.8% of 298 children [66].

– *Reactions also occur* in 1%–10% of patients with a negative history, with the exception of adolescents [121].

– In particular, the prevalence of *SPT positivity in children* is approximately 4.7% (range 0%–8.8%) [66, 93, 121, 211], which with PT rises to 10% [66], confirming the risk run by a considerable proportion of pediatric populations; however, many children may be incorrectly labeled as penicillin-allergic, resulting in ongoing avoidance of penicillins [93], especially when there was

no positive response to SPTs, and only 4% of children had a positive response to intradermal testing [93].

- *Cross-reactivity* is impressive in vitro, but variable in vivo: although allergic reactions to first-generation cephalosporins in patients allergic to penicillin make up 5%–16% of the pediatric population, cephalosporins cannot be considered a safe and routine alternative, because antibodies against the immunogenic epitopes have been found in the lateral chains, so that many patients react to specific epitopes belonging to these chains [185]. The meta-analysis of all published studies that evaluated the risk of administering a cephalosporin to a penicillin-allergic patient indicates that patients who have known penicillin-specific IgE antibodies may be at increased risk for a reaction to cephalosporins [190]. However, the risk of suffering from an allergic reaction on administering cephalosporins to penicillin-allergic patients seems to be very low, provided that patients use cephalosporins with a different side chain to the penicillin responsible for the allergic reaction [131]. Moreover, hypersensitivity to β-lactams was suspected from clinical history in 30 (9.2%) children: SPTs and OCTs led to the diagnosis of β-lactam allergy *in 24 (7.4%) and 15 (4.6%) of the children*, respectively [155]. In a third pediatric trial, OCTs confirmed that 4% of reactions were caused by drug allergy [118]. These results conflict with another study reporting positive SPT or OCT results *in 23.5% of children* [154].
- *Lateral chains* have acquired importance related to the prospect of cross-reactions with other β-lactams and with similar ones, although the nucleus which defines the class is different [20].
- Studies with *amoxicillin* have proved that many patients can react to one antibiotic and yet tolerate others: this suggests a specific response, which for many patients seems to be correlated to amoxicillin lateral chains, as confirmed by SPTs and RAST [19, 20]. However, only 50% of patients are positive to PTs [210], indicating that the other half responds to another determinant correlated to amoxicillin.

The frequency of reactions to ampicillin and amoxicillin varies between 9.8% and 20% for the first and between 33% and 58% for the second [10, 185]: the higher figures can be related to the higher number of prescriptions in a specific country [1, 18]. Amoxillin alone or associated with clavulanic acid was most frequently reported to cause adverse reactions in children [155], similar to the 61.6% seen by a recent study, considering an additional 87 individuals who had allergy symptoms with penicillin exposure *despite negative penicillin SPTs* [201]. In a study involving 34 subjects allergic to β-lactams, eight (24%) suffered anaphylaxis, seven of these (88%) to amoxicillin: 2/8 (25%) were aged between 12 and 19; the only other boy in the controls presented a generalized maculopapular rash to amoxicillin [10]. In another study on amoxicillin 4/7 patients aged between 15 and 21 who underwent provocation testing presented generalized pruritus and facial or generalized edema [210]. Reactions often assume unusual forms: the amoxicillin-clavulanic acid association has caused generalized urticaria in two adolescents [56], angioedema by cloxacillin taken orally, with no reaction to amoxicillin simultaneously administered IV [200].

- In addition to the lethal cases reported above, three children aged 5–9 experienced an anaphylactic shock to ceftriaxone, two of them within 3–4 min [170].

Sulfonamides

Sulfonamides have been increasingly used for treating *Pneumocystis carinii* infections. According to some statistics, they cause 25.5% of reactions, and divided per apparatus, 25% of skin eruptions, 10% of allergic skin, hematologic, hepatic, respiratory and renal complications [81]; the incidence of skin lesions is 2%, rising to 6% for TMP-SMX [29]. *TMP-SMX* reactions are usually caused by sulfamethoxazole, with a case of anaphylaxis caused by TMP-SMX [29]. In the 25 children those reacting to antibodies were aged 4.8 years [86]. In children with AIDS, TMP-SMX reaches reaction

Fig. 19.27. Urticaria by TMP-SMX allergy

Fig. 19.28. Angioedema by TMP-SMX allergy

levels between 29% and 70% [5] and TMP-SMX causes 12% of skin reactions [125]. In view of clinical characteristics and the laboratory data available, it has been concluded that they cause various kinds of reactions [221], with a considerable role played by CICs in vasculitis and by cytotoxic mechanisms in cytopenia [213]; cases of serum sickness, urticaria-angioedema (Figs. 19.27, 19.28), ACD, etc., mostly reactions of immunological type.

Uncommon Reactions to Drugs

Two children have been reported who had reactions during etanercept treatment for systemic-onset JRA. A 12-year-old boy developed SLE with high ANA (antinucleus antibodies) and anti-ds DNA titers [101] and a 7-year-old girl developed diabetes mellitus (DM) 5 months after the initiation of etanercept therapy [22]. Therefore evaluation of ANA and anti-ds DNA titers in every etanercept-treated child is recommended [101]. A 9-year-old girl diagnosed with asthma developed SLE after treatment with zafirlukast [57]. A 9-year-old girl with SLE nephritis developed cutaneous bullae and mucositis while being treated with IV methylprednisolone. Skin biopsy specimen findings supported a diagnosis of SJS [176].

Diagnosis

The DAR diagnosis causes a considerable degree of difficulty, both because the pathogenetic mechanisms are little known and because of the patient's attitude. Often an adolescent, or frequently the parents, tend to apply the *post hoc, ergo propter hoc* concept (after this, so in consequence of this) [17]. One component that is often neglected is that of self-prescribing or of parent or family "prescriptions," in addition to over the counter products, in which the composition is not always mentioned [215].

History

This is the foundation of etiological diagnosis (Table 19.37) [218], although a multitude of diagnostic tests are proposed [189], starting with a detailed family history following specific points:

Family History

Have the parents and/or relatives ever presented reactions to drugs? If the answer is positive taking a properly meticulous collection of data is the best method to minimize allergic and nonallergic ADRs [207].

Table 19.37. Clinical prerequisites to diagnose drug-related reactions

The reactions do not represent a drug-dependent adverse effect
The reactions are usually similar to those attributed to other allergens
The initial exposure is followed by a latent period of about 7–10 days
The reaction may be reproduced by cross-reacting chemical agents
The reaction may be elicited by minimal doses of the drug
The finding of blood or tissue eosinophils may be associated
The clinical reaction should resolve after the drug has been discontinued
The allergic reaction should involve only a small percentage of subjects

Data from [218].

Personal History

Ascertain whether the child has ever suffered from atopic diseases and investigate any likely prior exposure to drugs. In this specific case, acquire detailed information on which drug or group of drugs has been taken, including dose, route of administration, duration of treatment, clarifying whether the child may have ever taken a medication, either regularly or intermittently, and which reactions occurred during the period in which any medication was taken. Taking a detailed history should include all associated clinical aspects and symptoms provoked by prior or present exposure to the same or structurally related drugs, the temporal relationship of drug administration and symptom onset, how long symptoms lasted and *whether treatment discontinuation* will lead or not to a reduction or abatement of symptoms. To identify all potential causes, pediatricians must be informed of all medication taken, prescribed or not, also over the counter, nonregistered, herbal, homeopathic, etc. Having completed this initial chart, pediatricians will try to differentiate predictable from unpredictable reactions, and analyze temporal relations, so manifold risk factors will be clarified [225]:

- *Verification of the child* and classification of reactions
- *Identification of all potential causes*
- *Analysis of the drug's innate capacity to cause the reaction* in question
- Proof of a *clear temporal cause–effect* relation
- *Verification of the effects* obtained by treatment withdrawal
- Evaluation of whether to prescribe an *antihistamine*
- *Possible re-exposure* and comparison with prior reaction(s)
- *Focused* clinical examination [164]

Table 19.38. Differences between allergic and pseudoallergic drug reactions

Features	Pseudoallergic	Allergic
Dose necessary to induce reactions	Elevated	Very little
Cumulative effect	Often necessary	Usually absent
Correlation between effects and pharmacological action	Often present	Absent
Reproduction of the effects by pharmacologically different drugs	Rare	Common
Clinical pattern	Uniform	Different

Data from [218].

Laboratory Investigations

In vivo and in vitro tests which have proved to be useful for differentiating allergic and nonallergic reactions (Table 19.38) [218] are outlined in the following sections [47, 164].

SPT

- *Immediate reactions:* reliable for high-MW drugs (complete antigens) (Table 19.4), unreliable for low-MW drugs (haptens), with the exception of penicillin.
- *SPTs with high-MW drugs* and with penicillin reagents may predict anaphylaxis and urticarial reactions.
- Children with a *suspicious history* and negative RAST.
- *Delayed reactions:* little correlation with medical history and clinical picture with a few exceptions.

Patch Test

Patch tests are rarely positive in drug-induced cutaneous rashes.

In Vitro Tests [46]

- PRIST: *total IgE:* to identify atopic children
- *IgE-mediated RAST reactions:* IgE to penicillin in nonatopic patients; children who cannot tolerate SPTs
- *IgG- and IgM-mediated reactions:* direct and indirect Coombs tests are usually useful, hemagglutination rarely in agreement with clinical picture

Other Tests

- *LTT, MIF* (monocyte migration inhibiting factor), production of cytokine, of little importance because these can indifferently give positive or negative results.
- *Lymphocyte stimulation test* (LST) is useful in the diagnosis of drug-induced hepatitis in 54.3% of cases [233].
- *Radioimmune testing* of histamine is efficient, also because of the rarity of false-positive and -negative testing [95].
- Various drugs have shown *specific antibodies*; Table 19.39 [37] shows the relevant tests.
- In adults, the *nasal provocation test* (NPT) has been evaluated in the diagnosis of hypersensitivity to ASA, with positive results in 38% of study patients compared to 8% in controls [147].

Table 19.39. Drug-specific antibodies and related tests

Drugs	Antibodies	Tests
Amodiaquine	IgG	ELISA
Anesthetics and muscle relaxants (alcuronium, gallamine, chlorprocaine, thiopental, tubocurarine)	IgE	SPB
Captopril	IgG	ELISA
Cephalosporins	IgG, IgM	HA
Cyclophosphamide	IgG, IgE	RBA
Chlorhexidine	IgG, IgE	ELISA
Dapsone	IgG	ELISA
Elliptio	IgM	RBA
Ethanol	IgG	IF
Ethynylestradiol	NK	RBA
Halothane	IgG	ELISA
Methyldopa	IgG	IF
Mianserin	IgG	IF
Morphine	IgG	RBA
Nomifensine	IgG, IgM	HA
Penicillamines	IgG	SPB
Penicillins	IgE, IgG, IgM	ELISA
Phenytoin	IgG	HA
Practolol	NK	RBA
Salicylates	IgG	HA

Data from [37].
HA hemagglutination, *ELISA* enzyme-linked immunosorbent assay, *IF* immunofluorescence, *NK* not known, *RBA* radiobinding assay, *SPB* solid phase binding.

- In selected cases a *challenge test* can be used.
- A number of *in vitro assays* have been used for ADR assessment, but many such assays, since they are specifically research tools, show little usefulness in clinical practice [164].

In conclusion, SPTs are the foundation for a diagnosis, tests in vitro support, but do not replace in vivo tests [60]: SPTs were positive in 68% of cases, a rate rising to 77% when combined with RAST+ cases, therefore the remaining 23% of patients need PTs [199]. The future in diagnosis is now.

The convergence of pharmacogenetics and rapid advances in human genomics has resulted in *pharmacogenomics,* that is the influence of DNA-sequence variation on the effect of a drug. The time is rapidly approaching when the sequences of virtually all genes encoding enzymes that catalyze phase I and II drug metabolism will be known. The same will be true for genes that encode drug transporters, drug receptors, and other drug targets. Thus the convergence of advances in pharmacogenetics and human genomics means that physicians can now individualize therapy in the case of ADRs [223].

Differential Diagnosis

Usually ADR clinical pictures are so dissimilar that, to permit an exhaustive differential diagnosis [172], a number of specific diagnostic charts have been proposed [215].

The first is represented by the cutaneous manifestations such as EM. Various algorithms are available for establishing whether the eruption in question represents a hypersensitive reaction supported by an immune-mediated process, and if so, whether it should be considered ADR-induced, differentiating it from other similar manifestations. The following data are useful for achieving this objective [103]:

- Drug-induced allergic reaction occurs in *only a small percentage of children.*
- The *morphology,* as well as associated symptoms and signs (fever, pruritus, eosinophilia, etc.), must be characteristic of that specific drug.
- With *reactions occurring after the first exposure,* there should be a latent period of 1–2 weeks between the start of treatment and the rash appearance, necessary for developing immune reactivity.
- *The rash must not be dose-dependent,* nor should it repeat a well-known toxic or undesirable effect, characteristic of the drug's pharmacological activity.
- *Symptoms should abate* when treatment is withdrawn, and relapse as soon as the child is rechallenged.

Drug-induced fever is sometimes accompanied by a maculopapular or urticarial eruption, often with eosinophilia, thus providing a clue. In other cases, the rise of fever is exaggerated compared to clinical features, or the concomitant use of a well-known potentially harmful agent should be suspected [46]. The differential diagnosis with other conditions is not always easy, while at times a prompt diagnosis is imperative, since fever often precedes the appearance of hepatitis, vasculitis, exfoliative dermatitis, and/or drug-induced hematological reactions. This repercussion often parallels a diagnosis of "a fever of a nature to be determined."

Table 19.40. Clinical and laboratory findings that should alert pediatricians that drug-induced cutaneous flare-ups may be dangerous

1. Clinical findings
Cutaneous
Confluent erythema
Facial or only central facial swelling
Skin pain or irritation
Palpable purpura
Skin necrosis
Blisters
Epidermal detachment
Positive Nikolsky's sign[a]
Mucous-membrane erosions
Tongue swelling
General
High temperature (>40°)
Enlarged lymph nodes
Dyspnea or wheezing
Hypotension
2. Laboratory data
Eosinophil count >1,000/mm^3
Lymphocytosis with atypical lymphocytes
Altered tests of liver function

Modified from [172].

[a] The apparently normal epidermis may be separated at the basal layer and rubbed off with lateral pressure.

Table 19.40 [172] indicates diagnostic criteria and laboratory data useful for an earlier and prompt identification of more severe cases. To differentiate TEN from EM and SJS, the following criteria [103], expanded in Tables 19.41 and 19.42 [172], are valid:

- *Bullae or erosions* should involve >20% of the body or cover at least three different areas, including mucous membranes.
- Lesions develop *on an erythematous base,* respecting sun-exposed areas, and within 48 h of the rash onset the skin is tender when touched.
- *Unlike exfoliative dermatitis,* in TEN the skin peels off in sheets of ≥3 cm in size, as in second-degree burns;
- *Fever is present and SSSS* should be excluded: *Staphylococcus aureus* is commonly recovered from the skin and nasopharynx, blood culture results are frequently positive, skin biopsy shows intraepidermal cleavage in SSSS, whereas in TEN cleavage reaches the basal cell layer and total denudation occurs. *Nikolsky sign* (skin that apparently looks healthy peels off following the lightest friction) is not differential [172].
- *Biopsy* carried out within 48 h from rash onset already shows basal layer local necrosis [103].

Table 19.41. Pediatric differential diagnosis of severe drug-induced cutaneous reaction

Disease	Interval (weeks)	Mucous lesions	Typical skin lesions	Other frequent findings	Differential diagnosis	Useful laboratory tests
Stevens-Johnson syndrome (SJS)	1–3	Erosions usually at ≥2 sites	Small blisters or dusky purpuric macules or atypical targets, detachment of <10% of body surface area	10%–30% of cases involve fever, lesions of respiratory[a] and gastrointestinal tracts	Postinfectious erythema multiforme major, by HSV or mycoplasma infection	Testing skin biopsy with immunofluorescence
TEN	1–3	Erosions usually at ≤2 sites	Lesions as in SJS, confluent erythema, Nikolsky's sign, diffuse epidermal necrosis, detachment of <30% of body surface area	Nearly always fever, acute skin failure[a], leukopenia, lesions of respiratory[a] and gastrointestinal tracts		Testing skin biopsy with immunofluorescence
Small-vessel vasculitis	1–3	Infrequent	Palpable purpura, most often on the legs, nodules, ulcerations, urticaria	In 30%–50% of cases gastrointestinal symptoms[a], fever, neuritis, glomerulonephritis[a]	Infections, rheumatic diseases	Skin biopsy, blood count, eosinophil count, liver function tests
Serum-sickness or similar reactions	1–2	Absent	Morbilliform rash, often with fever, arthralgias urticaria	Fever, arthralgias	Infections	ANA, rheumatoid factor
Angioedema	[b]	Often frequent	Urticaria or swelling of the central part of the face	Respiratory distress[a], circulatory collapse[a]	Insect stings, foods	Platelet count, specific IgE, antibodies to penicillin

Modified from [172].

[a] Potential causes of death.

[b] Heparin 5–10 days, NSAIDs 1–7 days, penicillin, contrast media, anesthetics a few minutes to a few hours.

Table 19.42. Differential diagnosis of SSSS and TEN

Lesions	SSSS	TEN
Pathogenesis	Group II staphylococcus	Usually drug-induced
Morbidity/mortality	Low	High
Mucosal involvement	Rare	Frequent
Nikolsky's sign	Positive	Positive
Target lesions	Absent	Often present
Blister localization	Subcorneal	Subepidermal

Data from [172].

Skin Test Indications and Application

Indications

When planning SPTs, they should always be done first. If there is a history of a previous serious reaction, the SPTs – if done – should be diluted to start with. If truly indicated and based on the above, they must be done in the following specified cases:

- Positive history for adverse reactions to a drug that is a *complete antigen* (Table 19.4)
- Positive history for adverse reactions to a drug that has *no alternative for the ongoing illness*
- Positive history for adverse reactions to a drug when administration of a *cross-reacting molecule* is necessary
- *Doubtful history* for adverse reactions to a drug when the same drug administration or when a cross-reacting molecule is necessary
- *Negative history* for adverse reactions to a drug in patients at risk for allergies related to the class of drugs to be taken
- *Positive history* for multiple sensitization to drugs

Based on the divisions in Table 19.4, one can use, depending on the case, SPTs or intracutaneous reactions. SPT is initially applied using graded dilutions. With all negative results, it is possible to carry out intracutaneous tests, these too with graded dilutions (never without diluting the drug!), following standard methods [189]. These tests must be applied with extreme caution because they are *potentially hazardous in sensitized subjects,* due to severe generalized and sometimes fatal reactions [69, 121]. However, SPTs using soluble β-lactams diagnose a significant number of immediate sensitizations to penicillins and β-lactams [237].

Particular Features of SPTs for Penicillin: Chemical–Immunological Requirements

The β-lactam ring opening forms a covalent bond with serum proteins and creates a neoantigen, the penicilloyl determinant that, reacting to penicillin in 75% of allergic patients, constitutes the major allergen (Fig. 19.29), which is commercially available, BPO (benzylpenicilloyl); 5% of the penicillin will conjugate with cutaneous proteins producing minor determinants (Fig. 19.30), those with a reduced rate of metabolites (penicilloate, penilloate, penicilloyl-α-propylamine, etc.), from which another commercial product is prepared using BPO and Na benzyl-penicilloate [51]. Because the precise haptenic determinants of cephalosporins are broadly obscure, the free individual drugs are used as SPTs to detect IgE antibodies reactive to cephalosporins [170].

Testing Method

- As usual the positive and negative controls are first carried out.
- In patients at risk, the SPTs are applied using BPO starting with a dilution of 1:100.
- If negative after 15 min *the SPT is repeated* with a dilution of 1:10 or, if necessary of 1:1.
- If negative after 15 min *the intradermal (ID) test is employed* with the same, also with an initial dilution of 1:100.
- If negative after 15 min *the mixture of minor allergens* is employed, starting with a dilution of 1:1,000.
- If negative after 15 min *the ID test* is employed using the same methods [48, 213].

The concentration of BPO is of 6×10^{-5} M, that of penicillin and of mixture of minor allergens is of 10,000 U/ml [49, 228]. For ohter β-lactams, SPTs can be done using 0.25 mg/ml, 2.5 mg/ml to 25 mg/ml, and 2.5 mg/ml, 25 mg/ml for ID test if SPTs are negative [155, 213]. The amoxicillin used in Europe is soluble at 20 and 200 mg/ml [17], whereas 2 mg/ml for both ID and SPTs were used in a US study [111] and it seems that this amoxillin cannot be diluted at the maximum concentration recommended by European authors [17, 19, 155].

To obtain highly reliable results, this significantly predictive test, whether positive or negative, must include both allergens. One must also test the child's reactivity to the specific lateral chains of the diagnostic reagents (semi-synthetic products) [185]. The meta-analysis of four studies shows that the rate of SPT predicting reactivity to challenge tests is of 0%–50% when positive and of 0.2%–4% when negative [49]. More recently, a challenge test only using allergens may result in 7% [19] or 20% [18] of patients missing the diagnosis (perhaps non-IgE-mediated reactions), instead identified with PTs with allergens [19]. Blanca et al [20] were the first to demonstrate the importance of side-chain diagnostic reagents, and consequently the need to include semisynthetic penicillins and cephalosporins, which are responsible for SPT reactions. Since these substances prime reactions caused by sensitization to common allergens with penicillins, by using semisynthetic penicillins and

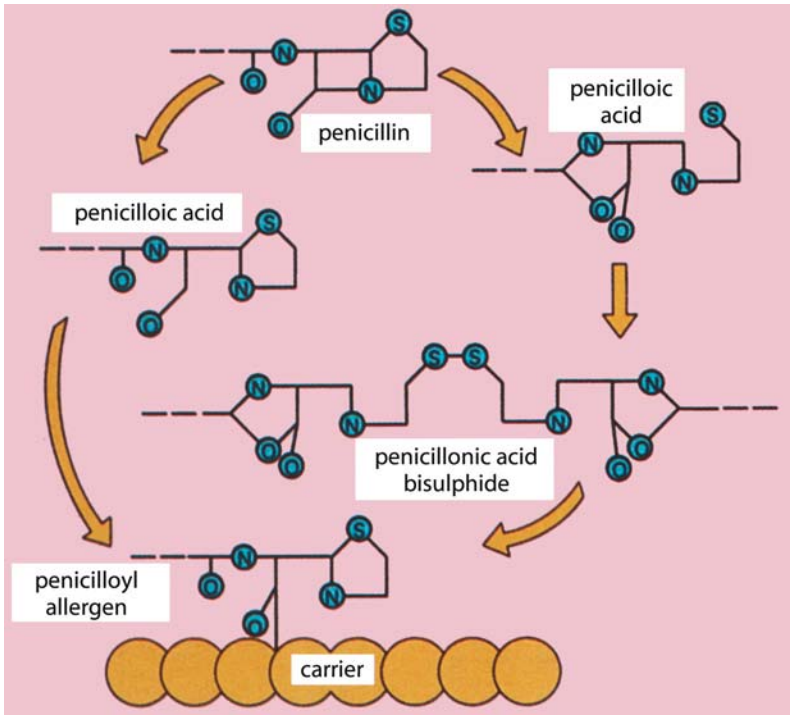

Fig. 19.29. Formation of major determinants

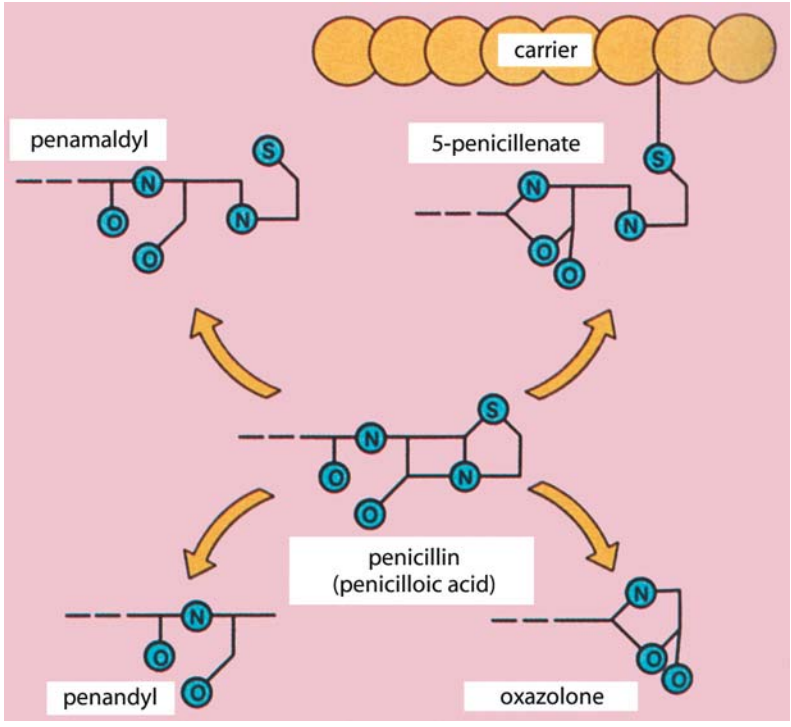

Fig. 19.30. Formation of minor determinants

cephalosporins for SPTs, cases of hypersensitivity to β-lactams are also disclosed, cases that otherwise were missed by using only penicillin major and minor allergens [18, 168]. Due to the well-known likelihood of causing clinical reactions simply by applying SPTs, it is possible to test the semisynthetic penicillin to be prescribed by eliminating the major and minor allergens involving penicillin to a certain extent, perhaps penicillin acid and a few more polyvalent compounds [18]. Allergopen, a kit for diagnosing penicillin-related allergies, is currently available.

Challenge Testing

Indications

Challenge tests are without doubt the only diagnostic tests for ASA and NSAID allergies: given the risks, it is only indicated if it is effectively necessary and urgent to administer the drug in question.

Requisites

- ADR must be *in remission.*
- The patient must abstain from taking any kind of drug *in the 24 h preceding the test* [155].

Testing Methods

A maximum degree of prudence advises to start with a dose of 1:1,000 of a single therapeutic dose (capsule or pill), increasing to 1:100, 1:10 with an interval of time between doses equal to that foreseen between drug administration and onset of reactions, which in turn will be suggested by history, therefore equal to or greater than the interval present in the specific case. If children present severe reactions it is advisable to begin with a dose equal to $1:10^5$ of the usual dose [47].

Tests are classified as follows:

- *Rapid challenge* test, with doses increased at least every 30 min, for example in ASA-induced asthma or urticaria
- *Slow challenge* test, with doses increased every 24–48 h as in fixed eruptions caused by sulfonamides [45]

In patients with late reactions to penicillin, test results may appear after 24 h in 45% of cases, and in 37% even after 48–72 h [199]. With SJS, TEN and agranulocytosis, such tests are excluded [47]; with PAs only alternative or less reactive drugs will be tested [36].

Treatment

There are three main periods of treatment:

- *Discontinuing* drug treatment, following specified instructions for a possible substitution. With antibiotics this measure must be adopted the moment a rash appears [5].
- *Skin eruptions* can be treated with oral antihistamines, and only in some selected cases could CS medications be applied locally or taken by mouth or parenterally, depending on the case [12].
- Treatment for *systemic manifestations* (Chap. 20).
- *ASA-sensitive children,* in addition to alternative drugs, can also follow an ASA-free diet following the indications in Table 10.11, but not all authors agree on this [147].

Table 19.43. Example of amoxicillin desensitization based on the weight of ±25 kg

Start with a 10 mg/ml solution		
Time (min)	**Dose in ml**	**Dose in mg**
0	1/10	1
20	5/10	5
40	1	10
60	2	20
90	5	50
In the absence of side effects go to the normal 100 mg/ml solution		
Time (h)	**Dose in ml**	**Dose in mg**
2	1	100
2 h 30′	1.5	150
3	2	200

The total dose reached over a period of 3 h corresponds to one-third of the daily dose for a child of 25 kg bw; for children above 25 kg bw, the last dose correlated to their weight, and calculated on the base of 50 mg/kg, shall be administered after 3 h.
Modified from [152].

- Treatment of *multiple sensitizations* is particularly difficult [81]: these children are the ideal candidates for desensitization when possible [149].
- Various *charts for desensitization* have been proposed:
  - For *children reacting to antibiotics,* ASA and NSAIDs there are several flow-charts, algorithms, and desensitization protocols that are effective also for adults [147, 198]. In ASA- and NSAID-sensitive children, the procedure is best carried out in settings where anaphylaxis can be recognized at its onset and treated immediately [146], we report an example structured on a bw of ±25 kg for amoxicillin desensitization (Table 19.43) [152]; in other cases the procedure is not based on bw or age of children.
  - Recently *five children and infants* with IgE-mediated reaction to TMP-SMX were evaluated; and 3/5 successfully desensitized [142].
  - For *drugs used in various diseases* in pediatrics such as sulfasalazine for juvenile rheumatoid arthritis [89] and enteric inflammatory diseases, ciprofloxacin [94] and tobramycin [180] for CF, and desferrioxamine for thalassemia [91, 150], charts are also available for other drugs [146].
  - For intervention *in cases of AIDS* prone to developing PAR.

Drug-Related Deaths

Penicillin causes 500 fatal cases each year only in the US: Fiori and Marigo [58] have published a series of 18 fatal cases, stressing that *unpredictability* is emphasized by the common administration in medical offices of ceftriaxone (two fatal and three anaphylactic cases) [96, 170]. DeSwarte [47] has clearly stated that 40% of fatal cases were prescribed penicillin treatment without any clinical indications. It is also believed that some 69 patients who died would not have died if all medical precautions suggested by individual cases were applied. The press announced that the MMR vaccine had been immediately taken off the market all over the world after the company producing it had ascertained that it caused meningitis-like complications in 1 case out of 11,000 instead of the predicted 1:300,000–1:500,000 [7].

Prevention

Prevention should always precede treatment: the best way is to prescribe drugs only if absolutely necessary [30]. Only 12 of 30 patients who died from anaphylactic shock caused by penicillin had a clear indication for this therapy [47]. Medications are often given without strict indication, thus sensitizing children to another drug, likely useful in the future. Prevention must follow a preestablished and approved order [48]. Research has also contributed, developing medications that are increasingly less sensitizing. Therefore *before administering a drug* known or suspected as hazardous, but that is considered indispensable for a certain patient an *accurate history* should be collected [46]. If this precaution had been followed rigorously, one-third of dead patients (or their relatives) could have warned doctors that they previously suffered from allergic reactions to penicillin [47]. One very severe observation is that 33% of drugs are used without respecting specific indications, dose and *child age* [61]. The *hidden sources* of penicillin (Table 19.36) and of drugs containing sulfites, dyes, and aromas have been mentioned above (Tables 19.32–19.34). *Small traces* of sulfonamides and penicillin can contaminate food and sensitize a predisposed child or cause reactions in sensitized children, although this event is rare [197]. *Unusual causes* are inhalation, cutaneous or mucous contact, sexual intercourse and intrasurgical contact [21]. To deal with any possibly severe reaction we suggest having at hand all equipment necessary to treat emergencies (Chap. 13); other extremely important preventive measures involve carrying out diagnostic challenge tests, desensitization measures, and premedication for at-risk patients if at all possible [149]. *Never trust a wheal test,* a practice that has proved to be potentially dangerous and also useless and not predictive [155]. Finally, one particular form of prevention is to control the *drugs taken by the mother* while breastfeeding a child who is at risk. It would also be extremely useful if legislators were to limit veterinary use of the more sensitizing drugs, from 100% penicillin *and to antibiotics that are in general totally useless, since they do not have the preventive effect for which they are used*, to avoid the risk of reactions and/or *drug-induced sensitization* [152]. To prevent reactions to x-ray examinations with contrast media, especially IV, follow the related analysis proposed in Chap. 20.

The future? The search for a safe, inexpensive, nonsensitizing, nonirritating, effective medication continues. Several therapeutic modalities both avoid side effects and keep costs low have been introduced in recent years. All these newer approaches to an effective treatment justify neither frustration, nor pessimism, nor multipragmatism in treating children, when profiting from the variety of available agents and using skilled techniques to avoid undesired side effects of drug treatment. We remember, however, that both time and patience are needed to develop the optimal treatment approach, and with regard to the tempting plethora of current therapeutic possibilities, that the ethical imperative *primum non nocere* remains binding [30].

Pediatricians and Drug-Induced Allergies and Pseudoallergies

The pediatrician's fundamental duty is to evaluate, taking each case individually, the possibility of avoiding the prescription for children of a drug suspected of having caused reactive symptoms in the past, even modest, or drugs with similar chemical structures that might cause cross-reactivity, or should it for some reason be necessary to prescribe it, this should be done with the necessary caution. There are no specific risk factors; neither age nor sex are significant. Reactions are less frequent in children although the clinical expression is not influenced and severe reactions are also always possible in nurslings and toddlers. However, expectations of pharmacological prophylaxis have a limited place since premedication can only be used for reactions to iodic contrast media.

During treatment a number of precautions concerning methods for administering drugs are useful [60]:

Inform parents or relatives of any possible eventual risks.

Write the prescription clearly and completely.

Prefer, if possible, oral administration.

To prevent some reactions or reduce their severity, administer antiallergic drugs simultaneously, including antihistamines, sympathomimetic, CSs, etc.

Unduly prolonged or intermittent exposure increases the potential for sensitization.

Children at risk, especially if treatment is injected, should remain under observation for 30 min.

After Administration. Children, parents, relatives, or caregivers should warn the doctor about the onset of

adverse reactions so that a suitable antiallergic therapy can be prescribed immediately. Pediatricians should provide the patient with a certificate including the treatment applied, drugs used, dose and administration as well as a description of episodes indicating an ascertained or suspected hypersensitivity to the drug. In more severe cases, children should carry the name of offending drug(s) reported on a card, or a bracelet or a tag that children should wear at all times (as often advised), and that will be useful to apply specific treatment in an emergency, even if children are in a state of shock or not accompanied by parents or informed persons. Also verify the composition of all drugs, including topical and/or over the counter medications [155].

Allergy and Central Nervous System and Other Allergies

Introduction

In this chapter we provide noncomprehensive review of miscellaneous conditions associated with pediatric allergy. There are other phenomena that can rightly enter within the symptom patterns attributed to both gastroenteric and genitourinary systems.

For a while the existence of neurological manifestations is reported in children following food-induced anaphylaxis [167] and of easy fatigue found in children with food allergy (FA) and from inhalants [41]. A concept of a tension-fatigue syndrome (TFS) has been introduced [178]; varied symptoms have been connected to allergy such as migraine, hyperactivity, cognitive dysfunctions, emotional and behavioral troubles, besides insomnia and anxiety alternating with periods of restlessness and fatigue [41]. Above all hyperactivity has been associated with FA, widening it to so-called sugar allergy [39]. Proof has not been provided, however, for instance with a double-blind, placebo-controlled food challenge (DBPCFC) [92]. Although the central nervous system (CNS) may be a center of migraine, behavioral troubles and psychiatric alterations, there are no definitive proofs that these affections are immune-mediated. However, it has been postulated that dietary manipulations may affect some CNS symptoms; even if viewed objectively the psychological symptoms are not easily quantified and some patients are prone to show a placebo effect [27], exclusively revealing the scarce frequency of DBPCFC studies [126].

Also, in other disorders there is a reappraisal of FA that is spread to all the organs and systems [27]. We have previously mentioned some disorders or syndromes imputable to a true FA or pseudoallergy (PA); here we will appraise the positive changes in the contested field of the clinical ecology, long in the limelight. On the opposite side of food intolerance there is food aversion [197], while at the clinical antipodes is found the Münchausen syndrome by proxy, possibly linked with disorders related to child abuse. To understand how the enormous enhancement of allergic affections has met a notable impact on citizens of all countries and categories, it is sufficient to remember that the pathological manifestations constitute an ever more remarkable problem in the populations of industrialized countries [4]. Accordingly, it is excessive that new syndromes are always labeled as allergic, while it may be opportune to remember conditions that in the past have not been correctly identified and defined [27]. It is generally believed that FA is underdiagnosed, while the colleagues in this field reply in opposite terms. It continues with a distrust toward traditional medicine [126], which is shown to be incapable of full dealing with maternal anxieties of wholly physiological events [197]. Nevertheless, misinformation has led to an exaggeration of the danger of foods [27]: as a result, not since mesmerism and phrenology were in vogue has the public appeared so gullible and so vulnerable to fashionable nostrums [109].

A typical example is the Feingold diet [63], popularized at the beginning of the 1970s: although it lacked the confirmation of DBPCFC studies, this diet has benefited from ample publicity that has propitiated citizens' support to spontaneously publicize the shaky correlation between foods (and food additives) and behavioral changes.

In this chapter we will examine what else can rightly enter within the symptoms pattern attributed to both gastroenteric and genitourinary systems.

Migraine and Allergy

Definition

The Ebers papyrus (3,500 years ago) told of a sickness of "half the head," surely migraine. Headache is considered one of the most common painful syndromes and migraine is the most frequent form of illness, and both have been diagnosed using clinical impression. To address the limitations of this method, the International Headache Society (IHS) developed and updated defined criteria for headache diagnosis [165]. These criteria, however, have been criticized for incompletely diagnosing childhood migraine disorders, since rather than having two coexistent headache types, children and adolescents with chronic daily headache have a single syndrome that, in many cases, will paroxysmally worsen and gather migrainous features [96]. Migraine in children and adolescents is a common problem. *Migraine* is defined as a recurrent headache with symptom-free intervals and at least three of the following symptoms: abdominal pain, nausea or vomiting, throbbing headache,

Table 16.1. Epidemiology of migraine in children aged 4–19 years

Country	Reference	No. of children	Age (years)	Subtype	Prevalence/incidence
Greece	[125]	4,000	4–15		6.8% (P)
				Without aura	3.4%
				With aura	2.8%
Norway	[221]	8,255	13–18		7% (P)
				Recurrent	18%
Poland	[99]	1,759	6–19		8.4% (I)
				Tension-type	28.7%
Poland	[180]	659	15–19		28%
				Without aura	19%
				With aura	9%
Sweden	[23]	9,000	7		1.4% (P)
			15 year		5.3%
Sweden	[52]	402	7–15		23%
Sweden	[105]	131	7–15		11% (P)
				Tension type	9.8%
UK	[1]	67	5–15		10.6% (P)
				Without aura	7.8%
				With aura	2.8%
UK	[60]	811	7, 8.2%		
		1,511	11, 15.4%		
Israel	[139]	312	8.4		54%
				Tension type	22%
UAE	[21]	1,159	7.4–13	Without aura	12.6%
				With aura	8.2%
US	[153]	6,072	Adolescents	Recurrent	30%
Hong Kong	[98]	2,120	6–13		2.8%
India	[171]	233	11–15		11%
		1,308	11–15	Recurrent	19.5%
		233	11–15	Tension type	3.6%
India	[189]	46	7–15		8% (I)

Migraine occurs in 35.6% of American Indian adolescents and 32.1% of white American adolescents [210]. Among Norwegian children, 69.4% of boys and 84.2% of girls reported headaches during the last 12 months and 21.0% of boys and 36.5% of girls reported recurrent headaches [221], in the USA, 37.6% of girls and 21.3% of boys [153]. The prevalence was 9% in boys and 14% in girls [171] and increased with age, similarly in girls and boys up to 11 years, and thereafter only in girls [105]. By age 11, significantly more females were reported to have frequent headache [60]. In 189 children from Baltimore aged 13±3.1 years, mean headache was present 27.3±4.1 days per month, with a mean pain intensity of 5.9±2.1 on a 10-point scale [98].
From [1, 21, 23, 52, 60, 98, 99, 105, 125, 139, 153, 171, 180, 189, 210, 221].

unilateral location, associated aura (visual, sensory, motor) and a positive family history (FH) [53]. The factors that instigate *headache* are physical activity, relaxing subsequently to stress, skipping a meal, sleeping inadequately or excessively, consuming alcohol, or atmospheric changes, trips, traumatic events, bright light, hormonal factors and hypoglycemic states, etc. [53].

Epidemiology

Prevalence estimates are shown in Table 16.1 [1, 21, 23, 52, 60, 98, 99, 105, 125, 139, 153, 171, 180, 189, 210, 221], which demonstrates that migraine without aura is present in 42.8% of children vs 22.8% of migraine with aura.

Table 16.2. Foods involved in the pathogenesis of migraine and causing symptoms in 40 babies

Foods	% Of children reacting
Apple	10
Bacon	10
Banana	8
Beef	40
Carrots	8
Cheese	53
Chicken	8
Chocolate	55
Coffee	24
Cow's milk	68
Egg	60
Fish	23
Goat's milk	15
Grapes	10
Lentils	8
Maize	20
Malt	8
Melon	8
Nuts (mixed)	10
Orange	30
Peaches	10
Peanuts	13
Peas	8
Pineapple	8
Pork	23
Potato	10
Rye	30
Strawberries	8
Sugar	8
Tea	18
Tomato	33
Wheat	53
Wheat flour	8
Yeast	10
Benzoic acid	35
Tartrazine	30

2.5% of children reacted to avocado, cauliflower, cucumber, dates, leeks, lettuce, mushrooms,or rabbit.
Modified from [54].

Pathophysiology

From the first observations of Hippocrates, it is suggested that several foods, including ripe cheese, chocolate, red wine, citrus juice, salted fish, fat foods, bananas, peanuts, green tomatoes, avocados, and pineapple provoked migraine [150]. A mechanism of hypersensitivity to foods including cow's milk (CM), egg, wheat, vegetables, cereals may provoke some cases of migraine; in fact clinical remission follows appropriate elimination diets, with symptom relapse after the reintroduction in DBPCFC of the offending foods [200]. However, only the classic study of the Soothill school in 88 children, affected by severe and frequent crises of migraine (>1 week) and submitted to an oligoantigenic diet has shown with the DBPCFC the allergic pathogenesis of child migraine. In 88.6% of children, there was a complete remission and in 4.5% a gradual improvement, regarding particularly the migraines precipitated prior to the institution of the diet, excluding physical exercise, emotions, irritating odors, and cigarette smoke, with a significant improvement also of other associated symptoms, including abdominal pains, behavioral changes, asthma attacks and atopic dermatitis (AD) [54]. The children were subsequently submitted to a crossover DBPCFC in 45% of cases, 82.3% of whom were positive to foods vs 52% of placebo ($p<0.001$). The interval between food challenge tests (FCT) and a precipitated migraine lasted from a few minutes to >1 week, with a mean of 2–3 days. The principal foods to which there were positive results are shown in Table 16.2 [54], and other products never suspected such as in 33%–37% of reactions to benzoic acid and tartrazine and in 15% to goat's milk. In this study there was no relationship between SPTs (skin prick tests) and RAST, but FCTs were positive in 93% of cases.

Other pediatric cohorts endorse these results [67] of relationships between migraine and FA that has been confirmed in 49 out of 92 children with migraine (53%) who presented SPTs and FCTs positive to one or more foods, total serum IgE levels >2 SD for the age (82%). In 31 children, elimination diets induced a remission and in nine the improvement of symptoms, also after start the reintroduction of the causative foods 6–12 months after starting the diet, and at the follow-up after 2 years [117]. In another 12 children, the positive FPTs were not associated with SPT and specific IgE; for example 2/7 children positive to cocoa had total serum IgE levels under 2 kU/l and 7/7 had negative IgE levels [75]. However, FPTs were negative in 35 children with a suggestive history of migraine associated with food intolerance [24], and no DBPCFC was positive to suspected foods and food additives; the elimination diet followed by five children who complained about >2 episodes per week were effective only in two children [5].

Pathogenetic Mechanisms

It is believed that many drugs, foods and food additives [203] can provoke migraine, through an IgE-mediated mechanism or PA, by a direct or specific mast cell and basophil activation (Chap. 10), resulting in the release of vasoactive amines: a migraine attack often coincides with an increased amine metabolism [203]. Among the medications and other agents incriminated in migraine pathogenesis we find the following:

- Pharmacological action: 5-HT (5-hydroxytryptamine or serotonin) caffeine, ethanol, nitrites, phenylethylamine, phenolic flavonoids, tryptamine, tyramine
- Immunological mechanism: food proteins
- Uncertain mechanisms: aspartame, glutamate [203]

However, the diffused flow reduction during a migraine associated with aura is rather the expression of a decreased metabolic requirement [92]. During a migraine attack vasodilation is present: the dilated intracerebral vessels become impermeable and it is assumed that consequent exudation of polypeptide fosters a sterile perivascular inflammatory reaction, that would activate in turn the nociceptive trigeminal vascular terminations [150]. Further studies have underlined a subsequent release of histamine, $PGD_{2\alpha}$, $PGF_{2\alpha}$ [120, 140, 181], substance P and additional tachykinins, which play a salient role in the transmission of the nervous impulses implicated in migraine pathogenesis [4, 40]. The histamine pathogenic weight can be supported by the diamine-oxidase deficit that prevents its breakdown [195]. It is possible that CICs (circulating immune complexes) increase the platelet aggregation and 5-HT (5-hydroxytryptamine or serotonin) release.

In a group of migraine sufferers intolerant to foods, it was shown that CIC levels increased following FCT. Moreover, the early T cell activation after the FCT indicates an involvement of IL_2-related receptor in food-induced migraine. These results have reinforced the idea of immune mechanism involvement in food-induced migraine, but it seems to be localized at a different step from what has now been hypothesized, with the involvement of the complex cytokine network [123]. In a parallel work in 21 patients with migraine of food origin compared to 10 controls, the activated T-cell assay has shown their increase 4 h after the FCT and their reduction 72 h later [120]. Following FCTs, it is shown that 5-HT decreases and 5-HLAA (5-hydroxyindoleacetic acid) increases in patients with rheumatoid arthritis (RA) intolerant to foods: this data points out that 5-HT are released by platelets during FCT in patients with food hypersensitivity [123], and it is hypothesized that a similar mechanism can also be working in migraine sufferers [71]. The question remains: is it a true allergy [4]? The alternative between this and PA favors allergy, based on the following points [54]:

1. The symptoms are potentially provoked by an ample spectrum of foods that, as far as is known, fail to have common characteristics. Nevertheless, the significantly elevated number of subjects that have reacted to the food rather than to the placebo is the proof correlating the afflictions to foods, each responsible in any association.
2. The SPTs often negative to foods or in contradiction with the clinical manifestations of the 88 children suggest a non-IgE-mediated mechanism.
3. Atopy was present in 66% of children and 26.3% of 300 children prospectively seen by us had positive FH [29].
4. A positive FH of migraine was found in 35% [171], 46.5% [20] and 79% [96] of entrants.
5. In the pediatric age, remission can be of IgE-mediated allergy, not of PA.
6. Foods precipitating headache also induce cutaneous and/or respiratory symptoms.
7. The positive DBPCFC (as in other disorders subsequently examined) validate the allergic background of symptoms [134].

Compared to the last two points, a study on 158 children aged 0.5–13 years with food intolerance confirmed by elimination diets and FCTs has shown that headache was much more frequently associated with asthma and urticaria than with AD [12]. In 40% of 30 children and adolescents aged 11–17 years with the diagnosis of migraine with or without aura, the migraine was associated with allergy cases [204]. The prevalence of both headache and migraine was significantly and proportionally higher in children with atopic disorders compared to those without. A history of atopy (especially rhinitis) supports the diagnosis of migraine in young children with paroxysmal headaches [135]. So far, based on available data we can conclude that migraine has a frequent relationship with foods, which could be at the base in an undefined percentage of cases with mainly an IgE-mediated mechanism. Moreover, the positive effect of the diet in children with negative SPTs recalls the intervention of type III or IV mechanisms [67].

Diagnosis

Diagnosis consists in an accurate history, with an objective examination that includes pressure measurement as well as a neurologic, hematologic and ophthalmologic examination. For the diagnosis of migraine ask for recurrent headache with symptom-free intervals: there is an IHS three-question headache screen based on the following [165]:

1. Headaches interfering with work, family, or social functions
2. Headaches lasting at least 4 h
3. Presence of new or different headaches in the past 6 months

A diagnosis of migraine was suggested by a yes answer to points 1 and 2 and a no answer to point 3. The three-question headache screen identified migraine in 77% of the study population [28]. However, 46.6% of

children had some of their migraine attacks lasting for at least 1 h and 26.6% had some of their migraine attacks lasting at least 2 h [2], which does not fit this scale. A ten-point scale (10 being the most severe pain) indicates the average severity of the migraine [148]. Clinically, children with migraine report neck and shoulder pain, abdominal pain, back pain, and otalgia significantly more often than those with nonmigraine headache [7]. In children with FA, neither SPTs nor RAST have been useful, lacking a correlation with FPTs [54], and if the tests are performed in more days, DBPCFCs may also increase the number of false-positive tests [54] for the recurrent migraine symptoms and of false-negative tests for the delayed onset of symptoms. Testing children only with the offending foods or food additives (according to their parents) [9] introduces a potentially restrictive bias on the positive results. In the differential diagnosis should also enter celiac disease with a 1.1% pediatric incidence of the association [25].

Treatment

Preventive agents include amitriptyline, cyproheptadine, propranolol, valproic acid, naproxen, nimodipine, imipramine, and topiramate. Amitriptyline was the most commonly prescribed agent (58%) [112]. The most efficacious acute treatments of pediatric migraine include the nonsteroidal anti-inflammatory agent ibuprofen at 7.5–10 mg/kg per dose or nasal sumatriptan [111]. Migraine relief 2 h after the dose was significantly greater for adolescents using 5 mg of sumatriptan NS (66%) compared with placebo (53%). Complete relief 2 h after dose was significantly greater for patients using 20 mg of sumatriptan NS compared with placebo [209]. The treatment of the forms linked to FA includes elimination diets following the FCT results; cromolyn (Table 7.20) may be prescribed to allow the child to enjoy dietary holidays, especially on special occasions such as birthdays, or ketotifen, which reduces the frequency, severity and duration of the attacks by 72% [134]. In 12 children given an antiallergic treatment for 6 months (pharmacological or diet restriction), the migraine index decreased significantly from 2.45 to 0.33. Headache intensity decreased as well [204]. Similarly, the histamine-free diet can be recommended, which shows good results [196] (Table 10.12). Treatment in children consists mostly of trigger avoidance, rest, and simple analgesics. Behavior therapy, including relaxation-response training, may be an effective adjunct in managing both the frequency and intensity of migraine attacks. Use of medicines for abortive and prophylactic therapy has not been extensively supported by well-designed, well-controlled research. In general, use of these agents should be restricted to the small group of children with frequent, severe attacks [201].

Prognosis

Although migraine is rare before the age of 4 years, its prevalence increases throughout childhood, reaching a peak at about 13 years of age in both sexes, affecting approximately 5% of all children [201] and up to 54% in children aged 8.4 [139] (Table 16.1). Recurrent migraine has an impact on a child's life in a number of ways, including school absences and reduction in performance, decreased home and family interactions, and decreased socialization with peers [148]. Migraine interfered with play in 80 children (55%), aggravated by routine physical activities in 84 (58%), associated with nausea and vomiting in 48 (33%), photophobia/phonophobia in 77 (53%), and visual aura in two (1.37%), which are aggravated in children with severe symptoms by routine physical activity (80%) [171]. Children with migraine reported more often being bullied in school, stress in school, and problems in getting along with other children than children without headache. The association of stress in school with headache was strongest in girls with migraine [131]. The most common trigger was playing on a computer (45.9%), followed by loud noise (41.5%), and a hot climate (37.1%) [20]. Children with headache are at an increased risk of recurring headache in adulthood and may complain of other physical and psychiatric symptoms [60]. However, the quality of life of children with headache is significantly affected by their health condition [148]. Strategies for coping with psychosocial adversity in childhood may improve the prognosis in adulthood [60].

Psychological and Neurological Factors and Allergic Disease

Several troubles have been attributed to allergy, essentially to foods, in addition to headache: discomfort, pain in different parts of the body, palpitations, dizziness, paresthesia, depression, insomnia, irritability, anxiety or panic attacks, etc., but a clear-cut association with allergy was established only in a restricted percentage of cases. The behavioral changes for which a food pathogenesis is suggested are the following:

Tension-fatigue syndrome occurs mainly in young children and has already been described in the twenties [167]. Speer has specified its clinical pattern [178]: it consists in the alternation of complex alterations in cenesthesia, hyperactivity that can become maniacal, sleeplessness and anxiety, indifference, inability to concentrate, apathy, drowsiness, dizziness and easy fatigue. Other symptoms are arthralgia, myalgia, mild and intermittent or serious headache. The onset is often insidious; the diagnosis is difficult, both for symptom subjectivity and the absence of a reliable laboratory examinations. The gastroenteric troubles (more often generalized abdominal or epigastric pains, are sometimes so

intense as to interrupt the child's sleep). They are attributed to foods including CM, egg, wheat, corn, etc. [178]. In three patients with allergic TFS, RAST scores for CM and for buckwheat flour were negative or slightly positive, but PBMCs (peripheral blood mononuclear cells) responded well to CM allergens and to buckwheat flour, but not to ovalbumin. Only in patients with immediate allergic symptoms were RAST scores for offending foods positive, contrary to PBMCs. Thus, proliferative responses of PBMCs to food antigens are very useful in detecting offending foods in allergic TFS [97]. Thus TFS is correlated with an allergy pathogenesis, also for the frequent association with respiratory allergy [178], particularly asthma [12]. We deem that other DBPCFC studies are necessary to corroborate this hypothesis [126].

Attention deficit hyperactivity disorder (ADHD) is the most common neurobehavioral disorder of childhood. Up to 50% of children recover and are well in adulthood. Thus >50% of children may maintain symptoms of ADHD as adolescents and as adults [73, 152]. It is characterized by motor hyperactivity, restlessness, excitability, impulsivity, distractibility, short attention span, learning difficulty and perception of motor functions, learning disability, incommunicability with their peers that is likely to result in adaptive dysfunctioning [157, 218]. In adolescents, it may interfere with school performance, self-esteem, family relationships, and driving, and may predispose to high-risk behavior [154]. ADHD is a poorly defined disorder that generally arises before the conclusion of the 7th year and has a prevalence of 3%–10% [157] or 1%–5% [202] in subjects <18 years. However, ADHD may persist into adolescence for 70% of children, and some teenagers are diagnosed with ADHD for the first time during their 2nd decade of life [154]. The most significant measure of the public and family conscience [186] has been implicitly deduced by the notable 240% increase in the visits and 286% increase in the use of methylphenidate [185], a medicine safely administered for years to children for ADHD treatment [186]. The hypothesis of a mental defect is fading away, the biological origin has been privileged, but several added and/or overlapping factors (heredity, atopy, FA, chromosomal anomalies, cerebral disturbances, epilepsy, psychosocial troubles, anticonvulsant drugs, interventions in neonatal periods, hypersensitivity to food additives and/or salicylate, the mother smoking or drug- or alcohol-addicted during pregnancy, metabolic disturbances, malnutrition) may play a part, each of them, however, as a source of great handicap for the involved subjects [217], especially on the relational level [145]. Recently growing evidence has been found for an association between antenatal maternal anxiety and the neurobehavioral development of the offspring up into adolescence [192]. ADHD diagnosis is shown in Table 16.3 [55] when foods and food additives are involved, and Table 16.4 [26] outlines the necessary assessment according to a diagnostic score. The AAP practice guidelines suggest some screening questions [144]

1. How is your child doing in school?
2. Are there any problems with learning that you or the teacher has seen?
3. Is your child happy in school?
4. Are you concerned with any behavioral problems in school, at home, or when your child is playing with friends?
5. Is your child having problems completing classwork or homework?

The approach most likely to be efficacious encompasses both *psychosocial interventions and pharmacotherapy.* Treatment planning should include the identification of social and adaptive deficiencies when therapeutic targets are established [157]. Evidence suggests that individualized dietary management may be effective in some children [15]. There are four good trials [26, 31, 55, 162] that report substantial improvement and significant reduction of symptom scores in ADHD children on a hypoallergenic diet; >70% of children responded in each study. The results were confirmed with DBPC challenges [26, 31, 55, 162]; significantly higher scores were recorded during periods on challenge food rather than on placebo. Of course, an elimination diet works for some children with ADHD; there is good evidence for the effectiveness of the few-food and no-additive diet, but the extent of its effect may be unrewarding compared with that of medication [15]. We stress that dietary management cannot be neglected as a possible access to treating ADHD children, although it is effective in only a minority of such children [162].

Medical treatments include four options:

1. Stimulant medication management alone: 10.8% of the children received psychotherapy and/or mental health counseling alone, which increased with each age group (6.7%, 5–8 years; from 11.3% to 13.6%, 13–18 years)
2. Combination of medication (28.2%–37.3%)
3. A standard community care group
4. 15.1% received no treatment beyond the office-based visit [155], which was the case of 85% of the children who received a stimulant medication [86]

More girls (18.7%) were receiving no treatment option compared to boys (13.9%) [155]. A recent MTA (Multimodal Treatment Study of ADHD) study has compared medication management (MedMgt) alone, medication and behavior management (comb), behavior management (Beh) alone, and a standard community care group (CC): the MTA medication strategy showed persisting significant superiority over Beh and CC for ADHD. No significant additional benefits of CC over Med Mgt and of Beh therapy over usual CC were found [137]. In conclusion 15% of children receive no treatment beyond the enrolling visit [85, 155]. Methylphenidate based on a child's weight is prescribed in the range of 0.3 to 0.6 mg/kg/4-h dose, with a maximum daily dose of 60 mg [2]. The daily prescribing schedule

Table 16.3. Foods involved in the syndrome of the hyperactive child

Additive	79
Apple	13
Banana	8
Beans	15
Beef	16
Carrot	7
Cheese	40
Chicken	11
Chocolate	59
Citrus	45
Coffee	10
Corn	23

Walnut	10
Watermelon	9
Wheat	49

Modified from [55].

Table 16.4. Diagnostic score for ADHD

1.	Fidgets and squirms, restless when standing, in adolescents it is sufficient to note that child is agitated or hyperactive
2.	Difficulty remaining seated as expected
3.	Easily distracted by extraneous stimuli
4.	Difficulty awaiting turn in games or group situations
5.	Frequently blurts out answers before questions have been completed
6.	Difficulty following through on instructions
7.	Poor attention span in schoolwork, play, chores
8.	Avoids activities or passes from one activity to another
9.	Difficulty playing quietly
10.	Talks excessively
11.	Interrupts or intrudes on others
12.	Often does not listen to what is being said
13.	Often loses things necessary for tasks or activities
14.	Often engages in physically dangerous activities, not conscious of possible consequences

To meet the DSM-IV diagnostic criteria of ADHD, a child must have exhibited 8 of 14 symptoms that had onset before 7 years of age and have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level.
Data from [26].

for short-acting methylphenidate (3–5 h) is 5–20 mg bid or tid, for intermediate-acting (3–8 h) is 20–40 mg or 40 mg in the morning and 20 mg early in the afternoon, for extended release (8–12 h), the dose is 12–72 mg. For short-acting dextroamphetamine (4–6 h) the daily dose is 5–15 mg bid or 5–10 mg tid, for intermediate-acting (6–8 h) is 5–30 mg or 5–15 mg bid, for extended release (daily) 10–30 mg [2, 155]. Despite the efficacy of stimulant medications in improving behaviors, only 38% of medically managed children in the MTA study received scores in the normal range at 1-year follow-up) [86]. Sustained treatment may lead to some growth failure [2] in addition to adverse affects including anorexia [73]. The association between reduced glucose metabolism in cerebral areas and ADHD and motor activity in adults that had suffered from ADHD since childhood and with children also affected requires clarification of whether the results are applicable to the whole subset of ADHD children; thus elimination of ADHD causes is preferable to ADHD pharmacological treatment [26].

- The *negative effect of food additives* on childish behavior was demonstrated 20 years ago with no scientific base. The Soothill school has shown (based on their parents as reporters) that with a markedly restrictive oligoantigenic diet for 4 weeks >81% of 76 studied children with ADHD had improved and 34% of them had regained a normal behavioral pattern: 28 children had been submitted to a crossover DBPCFC, resulting a positivity for different foods and even more for food additives and preservatives (79% of cases); also in this sample there was an unexpected positivity for some foods (Table 16.3). However, introducing parent reporting as a parameter to appraise the objectivity of improvements

[55] is an approach bias, also because an important cause of the hyperkinetic personality is really the relationship with their parents [82]. This again comes down to a classic work [147], the scientific demonstration of the impact of hyperkinesis in children on free diets, and the return to normal by an exclusion diet; currently such a position seems to be largely documented [26]. A significant behavioral improvement on an elimination diet and subsequent behavioral deterioration on DBPCFC was shown in 73% of hyperactive children. Atopic and nonatopic probands reacted to several preservatives and artificial colorings but the atopic children had a significantly greater response rate than the nonatopic group [26]. In a crossover study in which all food was provided to the families for 10 weeks, 58% of children (14/24) had a behavioral improvement with positive effects on their sleep, with a reduction in time falling asleep and the number of night awakenings [90]. In an intrasubject, 10-week crossover study in 24 preschool children [37], dyes and artificial aromas, preservatives, Na glutamate and any additional substances believed by parents to produce symptoms were excluded, sugar supplementation was reduced and the prevention of environmental inhalant and perfumes was associated. It is notable that up to 80% of parents of children with behavioral deterioration (37% of the sample) blamed food additives and preservatives [4]. The correlation between the syndrome and foods and food additives has subsequently been appraised by more studies in 3-to 12-year-old children. Of children subjected to a food- and additive-free diet, 76% improved; submitting 32% of them to a crossover DBFC demonstrated relation a cause–effect. In 74% of children correctly diagnosed and treated with an elimination diet, an improvement was also recorded, a result confirmed by DBPCFC (in 73% of cases). In this cohort, 40% of nonrespondents to the diet were atopic as well as 79% of the respondent: the foods incriminated were above all CM, artificial dyes permitted by the law, corn and wheat. In another sample a diet free of CM, egg and related by-products, and several foods of additive and/or histamine-releasers, produced a notable improvement of both attention and hyperkinesia in 79% of cases [196]. A double-blind study has shown a functional correlation between ingestion of tartrazine and behavioral changes (irritability, restlessness, and sleep disturbance) in 24 2- to 14-year-old atopic children; however the symptoms taken into account did not follow the strict diagnostic criteria of the syndrome (Table 16.4). Since 2 of 20 atopic controls on a dye-free diet also reacted to food additives in a DBPC dye challenge, the existence of *tartrazine hidden sources* is hypothesized. There is an evident relation between activity score and assumed doses; moreover doses of tartrazine >10 mg lead to prolonged behavioral troubles >12 h [160]. Entirely different is the randomized, DBPC study by Egger et al, who treated with EPD (enzyme-potentiated desensitization therapy) enriched with 45 foods, 10 dyes and preservatives, 40 children with poorly defined symptoms, 17 of whom (42.5%) were labeled as atopic. Also in this study, the results, statistically positive, were based on parents as reporters. In addition the poor description of symptoms and the exact composition of the medication make it impossible to reproduce EPD. The authors conclude that the treatment was able to stop the mechanism at the base, allowing children to consume the foods that were at first forbidden, even if eight children tolerated sugar after treatment, which nevertheless did not include it, underlining an aspecific effect of a therapy labeled as specific [58]. Certainly, the analysis of cost–benefit ratio is clearly for the natural method, which assures positive results in 58%–79% of children [26, 31, 90]. To us it seems that the problems related to dietary therapy reside rather in poor compliance, since it is difficult to carry out and too demanding for families [31]. In a recent, DBPC crossover trial, 52% of children following an additive-free diet worsened their behavior when challenged to calcium propionate, compared to the control children reacting to placebo (a preservative in bread consumed daily) (19%). Irritability, restlessness, inattention and sleep disturbance in some children may be caused by preservatives contained in daily foods [45].

- *Restless legs syndrome* (RLS) may affect >5% of the population. It is characterized by an unpleasant creeping sensation, generally felt between the knee and ankle, to which the subject finds relief continuously moving the legs about, particularly when falling asleep and/or while sleeping (periodic limb movements of sleep, PLMS); it is not associated with psychopathy [27]. Coffee, foods and drinks containing caffeine might instigate the syndrome, due to an increased sensitivity to caffeine [27], or to an effective allergy to coffee or more probably to substances contained in it [27]. Recently, it seems to be a current trouble in children 18 months to 16 years old with an autosomal dominant transmission [194] and in women affected with fibromyalgia or RA [215]. In this autosomal dominant mode of inheritance found in several large families, significant linkage on chromosome *12q* responsible for RLS has been identified [47]. The autosomal allele acts dominantly in RLS families with an early age at onset of symptoms and suggests that RLS is a causative heterogeneous disease [208]. Although little is known about the pathophysiology of RLS, it is generally segregated into primary and secondary forms. In at least 60% of primary RLS cases, a FH is reported which may increase from 64% to 92% when all first-degree family members are contacted and interviewed. This suggests that RLS is highly penetrant, although not always recognized [141]. Linkage studies have been hampered by the absence of any definitive diagnostic test, the subjective nature of the disease, the age-dependent penetrance, the possibility that several different pathologies result in a single phenotype, and the high frequency of RLS, which can often result in bilinear transmission. Furthermore, RLS symptoms may be caused by reduced iron stores, neuropathy, renal

failure, pregnancy, and possibly rheumatologic diseases, and cannot be reliably differentiated from primary RLS. Monozygotic (MZ) twin studies provide invaluable information regarding both genetic and environmental factors that can affect disease phenotype. In a study of 12 identical twin pairs, one or both members had RLS [141]. A study in 866 children (54.2% of boys) aged 2.0–13.9 years has recently ascertained that RLS may be associated with ADHD and PLMS and suggested that if either condition contributes to hyperactivity, the magnitude of the association suggests an important child health problem [32]. The prevalence of PLMS in 591 children with a preexisting diagnosis of ADHD was 7.1% [95]. Another pediatric study postulated that the amelioration of RLS and its associated sleep disturbance may result from the improvement in ADHD with monotherapy with levodopa or the dopamine agonist pergolide [195].

- The Soothill school has observed that *epileptic convulsions associated with migraine* and/or hyperactivity may also depend on the ingestion of small quantities of food allergens and that, even though resistant to pharmacotherapy, diet therapy responds to the diagnosis that has been set with crossover DBPCFC [56]. The finding that only children with the association of convulsions and migraine and/or hyperactivity have improved or have recovered with an oligoantigenic diet supports the existence of a syndrome as such, which is not that rare [56]. Even if only a minority of patients with epilepsy associated with migraine respond to dietary treatments, such data have a character of indubitable utility [117], considering that some patients could improve (or recover) simply avoiding specific foods. A component attributable to the hypersensitivity to given foods has been shown to be a pathogenetic factor of some psychic conditions, including neurosis, depression and certain forms of psychosis [143]. Certainly the cases of hyperactivity related to foods are a minority of mental disorders; however, this stimulating hypothesis can contribute to shedding light on the complex and partly unexplored genesis of psychopathies, or at least to a part of them.

Chronic Fatigue Syndrome

Definition

Chronic fatigue syndrome (CFS) was reported more than a century ago within neurasthenic forms. Beard [16] referred to fatigue as the "Central Africa of medicine – an unexplored territory which few men enter" and Seppilli [166] added that "the patient is fatigued from the very moment he gets up in the morning and fears being severely diseased." CFS is a chronic illness with unknown etiology characterized by persistent fatigue, exacerbated by minimal physical activity.

Epidemiology

The prevalence rate of CFS in children is 37.1×10^5 (5.5–9 years and 47.9×10^5 from 10 to 19 years) [115], or 33.4×10^5 in children aged 2–17 [120]; otherwise the median age was 14.3; 60% [30] 71% [101], or 73% [61] were female and 87% of mid or upper socioeconomic status [30]. In two open studies, the data were almost similar [100, 101], 50% of children aged 7–14 and 50% aged 15–21 [101]. In another case–control study, no differences between males and females were found [18]. This data provides a basis to understand how *the pediatric syndrome is different from adult CSF* [18, 30] (Table 16.5 [18, 30, 101, 175]).

Pathogenesis

It should be realized that the correlation with allergic disease was not thought to be sufficient to support a specific CSF pathogenesis, also because between 1985 and 1988 two unusual associations, one with EBV (Epstein-Barr virus) infection and the other with a clinical picture referred to as a chronic infectious mononucleosis were identified. Due to the CSF spread, many believed that the evidence provided was sufficient for the diagnosis of chronic EBV syndrome, patients were satisfied since the illness had a name and physicians because the search for a defined diagnosis might come to an end [91]. Subsequently, no consistent data have emerged, no specific infectious agents have been consistently linked to the illness [30, 175, 190, 205, 213], also because of the lack of diagnostic markers [205]. While the CFS etiology in children and adolescents is unclear, it was assumed to be multifactorial, so that symptoms such as depression, apathy, phobia, anxiety, cognitive dysfunction, difficulties with concentration, mood disturbances, confusion, headaches, and sleep disturbances can be found in several patients variously labeled, often convalescent from a systemic infectious disease [91]. Loneliness, social isolation and the stress of examinations, both independently and together, have been associated with *decreased natural killer (NK) cell* function in schoolchildren and/or medical students [88, 91]. Depressed individuals and/or those subjected to severe stress or psychological distress may undergo *immune deficits* [116]. However, apart from every possible stress, children and adolescents are often faced with significant psychological, emotional, social and existential dysfunctions, with considerable implications for normal psychoemotional development [30, 175]. In these children, a sign of their involvement is marked by depression, long histories of absence from school, accompanied by impairment in social and leisure activities, loss of peer relationships, heralded by an increased frequency of loss of peer group contact [205], different symptoms and sleep disturbances, the commonest symptoms of chronic fatigue (Table 16.5) [18, 30, 101, 175].

Mean age was similar: 11 [18], 14.3 [30] 14.6 [101], 14.5±1.7 [175].

Possible associations with FA are confirmed by the Straus et al data: 52.5% of patients show SPT and RAST positivity to food and/or inhalant allergens, 73%–83% a history greatly indicative of atopy [183, 184], 34% elevated levels of CICs (circulating immune complexes) [184] and serum total IgE [183]. Also in children, FH positivity (76%), history of allergies or asthma (71%) and recent ingestion of raw CM (81%) produced risk ratios of 23.3–44.3 [18]. Thus summing up the results, both genetic factors and increased IgE-mediated reactivity may be responsible for a rising expression of disease.

Several conflicting immune dysfunctions have been postulated, but no correlation was found with CFS pathogenesis. These include normal to decreased numbers of NK cells, reduction of IgG and subclasses, IgA and IgM, autoantibodies and CICs, reduced or increased CD4 and CD8 cell populations, with a decrease in circulating naive T cells and an increase in memory T cells, persistent CD8 activity and increased activation markers: CD38, HLA-DR on CD8 cells [104]. Evidence was found of a significant bias toward *Th2-type immune* responses in CFS compared to controls. Nonstimulated cultures revealed significantly higher levels of T cells producing IFN-γ or IL_4 in CFS patients [174]. Moreover, there was a reduction or increase in B cells also with significant evidence of HLA class II antigens. The class I antigen HLA-B61 and the class II antigen HLA-DR9 were positively associated with CSF (OR, 2.77 and 2.60, respectively) [85]. In a trial on 21 pairs of MZ twins discordant for CFS and 21 matched healthy control subjects, both sets of twins performed worse than the control group on all speed-dependent tests. Self-rated fatigue and dysphoric mood were only weakly correlated with cognitive performance [124]. Interestingly enough, significantly elevated ECP (eosinophil cationic protein) levels were found that link CFS to activity of eosinophil cells [36], suggesting that IgE antibodies and immune dysfunctions may be involved. In addition, such patients may display immune deficiencies as well as hypoactivity of the hypothalamic-pituitary-adrenal axis (HPA) following a CRH (corticotropin-releasing hormone) deficiency, which returns to normal levels following treatment [33].

Clinical Features

Prolonged fatigue after physical activity, headache, loss of ability to concentrate, inversion of the sleep–wake rhythm, excessive fatigue, myalgia following minor activity, nausea, abdominal pain, sore throat without coryza, *excessive dependency on parents,* and a feeling of *disturbed balance* were present in 87% of children, with symptoms rated as severe or moderately severe in >50% [30, 61]. Severe illness-related impairment (work, expectations, attendance), particularly through school nonattendance [69], or 94% attending school half-time or less [113], and high levels of illness-related school concerns was also recorded [69]. In children of a mean age of 11 years, there were statistically significant associations with allergic disease, *ingestion of raw milk* and other family members with CFS [18]. In the children referred to in Table 16.5, 60% *reported a history of allergies.*

There are no pathognomonic features or diagnostic tests to be assessed, but a complex interaction of physical and psychological components. Table 16.6 summa-

Table 16.6. Assessment of CFS

A. Criteria by Smith et al [175]
1. History of onset with an acute illness
2. Presence of profound persistent or intermittently prolonged fatigue in children or adolescents previously in good health
3. Symptoms for longer than 6 months and less than 3 years
4. Presence of at least three additional symptoms according to CDC criteria
B. Study by Carter et al [30]
1. The diagnosis of children was CFS for more than 2 months (instead of 6 months)
2. The syndrome should not be attributed to known causes
3. Symptom prevalence useful for assessment (in decreasing order) a. 55%–70%: headache, arthralgia, excessive sleep, concentration, sore throat b. 40%–50%: myalgia, dizziness, muscle weakness, depressed mood, decreased appetite, abdominal pain, fever
C. Oxford research criteria for diagnosis of CSF [151]
1. Syndrome characterized by fatigue of definite onset as the main symptom
2. The fatigue should have been severe and disabling, affecting physical and mental functioning
3. CFS symptoms should have lasted for a minimum of 6 months during which it was present for more than 50% of the time
4. Other symptoms may be present, particularly myalgia and mood and sleep disturbances
5. Patients with established medical conditions known to cause chronic fatigue should be excluded from the definition. All patients should have a history and physical examination
6. Patients with current diagnosis of schizophrenia, manic depressive illness, substance abuse, eating disorder or proven organic brain disease should also be excluded from the diagnosis. Other psychiatric diagnoses such as depressive illness, anxiety disorders and hyperventilation syndrome are not necessarily reasons for exclusion
D. Guidelines of CDC [80] **and of an international working group** [66] (see Fig. 16.1)
E. Protocol proposed by a joint pediatric-psychiatric team [193]
1. A definable onset of symptoms, potentially associated with a previous viral infection
2. Generalized fatigue
3. Easy fatigability
4. One of the following associated symptoms a. Headache b. Dizziness c. Moodiness d. Peripheral sensory change
5. Symptoms of sufficient severity to interfere significantly with normal social and/or school functioning
6. No detectable organic pathology to account for the above symptoms
E. Subsequent series of pediatric patients with CFS established the following [11, 100, 214]
1. Persistent fatigue was a common reason for referral to subspecialty clinics
2. The average patient was a young female teenager
3. More children reported antecedent illness
4. Results of physical examinations and routine laboratory results were normal
5. Children exhibited significant functional impairment and school absence
6. The majority of patients recovered

rizes North American and English classifications [11, 61, 80, 100, 175, 193, 214] compared with pediatric studies [18, 30, 121, 122, 151]. It should be noted that:

- The *Smith et al* suggestions [175] are more suitable to children aged 1–19, while CDC criteria [66, 80] are centered mainly on adults.
- The *Carter et al* study [30] introduces even more discriminatory pediatric characteristics: CFS patients score higher than healthy controls and depressed subjects on somatization; however, they experience less anxiety and depression, but less impairment in think-

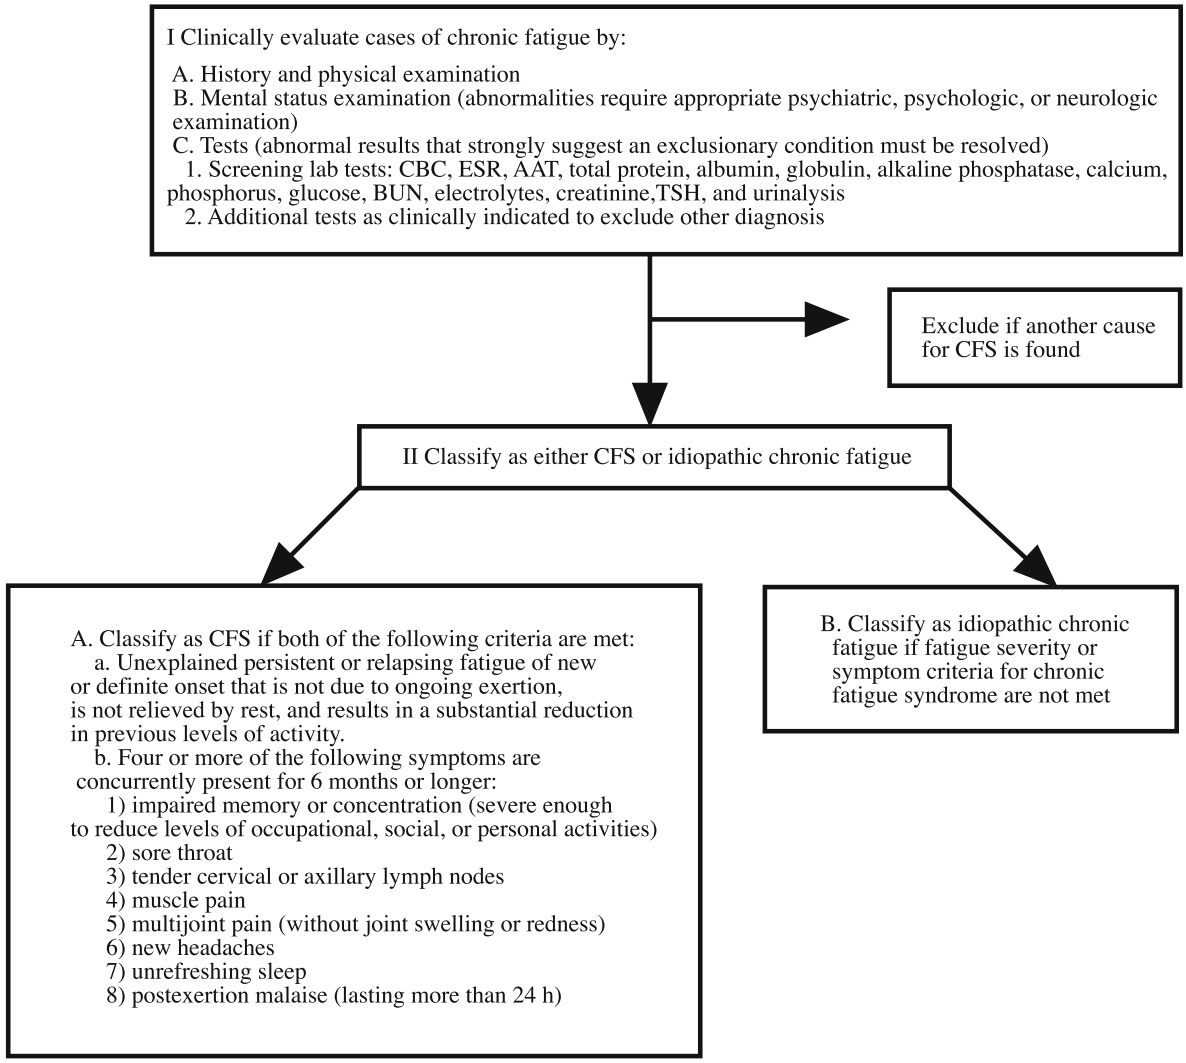

Fig. 16.1. Clinical evaluation and classification of CFS. *CBC* complete blood count, *ESR* erythrocyte sedimentation rate, *AAT* alanine aminotransferase, *BUN* blood urea nitrogen, electrolytes, creatinine, *TSH* thyroid stimulating hormone. (From [66, 80])

ing, and fewer social relationship difficulties than the conclusions of their parents.

- The *Oxford criteria* applied to 32 adolescents exclude psychiatric diagnoses [151].
- The *previous CDC criteria* [80] have been updated and simplified by an international working group [66] (Fig. 16.1).
- The *criteria proposed by a joint pediatric psychiatric team* [193] focus on psychiatric disorders, which should be excluded from the syndrome, even if they are usually present in some adult patients. Actually four of ten patients ranging in age from 10 to 16 years were affected with different forms of restrictions in physical mobility, which certainly cannot by related to the CFS constellation of symptoms.

Above all, pediatric studies establish more stringent criteria [11, 30, 61, 100, 122, 151, 175, 214]. Age was 4–21 years, follow-up 12–72 months, symptoms improved in 53%–100% of cases. Some researchers have rightly pointed out that the illness behaviors of children may be significantly influenced by parental expectations and responses [30]. The CDC criteria, which require 6 months of fatigue for the diagnosis to be made in adults, may be too long for children [121, 214]. Some pediatric studies have selected cases based on ≥6 months of fatigue [175], whereas others have used shorter durations such as 2 months [30] or 6 weeks [193].

Diagnosis

Children and adolescents are in a dynamic developmental state, and issues such as self-concept, autonomy, body image, socialization, sexuality and academic goals are of central importance. Early intervention in those individuals with persistent fatigue is therefore especially important [116]. There is an astonishing absence of specific physical signs and physical investigations fail to identify any organic pathology or current infection to account for the symptoms [175, 214]. The acute or nonspecific onset of the illness in children may cause problems for the doctor; moreover, symptoms often reported to be abrupt are marked by unexplained fatigue [175]. Furthermore, there is no available laboratory test [30]. Therefore, in children and adolescents, a diagnosis of CFS should be considered when unexplained fatigue persists for 3 months, rather than the 6 months stipulated in the adult case definition [116]. In a study in adult patients it emerged that some subjects with apparent postviral fatigue had complained of tiredness before their presentation with a viral illness [37]. EBV serological studies fail to ensure concrete results, also because several healthy individuals display high rises in antibodies to the early antigens of EBV, even years after a primary infection, thus a causal relationship with EBV cannot be found [30]. In a study using *in situ* hybridization, nine of 41 patients had a serological test positive for EBV; however, no statistical difference could differentiate males from females and control subjects [213]. The *differential diagnosis* should take into account several conditions that may mimic CFS: hepatitis B, fibromyalgia, multiple sclerosis, Lyme disease, AIDS and Münchausen syndrome by proxy.

Treatment

Acyclovir [183] has been tried, but the results could not reliably differentiate patients from placebo-treated subjects [183]. Interventions that reported adverse effects severe enough to cause withdrawal from the study encompassed several medications including acyclovir. Interventions that have shown promising results include cognitive behavioral therapy and graded exercise therapy [207]. Therefore, treatment tends to focus on targeting the symptoms of myalgia, sleep disturbances, affective symptoms, and fatigue. Evaluations of the effectiveness of different approaches suggest a variety of different outcomes. While there is some lack of agreement on management strategies, there is considerable agreement on elements of these strategies, even if terminology may suggest otherwise [214]. However, the management of CFS in children is not controversial [205]. *An active rehabilitation program should be offered to all cases* [181]. Actually, programs of rehabilitation rather similar to those now shown to be effective in adults, including some form of support, encouragement, behavioral management, and activation are now the mainstay of treatment in virtually all centers helping children with the syndrome and their families [205]. Receiving treatment was associated with increased school attendance, but one-third of subjects obtained no qualifications. Return to normal health or significant overall improvement was reported by 29/36 children [142]. Immediately following a multidisciplinary inpatient program (MIP) for CFS and up to 5 years after the program, 78% of 42 adolescents who were significantly incapacitated prior to entering the MIP had returned to school full-time or with occasional absences only and were functioning better in terms of physical activity and social interactions as compared with before the program [113]. The relapsing nature of CFS suggests that follow-up should continue for at least an additional 6–12 months after the intervention period has ended, to confirm that any improvement observed resulted from the resolutions of symptoms following the intervention and not to a naturally occurring oscillation in the course of CFS [17].

The *natural history is favorable:* the first follow-up study reported that about half of the children improved 2 years later [175], 24/31 (77%) returned to normal or improved with occasional relapse over a 2-year period [30], and 43% of families considered their child cured and 52% considered their child improved in a group of children and adolescents followed up for 4.5 years [101]. An overall good functional outcome was reported in 80% of participants an average of 13 years after illness onset [17]; in another cohort the rate was 74% 3 years after onset [151]. Follow-up of 23 children diagnosed as having CFS in a clinic found that most children had recovered after a median follow-up of 2 years [122]. Among these children, 76% reported a definite improvement at 2 years, with 38% continuing to have some occasional residual symptoms [122]. However, the participants who remain ill may have significant symptoms and activity limitation [31, 151], but after recovery several children may be left with mild to moderate persisting symptoms [31], or residual symptoms and handicap [151]. At the more severe end of the disability spectrum, 90% of 25 youngsters with CSF aged 15 years and 72% of their parents believed the illness was precipitated primarily by biological factors with an unrealistic view of normative fatigue levels. The tendency by children and parents to underestimate the children's actual levels of activity stressed distorted health perceptions or expectations with the children enhancing general disease conviction, in spite of medical evidence and reassurance to the contrary [68]. The family practitioner or pediatrician should seek the cooperation of the parents and other care givers in devising a supportive rehabilitation plan, including maintenance of peer contact and relationships with friends; academic and recreational activity; and physical activity, rest periods and sleep.

Clinical Presentation of Other Systems

Gastrointestinal Tract

Irritable bowel syndrome (IBS) is the most frequent nonorganic cause of chronic nonspecific diarrhea in children between 8 months and 3 years of age, due to a probable functional alteration in the intestinal motility, intensified or caused by diverse factors [76]. IBS is properly a heterogeneous term masquerading under a variety of affections highlighted by various gastrointestinal disorders in which there is alternating constipation and nonspecific diarrhea, or abdominal bloating, disordered defecation, and in many cases pain [191, 220]. IBS may be prevalent in girls following anatomical and positional abnormalities: ptosis of the transverse colon to the small pelvis [149]. In an IBS variant, constipation predominates (*spastic colon*) and gastrointestinal transit times are highly increased [93]. Often there is no radiological and/or histological evidence of organic disease. Heredity has been suggested to explain the finding that IBS tends to run in families: in 6,060 twin pairs, concordance for IBS was significantly greater in MZ (17.2%) than in dizygotic (8.4%) twins, supporting a genetic contribution to IBS [110]. IBS symptoms were noted by 17% of high school students and 8% of middle school students, representing 14% and 6% of all high school and middle school students, respectively [83]. Several patients with food intolerance have been reported [119]; however, the fraction of IBS sufferers with FA may be larger than believed [173]. Pediatric studies have confirmed this association [11, 220], to the point that a restricted diet improves symptoms in ≈77% of children, while the others found an improvement when cromolyn was added [11]. The incriminating foods in the improved children have been identified: CM, egg, wheat, spinach, tomato, etc. are most frequently involved [11]. An otherwise healthy 15-year-old girl presented with lower abdominal cramping, a variable bowel pattern, and autonomic signs (pallor and diaphoresis) [220]. Thus, IBS supportive symptoms include abdominal pain associated with stool changes, chronic history, normal physical examination and laboratory studies, while nonsupportive symptoms include weight loss and nighttime awakening [220]. The mechanisms at the basis of IBS could be those of a PA; however, the pleomorphic nature, variable in expression, as well as in day-to-day incidence [119], makes it difficult to demonstrate whether food intolerance has any role in IBS, because tests performed and interpreted improperly are liable to be misleading [126]. In several children, a correlation between symptoms and greater bloating, secondary to lactose intolerance and carbohydrate malabsorption have been recorded [136]. Similar conditions that may need to be considered in IBS differential diagnosis include gastrointestinal FA, carbohydrate deficiency, viral infections, inflammatory disease (Crohn's disease (CD), ulcerative colitis (UC), celiac disease) and cases where an excess of fibers or of unabsorbed food residues cause fermentation in the small bowel [220]. IBS diagnosis has been established by the Rome II diagnostic criteria of the condition, available at www.helpforibs.com/footer/rome_guidelines. asp (May 25, 2004). A differential diagnosis of IBS with organic disease was significantly associated with straining on defecation, diarrhea and abdominal bloating but not with pain in the upper abdomen, reflux and appetite loss. In comparison with extraintestinal allergy pain relieved by bowel movement, pain in the lower abdomen, pain in both the upper and lower abdomen, frequent pain and abdominal bloating were significantly associated. In comparison with FA, pain in the lower abdomen, relieved by bowel movements, frequent pain and abdominal bloating were also significantly associated [138]. Children are unlikely to comply with elimination diets, which would have to be carried out over a long enough period of time to exclude the likelihood of an improvement wholly related to chance [119]. Other useful adjuncts in individual children may be sequential dietary exclusion, use of hypoallergenic diets, cromolyn, and colonoscopic allergen provocation test [219]. In particular, oral cromolyn may be useful in chronic unexplained diarrhea and appears as effective as and safer than elimination diets [177]. May has discussed the difficulty of DBPCFCs with sufficient food antigens to provoke unequivocal symptoms [126]. Health care providers who work with these children need to be able to recognize the symptom complex associated with IBS, as well as the possible relationship to anxiety and depression [83]. Some children have their symptoms based on their malabsorption of carbohydrates and improve when placed on a diet without food high in fat, and caffeine, and those with predominant constipation should limit sorbitol, high-fructose corn syrup, stachyose, and raffinose [177]. Moreover, fat, fibers, fluids, and fruit juices should be normalized in alimentation [16, 136]. Thus the roles of *lactose and fructose intolerance* remain poorly understood [177]. If symptoms continue despite dietary changes, a variety of medications can be tried; however, the efficacy is often unclear [220]. Level II evidence is emerging for the use of probiotics and prebiotics in IBS, and in both UC and CD. The use of these therapeutic agents for the above disorders is rapidly moving into the clinical armamentarium [62]. The use of peppermint oil seemed to reduce the pain that children experienced during the acute phases of IBS [206].

Urinary Tract

The urinary tract as a shock organ for pediatric FA has been suggested by a few authors. Several children with respiratory allergy have coexisting *enuresis,* which disappears after elimination of certain foods and recurs after oral challenge. Enuretic children have been shown

to have associated allergic disorders more often than nonenuretic controls [214]. These studies have suggested a role of FA in the treatment of *nocturnal enuresis:* when a group of enuretic children was put on an avoidance diet as a complement of pharmacological treatment, the nocturnal enuresis ceased, the frequency of micturition decreased and the bladder capacity increased [65]. A number of articles report cases of cystitis with dysuria, nycturia and vesical tenesmus, secondary to FA, incriminating foods and food additives included CM, wheat, chocolate, cola, citrus fruit and colorants [35]. The impact of FA was stressed by the Soothill group who reported that enuresis in food-induced migraine and/or hyperactivity may respond in some children to withdrawal of provoking foods [57]; however, unusual therapies require further evaluation [65]. That an allergic reaction can occur in the bladder and result in *allergic cystitis* should not be surprising: histologically, the bladder resembles the respiratory and GI tracts because it is provided with a mucosal membrane, a submucosa rich in blood vessels and a smooth muscle layer. It is theorized that the *urinary bladder smooth muscle layer* may act as an allergic target organ, much as the airways' smooth muscle layer does in asthma, thus provoking a spasm causing decreased bladder capacity and thus enuresis [35]. However, due to the lack of well-controlled and statistically analyzed studies, the role played by FA has not been well documented.

The nephropathies purported to be induced or aggravated in some children by CM ingestion are as follows: orthostatic albuminuria, idiopathic nephrotic syndrome, certain cases of mesangial glomerulonephritis and urinary tract infections. The *lipoid nephrosis* or minimal change nephrotic syndrome is most common in young children [34]. The immunological abnormalities are very peculiar: IgG antibody decrease, IgE and IgM antibody increase, reduced responses to PHA and Con-A (concanavalin A), increase of β-microglobulin levels, a metabolite of HLA class I antigens, reduced IL_2 production and excess production of vascular permeability and immunosuppressor factors, respectively, by CD4 (Th2 T cells) and CD8 T cells [103, 163]. During the relapse phase, significant alterations were found of the NF-κB/IKBα regulatory pathway, whereas very low levels of $IL_{12}R\beta 2$ mRNA were detected, suggesting that T cell activation evolves toward a Th2 phenotype [161]. The Th2 predominance on Th1 T cells is fulfilled in this disorder, possibly with reference to HLA-DR7 allele preponderance absent in adults [103]. Several cases of lipoid nephrosis correlated with sensitivity to different foods, including shrimps, have been reported, with stable remission of symptoms following avoidance of the incriminated foods [50, 106]. Table 16.7 [106] outlines the responsible foods in 34 patients. In 6/17 children aged 1–15 with steroid-resistant nephrosis and minimal change or mesangial proliferation and CM intolerance (SPTs negative in three children tested), an improvement of renal lesions after 1 year on a CM-free diet was noted [172]; similar results have been reported in five subjects aged 7–26 [50] and in a 5-month old girl suffering from a clearly CM-induced nephrotic syndrome that remitted after the institution of a CM-free diet [43]. CIC glomerulonephritis was reported in a child with eosinophilic gastroenteritis and FA. CIC levels were >6,400 mg/dl) and contained κ-casein and bovine serum albumin (BSA). With strict dietary limitation of causative antigens and prednisone therapy, CIC levels decreased to 16,000 µg/dl and serum BSA antibody titer fell 32-fold over a period of 15 months. There was prompt symptomatic relief and amelioration of signs of nephritis [128]. Cromolyn associated with the elimination diet has a remarkable positive effect on the proteinuria, without the need for steroids and immunosuppressors [108]. In addition to food allergens, inhalant allergens are also present, Der p in 18% of pediatric cases [107]. Cross-reactions with different foods are possible when ragweed or grass pollens are implicated [103].

Table 16.7. Responsible foods in 34 cases of lipoid nephrosis

Food	No. of cases
Cow's milk	11
Gluten	6
Egg	4
Pork	4
Beef	2
Wheat	1
Chicken	1

Data from [106].

In cases of *mesangial glomerulonephritis,* IgA antigliadin antibodies are a possible marker of the condition; this specificity does not extend to antiendomysium or antireticulin IgA. IgA antibody anti-foods, lysozyme, ovalbumin, BSA, α-lactalbumin and anti-inhalants (Der p, pollens and feathers) have been observed [158]. History points out frequent cases of urticaria-angioedema and/or pollinosis; serum IgE levels are not higher than those found in the general population [107]. As regards treatment, food and gluten avoidance can lead to steroid withdrawal: in 30% of cases dietetic treatment associated with cromolyn is efficacious [38]. There is the risk that the nephropathy aggravates following a specific immunotherapy (SIT) for grasses due to possible cross-reactions between pollens and gliadin [107]. The case of *vaginal itching* as a manifestation of seasonal IgE-mediated rhinitis due to ragweed is interesting [48].

Scleroderma-Like Syndrome

Also known as toxic-oil syndrome, scleroderma-like syndrome began in an epidemic form in Spain in early May 1981, with clinical manifestations involving several organs in two clinical phases:

- *Acute phase* from May to October 1981: fever, pruritic skin rashes, nausea, vomiting, dyspnea, cough, malaise, acute pleural and lung disease (mostly pulmonary infiltrates), headache, myalgia, serum eosinophilia, lymphopenia, increase in lactate-dehydrogenase levels and elevated serum IgG [35]. Roughly 60% of children had flushed cheeks, enanthem and decreased salivary secretions were noted in some cases.
- *Chronic phase* after October 1981 (almost exclusively in the female sex; especially at risk were female patients with HLA-DR_3 and HLA-DR_4 antigens) [35]: neuromuscular and joint involvement, scleroderma-like skin eruptions, pulmonary hypertension, hepatic and pancreatic changes, disorders of the lacrimal and salivary glands, lymphadenopathy, weight loss, asthenia and hair-loss. Neuromuscular manifestations, the most severe, included myalgias, muscular weakness, yospasms, joint contractures, rapidly progressive muscular atrophies. Respiratory insufficiency was responsible for most of the deaths [187].

The physiopathology of eosinophilia-myalgia syndrome shares obvious contact points, mainly in the eosinophil activation [19]. A 6-year-old female presented with a rapidly progressive scleroderma-like syndrome (SLS) involving almost the entire integument. Initially clinical patterns and histopathological data of both eosinophilic fasciitis and SLS were present: thus both conditions might be subtypes of one disease entity [81]. A differential diagnosis is possible for the elevated IgE concentrations in 37%–50% of patients with SLS associated with tryptophan use [187] and not in the others [19]. The probable cause of this syndrome was the ingestion of rapeseed oil that had been diverted from industrial use and denatured by the addition of aniline and diluted with other seed oils and liquefied pork fat, fraudulently sold as pure olive oil by itinerant salesmen [187]. The oil contained anilines not removed by the treatment, and it is assumed that free radicals from aniline derivatives reacted with fatty acids, resulting in epithelial and vascular changes able to elicit the plurifocal lesions (Chap. 18). Over 20,000 people were ultimately affected, and >1,200 deaths from all causes have been recorded in the affected cohorts [187]. Finding this syndrome in an infant revealed the association with the toxic oil. The role played by high IgG, ICC and autoantibody levels is rarely elucidated; however, there could be a connection with autoimmunity [188].

Hypersensitivity to *Candida albicans*

The origin of this syndrome was the finding of IgE anti-*Candida* in atopic subjects, and above all from the popularity of the book *The Yeast Connection* [42], in which *Candida* is alleged to cause nonspecific and unproved findings, in other words, leading to everything except true allergy [22]. A causative factor should be the advent of antibiotics, essentially broad-spectrum antibiotics, which – to combat harmful microorganisms – also eliminate the useful bacteria, thus favoring yeast overgrowth. The yeast acquires the capacity of depressing the immune system by an increased toxin production; diets rich in carbohydrates and medications such as steroids could work similarly [22]. As a consequence, this exposure in susceptible individuals is alleged to produce multiple subjective symptoms that may involve any organ or multiple organ systems, as well as a sensation of chronic fatigue. Patients are therefore recommended not to take either the above medications or the yeasts, and to reduce their unrestrained craving for sweets and starchy foods [40]. It should be noted that oral nystatin, frequently prescribed for such a disorder, reduced symptoms significantly less than placebo [49]. The *AAAAI* finds that the very existence of this syndrome is unsubstantiated and that certain therapeutic approaches show no objective evidence to support the claim [5]. Moreover, no scientific proof from well-controlled studies has been provided [126], whereas the differentiation from the chronic mucocutaneous candidosis is important.

Allergy to Salt, Sugar, and Water

As pointed out several times, allergy has been very often cited inappropriately, and we are uncertain whether the zenith has been reached when reference was made to *sugar allergy,* a misnomer, as a phenomenon that adversely affects behavior and intelligence in children or when a nameless spokesman even incriminated *salt allergy* as a possible cause of hypertension. An additional chapter was opened up when some investigators mentioned carbohydrates and sweeteners as causative factors of this syndrome: a total of five studies investigating 108 hyperactive children aged 3–17 [74, 133, 211, 210] provided no sound basis for a cause and effect relationship. A DBPCFC study has demonstrated by significant statistical differences that no association exists between sugar consumption and children's behavior changes and a decrease in their cognitive performance [211]. Aspartame has also been questioned [168, 211] but it does not precipitate seizures or ADHD [10] as well as carbohydrates and sweeteners in general [94]. *Dietary salt* has been shown to increase asthma morbidity in children aged 9–15 years [146], whereas improvement in AD by reduced salt intake has been reported in a 4-year-old girl [13], a measure first suggested as long ago as 1912. Final-

ly, *water hardness* rich in Ca salts has been shown to be a risk factor for AD in children of primary-school age [129].

Münchausen Syndrome by Proxy

Münchausen syndrome by proxy is an extreme form of child abuse in which an adult repeatedly produces symptoms of illness in a minor under his or her care [14]. The presentations appear to be similar across the world with the exception of induced apnea, which emerged as notably uncommon [64]. Children can be victims even in a closely monitored pediatric intensive care unit (PICU) [89]. A child hospitalized for evaluation of confusing symptoms, was later shown to be a victim while on mechanical ventilation. The mechanism was intentional tracheal extubation by the child's mother [89]. Two cases were produced by poisoning with different substances (clozapine and clonidine) [14]. The differential diagnosis often includes this worrying syndrome of healthy children falsely presented by parents, especially by mothers [46, 160, 164], perpetrators in 76.5% [170] or 86% [64] of cases, according to two reviews, each including >400 cases [64, 170], who fabricate medical histories or cause symptoms by exposing the child to toxins, medications, infectious agents or physical injuries [46, 164]. The child is then presented to doctors as affected with hyperactivity, migraine, abdominal pains, enuresis, rhinitis, cough [198], *even totally simulated* [70, 130], although the true disease was FA or asthma [198]. In 15 children reported with false allegations of sexual abuse, cases of severe allergy, diarrhea, dermatitis, drug overdose and hyperactivity were found to be fabricated [130]. A more detailed investigation indicates that the children's families are usually involved, but mothers have an obsessive background, rave about the disease, showing an exaggerated desire to see the alleged diagnoses and related dietetic treatments confirmed, trying one doctor or specialist after another, finally coming to alternative medicine. The parents who urge the doctor (aggravating the symptoms) to prescribe a total RAST or additional, not invasive analysis, to find support for the supposed allergy, are also included [198]. The child is often taught to become an invalid [70], and ends up by colluding with the family delusion, and *from victim turns into a party to the falsification* [164]. Even if a child recognizes that it is wrong, victims may be afraid to speak up for fear of anger and more abuse at the hand of the abuser [77]. The annual incidence of these conditions in children followed up in a specialized department may be as high as 5%–8%, in children aged <16 is 2.0×10^5 [46] or 0.5×10^5 [127] and in children aged <1 is at least 2.8×10^5, the highest incidence [127]. Over 4 years a diagnosis was made in 23/41 (56.1%) children closely monitored by video surveillance [78]. As knowledge of the condition grows, a wider range of perpetrators is identified [170]. Typical victims may be either males or females [170] or males in 54% of cases [64], usually 4 years of age or even 4 months [160, 170] or between 3 and 13 years in 52% of cases [64]. Victims averaged 21.8 months from onset of symptoms to diagnosis [170].

This is one of the circles of innocents often subjected to incongruous and prolonged diets and/or inappropriate therapies, even with a great risk for their health and growth: 11 children with growth arrest had been forced to follow a severely restricted diet for an alleged food multiple sensitivity [156]. Most children (72%) present with multiple symptoms and over half (55%) have an underlying chronic illness [46]. The asthma prevalence is only 1%, but the pattern is different because, in addition to fictitious worsening due to the above-mentioned causes, even refusal of medical care and discontinuation of treatment in children with severe attacks have been recorded, until they comply with the battered-child syndrome, taking the shape of an induced worsening of symptoms [70]. However, the morbidity for the child in the majority of cases can be less severe, and following diagnosis there may be improvement or resolution of symptoms in 50% of cases [46]. On the other hand, medical conditions fabricated by children may go undetected for a variety of reasons or be diagnosed as somatization. Therefore clinicians should always be in contact with pediatricians, psychologists and social services teams [198].

Total Allergy

The media coined this label several years ago for *patients claiming reactions to several foods and different environmental factors*. Two surprising cases best exemplify the concept of total allergy: a 13-month-old girl with reactions to 12 different foods with an increase in circulating eosinophils and leukocytes [84] and a child with a double multiple sensitivity to food and inhalant allergens and anaphylactic reactions to foods [10]. A 6-year-old child (reported in the Italian lay press) had double allergy to inhalants (pollens and mites) and to numerous foods, so that he could eat only rice, beet, carrot, fennel, pumpkin, horse and lamb meat. He also could not tolerate odors and synthetic fibers. Many allergists and clinical immunologists manifest their widest skepticism for this syndrome that is taking root and flourishing [109]. However, given a large amount of attention received in the lay press, more and more patients are seeking a cure [109]. Typical is the aspect of a child with total allergy (Fig. 16.2). Over the years the spectrum broadened to include food additives and preservatives, and eventually petrochemicals, petrol fumes, environmental pollutants, perfumes, soaps and other make-up items [40]. The confusion ruling the syndrome has extended to a large number of hospitalized patients suffering from a myriad of complaints, but above all from malnutrition (Chap. 21). The symptoms

Fig. 16.2. A child with allergic rhinitis (allergic shiners, broad nasal bridge, nasal obstruction) conjunctivitis (puffy eyelids, injection in both eyes), eczema around the lips and elsewhere, asthma and multiple food allergy. A typical child with total allergy

include dyspnea or wheezing, arthralgias, transient skin eruptions, etc., with a lack of rigorous identification, but with a common characteristic: they cannot be attributed to any known allergic disorder. The current understanding refers to other diagnoses such as anorexia nervosa [197], thus implying a relationship with multiple food sensitization, or hyperventilation syndrome (in subjects with alleged FA) or current or past mood, anxiety, somatoform disorders, or finally a new chapter of Münchausen syndrome.

Clinical Ecology

The syndrome is also named the twentieth century disease, multiple chemical sensitivities (MCS) or clinical ecological illness, environmental hypersensitivity illness, cerebral allergy, chemical AIDS, sick-building disease, etc. [71], but sometimes it is also called the total *allergy syndrome* [93]. Clinical ecologists propose that chronic and recurrent complaints that superficially resemble those that apply to clinical allergy are instead imputable to low levels of chemical substances in the environment that are inoffensive to normal people [93]. Such theories may derive in equal parts from immunotoxicology (Tables 4.15–4.17) and from adverse reactions to food additives. The term "allergy" is understood in the broader sense, as opposed to the usual medical term, to include nonimmunological, pseudoallergic and other intolerance reactions. Clinical ecologists report that unrecognized immune system dysregulation develops after exposure to environmental pollutants (Chap. 4). Thus, the illness is defined as chronic and polysymptomatic, caused by adverse reactions to inhaled, absorbed, or ingested substances, modified by individual susceptibility and specific adaptability [71].

Off-gassing construction materials
Electromagnetic radiations

Data from [212].

A 4-year-old girl had symptoms such as CM allergy and poor weight gain as an infant, and then later developed symptoms (Table 16.8) [212] precipitated by an expanding variety of chemicals, foods, and allergens. Her mother no longer took her into public restrooms or grocery stores because the disinfectants provoked a vast array of complaints, and freshly painted walls in the hospital set off an asthma attack [212]. However, this syndrome includes a spectrum of symptoms, all with the common absence of widely accepted, standardized, clinical and epidemiological criteria, often based on unproved concepts, unproved techniques and an absence of adequately validated diagnostic laboratory tests [93]. As an example we find:

- *Stimulant reactions to foods:* aggressiveness, loquacity, depression, blushing, anxiety, inappropriate laughing, agitation, anger, panic, worrying, irrationality, muscle contractions, convulsions
- *Food deprivation reactions:* melancholy, hallucinations, torpor, apathy, amnesia, raving, paranoidism, urinary incontinence; additional affections such as headache, learning disabilities, arthritis, anaphylaxis, dermatitis, asthma, rhinitis, etc. remain indeterminate [93].

Alternative Diagnostic Tests

Clinical ecologists place special emphasis on several tests rarely employed in allergy diagnosis, including subcutaneous provocation and neutralization test, sublingual provocation and neutralization test, leukocytotoxic test, IgG concentrations, food immune complex assays, auricolocardiac reflex method, the Vega test or "black box" and hair analysis to detect possible traces of heavy metals. These approaches in addition to bioresponance, electrodermal testing, reflexology, the ALCAT

test [216] and the food allergy profile are definitely unorthodox, unreliable and expensive [71, 199]. Even if low concentrations of environmental pollutants over time are purported to damage the immune system, there is no scientific basis for environmental ecology, and as yet no DB, controlled, randomized clinical trials have demonstrated a diagnostic value for provocation and neutralization [40, 126]. In such a DB trial in 18 patients, control injection as placebo was equally as effective as active antigen (food extract) to induce either neutralization or symptoms [87], thus suggesting that neutralization may be *the effect of suggestion or chance*. Therefore, all these techniques have one thing in common: none has been validated in their application to any child affection.

Alternative Therapeutic Approaches

The overenthusiastic, uncritical and inappropriate application of unorthodox allergy treatment may be detrimental and costly. These include acupuncture, homeopathy, chiropractic and phytotherapy. Chinese medicinal plants are exposed to an alternation of conflicting communications [72, 169], such as the report of 2 of 27 children, who after a 1-year follow-up had reversible abnormalities of liver function tests [169], showing that it is insufficient that a treatment be effective to demonstrate that it works. Instead, we note a nonexistent reproducibility of the study as shown by Liu et al [114], who notwithstanding have obtained both formulas and dosages, but with negative results because six of eight patients with intractable AD dropped out of the study in the 1st week because of exacerbations of their AD, while the remaining two patients gave up the treatment after 2 weeks because their AD also worsened. These so-called remedies are apparently effective, but caution must prevail [79] since we are unaware of a reliable standardization, the precision of active ingredients, and published long-term data on the potential toxicity [72]. It is not surprising that beginning with Chinese herbal remedies [8, 79], it is pointed out that, similarly to the procedures mandatory for conventional drugs, prescription of these mixtures requires as much training as that required by governmental and/or medical regulations, they should be subjected to stringent procedures for *identification of active components* and quality control, and that medicines of any type should be combined with a careful study of the risk of *possible interactions* between different substances before their prescription. Because there is a lack of purity and consistency in dosage in their manufacture, if such products are sold without prior FDA authorization, and these materials are advertised as if they were medicines, they should be regulated as such [51]. Consumers (and pediatricians) may be misled by claims that herbal products can treat, prevent, diagnose, or cure specific diseases, despite regulations prohibiting such statements [134a].

Other causes	5

Data from [179].

There is evidence that related studies are not yet supported by statistically significant results in representative samples [126] and, we add, by DBPC studies. However, the interest aroused by unconventional therapy is shown by the preference of the subjects aged 18–24 years (16%) who consulted providers for allergic disease in 6.3% of cases [59]. Tables 16.9–16.11 [179] illustrate a study reflecting an 11% incidence in a pediatric outpatient department of a Canadian university hospital. Table 16.9 shows that more than half consulted either chiropractors or homeopathists for the most frequent complaints, respiratory and/or ear, nose, and throat disorders [179]. The investigation of a cohort of 53 children aged 13.8–16.9 years affected with juvenile

Table 16.12. Clinical diagnostic criteria in children affected with multiple chemical sensitivities

Nature of incitants provoking a response
Responses to offending environmental toxicants occur at levels of exposure below the 2.5th percentile for response in the general population
Child responds to multiple substances that are unrelated chemically (namely, causes lack of specificity). The symptoms are not confined to one or several environments (namely, only sick buildings)
Biological plausibility, identifiable exposure
Symptoms are reproducible with exposure with reasonable consistency, symptoms resolve after removal of incitant exposures
An identifiable exposure preceded the onset of the problem
Topology of responses
Adverse responses affect more than one bodily system
Primary complaints include neuropsychological symptoms
The child exhibits altered sensitivity to odor
Persisting nature of perceived changes
The disorder is chronic
Differential diagnosis
No single, accepted test of physiological function correlates with the symptoms
Subjective responses and ameliorating actions of affected children
The caretakers and/or child perceive the child's response as unpleasant or disturbing
The family has sought professional advice
The individual's caretakers believe that he or she has a disorder
The family takes action to avoid exposures to symptom-inducing chemicals

Data from [132, 212].

arthritis has ascertained that the patients consulted chiropractors in 24% of cases and acupuncturists in 19% of cases. From the therapeutic point of view, 43% followed diets, 68% used copper bands or bracelets, 38% patent medicines, and 24% skin creams [179]. A child treated by unconventional therapists following a severely restricted diet experienced a remarkable growth retardation and a pattern of hypothyroidism, remitted after an appropriate dietary intervention [102]. The parents of three girls aged 17–24 months and affected with RA perhaps persuaded of the benefits of alternative medicine made this choice because they wanted to try a different approach hoping it might yield better results [179]. These are the results: one girl returned to conventional medical care with hypertensive encephalopathy at 16 years of age, a 4-year-old girl was in the 50th percentile of height for and a 6.5-year-old girl was in had the 50th percentile of weight for and a prominent cushingoid aspect. The clinical manifestations improved, but no measurable growth occurred. In a girl admitted to the hospital because of lethargy and life-threatening starvation, hyperalimentation was successful. In a third girl aged ≈7 years, the RA had deteriorated [179]. "The devices reported above are used to diagnose nonexistent health problems, select inappropriate treatment, and defraud insurance companies. The practitioners who use them are either delusional, dishonest, or both. These devices should be confiscated and the practitioners who use them should be prosecuted" (Barrett St. In: www.quackwatch.org/) which recall the words in defense of breastfeeding [29].

Tables 16.12 and 16.13 include considerations about diagnostic criteria in children affected with MCS [212].

Pediatricians, Migraine, and Other Allergies

Allergic headache is an objective reality that can no longer be ignored, because it is not surprising that growing numbers of children improve following appropriate oligoantigenic diets. Children with migraines can experience comparable or more severe impairment in school and emotional functioning as children with other serious chronic illness conditions [148]. Pediatricians therefore care for these children and when necessary they refer to specific divisions of the local university or hospital or to other specialized facilities in the city where children live. Another facet of the pediatrician's importance is with ADHD children, above all in view of the possible correlations between the ingestion of food additives and behavioral changes. In teenagers, guid-

Table 16.13. Pediatric considerations in multiple chemical sensitivities

Diagnosis
There is no agreement upon case definition of MCSs in children and little that is evidence-based in the diagnosis or treatment of children. There is even less known about children thus diagnosed than adults.
It has been proposed that children's learning disorders or ADHD might be explained by MCSs, but without any convincing scientific evidence.
Adults with MCSs have often been diagnosed with psychiatric conditions, but it is unknown whether affected children or their parents or caretakers have specific psychiatric diagnoses. However, it seems evident that they are living with considerable neurosis and pain, but there is no need for a fatalistic acceptance of the disorder.
Management
Much controversy stems from the false view that fashionable therapies may imply that the illness is all in the mind, so an eventual failure is the patient's or family's own fault. This moves parents to frequently look for a doctor and seek alternative practitioners.
It may be difficult for health care providers to communicate with parents because of their frustrations and dissatisfaction with the response of physicians to their child's MCSs.
Therapies recommended by clinical ecologists may engender additional risks if used for children. For example, severely restricted diets can interfere with the basic nutritional requirements needed for normal growth and development.
Other therapies currently in vogue, including desensitization, herbs, or vitamins, may be especially harmful to children, whose developing body systems (that is central nervous and immune systems) are especially vulnerable to injury.
The limited capacity of liver and kidneys of infants and young children to detoxify and eliminate certain herbs, hormones, minerals and dietary supplements used by clinical ecologists and other practitioners as remedies in adults may consequently provoke a higher risk of toxic reactions.
The limited detoxicating capacity may render infants and young children particularly vulnerable to fluid and electrolyte imbalances provoked by laxatives or purging, also differently suggested and employed.
Public health and psychosocial issues
The social isolation that accompanies chemical avoidance strategies is particularly disabling for children. Such isolation impairs a child's ability to make friends and otherwise interferes with normal psychosocial development. School avoidance may impair their intellectual development.
Children are entitled to the protections afforded by federal laws under the Americans with Disabilities Act. This federal law has been applied to include patients with MCSs. For children, the law could be interpreted to include prior notification of parents if pesticide spraying or other chemical applications were planned at a school or day care center. The law might mandate other accommodation of the special needs of a child with MCSs.
Children depend on adults to make responsible choices concerning their health that are in their best interests. The diagnosis of MCSs can lead to lifestyle changes potentially adding stress to family relationships, especially if parents disagree between themselves or with health care professionals on the diagnosis and management choices open to them.

Data from [132, 212].

ance should involve education about ADHD and advice on parenting principles and coping with academic problems [154]. The CFS is often a prerogative of adolescents more than of children and requires careful assessment of behavioral changes, but primarily of a psychological and existential nature. It is irrelevant to overemphasize the young victims of Münchausen syndrome by proxy, battered-child syndrome according to Rezza, or the nonmedical cures advocated by clinical ecology, since it is an ill-defined illness with no adequately validated diagnostic laboratory tests; Lessof's comment [109] applies here. It is noteworthy that >25% of parents preferred unconventional remedies to patent medicine, although 59% noted an improvement in their child's health after using alternative medicine and about 50% said they were very satisfied with it [179].

Other Allergic Otorhinolaryngological Diseases

Von Waldeyer's Ring

The palatine and lingual tonsils, adenoids or pharyngeal tonsils and lymphoid pharyngeal tissue constitute the von Waldeyer ring [213] (Fig. 15.1) or NALT (nasal-associated lymphoid tissue) [51]. The tubal tonsils and lateral pharyngeal bands are less prominent components [85].

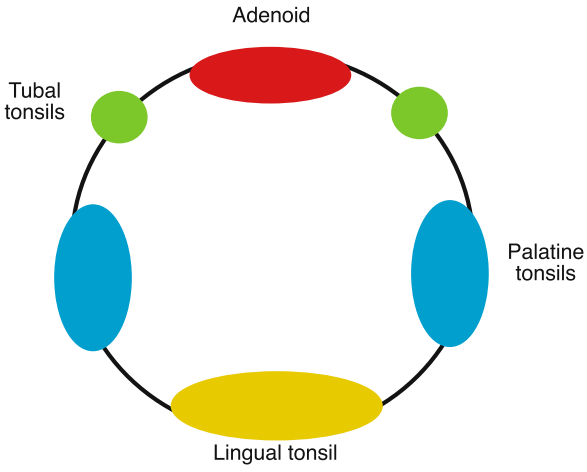

Fig. 15.1. von Waldeyer's ring. According to the original von Waldeyer report (May 5, 1884), the lymphoid pharyngeal ring was extended to the conjunctiva, cecum, ileum and uterus, with a direct and continuous pharynx–intestine passage and vice-versa [213]

Nasal-Associated Lymphoid Tissue

The NALT is located at the gateway of the respiratory (BALT, bronchus-associated lymphoid tissue) and alimentary (GALT, gut-associated lymphoid tissue) tract; thus an integral part of MALT (mucosa-associated lymphoid tissue) is similar to both BALT and GALT, because of its earlier development and location in strategic position and its antigen uptake capacity in inhaled air may be important for initiation of immunity in the upper respiratory tract [85]. Ontogenetically, there are marked similarities to Peyer's patches (PP), although these develop shortly before birth, earlier than NALT, which in rats is only present at birth, but not in human neonates [104]. This difference may reflect a more central role for PP in MALT, or may result from the gut's earlier exposure to antigens. These characteristics confirm the vital role played by these structures in defending the organs they protect [113]. Greater similarities can be found in the position occupied by macrophages in the NALT, at the border of connective tissue, which is comparable to the base of PP interfollicular area, by dendritic cells (DCs), situated in the corresponding B and T areas, and by M cells, which were present in the follicle-associated epithelium (FAE) that covers the lymphoid nodules placed above PP and on top of NALT follicular dome [194]. Histological analyses showed that after local reovirus infection, germinal centers (GCs) developed in NALT with the appearance of IgA^+ cells, whereas no GCs or isotype-switched cells were found in BALT. Thus, BALT lacks the typical lymphoid organization found in NALT and PP [239, 240]. Functionally, PPs are probably essential for the production of secretory immunoglobulins (sIg), while the NALT appear to be more involved in cellular responses. Within the respiratory apparatus, NALT is without question more active than BALT, a similarity that can be found in the T cell/B cell correlation, which in the NALT is more similar to that of BALT, while their respective functions diversify in terms of activation and number of B lymphocytes expressing membrane IgA (mIgA), rare in the NALT. In this respect BALT resembles PP more closely than does NALT [113].

Production of reovirus-specific IgA was observed in NALT and PP, but only small amounts of specific IgA were secreted by BALT [239]. The issue of antigen uptake to the NALT was addressed in Chap. 12: in particular, IgA-producing cells have been highlighted in the posterior cervical lymph nodes, indicating that these lymph nodes are involved in sIgA local synthesis, probably limited to the nasal cavity. IgA precursor cells, on the contrary, are supplied both to BALT and GALT. Instead, NALT is an important station in lymphocyte recirculation (Table 15.1) [17]. Lymphocytes migrate from this site, to return later, as well as to cervical and mesenteric lymph nodes; similar cells coming from the intestine settle in the NALT, in a definitely higher number than lymphocytes coming from PPs that return there, confirming the importance of NALT in both local and systemic immune reactions (Fig. 15.2) [113]. Signaling by lymphotoxin (LT) or TNF-α through the TNFRI

(p55) and LT heterodimers through the LTR (receptor) is of critical importance in secondary lymphoid organogenesis (NALT and lymph node [LN]). LTR is prominently expressed on LN- and NALT-HEV. Thus, there is a critical role for LT in LN and NALT development, and LTR signaling on HEV can regulate HEV-specific gene expression, via regulation of GlyGAM-1 (glycosylation-dependent cell adhesion molecule 1) [53]. Initial naive lymphocyte trafficking allowing binding to NALT HEV (high endothelial venules) (Fig. 1.3) involves predominantly CD62L and peripheral node addressin rather than $\alpha_4\beta_7$-addressin cell adhesion molecule-1 (MAdCAM-1) interactions, and that MAdCAM-1 and VCAM-1 (vascular cell adhesion molecule-1) (CD106) expressed by NALT follicular DCs (FDCs) may play an important role in lymphocyte recruitment and retention [45].

In conclusion the NALT seems to be the main lymphoid tissue for the respiratory tract mucosa, also because it develops before BALT, is more activated [113] and is chronologically the first provider of B cells for BALT, which has none during the first period of life [27].

Tonsil Immunology

Although tonsils are not actually the seat of allergic diseases, they do play an important role in antigen recognition and in synthesis of IgE and other antibodies, in addition to often entering the differential diagnosis of other otorhinolaryngological (ORL) problems. A study in 88 normal human embryos has shown that palatine tonsils play a prominent role in the development of the immune system, being the first organ in the lymph system that analyses and reacts to antigenic stimulation [139]. Their ontogenesis begins *during the 14th week of gestation,* when both B and T lymphocytes invade the mesenchyme below the tonsillar epithelium. During the 16th week primary follicles are found earlier than in other secondary lymphoid organs [25]. By the 20th week, the areas surrounding the primitive crypt are richly vascularized with HEV and, similarly in the thymic medullary region, T cells are in contact with HLA-DR, IDC (interdigitating dendritic cells) and Langerhans cells (LCs) present in the crypts by the 15th week [155]. Tonsils and adenoids apparently play an important immune-inductive role as components of MALT; however, these structures also show similarities with lymph nodes and may in addition participate as effector organs of local systemic-type as well as mucosal-type of adaptive immunity [26]. *As tonsils are the first site to encounter inhaled and ingested microorganisms,* they are the first line of defense against exogenous aggressors [85]. Tonsils are active especially between 4 and 7 years of life, when they achieve their largest dimensions, then gradually atrophy in most cases, except for the lingual tonsil, which appears to remain functional until the fourth decade [155].

Antibodies and Cellular Immunity

About 2 weeks after birth, activated B lymphocytes are found in the GCs of lymphoid follicles, in T cell-dependent B-cell activation induced by exogenous antigens [26], where they differentiate and proliferate, as well as in the mantle zone and reticular epithelium [25]. T cells occupy all compartments such as the intraepithelial lymphocytes (IELs), the interfollicular regions (both provided with HEV) and the follicles [155], but CD4 are also found in GCs [231]. Two B-cell subpopulations of human tonsils were found in the follicular mantle (expressing surface CD5) and marginal zone that displayed marked differences in phenotype, in response capacity to T cell-independent antigens, and in presentation of antigens to T cells [52]. Tonsillar B cells are found in a higher number compared to those of peripheral blood, unlike T lymphocytes (CD3), while CD8 are rare (Table 15.1). Signaling lymphocytic activation molecule (SLAM, CD150) identified in vivo as a monocyte activation marker was absent in blood, but was detected in tonsils, where it could be localized to T-cell areas and GCs [63]. Tr1 and 2 (T-regulatory 1 and 2) were expressed in the MALT on human tonsillar crypt epithelium. Although Tr1- and Tr2-positive cells were in proximity to T lymphocytes in vivo, lymphocytes themselves were devoid of Tr1 and Tr2 expression [141]. Animal studies show that T cells adhere better than B cells to NALT HEV, thus more T cells enter NALT: as seen in Table 15.1, tonsillar plasma cells produce all classes of Igs (immunoglobulins) [17]. IL_{15} induces Ig proliferation and synthesis by human B cells stimulated by T-cell CD40L (Table 1.5), to prime cognate interaction in tonsillar GCs: following centrocyte activation, another crucial event is bcl-2 expression to prevent apoptosis (Fig. 15.3) [25]. IgA secretion by palatine tonsils is significantly higher than in lymph nodes, suggesting that tonsils might play a relevant role in IgA synthesis [228], thereby assuming the MALT characteristics (Fig. 15.4).

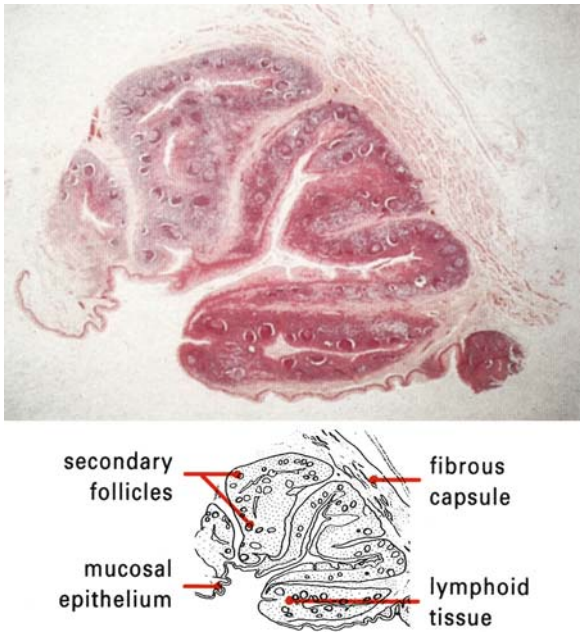

Fig. 15.4. Low-power view of human tonsil showing the MALT with several secondary follicles containing germinal centers

B lymphocytes with the J chain can differentiate into IgM or IgG plasma cells which in turn secrete Ig J (joining) [13], with differences between healthy and sick tonsils, but the isotype switching in tonsillar GC causes a high rate of extrafollicular IgA J which is reduced in recurrent tonsillitis [27] (Fig. 15.5). IgD and IgM immunocytes are found in the mantle zone, and continuing clonal differentiation both IgM and IgG antibodies are detected in the GCs [24] (Fig. 15.6) [25]. IgA and IgG are numerically correlated in the tonsils, unlike the serum; however, IgG appear to be more numerous and IgA are prevalently found in extrafollicular areas and in the crypt epithelium [231] (Fig. 15.7). Ninety-five per cent of IgA antibodies belong to IgA_1 subclasses as in peripheral lymph nodes and in the nose, but unlike the colon, IgG subclasses account in the following order

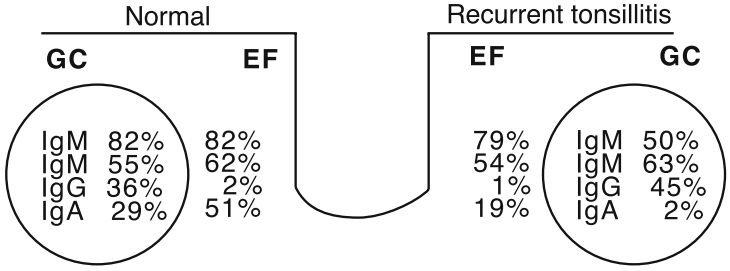

Fig. 15.5. Expression of J chain by tonsillar cells producing immunoglobulins in germinal centers (GC) and extrafollicular areas (EF) (mean values) in normal tonsils and in recurrent tonsillitis. (Modified from [27])

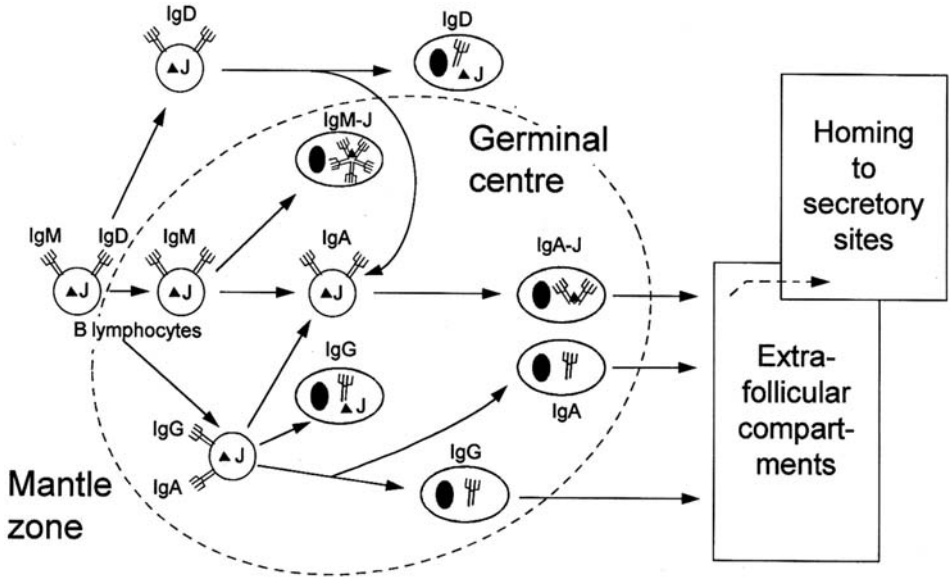

Fig. 15.6. Schematic depiction of putative B-lymphocyte developmental stages in tonsillar germinal centers (*dashed line*). The pathways to terminal plasma cell differentiation may include cytoplasmic J-chain coexpression. The J-chain-expressing plasmablasts may to some extent terminate their differentiation in extrafollicular compartments, but may also have a potential for homing to secretory sites (*dashed arrow*)

for 61%, 22%, 16% and 1% [24]. The adenoids often show patches of epithelium with SC expression and have MALT characteristics [24]. The adenoids appear to be functionally comparable to NALT in rodents [26]. It is therefore understandable how upper respiratory tract chronic inflammatory processes are associated with tonsil hypertrophy, resulting in an increased antibody synthesis [113], with qualitative and quantitative differences depending on the ongoing process [111]. The abnormal reduction of lymphocyte functions, associated with structural changes correlated with hypertrophy, may establish chronicity [111]. Surgical tonsil and/or adenoid removal in children leads to a significant reduction in Ig levels and especially in sIgA levels 1–4 months after surgery (Table 15.2) [35], which becomes particularly obvious when correctly interpreting the NALT role in sIgA synthesis [32]. A Medline search (1980–2004) shows that only the studies that have measured sIgA agree with our data [98, 99, 105]. Not only salivary sIgA concentrations were decreased to the control levels at the 30th postoperative day, especially if aged 5–7 and 8–10 years, but in the tonsillectomy group the number of IgA immunocytes of the extrafollicular area and the reticular part of crypt epithelium decreased below the control group levels [99]. Other authors, who visited at variable intervals, suggest a correlation between a decline in Ig levels and a reduction in antigen stimulation [67]. A study in tonsillectomized children found high salivary Ig levels after 3–4 years [115], thus demonstrating that these antibodies may need a long time to return to normal levels. IgA total levels in parotid and whole saliva, as well as serum IgA levels, were comparable in tonsillectomized and control children 6–14 months after surgery [41]. The parotid gland is not a part of the Waldeyer ring, however [85]. Several studies measuring IgA antibodies (not sIgA) concluded that the changes do not cause significant immune deficiency [92, 109, 154], that 6 months after operation a normalization of examined immunological parameters was observed [237]. In recurring tonsillitis the J-chain production by tonsils is greatly reduced (Fig. 15.5).

In conclusion, the examinations of the parameters of the immunological system (humoral and cellular) are necessary before planned adenotonsillectomy [35, 237]. Longitudinal studies with sufficiently large numbers of children also fully responding to ethical principles appear to be necessary to evaluate the immunological effects of an adenoidectomy and/or tonsillectomy [26]. We stress that 45% of children with adenoidal hypertrophy improved after 2 weeks of steroidal therapy. Among these children, an additional 24-week treatment at a lower steroid dosage was associated with a significant 52- and 100-week clinical improvement and with reduction in adenotonsillectomy [44], thus making surgery unnecessary.

IgE plasma cells have been identified in tonsils, in adenoids and in regional lymph nodes only in atopic patients [70], while instead IgE synthesis in the nasal mucosa has not been proved, even though APCs, CD4 and CD8 T cells as well as IgA plasma cells are present [21]. It is therefore thought that in atopic patients, both uptake and processing of inhaled allergens takes place in the NALT, and that IgE synthesis takes place at the first signal in the tonsils, in parallel or alternatively to the PP [25].

Antigen Recognition

Tonsils are immunocompetent organs without lymphatic afferent vases, supporting the hypothesis that they have the duty of processing the antigens that appear on their surface [25]. The lymphoid structures are closely linked to the superficial epithelium that forms the crypts, invaginations that extend inside the tonsils, and that can have the function of taking up minute particles of foreign substances that then come into contact with posterior cervical lymph nodes [27]. This procedure is facilitated by numerous crypts, 10–20 in the human palatine tonsil, which considerably increases the surface exposure for antigen uptake. Moreover, HLA-DR-positive cells are deep in the crypts that also appear to be essential in antigen uptake [13]. Antigens enter the crypt, and taken up by reticular epithelium and transported by M cells inside the GC are later processed by APCs [17]. IDCs in the extrafollicular zone, DCs in the GCs (DCG) [13, 19] and LCs [155], found in significantly higher numbers in the adenoids of allergic children

than in controls, present antigens to extrafollicular T cells [113] (Fig. 15.7 [24] and Fig. 15.8 [27]). Activated T cells (IL_2) are CD45RA and CD45RO, some expressing CD25 as a mark of recent activation and of tonsillar capacity of providing primary and secondary T reactions [24, 27] (Fig. 15.9a, b) [27] with B cells, with a high degree of final differentiation (Fig. 15.9c, d) [27]. Several adhesion molecules facilitate T-cell infiltration, first the couples CD49d/CD29-CD103 and CD34-CD62L, and CD54, thus stressing the role of integrins [155].

A facilitated route distinguishes particulate and soluble antigens: the latter may cross the nasal epithelial cells, encounter macrophages, with HLA presenting antigens and T cells, are then taken up by cells different from lymphocytes, or as free antigens seed the superficial lymph nodes, inducing more often a systemic immune reaction, or establishing tolerance. They drain into the posterior lymph nodes. Particulate antigens are cleared rapidly by the mucociliary sentinel, but because of repeated exposures, or if the ciliary apparatus is damaged (for example by the effects of passive smoking, environmental pollution or viral infection), they are taken up by M cells, thus reaching the NALT [113]. M cells in the NALT transport the Gram-positive pathogen across the epithelial layers in a manner similar to those in PPs. However, *Ulex europaeus-1,* an M cell-specific lectin, identified cells harboring streptococci at the epithelial surface of NALT and blocked bacterial colonization of this tissue [152]. In animals, an

alternative type of presentation was proven, based on circulating immune complexes (CICs) present in DCG processes [205]. CICs meet with GC antigen-specific B cells that present the processed antigento T cells : hence specific DCGs could act as APCs for B cells [205]. Furthermore, antigen presentation can stimulate memory B lymphocytes with IgDs and IgMs (surface) to switch into very mature clones with IgA and IgG antibodies [17] (Fig. 15.9 d). To be able to present antigen directly to T cells, memory B cells must express CD80/CD86, which bind T-cell CD25. A similar expression is needed for IgD and extrafollicular IgM antibodies to work as APCs. Naive B cells cannot present antigen to T cells unless they become activated by triggering CD40, but only at lower levels [119].

Tonsils as a Source of Immunocompetent Cells

The existence of a protective local immune system, almost independent of systemic immunity, was proposed in 1919 [18]. In this perspective the palatine tonsil can act as a distribution center for B_{IgA} J^+ cells for the nasal mucosa, middle ear (ME), parotid, tear, and

mammary glands [23, 24]. Studying a particular strain of *Streptococcus mutants,* a bacterium linked to dental caries, virtually nonexistent in the nasal or ME mucosa, there was confirmation of this important acquisition: B cells can mount specific antibody levels against this organism at these sites [15]. B cells arising from the tonsils are therefore capable of migrating to an adjacent site in the upper airways such as the ME. Because B J^+ cells originate in *the tonsils,* they *are considered the upper respiratory tract PPs* [24]. The considerable development of tonsillar IgA emphasizes the palatine tonsil capacity to work as a potential source of sIgA, at the same level as GALT and BALT. By stimulating in vitro tonsillar lymphocytes with β-lactoglobulin, IgA of tonsillar origin are produced, thus proving that they belong to MALT [147]. Therefore, if IgA are provided with such a broad specificity, it follows that the NALT structure, in addition to playing an important role in immune exclusion, also appears to be a source of dimeric IgA J^+ for the upper airway mucosa and the entire organism. Finding that nasal and bronchial mucosa, along with salivary and lacrimal glands, show an IgA_1 and IgD immunocyte distribution similar to that of tonsils supports the view that such secretory effector sites are seeded chiefly by B-cell blasts generated in tonsillar CD4 and CD8 T cells [15].

NALT is thus involved in regionalized B-cell dissemination rather being solely part of a common MALT structure [25]. The NALT strategic position sanctions the important role in the defense from aeroallergens: if damaged by tonsillar disease the way is paved for pathological evolution that results in AR (allergic rhinitis) and/or asthma [27]. NALT might therefore appear as the main respiratory tract mucosal lymphoid tissue [113], its activated appearance, its function as a T-cell organ, the lymphocyte-HEV binding sites in human tonsillar tissue and its strategic position at the airway entry, which emphasizes how adenoidectomy-tonsillectomy lacks a solid scientific basis, especially given the continuous acquisition of tonsillar immunological functions [32, 155] and also because surgery is not always preceded by immunological investigations [32]. It is worth remembering that CD31 and CD54 HEV levels have increased following repeated episodes of tonsillitis, with possible autoimmune complications, and that the tonsils can represent an entrance and a site for HIV replication [155]. These observations provide indirect evidence that *both palatine tonsils and adenoids are part of an integrated MALT and represent NALT in humans* [15]. Consequently, although tonsillectomy is either ineffective or of limited efficacy, the risks of hemorrhage and additional hospitalization outweigh any potential benefits unless a distinct indication for tonsillectomy exists [170]. A considerable immunological activity persists even in diseased tonsils and adenoids of children, therefore a conservative attitude toward adenotonsillectomy appears immunologically desirable, particularly in the young age group [26].

Otitis Media with Effusion

Otitis media is anatomically and immunologically unique, because the eustachian tube (ET) under normal conditions protects the tympanic cavity, the antrum and the mastoid from bacterial invasions. These sections are aseptic, so under normal conditions only a few immunocompetent cells are found in the ME. Antigen encounter stimulates the local and systemic immune system development, parallel to age-related growth, thereby contributing to the protection of tubotympanic structures from pathogenic bacteria [22]. Otitis media with effusion (OME) is a major pediatric health care issue, and is called the *silent disease.* The role played by allergies dates back many years: along with studies confirming the close links between allergies in 80% of cases, there are controversial results, even though there are few controlled clinical studies [207]. Long-standing OME might result in the maldevelopment of communication skills, frequently causing various degrees of hearing loss [75], and is considered the *most frequent cause of deafness in children* [110], although this has recently been questioned [150].

Definition

OME, a multifactorial illness, is characterized by the presence of a ME effusion (MEE) without clinical symptoms or signs of inflammation, frequently 3–16 weeks after an initial episode of *acute* otitis media (AOM) [9], with remission of symptoms on average within 3 months, with a 95% percentile at 12 [235]. Therefore a large number of spontaneous recoveries exist, which do not protect from a relapse in 50% of cases [235]. It is labeled *chronic* when the fluid persists for >3 months or when OME recurs ≥6 times over a 12-month interval [65]. It is an important event because of a frequent change into chronic or recurrent processes, although chronic forms are not always a consequence of acute forms [186].

Epidemiology

The first episode occurs at a mean age of 4.2 [146] or 6.3 months [62], 97% with at least one episode by the 1st year and 99% by the 2nd year [146], with a mean of between 1.3 and 1.9 episodes, respectively, and a mean duration of each episode of 1.9 months [62]. The proportions developing one or more episodes of OME between age 61 days and ages 6, 12, and 24 months were 47.8%, 78.9%, and 91.1%, respectively. The mean cumulative proportion of days with OME was 20.4% in the 1st and 16.6% in the 2nd year of life [157]. The OME that persists after onset of AOM is more frequent (20% at 2 months) than the chronic OME that concerns 4.4%–

10% of the pediatric population before the age of 5 years [135]. According to others, OME mainly affects children between the ages of 0 and 3 years with a bimodal curve, with two peaks at the ages of 2 and 5 years [236]: very frequent at 6 months (85%) [146], OME prevalence increases to between 10% and 13% during the 2nd 2-year period [164] and to between 15% and 20% in the third 2-year period with a 2nd peak around the age of 5 years, to progressively decrease up to 12–14 years [65]. In Chinese children, the prevalence rates of OME in different age groups were as follows: 11.3% for 3-year-olds, 12.4% for 4-year-olds, 11.8% for 5-year-olds, and 6.1% for 6-year-olds [40].

Anatomy

The ME includes the ET divided into a cartilaginous section and a bone section, the tympanic cavity, the antrum and the mastoid cells. The nasopharynx, although not anatomically part of ME, is correlated with it from a pathophysiological point of view, because the two mucosal structures communicate via the ET.

Genetic Factors

A number of studies suggest a genetic predisposition [103, 167], based on the significant number of HLA-A2 and HLA-Cw6 antigens seen in children with OME compared to controls [103]. A heritability estimate had a correlation significantly higher in monozygotic sets (0.65–0.77) than in dizygotic sets (0.31–0.39) for each year to age 3 years [37]. In twins suffering from chronic OME, the number of positive SPTs for inhalants is very high compared to healthy twins [64]. SPTs (skin prick tests) to 7 different aeroallergens were positive in 11 atopic children [138]. Family history (FH) and SPTs were positive in 35% of 100 children [12], and in 306 children with OM or OME-positive FH was a risk factor [56].

Data from [8, 58, 65, 135, 146, 149, 203, 234].

Predisposing Factors

Predisposing factors are summarized in Table 15.3 [8, 58, 65, 135, 146, 149, 203, 234], to which we add anatomical factors, adenoidal hypertrophy, breast feeding in a supine position [146], and sibling history of ear infection [203]. No significance was found for gender, passive smoking [58, 234], date of birth, FH of OME, parental socioeconomic status, histories of snoring, consultation of a physician [58], and birth weight [234]. Males are more affected than females [20, 75, 138], or males in the early stages and females at 18–24 months of age [146]. The bimodal curve of prevalence in the first part corresponds to the immune system maturation, influenced by day-care center attendance and the resulting infectious episodes, while the second part normally coincides with the 1st year of school and once again with infections [236]. Day care attendance was a significant risk factor for OME in larger cohorts described below [43, 204, 210]. Several *craniofacial malformation* syndromes are associated with OME (Table 15.4) [8]. *Anatomic factors* are less well known: the position of nasopharynx ostium related to the angle formed by ET plays an extremely important role for ensuring satisfactory drainage. In newborns and small babies, the angle of elevation is reduced to 100 (only in adults does it achieve a normal opening of 45° [22], thereby preventing adequate draining.

Table 15.4. Craniofacial malformations and syndromes associated with high incidence of OME

Trisomy 21 syndrome	Down

Data from [8].

Immunopathology

Data concerning the presence and activity of a ME mucosa immune mechanism is not entirely definite. Immunohistochemical studies have shown, in 86% of cases, *lymphatic tissue assimilable to NALT*, as results also in other structures that are part of the von Waldeyer ring [213]. Further research has confirmed that ME participates in selective antigen uptake from intraluminal spaces and can trigger immune responses following antigen exposure [173]. In the inflamed mucosa IgG, IgM and IgA are routinely found, but IgA antibody linked to bacterial antigens act as a defense [116]. *sIgA in nasopharyngeal secretions* may inhibit bacterial adherence, also *significantly reducing bacterial colonization,* the first step in the process leading to OME [114, 187]. Connective [222] or mucosal [73] *mast cells* could contribute to defense mechanisms [222] or to inflammation in its acute forms [73]. Animal studies have reported that the number of B_{IgA} cells in the inflamed mucosa is apparently lower than that observed in both GALT and BALT [162], which are sources of IgA precursors for ME mucosa, emphasizing the sharing of a common mucosal immunity (MALT) [116]. Strikingly, a cellular proliferation of MALT was found in the temporal bone of 21 neonates after the age of 1 month [104], which might reflect the activity that produces sIgA against invasion of foreign antigens [80]. Thus it may be a local response to repeated infections [104]. In specimens with purulent OM, the MALT had faint GCs that were complete in specimens with mucous OM [80]. However, while levels of adenoidal sIgA may be normal in children with OME, *SC levels are significantly lower than in healthy subjects* [68]. The role of $IL_{1\beta}$ in the pathogenesis of OME has been clarified: $IL_{1\beta}$ might be associated with endotoxin-induced inflammation in the ME and might play an important role in the induction of OME [221]. *T-lymphocyte trafficking* is reduced compared to that seen in nasal mucosal tissue, suggesting that ME is less often exposed to antigenic stimulation than both airway and alimentary tracts [91]. Otherwise it may be that the afferent limb of systemic immunity from ME operates less effectively and rapidly than that from the dermis [116]. Lymphocytes bind to epitopes released in the inflamed mucosa but not under normal conditions [134]. Concerning ME lymphocyte homing, such cells are not provided with specialized ligands or receptors that can recruit mucosal lymphocytes selectively to ME sites, since lymphocytes of different subsets show no preferential homing at this level [174]. The role played by immune mechanisms in the pathogenesis of OME follows three main routes: IgE-mediated hypersensitivity, CIC, and DTH (delayed-type hypersensitivity) [12, 207]. In particular:

- Local *IgE levels* are raised compared to plasma concentrations [153], indicating local production. The role of *IgE-mediated hypersensitivity* is not universally accepted, although there is a widespread support, varying between 20% and 93% [207]. The results of Todd's meta-analysis [207] which examined seven studies, are characteristic: the two studies confirming the association were based on SPTs and/or RAST, the five negative studies were limited to clinical diagnosis and questionnaires. The symptom frequency matches 29%, compared to 54% of FH^+ and 44.7% of OME [163]. Blood tests revealed a raised serum IgE in 28% and eosinophilia in 40% of 219 children [3]. It has been widely proved that hypersensitivity of both nasal mucosa and nasopharynx is generally able to cause ETD (ET dysfunction) [8, 12, 19, 20]. Furthermore, immediate and late reactions occurring in the ET are correlated with high levels of total and specific IgE (sIgE) in ME effusions (MEEs) [207]. Other frequently debated issues concern relations between OME and *IgE-mediated inflammatory edema* that obstructs the ET, and a possible involvement of the ME mucosa as sensitized tissue, therefore as a sort of shock organ [116]. In human beings, however, there is no convincing evidence that this immune mechanism is operative, although ETD has been demonstrated by a great deal of research on human beings and animals; following NPT (nasal provocation test) with pollens or with histamine in sensitized patients, in the aforementioned meta-analysis the correlation was present in 6/7 studies [207].
- *CIC (type III)* function is not very well documented. Findings in secretions probably represent bacterial or viral IgG complexes, which likely find access via ET, as proven by the anti-CM CIC-IgG, anti-egg and anti-wheat reported in 70% of children with OME and only in 16.6% of controls [12].

Table 15.5. Mean number (+ standard error of the mean) per field of cells in the nasal cytograms of 50 children

Disease	Eosinophils	Basophils	Neutrophils
Normal	0.11 (0.07)	0.15 (0.07)	4.87 (1.93)
OME	10.18 (5.7)*	1.42 (0.42)	6.53 (1.75)
Nonallergic otitis media	1.83 (1.04)	0.13 (0.07)	20.41 (6.78)*

*$p<0.05$ compared with other groups.
Data from [133].

- Studies suggest that *T cells (Th1) can mediate a DTH mechanism (type IV),* but there is not yet sufficient data to confirm this issue [174].

MEEs also contain higher NCF-A, PGD_2 and MBP levels derived from eosinophils, and histamine compared to serum levels. A study done on 50 children aged 2–7 (Table 15.5) [133] has highlighted a significant proportion of eosinophils in children with OME, and levels of histamine matching about 0.2 pg/mg of protein in normal and nonatopic patients and at about 5.5 (SEM about 1) in children with OME [133]. On a cellular level, neutrophils are an integral part of the inflammatory process in OME to a disproportionate degree among atopic children [89], although others have found neutrophils only in nonatopic OME sufferers [133, 138, 192]. However, the high number of neutrophils in the MEEs of these patients might represent the persistence of an infectious process during ETD [138, 192].

A possible *role played by immunodeficiency* in the pathogenesis of OME has been proposed, in particular an IgG_2 deficiency to *Pneumococcus* [46], *Streptococcus epidermidis* and other bacteria capsular antigens [12]. Furthermore, the delayed development of an antibody reaction to bacterial antigens, especially IgG reduced levels, might form the basis of OME susceptibility [159]. In this case the pathogenesis could be assigned also to a humoral immunity depression, very probably genetically controlled. Further controlled studies are needed to better consolidate this interesting hypothesis of this particular susceptibility of certain children to developing OME.

Allergen-Induced Eustachian Tube Dysfunction

The ET measures 31–38 mm, is shorter and narrower in young children and covered by a mucosal membrane, establishes communication between the tympanic cavity and the nasopharynx [22]. It consists in a bony portion lying within the temporal bone petrous portion and a fibrocartilaginous portion that communicates with the rhinopharynx via the ostium pharynx [22]. In physiological conditions its function consists in:

- Protection from nasopharyngeal sound pressure and secretions
- Drainage into the nasopharynx of secretions produced within the ME
- ME ventilation to equilibrate air pressure with atmospheric pressure
- Supplying the tympanic cavity with O_2 [22]

Although there are no definite data concerning the allergic pathogenesis of OME, there is nonetheless *a close correlation between upper airway allergy and ETD.* Prospective studies on children with chronic or recurring otitis media and ETO (Eustachian tube obstruction) of the functional type have reported that the simultaneous presence of an upper respiratory tract infection (URTI) provoked serious ETO of a mechanical type, revealed by tympanometric changes [8, 12, 19, 20]. In parallel, NPT with pollens induced OTE after 20 min (immediate reaction) and after 4–8 h (late reaction) in patients with AR and normal auricular parameters: the obstruction caused by this test is dose-dependent, correlated with serum allergen-sIgE levels and lasts longer than the AR accompanying it [65]. The phenomenon appears spontaneously during the pollen season in these patients [12]. Similar results are provoked by a NPT with histamine, but not in healthy patients: in laboratory animals histamine causes both extra- and intraluminal dose-dependent obstruction, to a greater extent in young animals than in adults [65].

It can be assumed that in children with respiratory allergy and OME, the developing pathogenetic events, based in some cases on ETD, may progress up to impairing the functions when upper airway disease is present Anatomophysiological studies have reached the conclusion that in the first period of life the ET function is compromised because of a TVP (tensor veli palatini muscle) insufficiency, or because of anatomical defects such as a different angle, by rendering the organ more sensitive to mechanical compressions and negatively influencing its functions. To understand the consequences, it is known that, unlike what occurs in the respiratory tract, the tube is usually closed, opening only when the muscle contracts. Animal experiments have confirmed this pathogenic mechanism: a tubal resection leads to the development of a condition that is similar to obstruction, with the formation of exudate in the ME after 3–4 weeks [22].

Mucociliary Dysfunction

Cilia on the respiratory tract epithelial surfaces continuously sweep mucus shed by ME (and nose, sinuses, eyes, and lungs) into the nasopharynx. Therefore, *primary ciliary dyskinesia* (mapped to chromosome *19q13.3-qter*) [130] or *secondary,* correlated either with congenital anomalies or acquired bacterial or viral infections (RSV, respiratory syncytial virus), plays a critical role in the development of nasopharyngeal viral replication. It is not clear whether the cilia function nor-

mally in the ME and ET in the chronic phase of OME. However, impaired ciliary function in primary ciliary dyskinesia is frequently associated with the development of OME. Interestingly, endotoxin in concentrations far in excess of those found in the ME with chronic OME had no effect on ciliary activity [126]. Obviously, a normal ciliary apparatus is needed for surface cleansing; a change in this delicate structure favors the establishment of allergens and/or contaminating substances of any type in the mucosa for a long period, thus reducing or blocking mucociliary transport [153] and potentially encouraging the development of infections. The defensive mechanism can be altered by viruses, because of their well-known ciliary tropism [36]. Since ciliary structures are totally correlated to function, any change that occurs during acute nasopharyngeal infections may reflect on impaired mucociliary clearance with dyskinesia and mucostasis. These events often precede the onset and perpetuation of the dysfunction that reverberates on the structures below, in turn leading to ETO and consequently to OME [19].

Eustachian Tube Dysfunction

Acute and chronic otitis media can be caused by ETO, normally of two types: mechanical or functional. The first kind can be intrinsic (caused by allergies and/or infections) or extrinsic (caused by allergies and/or enlarged adenoids), both well supported by an allergic inflammation highlighting the tubal obstruction related to edema. Functional ETO is common in infants and younger children since the cartilaginous tissue supporting ET is less scarce and less stiff than in older children, as is the case in those with palatoschisis [8, 19]. A significant role played by adenoids in OME pathogenesis has been excluded [74]. Another cause of ETD is an abnormal tubal patency, causing the air and any other possible unwanted secretion to flow freely from the nasopharynx into the ME, resulting in reflux otitis media. This excessive flux can also follow a modest positive nasopharyngeal pressure (nose blowing, crying, etc.), due to the elevated stretching capacity of tubal walls. This may also occur because of an active tubal opening (caused by TVP muscle contraction), even when the tube remains functionally closed and even if actively forced open. In parallel, nasal obstruction can cause ETD: during swallowing an initial positive nasopharyngeal air pressure is followed by a negative phase within the closed nasopharyngeal chamber [65]. The probable effect of such pressures on a yielding tube is biphasic: with positive nasopharyngeal pressure the secretions can flow toward the ME. If negative nasopharyngeal pressure dominates, the tube remains closed, because it becomes even more obstructed. This is known as the *Toynbee phenomenon:* by nose blowing, diving, swimming, or ascent in an airplane, or closed nose and mouth swallowing, the tympanic chamber is partially emptied [65]. A vicious circle is therefore established: the ME in fact, normally without secretions, contains air regulated by ET action; if the opening is reduced the air, no longer able to enter the ME, is reabsorbed. The resulting negative pressure, together with the O_2 absorbed by capillaries, causes mucosal swelling, with formation and accumulation of serous secretions. This transudate, containing sterile mucous, cellular debris and neutrophils, accumulates in the ME space in the case of prolonged ETO after rupturing the mucosal basement membrane and distorting nonciliated cells [19]. Infection transforms the transudate into mucous exudate with an increased protein content. With continuing pathological stimulation, the ME lining cells become hyperplastic; the ME mucosa changes to stratified respiratory epithelium and goblet cells, the muciparous cells proliferate, the mucosa invaginates to form submucosal cysts and the proliferation extends to glands and blood vessels with consequent hypersecretion [19]. A chronic state causes the secretion characteristics to change from yellow to grey-blue, the secretion becoming increasingly viscous, to the point of preventing, at advanced stages, small-bone and tympanic membrane movements [75, 128].

Pathogenesis

Role of Atopy

The role of atopy in OME has long been speculated but to date remains unquantified [170]. However, several studies do not examine atopy, or fail to provide a broadly accepted definition, or the diagnosis is based on variable criteria: however, *the prevalence of atopy varies from 23% to 80%* [12, 138, 192, 236] or 89% of AR, 36% of asthma and 24% of atopic dermatitis (AD) [157]. In 139 infants with recurrent otitis media atopy was associated with a relative risk (RR) of 1.9 [199]. In 8/22 (36.4%) children with recurrent OME unresponsive to drug treatment SPTs were positive for inhalant and food allergens vs 2/24 (8.3%) of the control group (p=0.032) [51]. In the MEEs of atopic children, *the percentages of eosinophils and Th2 lymphocytes are significantly higher* (7.7%±1.4% and 20.0%±3.2%, respectively) compared with those in MEEs of nonatopic children (0.9%±0.2% and 5.5%±0.6%, respectively), unlike metachromatic cells, in addition to significantly higher percentages of Th2-like IL_4, IL_5 [192], and eosinophil cationic protein (ECP) and tryptase in atopic, compared with nonatopic patients [89]. The percentage of eosinophils, T lymphocytes, and IL_4 and IL_5 cells was significantly higher in atopic children compared with nonatopic children and greater in the MEE than that seen in the torustubatis or adenoid tissue [138]. *In nonatopic children,* neutrophils and *IFN-γ positive cells were* present in *significantly higher* percentages [138, 192]. Elevation of Th2-driven IL_4, IL_6 and TNF-α in MEEs may contribute to the allergic OME persistence [97], thus evi-

dencing that allergy might play a role in OME pathogenesis [192]. Concentrations of IL_1, IL_6, and CD106 were significantly greater in the MEE and in serous (with E-selectin = CD62E) than in mucoid MEE of study children compared with those of control children [172]. Adenoidal lymphocytes appear to produce significantly less IL_2, IFN-ɣ compared to the patient's peripheral blood lymphocytes, whereas IL_4 and IL_5 appear to be synthesized slightly more in the homologous peripheral blood lymphocytes [14]. Children with recurrent OME have higher $IL_{1\beta}$ levels than the children with persistent OME; thus recurrent OME may be a stage that occurs before chronic OME [232]. These results are *consistent with the late-phase allergic response seen in other areas of the respiratory tract, which is involved in the pathogenesis of asthma, AR, and chronic sinusitis* [192]. The role played by food allergy (FA) is a recent example [140]. In 70 of 86 children (86%) with an average age of 4.6 years suffering from multiple food sensitization, elimination diets improved the clinical OME pattern, evaluated using tympanometry, audiometric and ORL examinations; in blind food challenges there was evidence of an OME relapse in 66 of 70 children (94%) [140]. Pathogenic factors such as nasal congestion and exposure to cigarette smoke increase atopy incidence nearly sixfold [20], and atopic children were reactive to dog dander (27.3%–62.3%), dust mite (50%–63.6%), cat dander (18.2%–25%), and tree mix and ragweed (13%–36.4%), with a 24.4%–30% incidence of atopy [138, 192].

The mechanisms linking atopy to OME are several [20]:

1. ME mucosa as a target for allergic reactions
2. Inflammatory edema with consequent ETO and ventilating dysfunctions
3. Inflammatory nasal and nasopharyngeal obstruction with inadequate secondary tubal functioning, thus affecting clearance
4. Seeding of bacteria-laden allergic nasopharyngeal secretions into the ME cavity

The first point has been confirmed by studies done on laboratory animals. However, allergen convergence to a relatively isolated site appears to be problematic; insufflation via ET seems to be an easily realizable method, but its accomplishment conflicts with concrete difficulties, also because the reaction appears to be limited to the allergen contact area [20]. With regard to the second and third points, untreated ETD of allergic origin can result in OME, as indirectly confirmed by ME under pressure following nasal antigen challenges in two pediatric studies [8, 142]. Persistent ETO in turn worsens with OME: in a study on >700 children suffering from AOM, the persistent effusion was highly prolonged in those with allergies compared to those without [160]. Increased mediator circulation after nasal or gastric allergic reactions has been proven as the cause of ETO and increased permeability of ME in experiments on animals: in theory these effects could alter gas exchange or increase ME vascular transudation, also contributing to OME development or persistence via this mechanism [160]. These results raise the intriguing likelihood that chronic OME and atopy development are closely interrelated, an association that warrants further investigation [157].

Role of Allergic Rhinitis

AR relations with OME are difficult to quantify: in 35 of 100 children suffering from AR, for 8% the target organ was the ME and for 27% it was the ET (Fig. 15.10) [12]. Rhinosinusitis and coincident AR were seen in 19% and 14% of 185 children with OME, respectively [143], and 21% of children aged between 5 and 19 with diagnosed ETD also suffering from AR [180]. The prevalence of nasal allergy in children >3 years with OME ranges from 35% to 50%, a 3- to 4-fold greater expression of AR among children with OME than among the general pediatric population [16]. Symptoms of AR, serum IgE lev-

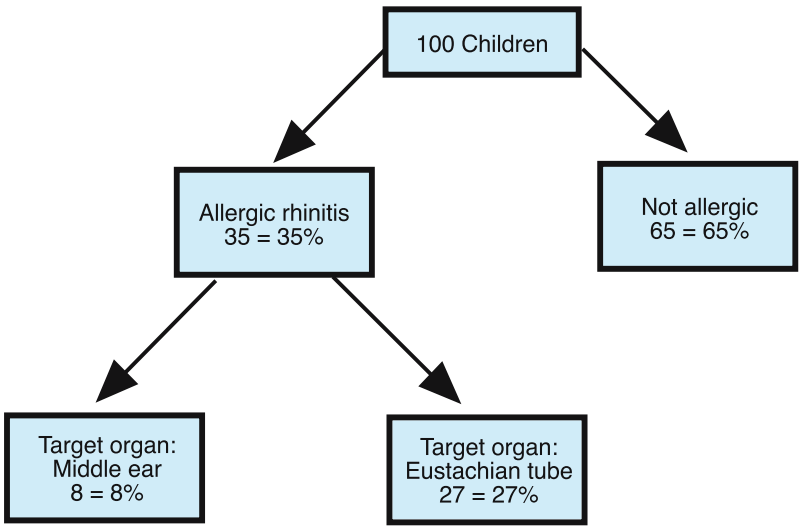

Fig. 15.10. Diagnosis of 100 children with OME: 65% had neither positive family history nor atopic symptoms. (Data from [12])

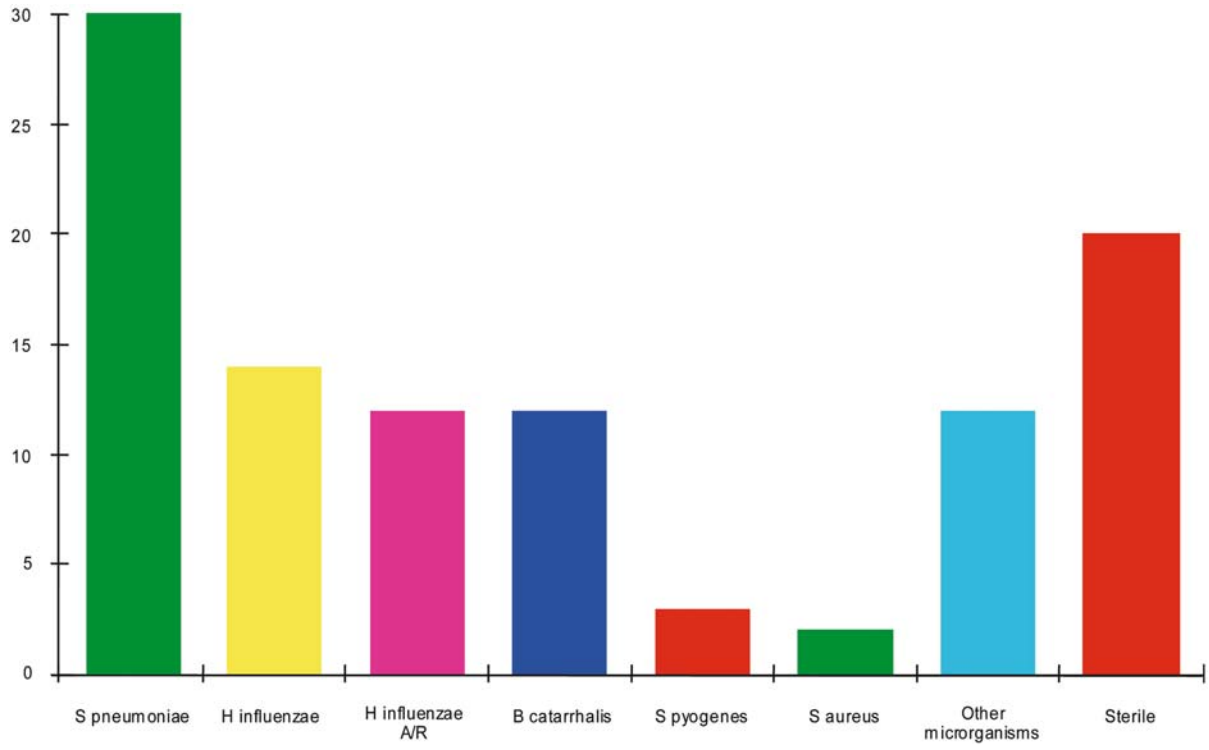

Fig. 15.11. Bacterial isolates from middle ear of children with acute otitis media. (Data from [65])

els, SPTs and nasal smear findings suggested a diagnosis of AR in 5/22 children with OME (23%), and in 1/13 children (4.8%) in the control group [106]. In 209 children, AR was found in 89%, asthma in 36%, and AD in 24%. SPTs were positive to one or more of eight common aeroallergens in 57% of children [3]. In 172 children, with OME symptoms associated with AR occurred significantly more frequently than in the control group (OR=3.34); however, the presence of AR or AD was significantly associated with OME [30]. Even without direct evidence, one can reasonably assume that seeding of nasopharyngeal secretions caused by AR can reach the ME via the Toynbee phenomenon, as for example in a crying baby. Furthermore, AR may cause a certain mechanical obstruction, either extrinsic (peritubular) or intrinsic (intratubular), but TVP muscle movement may counterbalance it. Patients with functional ETD are therefore at risk of developing a mechanical dysfunction leading to OME. If AR reduces nasal opening, a negative pressure derives from the second phase of swallowing, while a closed nose may obstruct the ET opening, and the tube itself, along with the ME negative pressure. This is characterized by ETD symptoms, fluctuating or persistent earache, hearing loss, *tinnitus* or vertigo. This occurs in AR because of swelling of the ET lining, which is similar and in continuity with that of the nose and nasopharynx, so this pathogenic theory appears to be undoubtedly plausible [65].

Role of Infections

Bacterial or viral infection of ME and nasal inflammation resulting from URTI are acknowledged as OME contributing factors. Data from epidemiology studies indicate that 25%–40% of URTIs in children <3 years are accompanied by an episode of MEE [65]. In exudates from 50%–80% of patients with OME (especially if chronic) it is possible to recover bacteria similar to those found in AOM: *Haemophilus influenzae* (20%), *Streptococcus pneumoniae* (30%), and *Moraxella catarrhalis* (20%) and *Streptococcus pyogenes* (4%) [102, 193, 206, 215], (Fig. 15.11) [65]. In another series, these pathogens accounted for 79.7% of all identifiable isolates: *S. pneumoniae* (11.3%), *H. influenzae* (21.7%), *M. catarrhalis* (28.9%), and *Staphylococcus aureus* (17.9%) [193]. Moreover, 57%–82% of MEEs do not show bacterial growth [223], and viral isolates are only present in 16%–19% of cases [185]. So, 5% of patients have positive bacterial cultures (*Chlamydia trachomatis, Mycoplasma pneumoniae*, or others), while in 15% viral antigens in secretions were noted. However, *Chlamydia pneumoniae, M. pneumoniae*, or any of the eight human herpesviruses do not seen to play a major role in the pathogenesis of OME in toddlers with OME [196]. Less common in normal children, these microorganisms adhere to the cells, damage them and affect mucociliary clearance, preventing the host defensive response and managing to replicate more freely [116]. It is obvious that *cilia dysfunction damages the mucosal membranes*

of the entire respiratory tract, with negative effects on both ET and ME, *with consequent tubal obstruction,* already physiologically *reduced in diameter early in life* [176]. It seems automatic to conclude that ETO is greatly influenced by URTIs, RSV, influenza and parainfluenza viruses, by inducing the receptors of involved bacteria, increasing their adherence to infected cells, allowing the virus to trigger bacterial ME colonization via ET. RSV-like viruses stimulate virus-sIgE synthesis, which sets off the army of mast cell inflammatory mediators, thus increasing capillary leakage, edema and OTE: RSV thereby establishes an IgE-mediated nasopharyngeal hypersensitivity [12]. It follows that viral infections constitute the highest risk factor for ETD leading to OME, which therefore is a common complication in these infectious episodes [219]. In conclusion, nasopharyngeal infection and allergy are likely related to OME development [143].

Role of Passive Smoke

Children <3 years exposed to passive smoke fall ill with OME more easily and for longer periods than their unexposed peers. Based on serum cotinine levels, smoke increases the frequency of otitis media episodes by 38%, anticipates the onset [163] and prolongs its duration (28 days vs 19), becoming responsible for 8% of all episodes and for 17.6% of persistent endotympanic effusion [60]. In young babies, the onset of symptoms was under 6 months in 51% of babies, with >6 episodes in 68% of babies and three to six episodes in 16%, with associated nasal symptoms in 59% of babies [163]. In a cohort of babies monitored by tympanometry, exposure to >30 cigarettes prolonged the illness persistence in the 2nd year of life by 38% and by 31.3% if <30 cigarettes, *also in those not exposed* (26.6%) [146], possibly due to the effect of environmental tobacco smoke (ETS). In one of two Turkish studies, 73.7% (84/114) of the study children and 55.0% (22/40) of the control children were found to be exposed (p=0.0461). The cotinine urinalysis results showed that 23.1% (9/39) of the children *without parental smoking histories* were exposed to tobacco smoke vs 84.3% (97/115) of the children with parental smoking histories [93]. In the other study children, the case group was exposed to a mean of 19.6 cigarettes per day vs 14.4 cigarettes per day for the control group (p<0.004). Maternal smoking was a significant factor [94]. Passive smoke is significantly correlated with a threefold increased risk of lower respiratory tract infections [87]. Etzel [59] studied ETS effects on OME, meta-analyzing ten studies involving a total of 4,310 children between 1–15 years of age. In seven of these studies, the damaging effect of parental smoke was noted and *in three studies neither parent smoked.* In the 2/10 studies based on cotinine levels [60, 197], 33% [197] and 8% [60] of OME cases were related to passive smoke. In a further meta-analysis of 28 studies on ETS, 53.6% showed a statistically significant risk of OME, seven more studies on children aged 6 (few) to 19 [49] were meta-analyzed, finding a RR in 2%–13% of cases, which rose to 1%–26% with tympanostomy (Table 4.25). Since sidestream smoking increases the risk of OME, legal regulations and guidelines must be established to protect these children from passive smoking [93].

Global Pathogenetic Hypothesis

It is possible that allergens interfere in OME pathogenesis (Fig. 15.12) [8], in two different ways:

- *Lymphocyte proliferation* causes ETD via lymphoid hyperplasia, with an increase of ME secretory cells.
- *IgE intervention* following mast cell mediator release results in mucosal membrane swelling. An increase in nasal secretion containing *pabulum* (where the bacteria that interact with RSV and other viruses grow) follows. Furthermore, prostaglandins may have a positive effect, decreasing vascular permeability and therefore the invasion of microorganisms.

Clinical Presentation

OME is an asymptomatic illness: it often goes unrecognized in babies before the onset of overlapping secondary infections causing an acute picture. Older children are often catarrhal (Fig. 15.13), complaining about earaches, buzzing, a feeling of ear occlusion (that can be modified with the Valsalva maneuver or by nose blowing) and transmissive hearing loss, which can be intermittent and of variable intensity, linked to swallowing and yawning, but often difficult to identify, especially in younger children. Parents notice that the child is distracted, that they are obliged to raise the voice or repeat words to be understood, teachers reproach these children because they do not follow lessons and are inattentive and sloppy [75]. This may depend on prolonged early MEE, which can result in significant sequelae, including hearing loss and lower scores on tests of cognitive ability, speech and language, and school performance at age 7 years [202]. However, language deficits are of small magnitude and may or may not be clinically significant [129], even if recently this deficit was not found in children >3 years of age [150].

A widely debated question is whether the illness lasts for >6 months, as for example, babies exposing to passive smoke can lead to a worsening of hearing loss, with a medium-moderate deficit of 25 dB conduction complicated by language and psychosocial developmental delays [110]. These complications are not confirmed [127]: in general OME may not affect later speech and language development or academic achievement [165]. Two large-scale investigations [164, 197], a very recent meta-analysis [166] and a randomized controlled trial [208] did not find any significant associations between

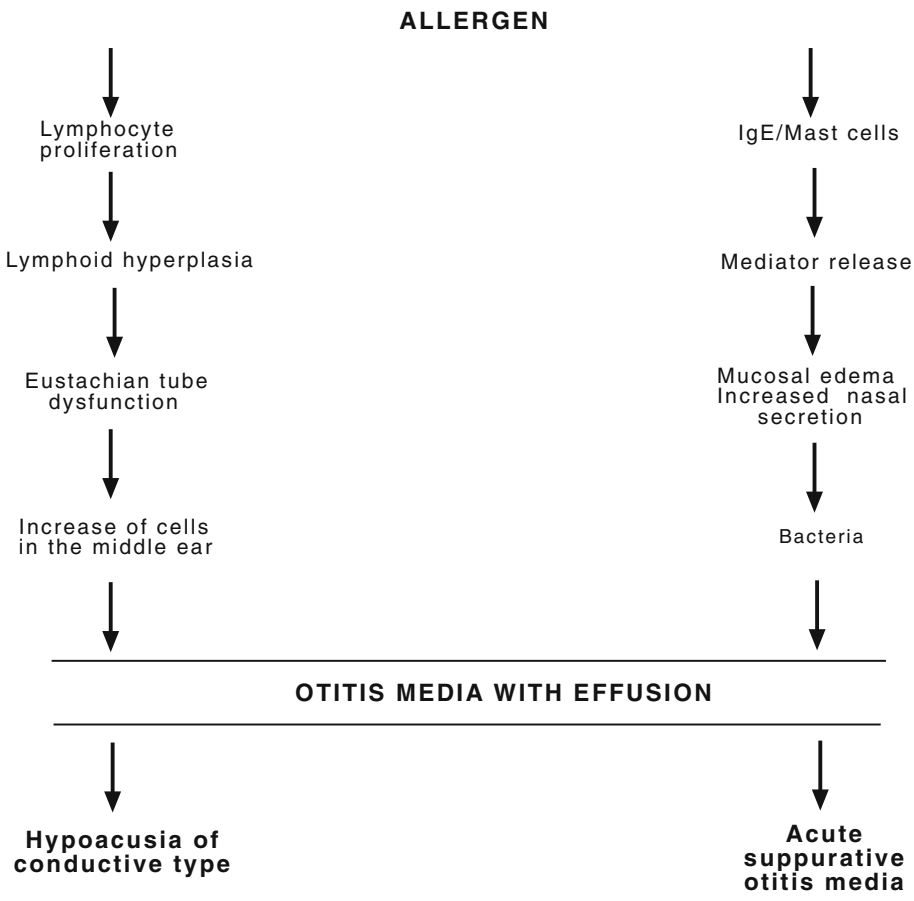

Fig. 15.12. Pathophysiology of otitis media with effusion. (Modified from [8])

OME, hearing loss [164, 166, 208], language changes and verbal expression [164, 166, 208], in children aged between 1 [164] and <4 years [197], nor in older children in language and attention progression [197]. Children with a history of OME scored lower on measures of speech and language development in some studies, compared with children who infrequently experienced OME. The data reflect outcomes for an average, otherwise healthy child; factors affecting the language development of a single child must also be considered [166]. Other results are consistent with observational studies in showing that day-care attendance increases the risk of OME, although no evidence of delay in language acquisition or behavioral problems was found [208]. It is possible that defects diagnosed in preschool age are partly correlated with an altered mother-child relation due to OME [164] and that these are overcome by the child in parallel with OME resolution [179].

Diagnosis

Family and personal history is generally an indication; most symptoms mentioned are diagnostic. Investigations commonly start from the causes, course, and progression of recurrent ear disease, including previous ear infections, allergic reactions, especially rhinitis or rhinoconjunctivitis, and food. An environmental history should identify the child's living environment, allergic or irritating factors such as passive cigarette smoke, mites and/or molds, pets, etc., any possible change to the

face's normal conformation, the type of respiration, any possible language and/or hearing disorders, etc.

If medical history suggests an allergic cause see Chap. 6 for a careful evaluation, since FA can be a cause in subgroups of children, especially if they suffer from AR and/or are multiply sensitized [140]. Nasal examination may reveal, as commonly occurs, turbinate mucosal edema and signs of hypertrophy. For young sufferers of recurrent ME infections, see Chap. 22. Recently, the Canadian Task Force on Preventive Health Care reported that insufficient evidence was available to include or exclude routine early screening for OME in children up to 4 years of age [31]. However the American Academy of Pediatrics (AAP) Subcommittee on OME recommended distinguishing children with OME at risk for speech, language, or learning problems from children with OME without such risk and more promptly evaluate hearing, speech, language, and need for intervention and manage children with OME not at risk with watchful waiting for 3 months from the date of effusion onset (if known) or diagnosis (if onset is unknown). Hearing testing should be done when OME persists for ≥3 months or at any time that language delay, learning problems, or a significant hearing loss is suspected in at child with OME. Children with persistent OME not a risk should be reexamined at 3- to 6-month intervals, unless significant hearing loss is identified, or structural abnormalities of the eardrum or ME are suspected [170].

Diagnosis is based on finding an otorrhea, or a type B tympanogram (flat) indicating a serous effusion, or a type C tympanogram with peak compliance to negative pressure values (tubal stenosis) plus the results of tonal audiometry (any conductive hearing loss with a deficit in prevalence on medium-low frequency) [47] in children aged >5 [146]. In children aged <6 months, the tympanic membrane was not thickened, but it was immobile and the tympanogram showed a flattened tracing [55]. The following notes on additional ORL tests that are essential for diagnosis in children may be helpful for pediatricians [65].

An *otoscopic examination* shows an accumulation of mucous secretion in the ME, with increased pressure; the tympanic membrane appears to be normal or slightly retracted, or also opaque, wrinkled, thickened, and with poor mobility (Fig. 15.14). An extreme immobility with increased viscosity of the fluid present in the ME indicates a glue ear [127]. In some cases one may see, beyond the membrane, little bubbles or a fluid level [47].

With a *pneumatic otoscopy* the structure and functionality of the tympanic membranes are identifiable, as regards to coloring, position, retraction or extraversion, opacity and air-fluid levels.

Tympanometry [238] has two considerable practical advantages: it is noninvasive and does not require the child's cooperation; the only problem is that younger children do not always remain seated for the whole test duration [224]. It is an objective method for evaluating the air pressure and impedance of the tympanic membrane of ossicles, for measuring ME pressure and establishing functionality; it often reveals a lack of elasticity of the tympanic membrane [47]. This technique remains, however, useful in the diagnostic process and for screening silent diseases [65].

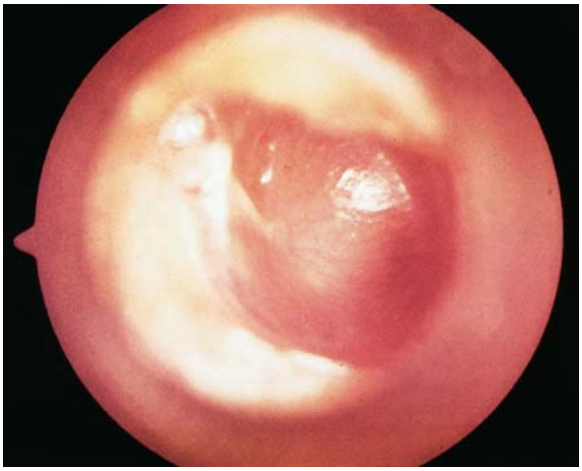

Fig. 15.14. OME in a 9-year-old girl, with no related history, but with perennial AR (PAR). Hearing impairment was noted at school. A paucity of findings is common, but OME may be demonstrated by a low level of eardrum mobility on pneumatoscopy

The tonal audiometry is a standard technique for use in children >18 months [57]. With younger children, *impedancemetry*, *behavioral audiometry*, or more sophisticated tests such as *brainstem auditory evoked response* may be used. The problem is that invasive procedures to establish any hearing loss will be impossible to carry out in children who are too young, or in older but frightened children. In this case, pediatricians can organize different tests according to age in their office with a non-quartz watch. We stress evaluating the extent of hearing deficits even in younger babies [164].

A final diagnosis is also obtained in younger children using pneumatic otoscopy and tympanometry [164], in older children with myringotomy (see below), or surgical incision followed by drainage.

Treatment (Table 15.6) [75]

General Guidelines and Allergen Avoidance

The general guidelines consist of interventions for allergen avoidance, also eliminating any possible adjuvant factor. Therefore nurslings should not be allowed the following: pacifiers, feeding bottles with too narrow openings and feeding in a supine position, associated with an early onset of the illness [146].

Environmental controls include articulated interventions for allergen avoidance: if allergy is the cause,

Table 15.6. Indications for OME therapy

No. of events per ear	Duration of events (months)	Hearing loss (months)	Behavior, language, school	History		Tympano-grams	Audio-metry	Diagnostic approach
				Personal	Family			
<4	<2	<2	Normal	–	–	–	–	Observation
>4	>2	>2	Normal	±	±	Normal	<20 dB	Observation
>4	>2	>2	Poor	±	±	Flat curve	<20 dB	Complete otological and allergic evaluation

Modified from [75].

Table 15.3 offers suggestions. Measures ensuring a good environmental humidification can help maintain the respiratory mucosa under normal physiological functions.

Therapeutic Strategies

In OME infection oral antibiotics are useful for 14–21 days [9], to be chosen on the basis of the prevalent organisms in MEEs (Fig. 15.11). It is worthwhile cultivating the drained fluid (if this does not spontaneously flow out, a myringotomy should be carried out), allowing active antibiotics to be chosen for possible resistant bacteria if the desired therapeutic effect is not achieved [65]. About 40 % of children who suffered from AOM, were left with residual MEE 1 month after onset following antibiotic treatment [96]. Whether AOM antibiotic treatment prevents OME outcome is a controversial issue [226]: antibiotic therapy is no better than placebo in OME resolution [204]. A meta-analysis has shown that efficacy of antibiotic use was limited in the short-term and non-significant in long-term use [226]. Results are definitive only when corticosteroids (CSs) are associated, as revealed by other meta-analyses [11, 168, 169]: antibiotic therapy alone is effective in 39.3 %, when associated CSs in 63.6 % of cases [11]. In children 1–9 years, after 14 days of treatment, there was a significant difference in the proportion of children who were effusion-free immediately after treatment with CSs and amoxicillin compared with those who were treated only with amoxicillin [122]. Intranasal or oral CSs can be recommended, for example, 1 mg/kg of prednisone or prednisolone in two refracted doses, for short 1-week cycles [10] or if indicated, also chromones can be used if suitable. Antimicrobials and CSs do not have long-term efficacy and should not be used for routine management [170]. Antihistamines and decongestants may reduce nasal congestion in children with AR [233]; however they are ineffective for OME, and should not be used for treatment [170].

Surgical Treatment

Surgical treatment is indicated for chronic forms:

- Clinicians should use *pneumatic otoscopy* as the primary diagnostic method and distinguish OME from AOM. It is recommended that clinicians document the laterality, duration of effusion, and presence and severity of associated symptoms at each assessment of the child with OME (Fig. 15.14). *Myringotomy with tympanostomy tube* (Fig. 15.15) is used when hearing loss ≈20 dB is present [195]; the tubes remain *in situ* for a time considered useful by ORLs, but no >6–12 months [19]. One of the main aims of treating glue ear is to improve the conductive hearing loss, and it is expected that the improved hearing will prevent problems with speech and language development, problems in the classroom, behavior, etc. [1]. The tube acts as a substitute for the blocked ET, after which tympanic membrane appearance and hearing generally return to normal [57]. *Otorrhea* is a frequent complication of this operation with a fairly high incidence (5 %–38 %) and immediate onset [74]; treatment with topical antibiotics is ineffective [74]. Young children randomized to early vs late tube insertion for persistent OME showed *no behavioral benefits from early surgery* [150, 151] and did not improve developmental outcomes at 3 years of age, regardless of baseline hearing [151].
- *Tonsillectomy* alone or myringotomy alone should not be used to treat OME. [170]. Tonsillectomy is no more effective than a simple *adenoidectomy* [104], but after a sound evaluation of the immunological data [35], it may prove beneficial in persistent forms [9] if a real obstruction is detected [19] requiring the insertion of ventilation tubes [51]. The benefit is apparent at ≥3 years of age, and independent of adenoid size [127, 148], as adenoidal tissue may regrow. As a consequence, adenoidectomy should not be performed unless a distinct indication exists (nasal obstruction, chronic adenoiditis) [170].

Further measures are for the specific competence of specialists to evaluate the role of atopy in children unresponsive to medical-surgical treatment [51]. The deficiencies mentioned up to now may appear more frequently in patients who have undergone *surgery* [179],

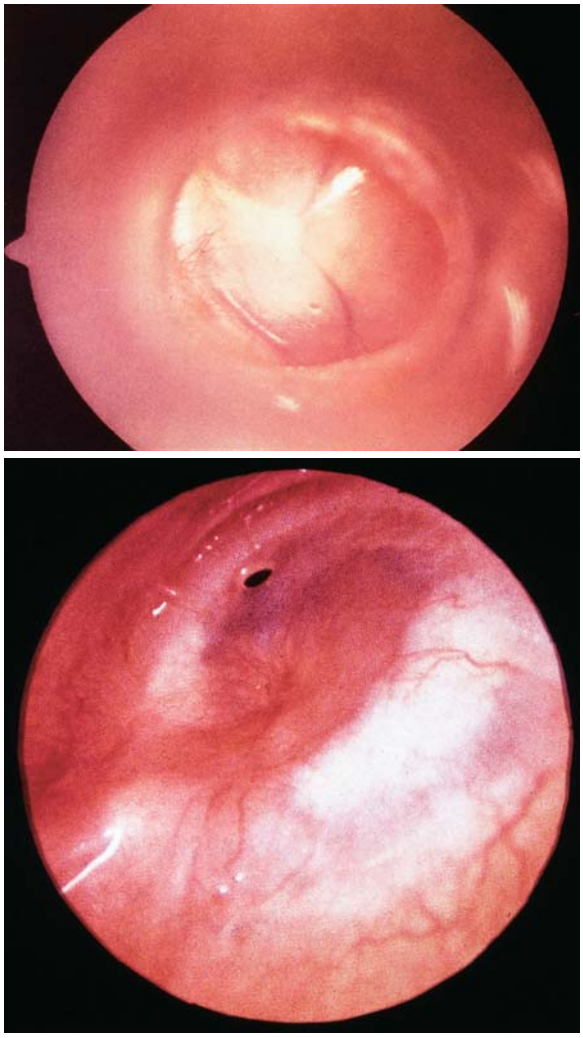

Fig. 15.15 a,b. Insertion of myringotomy tube in the tympanic membrane of a child

not resulting in improvement compared to untreated controls [235]; therefore a conservative attitude is advised [179].

Prevention

It is important to stress the protective role played by maternal milk [56, 83], rich in immunological factors (Tables 2.15, 2.16), with a sIgA defensive effect able to block microorganism adhesion (*H. influenzae*) to retropharyngeal cells and therefore their adhesion to the ME. Antigen-specific IgA are inversely proportional to OME episodes [83]. The superiority of exclusive breast-feeding affects nasopharyngeal colonization by ME bacteria, significantly reduced in 257 nurslings aged 4–6 months compared to bottlefed controls (23%–31%) vs 45%–56% breastfed babies [61]. Studies have debated the utility or not of breast-feeding; apart from the Saarinen study on 327 cases [175], some favorable [135, 153], particularly in 13,751 children [2, 55, 56, 61, 107, 146, 203, 210, 234] with significant odds ratio (OR) and confidence intervals (CI), and others not [171, 177, 199], various studies have examined different aspects: protection depends on the *duration of breast-feeding and its exclusivity*. In 1220 babies followed over 1 year, the rate of OME was 10% if the child was breast-fed for ≥6 months, 20.5% for ≥4 months [55], 19%–21% for <5–6 months [61], or 23.6% if for <3 months [146]. Infants who were breast-fed for the first 6 months of life had a 10% decrease in the amount of OME during this period compared to bottle-fed infants [146]. Among 877 children still being followed at 1 year of age, breast-feeding was found to be significantly protective for one or more episodes [203]. The risk estimates presented for bottle-feeding compared with breast-feeding are reported in several meta-analytic studies published recently [55, 204, 210]. A meta-analysis of recent follow-up studies concluded that breast-feeding even for 3 months was protective in decreasing the risk of OME [210]. These studies indicate a beneficial effect of breast-feeding (even for short durations) on reducing OME episodes in infancy [55, 204, 210].

Sinusitis

Paranasal sinuses, from an anatomohistological point of view, *are an integral part of the respiratory system.* The mucosa that covers them passes, with no breaks, in the mucosa that covers the nasal cavities, and is formed by the same type of ciliated and muciparous cells that completely cover the whole airways. Thus, processes affecting the nose would be expected to extend into the nearby sinus cavities. Therefore, sinuses are usually the target for complications in respiratory allergies; but in early infancy, a number of particular problems related to them are present, acknowledged after pioneering studies carried out by Wald [215–220] and using new sinus visualization techniques [95]. Bouts of sinusitis in early infancy are very often underestimated or labeled as banal colds that heal spontaneously. One reason for such an oversight is the only recent individuation of both maxillary and ethmoid sinuses already at birth, sinuses that are sufficiently developed to assume clinical importance before the 2nd year of life [233]. Persistent or recurrent colds depend in fact on sinus infections. Another reason for which sinusitis in this age group can be underestimated is the excessive attention paid to adenoids and tonsils in young patients, and the widespread tendency to indiscriminately blame these for all infectious episodes: there is no question that they are often diseased, but it is equally certain that the paranasal sinuses and not the tonsils or adenoids are often responsible for clinical symptoms [33]. However, an increased awareness of the magnitude of the problem of sinus disease has led to recognition that it is a major health problem in children [158].

Definition

Pediatric sinusitis is a clinical condition characterized by mucosal inflammation of the paranasal sinuses, often classified chronologically as an acute, recurrent acute, subacute, or chronic (persistent) disease process [57]. Sinusitis is defined as acute when the symptoms complex accompanying inflammation of the sinuses is present for <12 days in children (to be differentiated from viral URTI), subacute if it lasts from 2–6 weeks and chronic when it persists for 30 days [217] or >3 months [183]. For the frequent association with nasal symptoms, it is also called *rhinosinusitis,* which seems to be a more correct term, because most children begin with or have a concomitant rhinitis [76].

Prevalence

Prevalence is certainly higher in allergic children, especially in those with chronic respiratory symptoms. Sinusitis commonly has a prevalence of 5% [183]. A study based on the premise that URTI with a prolonged course corresponds to episodes of sinusitis came to the conclusion that 6%–13% of children, especially if attending day nursery, suffer from sinusitis during the first 3 years of life [219]. In children attending the primary care centers, 8.3% had a diagnosis of sinusitis: the prevalence rate was greater among children aged >5 years than among those younger (9.3% vs 7.2%) [100]. Prevalence is lower during the summer months – allergic patients are sensitive to grasses, pollinating trees and household pets – is more often prevalent in the colder seasons [90, 100] and coincides with the regional epidemiology of viral respiratory infections (VRI) common during that time of the year [90].

Genetic Factors

The role of genetic factors in sinusitis is highlighted by the association with persistent sinus disease of two well-defined genetic disorders, cystic fibrosis and primary cilia dyskinesia (Kartagener's syndrome). Immunodeficiency (ID) may be the cause of sinusitis, especially in treatment-resistant forms [158, 184]. Various primary IDs (PIDs) are also associated with recurrent chronic infections, including common variable ID, selective IgA and IgG deficiency or of subclasses [158]; exanthematous diseases such as measles and scarlet fever often cause sinusitis [162]. In class I antigens, B54 antigen is significantly increased in patients with chronic sinusitis (RR 3.23) compared with the normal control group. For class II antigens, no antigens were significantly increased [200]

Pathophysiology

Outlines of Embryology, Anatomy, and Physiopathology

The paranasal sinuses are pneumatic cavities that form as invagination of the nasal mucous membranes, apart from the sphenoid sinuses that derive from the posterior nasal fossa (Fig. 15.16) [216]. All *are lined with the same mucosa as the nose:* the sinuses are lined with ciliated pseudostratified epithelium and are covered with a mucous blanket. The epithelium is rich with mucus-producing goblet cells, but seromucous glands are sparse [145]. Both ethmoid and maxillary sinuses appear as early as the 3rd–4th month of intrauterine life, the frontal sinuses by the 6th–12th month of extrauterine life, and are recognized on imaging at age 7–8 years but are not completely developed until late adolescence, the sphenoid sinuses later, as they are generally pneumatized by 5 years of age [19, 227]. Development from birth to adult age is shown year by year in Figs. 15.17 and 15.18 [78].

The *maxillary* sinuses are the largest, beginning as little more than slits that widen progressively before taking on a quadrilateral form. Since the sinus opening, the ostium, is situated high, drainage by gravity is difficult, thus favoring mucus retention and therefore infections. The *ethmoid sinuses* are a complex system of air cells, each drained by an independent ostium. This anatomical form easily predisposes to infection, given that even a modest mucous surface inflammation is sufficient to cause its occlusion. The *frontal* sinuses, of various size and extent, are uncommon sites of infection. Sometimes they may constitute *foci* for the spread of infection to the orbit or the central nervous system. The *sphenoid* sinuses are surrounded by important anatomical structures, including the internal carotid artery, the cavernous sinus and the pterygoid canal nerve. Posterior ethmoid and sphenoid sinusitis results from obstruction of their respective ostia, which collectively drain through the sphenoethmoidal recess, while isolated infection is rare [214, 217].

The mucous covering of the walls is formed from a layer of pseudostratified columnar ciliated epithelium, interposed with caliciform muciparous cells [50]. It has a special importance:

- In cleansing entrusted to the mucociliary system
- In immune reactions to pathogen agents
- When compromised by inflammatory or hyperplastic events, etc.

In these events, ostium obstruction is a key physiopathological mechanism in sinus pathology [214]. The ostia are placed in the meatus below the three turbinate bones: inferior, middle and upper. Their small dimensions make them easily obstructed: the maxillary ostium measures 2.5–4 mm and the diameter of each ethmoidal ostium is 1–2 mm [183, 217]. When the ostium is totally obstructed because of crucial events such as mucosal edema or mechanical factors

(Tables 15.7 [183, 189, 190], 15.8 [162, 189, 190]), after an endosinusal pressure transitional increase, negative pressure forms inside the cavity: when the ostium opens again, the contrast between the negative endosinusal pressure and atmospheric pressure can allow bacteria to enter the normally sterile sinus cavity [217]. In this sense, the ostium forms the gateway for sinus infections,

as we have seen in the ME via the ET. In case of sinus inflammation, not only ciliary clearance is blocked, but also mucosal edema with sinus ostia closed or nearly closed with consequent interruption of sinus mucous drainage [120]. Inflammatory thickening of the mucosa and the accumulation of purulent secretions concur in blocking the ostia, *causing a dramatic O_2 reduction and a concomitant CO_2 increase,* with the consequent inhibition of the granulocytes and ciliary transport (Fig. 15.19) [50]. Because of the partial fall in O_2 pressure, further amplified by inflammation, draining the accumulated secretions seems to be impossible: they stagnate and are easily infected by anaerobic bacteria or viruses of endonasal origin, normally innocuous [120,

190]. The paranasal sinuses play an important role in various functions, as shown in Table 15.9 [19].

Immunopathology

The paranasal sinuses are equipped with efficient defense mechanisms against infections, consisting of mucociliary clearance and a local immune system at the mucosal level, which acts as a first line of defense: the sinuses in fact protect themselves from infection with an efficient apparatus [216]. The sinus lining is in part covered by a mucous layer that, with all the impurities it contains, is drained into the nose via the ostia by a coordinated ciliary movement; this self-cleansing mechanism depends on the normal ostial functioning, the correct mucous fluidity and the rhythmic ciliary movement [101] (see Chap. 12). The sinus mucosa, like mucosa in the nose and ear, contains seromucous subepithelial cells that contribute to *sIgA production;* IgG and IgM antibodies, C3 and C4 are also present [101]. Any factor capable of damaging the defensive structure fosters pathogen entry into the sinuses, automatically opening the doors to infections. The MBP (major basic protein) in particular [86] and viruses [162] have *direct cytotoxic effects on the cilia* [86, 162]. These children may have higher than average IgE levels (8%), positive SPT for aeroallergens (36%), low Ig levels (18%) and a weak response to vaccines in 10% of cases [184]. However, 14/44 children (31.8%) had extensive sinus disease, but no significant difference in the average of total and specific IgE compared to children with limited disease [117].

The immunopathology of *chronic sinusitis* is better characterized in children. Key features of this type of inflammation include the presence of chronic inflammatory cells, and large numbers of eosinophils, and in one study more lamina propria and intraepithelial eosinophils were evident in the tissue of children with chronic sinusitis, especially in those with concomitant asthma [7]. However, *the sinus mucosa of young children with chronic rhinosinusitis has less eosinophilic inflammation, basement membrane thickening, and mucus gland hyperplasia* characteristic of adult patients [39]. The densities of IL_{1b}, TNF-α, IL_{13}, and RANTES mRNA$^+$ cells were all increased in nonallergic patients compared to normal controls. Decreased expression of IL_{12} (p40) mRNA was demonstrated in sinus biopsy specimens of patients with chronic sinusitis [229]. In allergic asthmatic children with chronic sinusitis, very significant correlations were demonstrated between IL_4 and IL_{12}, IL_{12} and IFN-ɣ, IL_8 and neutrophils, and TNF-α and monocytes/macrophages. IL_4 and IL_{12} were significantly correlated as well as IL_8 and neutrophils in nonallergic children [161]. Increased levels of GM-CSF (granulocyte-macrophage colony-stimulating factor), IL_3, and IL_5 mRNA correlated with the density of tissue eosinophils, have been observed within the sinus mucosa, and up-regulation of CD106 and elaboration of RANTES may contribute to the marked accumulation of eosinophils in chronic hyperplastic sinusitis [82]. Chemokines such as MCP-3, MCP-4, and eotaxin are significantly increased within the sinus mucosa of both allergic and nonallergic chronic sinusitis and are associated with the accumulation of inflammatory cells, particularly eosinophils [230]. Like AR, the pathophysi-

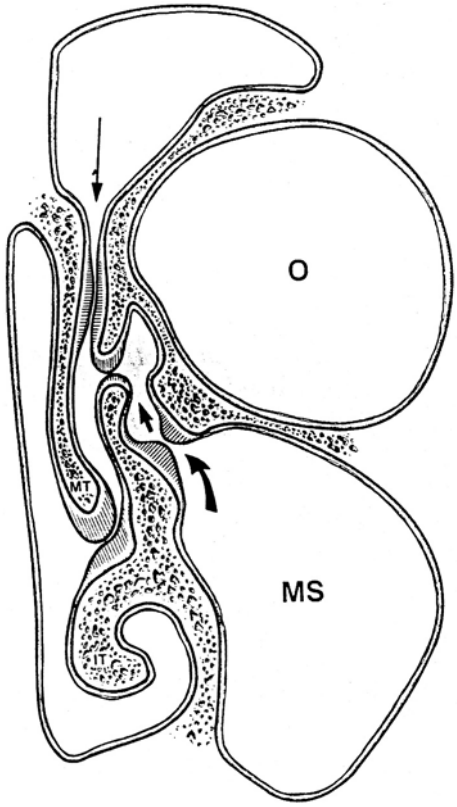

Fig. 15.20. Coronal section through the ostiomeatal complex. The *shaded area* delineates the sites of potential narrowing and obstruction. The *short arrow* indicates the infundibulum area, the *long narrow* and the *larger curved arrows* depict the drainage route of frontal and maxillary sinus, respectively. *O* orbit, *MS* maxillary sinus

ological features of chronic sinusitis has been largely attributed to the production of Th2-like T cell ILs [81]. *Allergic and nonallergic children share a typical Th2 IL pattern,* thus suggesting the existence of a common pathophysiological mechanism shared by upper and lower airways that is consistent with the concept of *united airway disease* [161].

Predisposing Factors

The conditions that more commonly act as predisposing factors, especially in chronic forms, are summarized in Tables 15.7 and 15.8. Another priority factor is the age from 2–6 years [137] (p=0.0001), as young children have not yet acquired the resistance to infections that characterizes adults and the paranasal sinus defense mechanisms that work effectively when the ostia remain open [120]. Other damaging factors are cold and/or dry air, the use of vasoconstrictors, exposure to polluting environments [162], and cigarette smoke [198]. Children exposed to passive smoking in the household had clinical sinusitis significantly more frequently than those not exposed (68.8% vs 1.2%) [100]. The importance of the so-called *ostiomeatal complex* (Fig. 15.20) has also been recognized as the area situated between the middle and lower turbinate bones, where frontal, ethmoidal and maxillary sinuses meet [214]. Two mucous surfaces come into reciprocal contact at various degrees in this complex, increasing the risk of negative effects on the delicate mechanisms of mucociliary clearance. Furthermore in younger children the duct channels are long and narrow and can easily become obstructed [120]. This is particularly evident when the defense mechanisms are damaged, causing the mucus to accumulate and stagnate, and drainage changes can be followed by bacterial infections [214]. Viral infections or abuse of nasal decongestants (rhinitis medicamentosa) often overlap allergy-caused occlusions, amplifying infectious and inflammatory assaults. It is understandable that obstruction of the ostiomeatal complex necessarily involves that of the sinuses [120], favored by anatomical causes. Oral respiration and nasal obstruction caused by adenoidal hypertrophy are often factors that contribute to lengthening the course of sinusitis. Hypertrophic adenoids could act as a foci of infections.

Allergic Sinusitis

The existence of allergic sinusitis is not certain, even though the paranasal sinuses, situated in a position of close continuity to the nasal cavities, may significantly suffer correlated anatomopathological alterations: the following data can identify the allergic pathogenesis of sinusitis [5, 162]:

- Positive family and personal history
- Signs of nasal allergies
- Frequent association with asthma
- Frequent presence of OME, up to 50%
- Positive SPT and sIgE, significant increase of total IgE, positive NPT and eosinophil count (>10%)

Figures 15.21 and 15.22 [5, 33] show the incidence of signs and symptoms in children with sinusitis associated with asthma, respectively. More than half of sinusitis is closely associated with asthma, a recognized allergy-mediated disease [138]. More than 80% of children with sinusitis have a FH of allergy (FHA), as opposed to an allergy frequency of 15%–20% in the general population [207]. A study on 413 children (aged 3–15 years) with AR provided evidence that PAR patients have a higher prevalence of sinusitis than those with seasonal allergic rhinitis (SAR). This increase was seen in children of all ages, but especially in the 1st year in children with SAR (p=0.0001) and in the 2nd and 3rd year in those with PAR (p=0.0001) [90]. In young conscripts with acute sinusitis, allergic symptoms were more frequent and positive SPTs considerably more numerous than in controls [178], up to 59% of cases [137]; furthermore atopic children present on average a higher number of sinusitis episodes compared to healthy ones

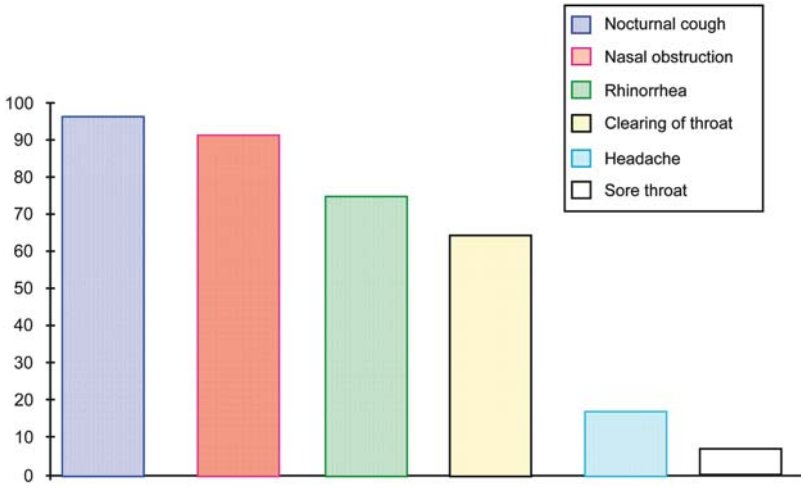

Fig. 15.21. Signs and symptoms in children with allergic sinusitis. Data from [5]

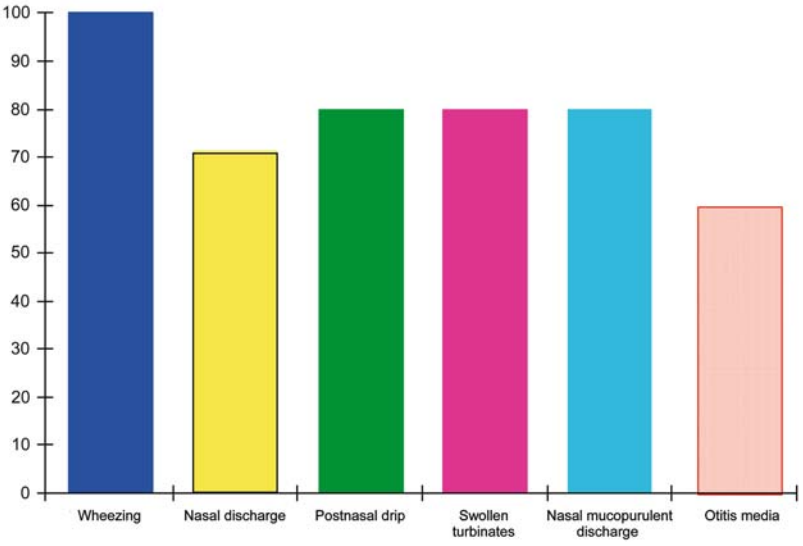

Fig. 15.22. Signs and symptoms in children with sinusitis and asthma. Data from [33]

(p=0.012) [69]. A closer link between atopy and sinusitis is proven by eosinophils as effector cells in chronic inflammation of paranasal epithelium [84].

Relationship Between Asthma, Allergic Rhinitis, and Sinusitis

Animal studies have shown that sinusitis can increase airway hyperactivity although the mechanism is not entirely clear [190]. It is known that sinusitis occurs frequently in allergic children, in whom it can be associated with asthma worsening or forms of difficult asthma [25], but above all in those with AR, which is the most important predisposing factor [69]. Mounting experimental evidence suggests that the sinusitis–AR association is an event encouraging the production of mucus and nasal mucosa swelling, with ostial obstruction that becomes an obstacle for bacteria removal [69]. The hypersecretion present during persistent and chronic AR is in fact capable of causing ostial occlusion, with a fall of sinus pressure and bacterial aggression. AR and sinusitis may coexist in 25%–70% of cases [69, 162]. In children with recalcitrant sinusitis and evaluated for allergy and ID, ≈50% were atopic, thus supporting the connection between AR and sinusitis [184]. An increased incidence of sinusitis defined as above was reported in children referred for evaluation of rhinitis, a large proportion of whom were atopic as proved by SPTs, again supporting a connection between AR and sinus disease [181]. Approximately 30%–50% of asthmatic children suffer from sinusitis, and a similar rate of

sinusitis sufferers are affected by asthma [137, 162]. In the study of 44 children, 34 (72.3%) had a diagnosis of asthma: those with extensive sinus disease had a significantly higher prevalence of moderate to severe asthma than the children with limited disease [117]. X-ray studies have emphasized significant changes in 27% of asthmatic children aged 3–16 [162], in 31% of 6- to 19-year-olds [238], and 36% of nurslings <12 months presented opacification of the maxillaries and/or inspissation of >4 mm vs only 6% of older children [112]. The correlation between these children has been confirmed by the results of a trial on entrants affected by sinusitis and asthma, in whom we have proved that treatment of sinusitis caused an amelioration of asthma [25]. Similar results were reported in a later study [190]. Chronic sinusitis in children with difficult-to-control asthma should be carefully evaluated, especially between the ages of 2 and 10 [69].

The *pathogenetic mechanisms* responsible for the triple *asthma-rhinitis-sinusitis* pathology have not yet been sufficiently explored. In his classic studies Slavin [189] has formulated various hypotheses, still a valid point of reference:

1. *Seeding into the lower airways* of bacteria originating from paranasal sinuses and containing mucopurulent material, which probably causes the tracheobronchial mucosa inflammation, a hypothesis that has recently been the object of conflicting views [6, 28]
2. *Inhibition by infections* of β-adrenergic receptors of the airways and responsible for a bronchodilator effect
3. *Reflex bronchospasm* mediated by the parasympathetic system, as nasal and sinus afferent fibers end in the mesencephalon and cause parasympathetic stimulation of airway smooth muscles
4. *Obstruction of nasal cavities* and consequent open-mouth breathing, resulting in wheezing caused by airway cooling, or bronchial mucosa exposure to allergens, or to other potentially inhaled irritating substances
5. *Bacterial toxins* causing mast cell and basophil mediator release producing a powerful bronchoconstrictor effect

The hypothesis of a reflex arc → nose → sinuses → airways is very stimulating, and could explain the association of asthmatic and rhinosinusal symptoms: chronic nasal inflammation, postnasal drip, and repeated throat clearing can trigger a parasympathetic reflex arc with consequent asthma worsening, while rhinosinusitis treatment would decrease stimuli, thus improving asthma [190].

Authors who later investigated this point did not reach unambiguous conclusions [6, 28, 43, 190]. Considering point 1, pharyngeal receptor hypersensitivity caused by local spreading of the inflammatory process provokes constrictor reflexes [28]. Points 2–5 suggest that *the nasal and upper airway filtering action protects the tracheobronchial tree from aggressive aeroallergens and noxious infectious agents,* but it is rendered inefficient by any noxa. The exclusion of this defensive mechanism added to nasal obstruction and mucosal inflammation could expose the lower airways to harmful substances which, causing inflammatory changes, may occasion bronchospasm [6].

The striking suggestion that *a single allergic stimulus* might *act simultaneously on paranasal mucosa causing sinusitis* and *on the bronchial membranes causing asthma* [189] has been corroborated by significant pathogenetic and histological acquisitions, common to patients suffering from allergic asthma and sinusitis [84, 86]. More precisely, eosinophil and MBP concentrations in the paranasal tissue appear to be significantly higher in subjects with both affections compared to patients with chronic sinusitis only [84]. In vitro it has been ascertained that MBP damages the epithelium of sinusal mucosa and causes ciliostasis, similarly to findings in vivo [86]. This data suggests that sinusitis in asthmatics is caused by the same mechanism that damages the bronchial epithelium.

Clinical Presentation

The symptoms (Fig. 15.21) are strictly related to patient age [5, 19, 162, 217]:

- *In unweaned babies* and young children (until the age of 2) slight fever, anorexia, pallor, and irritability are noted; no sign of pain or headache is apparent but when current, young children are unable to complain about their symptoms.
- *Older children* may complain of paranasal pain, moderate nasal occlusion and rhinorrhea of varying degrees, with secretion often completely retronasal as to escape observation, sore throat, voice loss, hyposmia, and breathing difficulties.
- *Sinusitis associated with AR* is characterized by a brief course, frequent attacks of nasal congestion, watery rhinorrhea, sneezing and itching with sudden onset and quick resolution; both nasal obstruction and secretion are usually of varying degrees, often accompanied by ticklish sensations in the nose, retronasal cavity or palate.
- *Chronic sinusitis* is usually a complication of AR or asthma especially chronic; persistent symptoms characterized by nasal obstruction and mouth breathing if nasal congestion prevails, or coughing especially at night if retronasal discharge is predominant, chronic rhinorrhea with little or no purulent discharge, OME and symptoms of chronic asthma with possible associated sinusitis (Fig. 15.22) [33]. Poor school results and frequent absenteeism are motivated by continual tiredness, chronic headaches, fatigue, irritability, halitosis, etc. [162].
- In some cases there are serious forms with *hyperthermia* >39 °C and purulent nasal secretion for at least 4 days, occasionally accompanied by an intense headache [217].

Table 15.10. Clinical presentation of hidden sinusitis

1.	Chronic nasal congestion
2.	Extensive school absences
3.	Tiredness
4.	Malaise
5.	Headache
6.	Perennial cough
7.	Possible coexistence of asthma
8.	Missed or delayed diagnosis
9.	Purulent nasal discharge
10.	Rx abnormalities of paranasal sinus

Modified from [182].

- Sometimes sinusitis can appear to be a *hidden disease* [182] stemming from a number of factors; the main ones are summarized in Table 15.10 [182]. The main issues are *missed diagnosis* and different symptoms compatible with chronic sinusitis that consequently is mistakenly diagnosed as a perpetual cold. Isolated sphenoid sinusitis in young children may masquerading as acute, subacute, and chronic headache thus suggesting a new aspect of sinusitis [34]. *Isolated inflammatory sphenoid sinusitis* (11 cases) should be considered in children aged ≈7 years who present with headache that does not respond to simple analgesia and visual disturbance [211].

Craniofacial Alterations

A combination of chronic nasal obstruction and mouth breathing in children can cause craniofacial modifications, not always associated with adenoidal hypertrophy; the main causes of chronic nasal obstruction in infancy are summarized in Appendix 12.2.

Complications

The principal complications are orbital cellulitis and endocranial complications, especially subdural empyema, made less frequent by medicosurgical interventions [34]. They are mentioned because they may occur *in children aged 10 months* [95], and orbital cellulitis was present in 139 children, 72% of whom presented with preseptal cellulitis, 19% with *orbital cellulitis,* and 9% with subperiosteal abscess. AR is frequently underlying the condition. Older children are more likely to develop subperiosteal abscess, while *preseptal cellulitis* is more common in younger children [88]. Preseptal complications of sinusitis can be diagnosed clinically without a CT (computerized tomography) scan and mandate an appropriate course of IV antibiotics [191].

Table 15.11. Diagnosis of hidden sinusitis based on clinical and laboratory parameters

Signs and symptoms	
A.	Major criteria
	Cough
	Purulent nasal discharge
	Purulent pharyngeal drainage
B.	Minor criteria
	Earache
	Facial pain[a]
	Fever
	Foul breath
	Headache[a]
	Periorbital swelling[b]
	Pharyngitis
	Tooth pain[a]
	Wheezing
Diagnostic tests	
A.	Major criteria
	Plain radiography in the Waters projection showing specific findings (see text)
	Coronal CT scan showing mucosal thickening and sinus opacification
B.	Minor criteria
	Nasal cytology (smear) demonstrating neutrophils and bacteria
	Sinus ultrasound demonstrating fluid levels
Assessment of diagnosis	
	Signs and symptoms: two major criteria or one major and = ≥2 minor
	Diagnostic tests: 1 major = confirmatory, 1 minor = supportive

Modified from [183].
[a] More common in adults.
[b] More common in children.

Diagnosis

The main clinical, instrumental and laboratory parameters facilitating diagnosis are exemplified in Table 15.11 [183].

Family and/or personal history is often positive and along with the typical symptoms, usually allows a correct diagnosis: sneezing, watery and/or purulent rhinorrhea, allergic salute nasal itching, pale and edematous mucosa. A *careful ORL examination* is also necessary. Coughing is a common symptom of sinusitis; the chest must be auscultated for signs of any wheezing. If the case is indicative and the child young, a *battery of specif-*

ic allergens is sufficient [69], which can be completed with total and specific IgE.

The *cytological examination* of nasal secretions shows polynucleates often containing intracellular bacteria and few eosinophils, which instead are prevalent in AR (see Appendix 12.1). Finding eosinophils and neutrophils in the secretions is distinctive, as confirmed by recent studies [54, 183], although consensus is not unanimous [238]. Significant neutrophilia (>5 neutrophils per high-power field) has been shown to be correlated with X-ray pictures and proves to be particularly useful *for the detection of hidden sinusitis* [43, 182, 183].

The diagnosis of acute bacterial sinusitis in children ≤6 years should be based on clinical criteria [108]. The *bacteriological examination* of the cultures, obtained by sinus direct puncture, emphasizes the same bacteria responsible for AOM: *H. influenzae, S. pneumoniae* and *M. catarrhalis* [193, 206, 215], especially the first two in children aged 0 to 2 years; [206]; the agents are the same in the acute and chronic forms [183]. Cultures are often negative (40%) [206], or positive in 34% of samples [193]. In the latter case, four pathogens accounted for 79.7% of all identifiable isolates: *S. pneumoniae* (11.3%), *H. influenzae* (21.7%), *M. catarrhalis* (28.9%), and *S. aureus* (17.9%) [193]. Bacterial recovery is not recommended for routine diagnosis in children [108].

Imaging studies are generally considered useless in nurslings and in a first episode, but useful in all other cases [216], especially due to the favorable cost/benefit ratio and the lower rad dosage compared to limited CT (0.6 vs 2.6) [72].

Examination of the Waters occipitomental projection shows maxillary sinus opacification, air–fluid level and evident mucosal thickening (4 mm) correlated with the invasion of noxious microorganisms, with a sensitivity of 76% and a specificity of 81% [72]. Other projections are the *occipitofrontal Caldwell projection* for ethmoidal sinuses and submentovertical for sphenoid sinuses; the first also show the frontal sinuses. The AAP [218] suggests that these studies can be safely omitted from an appropiate diagnosis because studies of children ≤6 years have shown that a positive history frequently predicts the finding of abnormal sinus X-rays. However, controversy exists about the need for X-rays to confirm acute sinusitis in children >6 years of age with persistent symptoms and for children of any age with severe symptoms [108].

CT is a great help for *visualizing the ostiomeatal complex* [120]; this is more detailed in children [72, 120] and is usually indicated for complications, recurring sinusitis and chronic treatment-resistant forms [137, 216].

Transillumination and *ultrasonography* are not of much use, also because the former is difficult to perform in young children [183] and can be used after the age of 10 [217], while the latter is not suitable for screening patients with limited lesions [120].

Sinus echography is instead useful for checking treatment progress [54].

Rhinoscopy with fiberoptic endoscope can be used for evaluating uncertain cases of sinusitis or cases that have proved to be refractory to usual medical treatment; this test permits a direct visualization of most of upper airways, often facilitating the diagnosis, unless previously confirmed, of sinusitis and adenoidal hypertrophy, in addition to nasal polyps, endonasal foreign bodies, etc. Its use in pediatrics is not recommended due to poor child cooperation [184].

Magnetic resonance imaging has made it easier to diagnose sphenoid sinusitis, a probably under-recognized disorder [137].

*Sinus aspiration*s, a definitive but not routine test [182], is carried out by an ORL specialist after sedation or a general anesthetic to obtain an adequate immobilization of young children [217]. Bacterial isolates at a concentration of at least 10^4 CFU/ml (colony forming units) is considered as representative of an ongoing infection. At least one microorganism per high-power field with Gram stain is correlated to a rate of 10^5 CFU/ml [217].

Decisions on any invasive diagnosis should be based on each individual case [123] and of cost/benefit ratio [54].

Differential Diagnosis

With acute viral URTI, consider the duration of symptoms limited to 5–10 days, the finding of nasal congestion and retronasal discharge, not accompanied by cough, that tends to recede after 10 days or little more [220]. A distinction between viral URTI and acute bacterial sinusitis is the nasal involvement that occurs in VRI. In acute bacterial sinusitis, the nose merely acts as a conduit for eliminating purulent secretions produced in the sinuses [108].

The conditions indicated in Table 15.12 must be taken into consideration for chronic forms [33]. In particular, sinusitis should be considered in *children who have severe asthma, do not respond to effective treatment,* have no obvious causes for their asthma, and have significant upper airway symptoms [144].

Particular tests can distinguish allergic children from ID children, who present frequent episodes of serious, persistent and treatment-resistant pansinusitis (>3/year), with a relapse a month after withdrawal of appropriate antibiotic therapy and after operations [158]. Diagnostic immune testing typically includes total Ig levels, IgG subclass levels, and postvaccination titers to pneumococcal and *H. influenzae* type b vaccines. Ig replacement and daily antibiotics are the basis of successful therapy [158)].

Given that children predisposed to sinusitis are mostly allergic rather than immunodeficient, it is always advisable on the basis of experience and probability, to give precedence to allergological investigations [158]. Another differential diagnosis to be carried out in sub-

Table 15.12. Differential diagnosis of chronic sinusitis

Adenoidal hyperplasia
Allergic rhinitis
Anomalies in visual refraction
Causes of persistent cough
Bronchitis by *M. pneumoniae*
Unusual diagnosis, including congenital ciliary dyskinesia
Cystic fibrosis

Idiopathic/vasomotor rhinitis
Nasal polyposis
Obstruction of sinus ostia

Modified from [33].

jects not affected by concomitant hypersensitivity to ASA concerns the rare form of sinusitis caused by fungal allergy: 141 cases in the literature in children aged 1–19 years [48, 77, 79, 121, 123, 225]. In 215 children with PAR (perennial allergic rhinitis), there was a higher risk than in those with non-mold allergy (RR, 2.49 vs 1.50, respectively) [90]. Children with allergic fungal sinusitis have symptoms of rhinosinusitis and obvious abnormalities of their facial skeleton, unilateral sinus disease, asymmetrical disease, and bony erosion, with more frequent extension of disease; findings on CT scan show bony erosion with extension of disease into surrounding structures [123].

Treatment

Treatment is based on the use of antibiotics via aerosol or nasal sprays, which has been supported by numerous controlled studies; nearly all experts advise against the use of other drugs [50, 215, 233]. The AAP recommends [218] that antibiotics be used in the treatment of sinusitis of suspected bacterial etiology. The most effective antibiotic against bacteria producing β-lactamases are the following (the percentage of children cured is shown in parentheses) [215]: amoxicillin (67%–100%), erythromycin-sulfisoxazole (95%), and cefaclor (78%–92%). In contrast to the AAP, other guidelines recommended that children with mild sinus disease and no antecedent antibiotic use in 6 weeks receive amoxicillin/clavulanate (93.5% efficacy), low-dose or high-dose amoxicillin (91% efficacy), cefpodoxime (86.7% efficacy), or cefuroxime (83.7% efficacy) [188]. The usual starting dosage of *amoxicillin* in children <2 years with mild to moderate uncomplicated acute bacterial sinusitis, who have not recently been treated with an antimicrobial (within 3 months), is 45 mg/kg/day in two divided doses or a high dose of 90 mg/kg/day in two divided doses [76, 108, 218] with clavulanic acid [233]. The broad-spectrum erythrosine-derived macrolides clarithromycin and azithromycin bind to ribosomal subunits, thereby inhibiting bacterial synthesis [95]. In acute, serious, but uncomplicated cases, 10 days of treatment are sufficient (*azithromycin,* 10 mg/kg/day on day 1, 5 mg/kg/day for 4 days as a single daily dose, or *clarithromycin,* 15 mg/kg/day in two divided doses). In children with chronic forms, it is necessary to administer them for 3–4 weeks; if the desired effect is not achieved, the cycle may be repeated [108, 218]. In a randomized single-blinded control study on 42 children aged 5 to 16 years, amoxicillin/clavulanate and azithromycin were well tolerated by 95% of children [136]. A marked improvement of symptoms was reported among children who received antibiotics (91%) compared with children who did not (21.4%) [150]. If treatment fails to eradicate the infection, the agents obtained by sinus puncture [54] or by nasal swab samples [193] should be cultivated. *S. pneumoniae* had a 32%–35% rate of resistance to erythromycin, azithromycin, and clarithromycin. *H. influenzae* showed a high rate of resistance to clarithromycin (36%). *M. catarrhalis* had a 15% rate of resistance to erythromycin and a 91.5% rate of resistance to penicillin [193]. It is also possible that *H. influenzae* and *M. catarrhalis* are resistant to β-lactam antibiotics such as ampicillin due to β-lactamase production. Instead, *S. pneumoniae* and *S. aureus* can be resistant to the penicillins and most other antibiotics by a genetic alteration in penicillin-binding proteins [76]. Children with *amoxicillin intolerance* should be treated with a cephalosporin, such as cefuroxime [76], and severely intolerant children with a macrolide as azithromycin, or clarithromycin [76]. *For children who do not respond* or who worsen while receiving amoxicillin, amoxicillin/clavulanic acid, cefuroxime axetil, and clindamycin are also recommended [102]. In children treated with antibiotics, *91% recover more quickly* and more often than do children who were not (21.4%), as early as at the 10-day follow-up visit [100], at 24–48 h after the follow-up visit, and again at 10–14 days after the office visit [1]. The inefficacy of treatment should lead the pediatrician to suspect a possible viral form [42]. The reason may be another: a recent, randomized study of 188 children with bacterial sinusitis between 1 and 18 years showed instead that antibiotic therapy is no better than placebo in sinus symptoms; however, this study included older children and *excluded sicker children* [71]. Treating sinusitis early with an antiviral may ameliorate or prevent this process: since most sinusitis is precipitated by viral infections, and because most clinicians consider sinusitis to be a bacterial infection, acute sinusitis is often overtreated with antibiotics [145]. A recent guideline suggested that children with

Table 15.13. Clinical presentation in 55 asthmatic children with or without Rx abnormalities of paranasal sinuses

Symptoms	Sinusitis

chronic sinusitis should be treated with a combination of an antibiotic and a nasal steroid spray, without giving specific recommendations about duration of therapy and choice of drug [38]. In children with persistent sinusitis, to decongest the mucosa, CSs including beclomethasone dipropionate (BDP) or flunisolide may be administered to facilitate drainage of sinus secretions and reduce local edema [43]. A multicenter study [132] has proved that *flunisolide nasal spray* produces significantly safe positive effects on symptoms, shown on X-rays and sonographic signs, and on local inflammation, reducing in particular headache, facial pain, edema and/or turbinate obstruction, secretions, etc. [132]. The addition of *mometasone furoate nasal spray,* 400 µg twice daily (bid), to antibiotics significantly reduces symptoms of recurrent sinusitis in children ≥12 years compared with antibiotic treatment alone [131]. In acute sinusitis, do topical CSs play a role in effective management? In recurrent sinusitis, do topical CSs reduce recurrence rates? In chronic sinusitis, do CSs induce symptomatic relief? [102]. *Delayed diagnosis* and advanced disease may lead to life-threatening complications [211].

To evaluate the prevalence of sinusitis, its relationship to asthma and whether its treatment leads to an improvement of asthmatic symptoms, we conducted a trial [29] on 80 children suffering from asthma who were aged 4–14 years with positive SPT and sIgE to Der p in 95% of cases (confirming the high prevalence of atopy in infantile asthma). Of the 80 children, 55 (68.7%) presented objective symptoms (nocturnal coughing, nasal obstruction, rhinorrhea, etc.) and X-ray evidence of sinusitis (mucosal thickening, opacity, air–fluid levels) (Table 15.13) [29]. Children were evaluated 30 days following specific treatment with either inhaled nasal CS or ampicillin plus an antihistamine/decongestant; 34/55 children (62%) showed an X-ray improvement (Table 15.14) [29], while in 20 (36%) a significant improvement of asthma severity was noted (Table 15.15) [29]. Zimmerman et al failed to confirm

the cause-and-effect ratio between sinusitis and asthma severity [238]. In a subsequent study, 28 children with AR and sinusitis with asthma improved their bronchial hyperresponsiveness (BHR) to methacholine and decreased their symptoms with appropriate response of their sinuses to clinical therapy compared to controls. Thus, treatment of sinusitis, which afflicts a substantial percentage of asthmatic children, can have a significant influence on the basic illness [29, 124, 125]. In another prospective, open-label study, the clinical symptoms and signs of sinusitis, but not FEV_1, showed a significant improvement after antibiotic treatment. After aggressive treatment for sinusitis, it was found that the provocative concentration of methacholine caused a 20% drop in FEV_1 of 61 children with mild asthma, and sinusitis was significantly higher after treatment [209]. The results [24, 209] suggest that every asthmatic child needs to be carefully evaluated to determine whether concomitant sinusitis is present.

Possible invasive therapies should be decided depending on each individual case [123]. *New treatments have been suggested.* Parenteral antibiotic therapy may have a role in avoiding sinus surgery in selected pediatric populations [201]. Studies have shown that adenoid removal will improve sinusitis for 70%–80% of children [212]. Nutritional supplements such as flavored cod liver oil and a multivitamin-mineral with selenium have been suggested as adjunctive therapy for children with chronic or recurrent sinusitis [118].

Pediatricians and ORL Diseases

The *Nelson Textbook of Paediatrics* (15th ed or p 1194) states that "it seems prudent to avoid surgery in most cases," hence adenotonsillectomy seems to be justified in children suffering from recurring tonsillitis (as shown in Fig. 15.4), with very significant statistical differences between healthy and sick children with regard to tonsillar GC. The operation should only be performed in infancy when the pertinent indications are accompanied by normal immunological tests and after ascertaining that the child is not allergic to anesthetics. A 7-year-old girl died in Rome on October 30th, 1998 during a tonsillectomy (we hope that this was the last death of this kind); probably her degree of reactivity to anesthetics was not tested. As highlighted by Pisacane et al, passive smoking causes surgical risks in 16%–24% of children undergoing surgery (Table 4.25), while breast-fed children appear to be significantly more protected [156]. Other points should not be disregarded. Firstly, persistent or recurring OME frequently causes different degrees of hearing loss in children, both in babies and in infants, to the point of being the most common cause of deafness in children, but it can be prevented, even in this case, by breast-feeding. Secondly, sinusitis can hide overlooked asthma. In fact we believe that paranasal sinuses should always be examined in asthmatic children or children with recurring symptoms such as nasal obstruction, rhinorrhea or nocturnal coughing to reveal any involvement.

Anaphylaxis

Historical Outline

The first description of an event similar to anaphylaxis was made at least 4,600 years ago [179]; however, only in 1765 was a fatal case reported in Europe (Chap. 17). In 1905, the first cases (one lethal) of food anaphylaxis were reported [72, 174], the subject of a book appeared in 1919 [111], and since 1926 [214] such cases have continued with an impressive frequency. The term "anaphylaxis" (from the Greek "αναφυλαξις", away from protection) was coined by Portier and Richet in 1902 during a Mediterranean voyage [156] to define the paradoxical effect of an experimental protocol. While attempting to immunize dogs to the venom of the sea anemone, after the first nonlethal tolerated dose, they unwillingly sensitized the animals with the second dose injected after 2 weeks, either equal to or less than the previous dose, and noted that the dogs exhibited severe manifestations, even lethal. Therefore the first injection sensitizes the animal, provoking synthesis of IgE antibodies; after a latent period for sensitization, re-exposure to the inciting allergen triggers within a few minutes the very severe clinical manifestations called anaphylactic shock, the reverse result of the prophylaxis envisaged by the scientists [156]. Subsequently, reports of severe episodes occurring in humans began to appear following vaccinotherapy and serotherapy. It was thus recognized that foreign substances eliciting an anaphylactic shock include either very complex molecules, such as proteins, or simple elements. However, the inciting agent, for example any foreign protein, need not accumulate to cause its effects [129].

One of the greatest dangers of today's therapy was undoubtedly until recently the allergic shock to the ever-increasing number of chemicals and drugs, all potentially sensitizing, which have all been reported more frequently since 1902 (Chap. 19).

Definition

Anaphylaxis is a life-threatening systemic reaction resulting from a severe type I, IgE-mediated hypersensitivity reaction, triggered by allergen reintroduction, with release of chemical mediators from metachromatic cells. It is manifested in the most severe form with an *anaphylactic shock*, a sudden, systemic and potentially fatal reaction. Clinical reactions indistinguishable from true anaphylaxis, *anaphylactoid reactions*, are not IgE-mediated, thus indicating the absence of specific antigen recognition. In a certain number of cases (approximation by defect), similarly severe, the cause remains unknown: these cases are defined as *idiopathic anaphylaxis* (IA). In addition to uniphasic forms, with immediate or late onset, there are biphasic reactions with characteristic clues: acute episodes followed by asymptomatic periods, then a relapse lasting several hours, and others protracted and potentially severe [63, 194, 212].

Epidemiology

The incidence and/or prevalence rates are as high as 0.0004% [136] to 0.0032% [104] in adults, 0.0006% in English hospital discharges [181], 0.004% in hospitalized children [63], and 0.04% [54] to 0.0016% [63], in not hospitalized adults and children, respectively. Over a 6-year period, a child aged 6 months to 10 years has been admitted every year to a US allergy-immunology department, for three IA episodes (0.002%), and one by vaccination, by penicillin, or exercise-induced (0.0007%) [63]. An international study estimated that the annual incidence of the overall risk of severe anaphylaxis was 154×10^6 hospital admissions, but including the possible cases, the risk was 196×10^6 [93]. In a US county, an anaphylaxis occurrence of 30×10^5 person/year was reported over 5 years [223] and the incidencerate was 21×10^5 person/year or 10.5 episodes $\times 10^5$/person/year in 229,422 children aged <18 [28] . In a school-based study in Australia the parents of 4,173 children aged 3–17 reported a history of food-induced anaphylaxis rate of 0.59% [29]. Extrapolating for the US population, one might calculate 84,000 anaphylaxis cases and 840 annual fatalities (presumed mortality rate, 1%). In England, there were 8 deaths over an 11-year period, with an incidence per year of 0.006 deaths $\times 10^5$ children aged 0–15 years [124]. Between 1991 and 1997, 67 episodes of anaphylaxis were identified in children, resulting in 10.5 episodes $\times 10^5$ person/year [28].

In England, the hospital discharges with a primary diagnosis of anaphylaxis increased up to 47.4% between 1991/1992 and 1994/1995 [181]. However, there is no available data to exactly establish the cases of anaphylaxis or the number of fatal cases, neither in children, nor in adults. On the contrary, the incidence of severe nonfatal events is 0.2×10^5 children per year [124]. Apart

from the predisposition due to preceding exposures, there are no epidemiological characteristics that are useful for identifying subjects that should be considered at risk. Fortunately, this is an extremely uncommon event in infancy, but not unheard of [22, 172, 224]. Significantly, a voluntary registry for peanut and tree nut allergy has found that 89% of 5,149 registrants were <18 years of age; the median age was 5 years, and about 45% of the total were children aged 4 to <13 years [185]. Among 2,320 emergency admissions over a 4-year period, *infants aged <1 made up 17.9%* [2], thus moving the age index to the left.

Several studies have concluded that between atopic and nonatopic subjects, there are quantitative differences related to the risk of experiencing IgE-mediated and non-IgE-mediated anaphylaxis reactions. In the US, it has been calculated that fatalities from anaphylaxis result only from penicillin; the nearest causes are Hymenoptera stings [103].

Data on biphasic and protracted episodes vary, there being a 20%–23% and 23%–28% incidence, respectively [171, 194]. A recent trial has found a 6% incidence in 105 children. Delayed administration of SC epinephrine was associated with an increased incidence of biphasic reactions [117]. However, systemic biphasic anaphylaxis occurs in up to 7% of subjects [63]. Two cases of severe anaphylaxis by jellyfish are known, one IgE-mediated, the other fatal with a clinical and atopic pattern of the anaphylactic type [16].

Incidence of Anaphylactic Shock Episode, Responsible Agents [136, 210]

- *Penicillin:* 1:1,000–1.5:10,000 and 0.01%–0.05% of treatments, with 500 fatal cases/year or from 1–5:10,000 [183] to 1–7.5:1,000,000 [136] treatments and a risk of 0.0015%–0.002%, =1:50,000–1:75,000 treatments [183].
- *Muscle relaxants:* 1:4,500.
- *IV anesthetics:* 1:300–1:29,000; the incidence of mortality due to anesthetics in children is between 0.012 and 0.029:10,000 [90].
- *Dextran:* 1:383.
- *Hemodialysis* 1:1,000–1:5,000.
- *IV radiocontrast media:* 1:1,000–1:14,000, fatal 1:10,000–1:75,000, 1:4 if of low osmolality; the lethal cases can be lowered to 1:169,000 without differences between ionic and nonionic types [100].
- *SIT* (specific immunotherapy): one fatal case: 12×10^{18} injections (Tables 13.10, 13.11).
- *Hymenoptera venom:* 0.8%–3%.

Incidence of Reactions by Causal Factors

Food anaphylaxis has made its appearance in children in a dramatic way [170, 171]. After Hymenoptera venom, *medications* are the best known causes of anaphylaxis and anaphylactoid reactions, with a mean frequency of 1:27,000 admissions (0.00003%). Even if <10% of such reactions are fatal, they are responsible for the great majority of anaphylaxis cases (Table 19.9). The higher prevalence of the reactions to such agents is likely secondary to several factors, including above all the relative frequency of exposures and the parenteral route of administration; however, both sensitizations and systemic reactions (SRs) were also reported after oral administration. An allergic shock may occur, although sporadically, during SIT, skin prick tests (SPT), or provocation test, but in children and with appropriate emergency equipment and medications available on site, the rate approximates 0%. The repeated exposure to an anaphylactic agent may affect the incidence of anaphylaxis, but *not all persons undergo relapses:* in positive cases they always experience less severe symptoms than in the first anaphylaxis. Several factors able to influence the risk variability have been suggested, including the time interval between the original and repeat exposures, and the dose of the inciting substance [155].

IA is more unusual, to the point that few specialized journals mention it, despite being characterized by life-threatening episodes associated with urticaria and/or angioedema and possibly by upper airway obstruction [179]. However, recently a growing interest has drawn attention to this current major medical problem [83, 150, 196, 218], with reports *in three infants* [26], a child of 4 years [23], children aged 3–10 [63, 64], 2–17 [26] or 10–19 [63], but pediatric cases are on the rise [83]. Apart from preferring the female sex, relations with professional factors and medications are apparently lacking.

Physiopathology

The release of a wealth of mediators, mostly vasoactive, sets in motion a mechanism with a final outcome of the vascular collapse, related to the functional loss of intravascular blood into the interstitial spaces and this shift in the rate between extent (of the vascular bed) and volume (of the vascular mass). Hypotension and shock result from generalized arteriolar vasodilation and remarkably increased capillary permeability; the consequent transfer of 50% of intravascular fluid into the extravascular space (within 10 min) [103], via the small postcapillary venule leakage, can lead to hypovolemia and shock, with resulting edema (angioedema) in skin, pooling of venous blood in the visceral bed, hemoconcentration and an increase in blood viscosity. Low cardiac output causes inadequate coronary perfusion, and low peripheral vascular resistance causes myocardial hypoxia, dysrhythmia and subsequently cardiogenic shock [87]. In vitro studies show that histamine release provokes tachycardia and arrhythmia, while prostaglandins, leukotrienes (LTs) thromboxane A_2 and PAF (platelet activating factor) are upstream from re-

duced contractile force and coronary flow. However, as yet no direct effect of anaphylaxis on both myocardium and coronaries has been documented. In some cases the shock starts rapidly, before an extended vasodilation occurs, with an exceedingly short latency time between exposure and onset of the clinical picture, indicating a possible involvement of reflex neurogenic mechanisms [129]. If the shock has a sufficient duration, organic insufficiency may occur mainly on the renal emunctory or central nervous system. When the latency time is protracted, the shock may stem from a delayed IgE-mediated reaction or the insufficiency of other organs. Alternatively, primitive abnormalities of microcirculation may play a role in provoking severe effects, by which vicious cycles result in negative effects directed against vital organs with lesser resistance [179]. In the lungs, both histamine and LTs display bronchoconstrictor activity, the first involves the proximal airways, whereas LTs act preferentially on peripheral organs. Bronchial obstruction has an effect on gas exchanges, with resulting hypoxia, for a further aggravation of the vascular effects of anaphylaxis; pulmonary edema and intra-alveolar hemorrhages are rather frequent complications. NO_2 (N dioxide) on the one hand may decrease both signs and symptoms of anaphylaxis, and on the other aggravates associated vasodilation [103]. When anaphylactic reactions involve mucosal sites, the proteins may cross the enteric and vascular barrier, also because of increased permeability. In addition to their uptake, the lactulose/rhamnose rate augments, while histamine concentrations and mucosal enzymes and H_2O and electrolyte absorption decrease; both villi and crypts remain unhurt. *Tryptase levels,* a neutral protease found in mast cell secretory granules, is also a possible marker of intestinal anaphylaxis [176]. Unlike Hymenoptera or drug-induced anaphylaxis [229], none are diagnostic in food anaphylaxis, since the levels are detected in some patients [229] but not in others [171].

Histopathology

In the cases of fatal anaphylaxis, intense phenomena of glottis congestion have been observed, the lungs appear to be hyperinflated, with mucous plugs and focal atelectasis. The microscopic aspect shows specific findings such as edema, vascular congestion and diffused eosinophilia of the lamina propria of the larynx, trachea, epiglottis and hypopharynx. In the lower airways, there is spasm of bronchial muscles, with edema, eosinophil inflammation of the mucosa and mucus hypersecretion, undifferentiated from the findings of an acute asthmatic attack [87]. In the absence of an early and adequate treatment, a pattern of acute heart failure is caused, possibly leading to respiratory insufficiency: the *exitus* is propitiated by asphyxia, edema and upper airway congestion [129]. In the remaining organs, in several cases myocardial ischemia has been seen, most likely secondary to shock; occasionally myocardial infarct is seen. Liver, spleen and other visceral organs often appear to be macroscopically congested, microscopical investigations show hyperemia and edema. Eosinophils are detected in both sinusoids and liver [55, 177].

Pathogenesis

The list of the most common responsible agents increases uninterruptedly following the promotion of new therapeutic and diagnostic means, and of food allergens. It is possible to divide the most frequent causes of anaphylaxis into three main categories.

1. In the known mechanism (Table 20.1) [22, 113, 136, 204], the exposure of susceptible subjects to foreign proteins either in the native state or as a hapten, after a covalent binding to a carrier protein, induces an *IgE-mediated reaction*: IgE antibody rapidly associates with high-affinity receptors (FcεRI) on metachromatic cells. With subsequent allergen exposure and cross-linking of IgE antibodies, mast cell degranulation is primed, with a rapid release from storage granules of newly generated mediators, including tryptase of TC mast cells, which can cleave C3 to generate C3a anaphylotoxin [22]. The activated mast cells release a number of cytokines, including IL_6 and TNF-α, which have been implicated in the pathogenesis of hypotension in endotoxic shock [136]. It is likely that the release of mediators and/or cytokines by cells bearing low-affinity (FcεRII) receptors can induce a marked decline in pulmonary conductance and dynamic compliance, hypotension and death. The observation that in children with fatal food-induced anaphylaxis the tryptase levels were not substantially elevated [171, 229] has suggested three possible pathogenetic mechanisms:

– *Mast cells* release low amounts of tryptase and normal amounts of other mediators after receiving certain activating signals.
– *Basophils* do not release histamine in the early stages of food-induced anaphylaxis, and this could play a critical role in the later stages of anaphylaxis.
– *Additional cells,* including macrophages, monocytes, endothelial cells), may be activated by FcεRII receptors via cytokines and/or mediators released in the early stages of anaphylaxis [171].

Anaphylaxis may also depend on the exposure setting and the dose of implicated allergen; in several cases associated with drugs, foods or insect venom, it is hypothesized that *non-IgE-mediated* potentiating factors may activate mast cells, basophils, other cells via FcεRII or target organs. The physiopathological mechanisms of clinical manifestations are the result of the crucial role played by *histamine and mediators* in provoking histopathological changes and clinical manifestations upon most organ systems [22], in particular at the expense of skin, airway and circulation; relative to

Table 20.1. Pathogenetic mechanisms of causative agents of systemic anaphylactic reactions

Pathogenetic mechanisms	Causative agents	Examples
IgE-mediated reactions against native proteins	Venoms	Hymenoptera, Solenopsis, snakes, jellyfish
	Inhalant allergens	Pollens, molds, epithelia
	Foods	Cow's milk, egg, nuts, fish, shellfish, crab, peanut, etc.
	Enzymes	Trypsin, streptokinase, chymotrypsin, chymopapain, penicillinase, asparaginase
	Heterologous serum	Tetanus and diphtheria antitoxin, antilymphocyte globulin
	Human proteins	Serum and seminal proteins, ACTH, insulin, vasopressin
	Others	Protamine, latex
IgE-mediated reactions against protein–hapten conjugates	Antibiotics	Cephalosporins, aminoglycosides, penicillin, sulfamides, polymyxin B, tetracyclines
	Chemotherapeutics	Adriamycin, bleomycin, alkylating agents, cyclophosphamide, methotrexate, cisplatin
	Disinfectants	Ethylene oxide
	Others	Muscle relaxants, heparin
Complement activation and generation of anaphylotoxins	Human proteins	Gammaglobulins, other human product (transfusions in patients with IgA deficiency)
	Dialysis	Blood contact with dialysis membranes
Direct activation of mast cells and/or basophils	Hypertonic solutions	Mannitol, radiocontrast media, muscle depolarizing drugs
	Drugs	Opiates, curare, d-tubocurarine, and mediator release vancomycin
	Others	Dextran, acacia, fluorescin for angiography
Unknown mechanism	NSAIDs	ASA, indomethacin
	Anesthetics	Lidocaine, thiopental
	Preservatives	Metabisulfites, benzoates
	Steroids	Progesterone, hydrocortisone
	Exercise	
	Exercise and foods	
	Cold-induced urticaria	
	Cholinergic urticaria	
Endogenous cell stimuli	Anti-idiotype antibodies	
	Anaphylotoxins C3a, C5a	
	Chemokines[a]	
	Interleukins[b]	
	GEF	
	Neuropeptides[c]	
	MBP	
	Platelet factor 4	
	Connective tissue activating protein-III

other organs such as the nervous system, the mediators responsible for symptoms are unexplored [225].

2. *Anaphylactoid reactions* (Table 20.1) recognize non-IgE-mediated mechanisms: circulating immune complexes or other agents activate the complement cascade with the resulting generation of anaphylotoxins (C3a, C4a, C5a), capable of inducing mediator release from metachromatic cells; *exogenous agents* such as opioids, mannitol, morphine, and radiocontrast media, and the endogenous stimuli may stimulate mediator release directly by a pathogenetic mechanism not yet well understood, but decidedly independent of both IgE antibodies and complement [179]. Complement-mediated reactions occur instead in children with selective IgA deficiency (sIgAD) and subjects with common variable immune deficiency [204] (see "Complement Activation"). Otherwise a proper pathogenetic mechanism was not identified, for example onset of bronchospasm, urticaria and/or angioedema and systemic symptoms after taking ASA (acetylsalicylic acid) or NSAIDs (nonsteroidal anti-inflammatory drugs), muscle relaxants and radiocontrast iodinated media [204], exercise-induced anaphylaxis (EIA), anaphylactoid reactions in food pseudoallergy (Table 10.19) and the cases of IA (Tables 20.1, 20.2) [129, 204].

3. The underlying *IA physiopathology* is unknown. A pathogenetic mechanism based on non-IgE-mediated activation of mast cells (and basophils) is speculated; however, no immunological parameter appears to be compromised, apart from hyperhistaminuria reported during acute IA episodes, returning to normal values at other times [83]. Unlike systemic mastocytosis, where mast cells infiltrate the bones and skin, increasing in number remarkably, in IA no rise in mast cells has been reported, nor is the skin reactivity to bioactive mediators including histamine, PAF, and LTs increased [83]. Nevertheless, symptoms in IA may be tentatively correlated with the systemic release of mediators, although occasionally. In one report, 46% of patients were affected with urticaria and/or angioedema, which continued to be observed in 22% of 94 patients on therapy, though in the absence of other clinical manifestations [218], whereas 225 patients were all affected with urticaria and angioedema [150]. Therefore, IA might be a severe form of reaction of the immediate type caused by abnormal or inappropriate mast cell and/or basophil activation. The elevated prevalence of atopy, up to 43%–58% [150, 218], higher than that of the general population, suggests a correlation between IA and atopy, thus postulating the existence of states of IgE-dependent sensitization to barely known natural allergens. It therefore seems likely that IA results from the combination of different factors, for example, a low sensitization in itself or a high IgE affinity for mast cell receptors, which make its serum levels too low to be detected by diagnostic tests. Consequently, histamine release associated with other factors, in addition to vasodilation and mucosal increase of permeability, causes an epithelial irritation

Table 20.2. Non-food agents that most frequently cause anaphylaxis

Antibiotics
Amphotericin B
Ampicillin
Bacitracin
Cephalosporins

[a] More frequently incriminated; see also Table 20.1.

triggering in turn axonal reflexes, tachykinin release and in the final analysis mast cell degranulation. IgE antibodies are heterogeneous, owing to this physicochemical peculiarity, and in certain subjects could undergo a structural adaptation similar to that pertinent to mast cell activation [83].

The knowledge of new involved molecules such as the *panallergen profilin* [69] suggests that some inexplicable cases may fit cross-reactions, as shown by those between latex and fruit (Table 8.14). The food neoallergens revealed during cooking match this analysis [126], at variance with the prevalent dogma of a reduced allergenicity following warming. The report of tryptase levels that are significantly elevated in infants who died from SIDS (sudden infant death syndrome) compared to healthy controls, a proof of mast cell degranulation [89], makes us suspect that the list of cases *classified as idiopathic or by unknown causes* can be added to other risk factors *including the hidden sources of foods*, which certainly underlie even lethal cases of anaphylaxis.

Risk Factors

The elements that predispose a child to anaphylaxis are rarely acknowledged: if on the one hand there appear to be no apparent correlations with age, sex, race or nationality, on the other hand it is usually assumed that

Table 20.3. Emergency anaphylaxis admissions in 530 children by age and etiological trigger

Trigger	Children (%)	Infants (%)	Preschool (%)	Junior (%)	Adolescents (%)

Data from [2].

the administration of stimulating agents by the parenteral route, the duration and frequency of exposure, and the time elapsed after the last exposure are all paramount factors in determining the risk of developing a SR: in a patient sensitized to an antibiotic, the risk of reacting to another antibacterial is increased nine-fold [224]. Recent data show that even for babies aged <1 year (17.9%), emergency anaphylaxis admissions were necessary. The preschool age is the group most at risk (35.9%) (Table 20.3) [2]. Twenty-three children with anaphylaxis (42%) were aged 1–5 years [57], more are males [57, 125, 153] and 54% are allergic [57]. Factors to be considered further are the patient's inability to identify the cause, the inexperience of those present, and the delayed recognition of case severity [224]; moreover, as regards food anaphylaxis, the public place and the lack of emergency kits are additional factors [171].

Several factors potentially causative of anaphylaxis and of anaphylactoid reactions are outlined in Table 20.2. The rates reported in children are as follows [2, 26, 57, 145]

1. Insect stings (10%–22.4%)
2. Foods (25%–57%)
3. Exercise (2.2%–9%)
4. Anesthetics
5. Muscle relaxants (1%)
6. Antibiotics (4%–9%)
7. Hormones and enzymes
8. Plasma expanders
9. Latex (1%–27%)
10. SIT and SPTs (1%)
11. Vaccines (2%–12%)
12. Age
13. Complement activation
14. Radiocontrast media (2%)
15. ASA and NSAIDs (5%)
16. Additives (1%)
17. Aeroallergens

The route of exposure to the agent was IV in 38% of the episodes, oral in 27%, and transcutaneous or subcutaneous in 20% [57].

Insect Sting Anaphylaxis

Insect stings are sufficient to produce a severe, even lethal, anaphylactic reaction in sensitized persons. Sensitization results from prior stings and patients allergic to common or cross-reacting antigen may endure another anaphylactic reaction after being re-stung by any Hymenoptera insect species [204]. More frequently, children with Hymenoptera venom anaphylaxis have a negative personal atopic history and negative SPT to inhalant and food allergens [145].

Food Anaphylaxis

The field of food anaphylaxis has recently known several new aspects related to the cross-reactivity between proteins contained in different foods such as the profilins (Table 1.72) or between foods and aeroallergens (Table 1.73). The cross-reactivity between latex and vegetables (Table 8.14) and between vegetables and pollens (Table 9.48) are paradigmatic examples of this phenomenon. Anaphylaxis is frequent in children: 27 out of 544

(4.9%) investigated children with food allergy (FA) had anaphylaxis as part of their clinical presentation [161] or FA accounted for ≈50% of severe anaphylactic episodes in children treated in an ED [145]. In 76 children 95 cases of anaphylaxis occurred, 62 of them (82%) had a *personal history of atopic symptoms;* foods were identified as causative agents in 57% of the episodes of anaphylaxis [145]. Usually symptoms are elicited between a few minutes and 1 h, on average after 15.4±27.5 min [145], sometimes after a longer interval. The reaction severity is directly proportional to the onset speed and depends on that of the stimulus (dose–response mechanism). In 1982, Fries [75] reported 61 cases of peanut allergy, including a fatal case in a child who accidentally ate a small amount of peanut butter. Peanuts hidden in a cake were responsible for one fatality in France: not even a quick injection of epinephrine saved the child's life [18]. Anaphylactic shock was triggered in 17 children and adolescents [171, 228]. The most striking pediatric case series published reviewed 13 cases of anaphylaxis, with *fatal results in six* and near-fatal results in the other seven [171]. The foods incriminated in fatal cases were peanut in three cases, cashew in two, and egg in one. In the near-fatal cases, peanuts were incriminated in one, walnuts, pecan and Brazil nuts in four, and CM and fish in two cases. All children were asthmatic and all had previously experienced anaphylactic reactions to the same food but were unaware that the allergens were contained in *common foods* such as candy, cookies, sandwiches and pastry [171]. Thus, *coexisting asthma is more strongly associated with a severe reaction* than the severity of previous reactions [13, 124, 128]. Several children and adolescents were *both atopic and asthmatic* [27, 171, 228]. Sixteen fatal cases were induced by peanuts [27, 30, 178, 228], and cod, crab and pecan nut caused one each [228]. In a report of 32 fatalities [27], 17 (53.1%) were ≤18 years old and 3 of 17 (17.6%) were aged 2–6 years, other victims were 5, 8, or 9 years old [159]. Remarkably, 9 of 17 (52.9%) died of peanut and 5 of 17 (29.4%) of tree nut anaphylaxis [27]. These fatalities occurred in association with foods from restaurants or other food establishments [27]. A severely nut-allergic 12-year-old girl perceived a nut-taste as soon as she ate a home-made cake, and soon systemic symptoms were triggered. Nobody had epirephrine at hand, and the girl despite the ED (emergency dept) died of anaphylactic shock (Italian press report, March 2004). The high prevalence of peanut allergy is caused by the marked potency of this allergen, capable of sensitizing 18.3% of children <12 months (Table 5.5), to the point that patients are positive to SPTs at a $1{:}10^7$ dilution [149]. In England, there were eight deaths over an 11-year period in 3-month- to 15-year-old children, four caused by cow's milk (CM) (50%), two by peanut, and one each by egg white and mixed food [124]. Over 2 years (1998–2000), there were six near fatal reactions (two caused by mixed food and one each by CM, egg, lentil, and walnut) and 49 severe ones (among which 13 were caused by nuts, ten by peanut, and nine by mixed food), yielding incidences of 0.02 and 0.19×10^5 at 0–15 years per year, respectively [124]. Regardless of the nature of the initial reaction in 60 children, the majority (52%) experienced potentially life-threatening symptoms to subsequent reactions [207]. CM may be a *silent killer of toddlers:* one girl aged 3 in the 32 fatalities reported (12%) [27]. Luckily enough, these are rare cases: over the past 10 years, four children have died (incidence of 0.003 deaths per 1×10^5 children aged 0–15 years per year) and 0.19 severe reactions per 1×10^5 children up to 15 years of age [124]. Near-fatal reactions to CM have been experienced by 13 children aged 9 and 12 (15.4%) [171]. CM is responsible for cases of anaphylaxis in up to 11% (Fig. 9.4), and 22% of cases [145]. To these cases we add CM-induced anaphylaxis/shock in 3 infants aged 1–15 months [23], a girl of 3 years [27] and 2 patients 2–17 years of age [26] as well as severe reactions triggered by 1–2 drops put upon the inner border of the lower lip [38], even causing anaphylactic death [27]. A CM-sensitive infant was hospitalized with systemic anaphylaxis that developed immediately after the application of a diaper rash ointment that contained 5% Ca caseinate [94]. Four babies aged 6 weeks to 6 months experienced severe life-threatening reactions, all related to unsupervised self-challenge with either a CM-based formula or a dairy product [182].

Food anaphylaxis and severe respiratory and cutaneous reactions were provoked in schoolchildren by peanuts (73%), egg (13%), CM and lupine (11%) and eight other foods [140]. Table 9.19 shows that foods may provoke respiratory reactions in 3%–46% of children (DBPCFC). Additional foods more frequently implicated are seafood (11%), nuts (13%), fish (19%), egg and fruits (11%), cereals (5%), goat milk from 4% [145] to 92% [15], nuts, figs and peas [214], squid [41], mustard and other foods and additives causing anaphylaxis or anaphylactoid reactions (Table 20.4) [6, 7, 9, 10, 11, 14, 15, 18, 22, 24, 30, 38, 41, 42, 45, 49–51, 53, 54, 65, 67, 68, 70, 71, 73, 79, 95, 97, 98, 107, 113, 122, 124, 126, 137, 140, 141, 143, 145, 147, 151, 152, 160, 161, 163, 164, 168, 170, 171, 173, 185, 196, 200, 202, 203, 209, 224, 228]. Limpet cross-reacting with Der p has induced anaphylactic reactions in five Der p-sensitized asthmatics [11]. A child we have seen experienced anaphylaxis to watermelon and peach and tested positive to a number of other foods and vegetables: his mother reacted upon seeing Italian squash and peach. Severe reactions were to skin contact with egg white and shrimp [12] as well as CM, wheat, peanut, and tomato in four children [199] and with drops of CM inadvertently spilled on the leg of a CM-allergic boy we have treated, and on the head of a girl [199]. Similarly, accidental skin contact with a drop of CM provoked systemic symptoms in a 16-year-old boy [119]. Additional severe symptoms were triggered upon trivial skin contact with minute doses of allergen in infants, children and adolescents [65, 186]. In 100 subjects aged 9 months to 19 years, skin contact reactions were present in 90%, severe in 23% and treated with epinephrine in 13% of cases [186]. Hydrolysate formulas have provoked 13 cases of anaphylaxis

Table 20.4. Foods and additives leading the list in frequency as cause of anaphylaxis (also fatal) or anaphylactoid reactions

Foods

Allspice
Almond [68, 185]
Anise seed [196]
Apple
Artichoke
Avocado [147]
Baker's yeast
Banana [76, 173]
Barley [145]
Bay leaf
Beet [24]

(5 in Table 9.28 [34]), three apparently life-threatening events, and 13 systemic reactions (Tables 9.31, 9.32) and in babies in allergy prevention (Chap. 24). Indirectly implicated are drugs [18] and baby ointments [94, 115]. Pear, potato, soy, tangerine, beet, and chocolate have yielded no reaction to SPTs in 102 patients; moreover, it is instructive that food provocation tests have confirmed only 22% of food-positive SPTs [196] (Table 20.4). The literature reports four cases of anaphylaxis to soy, one every 22.3 years [39]. However, four asthmatic children [74], all highly peanut-allergic but none soy-allergic, apparently unknowingly ate foods containing 2%–7% of soy protein and died within 10–36 min from rapidly deteriorating asthma, probably connected with a peanut-soy profilin cross-reaction (Table 1.72) (only inhaled soy causes asthma) [39], as did two more children who ate foods containing peanut [74]. Two additional children with peanut allergy but not recognized as at-risk by school staff died after eating soy-containing foods [222]. Moreover, 9 out of 17 patients have unknowingly eaten foods that contained peanut, which had previously provoked reactions to them [27].

Table 20.5 [163, 222, 230] summarizes 20 severe reactions, also fatal and provoked by hidden sources, as emphasized in Table 9.34 and Appendix 9.10. Several episodes have threatened the life of some patients in a wholly unpredictable way, including unnoticed ingestion of nuts in young allergic men [223], or a cookie containing pine nut butter, an IgE-mediated allergy to pine nuts that had never been ingested before [107], and chocolate, an unsuspected source of reactions if it contains peanut paste as a hidden allergen [86]. Children with CM allergy (CMA) have experienced acute, even severe, reactions due to the *unspecified presence of sodium caseinate in products labeled as non-CM-based*, because the FDA (Food and Drug Administration) allows labels not to specify CM, since it is considered a natural flavoring [81]. In Spain it is an authorized additive [131]: this is the cause for the unsuspected presence of CM in numerous meals [81, 131]. Fifty severe reactions, often fatal, by *allergens hidden* in foods *guarantied as allergen-free* by manufacturers or vendors, or in unknowingly eaten foods containing the allergen that had previously provoked reactions are outlined in Table 20.6 [9, 18, 22, 30, 56, 61, 69, 74, 86, 95, 124, 134, 147, 163, 195, 229]. In 1999, the death of a CM-allergic young man who ate an Easter egg made with dark chocolate was reported by the Italian daily press, as he believed that it was CM-free. In 1993, the English press reported that a peanut-allergic girl died after eating a biscuit at school, and in 1996 a 26-year-old with an acute fish allergy was assured by the manager that nothing in the appetizers had seafood in it, but on eating just three small spring rolls the man collapsed and died half an hour later in hospital [221]. In 13 cases of anaphylaxis, all were attributable to masked allergens [171] (Tables 20.5, 20.6). The case of an 18-month-old boy who experienced three systemic allergic reactions at home after eating a few spoons of mashed peas is also remarkable. But when a challenge test was performed in the hospital with the same mashed peas, although the child ate three spoonfuls willingly, he soon collapsed and died despite emergency treatment [214].

Potentially lethal food substitutions include mustard [99], buckwheat, peanuts and Atlantic pollock (sometimes used in surimi) for more expensive almonds and crab meat, respectively [36], nuts contained in foods and cakes, or unspecified sesame seeds [98]. On May 23, 2004, a 12-year-old girl died in northern Italy while eating a cake made with nuts, unknowingly to this severely nut-allergic girl. On June 12, 2004, a 9-year-old boy severely allergic to CM died in Rome after having touched drops of CM spilled from a pizza in a pizza parlor where he went with his classmates (daily press reports). Similarly, a CM allergic boy experienced systemic anaphylaxis after eating a pizza *declared as cheese-free*. Investigations showed that the pizza-maker added a small amount of CM to the pizza dough [119]. A young man allergic to chicken meat suffered from anaphylaxis when he ate white sausages made not with pork but with chicken meat: the butcher admitted the adulteration. Clearly chicken is a food and he transgressed no law; *however*, *he should have declared the change on the label* [163]. A peanut-sensitive young woman ordered a beef burger but was served a vegetable burger mistaken for a beef burger and after taking a bite she was hospitalized. Vegetable burger and beef burger have a similar appearance and presentation, but a beef burger is a kind of minced meat, whereas a vegetable burger should be prepared only with vegetables, but in this case it contained peanut seeds [61]. In 50% of cases, the food item was hidden (in sauces, dressings, egg rolls, etc.); visual identification was thus impossible [99, 138, 222]. Repeated anaphylactic episodes occurred in a child between the ages of 16 months and 4 years because of whey being mistakenly used in a *pareve cookie* instead of soy protein [73], and in a CM-allergic girl for parme-

Table 20.5. Twenty hidden allergens and foods containing them that have provoked severe reactions in sensitized children aged 3–15 years in an interval of 3 years

Food	Allergen detected	Concentration (%)	Background
Chocolate cake	Hazelnut	0.2	Undeclared
Meatballs	Egg (ovalbumin)	0.14	Undeclared on the label, recipe changed
Pasta	Egg (ovalbumin)	<0.013	Undeclared in 19/76 commercial products
Meatballs	Egg (ovalbumin)	0.16	Undeclared
	Egg (ovalbumin)	1.1	Undeclared
Ice cream (soybased)	CM (casein)	0.2	Contamination by previously processed ice cream
Plain chocolate	CM (casein)	0.8	Contamination by previously processed CM chocolate
Lollipop, strawberry	CM (casein)	0.2	Undeclared
Sausage	CM (casein)	1.0	Contamination
Sausage	CM (casein)	0.06	Contamination, fatal anaphylaxis after eating 1 kg
Hot dog	CM (casein)	0.04	Contamination
Ham	CM (casein)	2.5	Added as binder; undeclared
Meringue	CM (casein)	1.1	Undeclared
Buckwheat flour	Wheat gluten	1.3	Undeclared wheat flour added (15%–25%)
Whole pasta, wheat-free	Wheat gluten	7.8–11.9	Falsely declared as wheat-free
Corn pasta, wheat-free	Wheat gluten	8.3	Contamination
Hamburger	Soy protein	2.1	Declared but not recognized as risk by school staff (child with peanut allergy)
Kebab	Soy protein	7.0	Declared but not recognized as risk by school staff (child with peanut allergy)
Ham roll	Chicken proteins		Meat other than pork not allowed in the product; casein and soy declared additives
Cake	Peanut protein		Undeclared, believed to be almond, anaphylaxis
Crab sticks	Soy protein	0.5–0.9	Undeclared, not recognized as risk, anaphylaxis

Crab sticks (surimi) produced in China and Korea contain soy protein in the majority of cases.
Data from [163, 222, 230].

Table 20.6. Fifty additional pediatric cases reported in the literature

Food	Hidden allergen detected	References	Background
Acme tuna	Na caseinate	[69]	Undeclared, no indication
Almond flakes	Peanut protein	[74]	Replaced by peanut flakes by the baker, fatal case
Almond icing	Peanut protein	[56]	Unidentified, fatal case
Biscuit	Peanut protein	[134]	Unidentified, fatal case
Bologna	Na caseinate	[69]	Undeclared, no regulations[a]
Burrito	Peanut?	[22]	Unknown presence of allergen, fatal case
Cake	Nuts	[124]	Undeclared in a commercial food
Cake	Peanut	[22]	Unknown presence of allergen, fatal case
Cake	Peanut butter	[195]	Undeclared, fatal case
Cake	Peanut protein	[9]	Unidentified
Cake	Peanut protein	[18]	Undeclared, fatal case

Table 20.6. (Continued)

Food	Hidden allergen detected	References	Background
Cake	Pecan	[30]	Undeclared, fatal case
Cake/pastry	CM	[147]	Unknown presence of allergen
Cake/pastry	Filberts	[147]	Unknown presence of allergen
Cake/pastry	Filberts	[147]	Unknown presence of allergen
Candy	Cashews	[147]	Unknown presence of allergen, fatal case
Candy	Cashews	[147]	Unknown presence of allergen, fatal case
Candy	Peanut	[147]	Unknown presence of allergen, fatal case
Candy	Peanut	[22]	Unknown presence of allergen, fatal case
Candy	Walnut	[22]	Unknown presence of allergen, fatal case
Candy bar	Peanut	[22]	Unknown presence of allergen, fatal case
Cereal	CM	[147]	Unknown presence of allergen
Chili dish	Peanut butter	[195]	Undeclared, fatal case
Chili sauce	Peanut protein	[30]	Undeclared thickener, fatal case
Chocolate	Peanut protein	[86]	Unidentified, fatal case
Cookie	Brazil nuts	[147]	Unknown presence of allergen
Cookie	Peanut	[22]	Unknown presence of allergen, fatal case
Cookie	Peanut	[147]	Unknown presence of allergen
Cookie	Peanut protein	[195]	Unidentified, fatal case
Cookie	Walnut	[22]	Unknown presence of allergen, fatal case
Cookie	Walnut	[147]	Unknown presence of allergen
Cupcake	Peanut	[147]	Unknown presence of allergen, fatal case
Dessert	Nut	[22]	Unknown presence of allergen, fatal case
Dinner	Pecan	[22]	Unknown presence of allergen, fatal case
Easter egg	CM	[b]	Undeclared, fatal case, see the text
Egg roll	Peanut	[22]	Unknown presence of allergen, fatal case
Frozen dessert (2 cases)	Na caseinate	[69]	Undeclared, no regulations[c]
Hamburger roll	Egg	[147]	Unknown presence of allergen, fatal case
Hot dog	Na caseinate	[69]	Undeclared, no regulations[a]
Ice cream	CM	[124]	Contamination of previously processed ice cream
Ice cream	Nut	[124]	Contamination of previously processed ice cream
Lunch	Fish	[22]	Unknown presence of allergen, fatal case
Mixed nuts	Brazil nut	[22]	Unknown presence of allergen, fatal case
Nuts	Pistachio	[22]	Unknown presence of allergen, fatal case
Raspberry sorbet	CM	[95]	Labeled as "Kosher-pareve, dairy-free"
Sandwich	Peanut	[147]	Unknown presence of allergen, fatal case
Sausage pizza	Soy protein	[229]	Undeclared, fatal case[d]
Sausage roll	Chicken	[163]	Undeclared, no regulations
Snack mix	Peanut	[22]	Unknown presence of allergen, fatal case
Vegetable burger	Peanut seeds	[61]	Believed to be a beef burger

CM cow's milk.

[a] Foods labeled as "CM-free."

[b] Reported by Italian daily press in 1999.

[c] Label mentioned "natural flavorings."

[d] See text.

san cheese accidentally falling into her dish or eating a roll cut with the same knife used for butter [144]. An egg-sensitive infant developed severe generalized urticaria after playing with a pan that had just been used to prepare an egg-containing dough [12]. A child we have treated was hospitalized for anaphylactic shock after having mistakenly eaten a few drops of CM, to which he is severely allergic.

A survey on the management of anaphylactic reactions has revealed unexpected contamination during cooking (with a spoon or a spatula with food residues) and reactions occurring at schools, restaurants, or at home [65]. A CMA child was kissed by an adult who had eaten a pizza containing cheese, and another child, allergic to nuts, was kissed by another child who had eaten walnuts [65]. A girl with CMA seen by us developed angioedema where she was twice kissed by her brother, while eating a CM ice or drinking a cup of milk. An uncommon reaction happened in a playground due to contact with a football touched by another child who had just eaten fish [65]. Additional severe accidental reactions were caused by a peanut-free ice-cream stored in a container previously used for peanuts, and eating a banana that had been stored next to an open peanut bin [65]. David has reported unpredictable reactions during food reintroduction into a diet [50] and Bock several cases also in 3- to 4-year-old children due to peanut, walnut, shrimp, spices, and to sulfite-containing foods such as catsup and vinegar [24]. In Tables 20.5 and 20.6, 70 cases are summarized: 23 (32.4%) to peanuts, 17 (23.9%) to nuts, 13 (18.3%) to CM, and five to eggs (7.0%), but in the 17 children, peanut and nuts accounted for 15 (88.2%) deaths [27]. Indeed, commercial catering caused 76% of food-related reactions [159].

Unsuspected allergens are responsible for cases of anaphylaxis, including mango [6, 137], royal jelly [31, 164] with a fatal case in one girl [31], *Litchi sinensis* [69], kiwi [70, 79, 140], coconut [203], avocado [171], heated pecan nuts [126], lupine [140], raw potato [14] and anaphylaxis triggered by cream puffs contaminated by *Der farinae* in an adult [66] and a girl [193]. Three incredible cases caused by CM-inhalation occurred, once when a young woman with CMA walked into a grocery store where CM was sold, and she died after anaphylaxis by inhalation of CM protein, as reported in 1992 by the Italian daily press; an 18-year-old girl severely allergic to long-term eliminated CM inadvertently entered a dairy shop where she inhaled CM proteins and experienced a fatal reaction [13]; and a child had repeated episodes of acute bronchospasm, also by CM inhalation, that were so severe that his younger nonallergic brother had to follow the soy-based diet of his elder brother [166].

Sulfites and other food additives (Table 10.3) may induce severe anaphylaxis: the Na metabisulfite sometimes found in epinephrine formulations [123] (Table 19.32), in certain corticosteroids (CS) and other drugs is puzzling (Fig. 10.3, Table 19.32).

Exercise-Induced Anaphylaxis

EIA was first described 18 centuries ago, and recognized as a clinical entity between 1970 and 1980, and later the relationship between sporting or agonistic activity and inciting factors such as EIA occurring postprandially was soon evidenced (thus entering the *differential diagnosis with food anaphylaxis*) (Fig. 20.1). The surge in incidence is due to enhanced popular commitment to physical fitness including jogging, running, sprinting, volleyball, basketball, tennis and soccer, skiing and aerobic exercise [200]. Cases are known in 10-year-old children, but have been observed even in children of 4.5 years [112]. Predisposing factors include family history (FH) [121], atopy [91, 145], heat (64%) or cold (23%) ambient high humidity (32%), and drugs, for example ASA (13%) [91]. EIA can be associated with cold, so exercise in warm environments, or exposure to cold with no activity fail to elicit clinical reactions; some patients manifest symptoms of cholinergic urticaria,

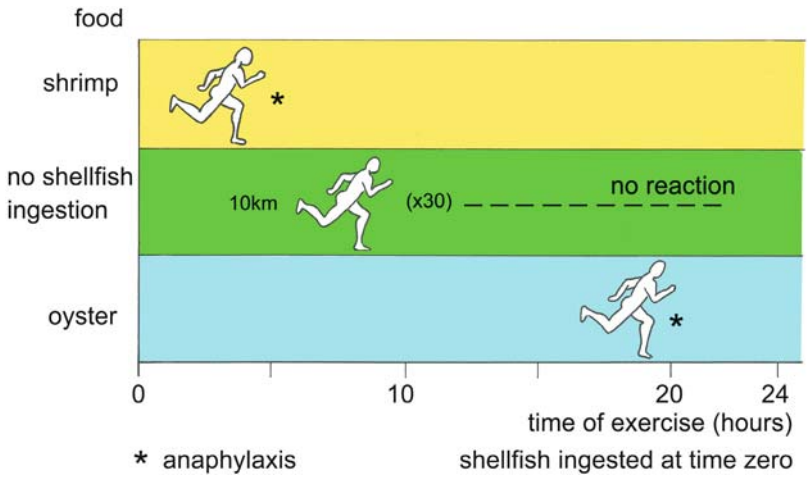

Fig. 20.1. Exercise-induced anaphylaxis associated with food ingestion. The runner with anti-shrimp IgE antibodies had severe anaphylaxis during exercise only after eating shellfish

viewed by some investigators as a less severe form than EIA [91]. EIA typically is heralded by the onset of *premonitory symptoms,* including asthenia, pruritus, warmth sensation, flushing, followed by the development of angioedema, urticaria and gastrointestinal symptoms such as abdominal cramps, nausea, vomiting, then, in the blown-up phase, progressing to wheezing, profuse sweating, vascular collapse and transient loss of consciousness [91]. In 3/4 of children aged 7–11, there was a food-associated EIA (FEIA), but a generalized pruritus was premonitory in only one [35].

Table 20.7 [43] sums up the symptom prevalence depending on the association either with exercise or with FA. Urticaria (80%–85.7%) and angioedema (48.6%–64.3%) dominate up to a real pattern of shock in 40%–43% of cases. The statistical analysis is very significant for warmth and flushing, which make cutaneous symptoms distinctive of non-FEIA, in which hypotension is significant [43]. The timing is characteristic, that is the interval between the start of exercise and the onset of anaphylaxis: the quickest onset of EIA was 5–20 min [112] and the longest 3.5 h [200], up to 25–72 h (if late reactions are operative) after eating the suspected food [91], although food ingestion not followed by exercise does not provoke any symptom (Table 20.8) [213]. The meal prerequisite may not be operative, or is operative without the food specificity, or ingestion of food(s) triggering the reaction (not followed by exercise) does not provoke any symptom; otherwise it is sufficient to *only view* the food [60]. The most common causative foods are shellfish and shrimp [60, 135, 200, 216], orange [53], chestnut [35], wheat [5, 60, 216], hazelnuts [130], tomato [35], rice [35], peach, celery, egg, grapes [43, 91] and CM derivatives [205]. The cross-reactivity between latex, fruits and foods (Table 8.14) may amplify the avoidance of foods. The incidence of FEIA has been studied in Japan in a survey of 11,647 children with 0% in kindergarten, 0.06% in elementary schools and 0.21% junior high school [200]. Among 76,229 junior high school students, the frequency was 0.017% and was significantly higher in boys than in girls. The frequency of EIA was 0.031% with no sex difference [1]. Cases precipitated by ASA [60] and NSAIDs [208] ingested before exercise are known. Related to pathogenesis, in some skin biopsies varying stages of *mast cell degranulation* were reported: ultrastructural evidence shows that before exercise mast cells are indistinguishable from those of control subjects, but immediately after exercise the loss of granule density is indicative of degranulation [180]. The data lead to speculation that a food-induced IgE-mediated reaction may be associated with specific food allergens [104]. It is likely that elevated plasma histamine [175] and tryptase levels further document that mast cells play a central role in EIA pathophysiology [175]. Several factors propitiate non-immunological mast cell degranulation or alter its threshold, namely neuropeptides, endogenous opioids, cytokines and chemokines [91]. The precise sequence of events has been less explored; however, the possible influence of genetic susceptibility to allergic disease may be an area of increasing interest in EIA pathogenesis [121]. In one family, two siblings shared an HLA haplotype with their atopic father. Both siblings developed EIA during running, but not during cycling, swimming, and on sun or cold exposure, they had no food-related symptoms. It is of note that all three individuals shared the *A3-B8-DR3* haplotype, thus suggesting heritable predisposition for EIA in some patients and families [121].

Table 20.7. Exercise anaphylaxis: clinical presentation

Symptoms	Exercise (n=35) (%)	Food-dependent (n=28) (%)
Abdominal pain	14.3	14.3
Angioedema	48.6	64.3
Asthenia	42.8	25.0
Conjunctivitis	2.8	0
Cough	5.7	10.7
Cutaneous warmth	48.6	3.6
Diarrhea	14.3	25.0
Dizziness	8.6	10.7
Flushing	68.6	35.7
Headache	11.4	7.1
Hypotension	17.1	35.7
Laryngeal stridor	40.0	28.6
Nausea	0	7.1
Pruritus	71.4	50.0
Shock	40.0	42.9
Syncope	2.8	3.6
Urticaria	80.0	85.7
Vomiting	14.3	7.1
Wheezing	34.3	17.9

Modified from [43].

Table 20.8. Exercise anaphylaxis subtypes

Subtypes	Characteristics
Classic	10–15 mm urticaria
Variant	1–3 mm urticaria
Familial	HLA haplotype correlated
Food-dependent	After any food eaten
Food-specific	After food allergen only

Modified from [213].

Anesthesia Anaphylaxis

Type I, II and IV immune mechanisms are operative. Clinically, toxic responses may be experienced by normal subjects (local, systemic) or by susceptible subjects (allergy, idiosyncrasy) [102, 210].

Anaphylactic reactions to local anesthetics have been reported. The prevalence of induced reactions follows [102, 210]:

- Barbiturates:
  Methohexital (1:700–23,000)
  Thiopental (1:1,400–30,000)
- Non-barbiturates:
  Etomidate (1:2,200–500,000)
  Propanidid (1:500–5,000)
  Propofol (rare, unknown)

The reactions are more frequent in allergic subjects than in other patients: bronchospasm, 43.5%–28.5%; cardiovascular symptoms, 82.6%–78.6%; and cutaneous reactions, 82.6%–57.1%. In allergic subjects muscle relaxants are also implicated in 75% of cases of shock. Elevated tryptase and histamine serum levels have not been considered as diagnostic [85]. Humoral immune responses are rare [78]. In some cases, vasoconstrictors and preservatives (parabens, sulfites) have been implicated [102], however not in patients subjected to challenge [78]. Local anesthetics employed in dentistry frequently provoke local and systemic reactions, rarely allergic [78], and are often complicated by latex gloves [132].

Muscle Relaxant Anaphylaxis

Muscle relaxants are widely utilized in operating rooms, making it possible to reduce the anesthetic dose, thereby facilitating surgeons' work [20]. They account for 70%–80% of all the allergic reactions occurring during anesthesia, 80%–95% of which are in females [102], also in girls of 5.5 years [133]. The prevalence of anaphylactic shock is 1:4,500 anesthesia doses given, and 6% of accidents are fatal [207]: alcuronium, 7.6%; atracurium, 6.8%; gallamine, 5.6%; pancuronium, 13%; succinylcholine, vecuronium, 37%; suxamethonium, 43%, etc. [20]. Between 1988 and 1992, suxamethonium caused 48% of severe reactions [217]. IgE-mediated reactions, positivity of Prausnitz-Küstner tests and RAST and nonimmunological release of histamine have been reported [19]. Studies with RAST inhibition have detected IgE antibodies directed to tertiary or quaternary ammonium ions present in muscle relaxants, thus a shared ammonium group may cause *cross-reactivity* among the various agents [102]. Since most of them share *two ammonium ions*, they are functionally divalent and therefore able to establish cross-linking cell-surface IgE from one side and to induce mediator release from metachromatic cells from the other [102], so binding to a carrier is not necessary to cause reactions. Cross-reactivity is common to all compounds provided with tertiary or quaternary ions such as the preservative benzalkonium chloride [192]. Muscle relaxants are widely diffused in drugs, foods, cosmetics, disinfectants and industrial materials, so patients are possibly sensitized to such compounds also via environmental contacts. Their very high prevalence in females may suggest that reactions are elicited by exposure to ammonium ions with epitopes present in cosmetics and the like [102].

Antibiotic Anaphylaxis

Antibiotics causing anaphylaxis (penicillin and β-lactam ranking first) [183] are outlined in Table 19.9, including two cases of anaphylactic shock provoked in surgical cases by local administration of rifamycin [40]. Penicillin can be detected in drinks and in frozen meat, as well as in CM as a contaminant (Table 19.36), so allergic subjects may manifest an anaphylactic shock while drinking a cup of CM containing even minimal amounts of penicillin and be labeled as CM-allergic [183]. Considering the huge number (in geometrical progression) of antibiotic prescriptions written on a yearly basis, it is understandable that the anaphylactic episodes provoked by antibiotics is a substantial challenge at a world level. In Chap. 19 we reported two fatal cases and three of anaphylaxis to ceftriaxone. Non-β-lactam antibiotics are also responsible for reactions (aminoglycosides, metronidazole, sulfamethoxazole, trimethoprim and vancomycin) [183].

Hormone and Enzyme Anaphylaxis

These substances, acting as complete antigens (Table 19.4), cause anaphylaxis and other clinical manifestations based on a mechanism that is almost always IgE-mediated.

Hormones

ACTH and Synthetic Corticotropin. The incidence of reactions (urticaria, angioedema, maculopapular erythema, wheezing, anaphylactic shock) was considerably reduced by the introduction of corticotropins. Synthetic derivatives have a different spatial configuration which makes them less allergenic.

Calcitonin. The reported incidence varies from 0.00003% to 6%, clinical manifestations are cutaneous and respiratory.

CS reactions are immediate (shock, cardiorespiratory arrest, bronchospasm, worsening of ongoing asthma, pruritus, urticaria-angioedema), and delayed (allergic contact dermatitis). The prevalence of IgE-mediated re-

actions is very low; it is more frequent to find pseudoallergic reactions by preservatives, excipients, contaminants such as succinate, with one fatal case occurred a few minutes after intramuscular injection of methylprednisolone [157], implicated also in hydrocortisone medication.

Insulin. Local reactions (immediate or delayed) may involve 5%–15% of patients, SRs (in addition to shock, mostly urticaria-angioedema and wheezing) only 0.1%–2% of patients. In the pathogenesis, immune mechanisms of all four types of reactions are implicated, in particular Arthus-like reactions by anti-insulin IgG antibodies and cell-mediated, especially to Zn, which is included in non-insulin contaminants along with protamine and proinsulin.

Enzymes

Chymopapain. Currently seldom used, chymopapain is injected intradiscally to remove the mucopolysaccharide–protein complexes of the nucleus polposus of prolapsed intervertebral discs (chemonucleolysis). Reactions upon the first injection involve 40% of cases, upon the subsequent injection 9% are involved; the incidence of severe anaphylactic reactions is 0.18% and of fatal cases is 0.01% [102]. Since this enzyme is present in several foods and various substances (Appendix 8.2), everyone is potentially at risk of sensitization from the first meal with meat or fruit juices.

Aprotinin. Aprotinin is widely used in the treatment of extensive burns. The reactions – anaphylactic, respiratory, and cutaneous – have a mean incidence of 1% (0.72% upon the first and 9.1% upon subsequent administration) [210].

Streptokinase. Streptokinase is used as a thrombolytic agent. Anaphylactic reactions, including delayed reactions, have an incidence of 1.7%–18% [210].

Plasma Expander Anaphylaxis

Use of plasma expanders has dramatically increased following the great concern brought about by HIV-infected blood. The incidence of anaphylactic and anaphylactoid reactions to dextran ranges from 0.008% to 0.069% of administrations, to fluid gelatins from 0.03% to 0.14% [162], which cross-react with food gelatins [215], to plasma protein solutions from 0.02% to 0.25% [102, 162], and to hydroxymethyl starch the incidence is 0.08% [116]. In patients with anaphylactoid reactions to dextran, the incidence of shock can be as high as 15.9%; cases of anaphylactoid reactions to serum albumin have a 0.012% incidence [162].

Latex-Associated Anaphylaxis

The cases of latex-specific IgE-mediated hypersensitivity reactions are increasing [21, 223], from 0.5% in 1989 to 12.6% in 1993 [114], mostly because of a rise in the demand for latex gloves [197] following the HIV epidemic [116]. The pertinent allergic pathogenesis is analyzed in Chap. 8. Among the several published cases of anaphylaxis chiefly in atopics [148], there are 25 episodes in children affected with spina bifida or urinary malformations exposed to latex catheters [62, 102, 197]. The risk factors are numerous: spina bifida (28%–57% of cases) [20, 62], contact with latex, FA and cross-reactions with fruits (Table 8.14), anesthetic induction [102], operations [62, 133], atopy and children, because 80% of intraoperative cases are due to latex exposure [198]. In 12 cases, anaphylaxis began 5–30 min after the start of anesthesia preparation before the operation [102]. An additional 12 cases were induced by intraoperative contact with latex gloves [62], as well as a very severe case in a 14-year-old girl [197], and in a girl who was 10 months old due to a pacifier [198]. Latex positivity has been documented by SPTs and sIgE, with the RAST better than with ELISA [102]. SPTs with pacifier eluate in a latex-sensitized adult resulted in wheals with a diameter of 5–6 mm [198]. Given the reactions induced by latex gloves, use of vinyl gloves is suggested [127]. In Chap. 8, we reported four children experiencing anaphylaxis while playing with plastic balls. In 15 of 23 (65.2%) hospitalized children [57], not only was latex the single most common causative agent, it was often overlooked in this role.

SIT and SPT Anaphylaxis

The incidence/prevalence is 0.03% in adults ($1{:}2 \times 10^6$ injections) and 0.0016% in children. The fatal cases – statistically nonexistent in children – could be $1{:}10^6$–10^7 injections in adults. Among the 47 cases reported before 1973 and up to 2001 (Tables 13.8–13.11) are seven children 7–18 years old. However, only two cases can be imputed to SIT. Two fatal cases to SPT were reported in the US in 1964, thus confirming that *children run no risk*. Two retrospective studies have been reported:

1. *SPTs:* six infants <6 months of age who suffered from generalized allergic reactions after duplicate and multiple prick tests with fresh foods whose generalized reactions responded promptly to epinephrine: the babies were breast-fed and were tested with several foods [56] and the hypersensitivity to food proteins ingested by their mothers is also known (Table 9.1). In a retrospective study on a larger series of patients (mean 30 years), six mild SRs occurred, with a total rate of 33 reactions per 10^5 SPTs, but no reactions to SPTs for food or venoms [206].
2. *SIT* (Tables 13.8–13.11). Among 95 children there was one case, or 0.3% cases/year [145] and 4 probable cases among 39 cases, or 1.3 cases/year [28].

Vaccine-Induced Anaphylaxis

Severe reactions to influenza, measles, mumps, rubella (MMR), pertussis, and tetanus vaccinations have been reported [48, 225], including in an infant of 6 months [63]. Two children aged 4.5 and 4 years had anaphylaxis after MMR vaccination but recovered promptly [145]. In Finland, for over 15 years 18 cases of suspected anaphylaxis were reported in children aged 5 years 11 months (median) [125]. Subsequently, a study was done on the serum samples of 18 vaccinees; however, for ten of the 18 patients (55.6%) with reported anaphylaxis, only three received epinephrine [152] with three more cases of anaphylaxis in non-egg-allergic children; however, one of them had IgE binding to gelatin [152], so in fact there are two cases. The anaphylaxis to MMR vaccination is caused by other components of the vaccine, including gelatin, more and more frequent in vaccinations [92, 144, 152, 169] and neomycin, but not to egg protein or to egg allergy [48].

Age-Induced Anaphylaxis

Children have a greater body surface than adults in proportion to their weight, so children disperse a higher quantity of fluids, which requires a greater administration of fluid replacement. A recent study has shown that *the 0–4 age range* suffered anaphylaxis in 20.5% of cases; however the age range of 10–14 years is more at risk (31.8%) [28]. See Table 20.3: *infants (<1)* had food-induced emergency anaphylaxis admissions in 62% and preschool (1–5) in 48% of cases [2]. Even an infant *aged 1 month* suffered from anaphylaxis [145].

Anaphylactoid Reactions

Complement Activation

The most frequent complement reactions are hemolytic ABO-incompatible blood transfusion reactions either during blood transfusions or IV immunoglobulin (Ig) administration to subjects with selective IgA deficiency or an IgG subclass, who may have pre-existing IgG anti-IgA antibodies, so IgA/IgG-anti-IgA complexes can activate complement by the alternative pathway, resulting in C3a and C5a release. These anaphylotoxins contract smooth muscles, causing alterations in vascular tone, an increase in vascular permeability and bronchial constriction [136, 204, 219].

ASA and NSAIDs

ASA and NSAIDs, inhibiting cyclooxygenase enzymes of the arachidonic acid cascade, block prostanoid formation and, acting as haptens, cause hypersensitivity reactions (Table 19.9), even systemic anaphylactoid reactions, without differences in clinical features in healthy subjects and in patients with mastocytosis, while NSAIDs cross-react with ASA [195]. ASA 30 min after being ingested by a boy, together with a cake containing peanuts, potentiated the effect of peanut allergen possibly by increasing intestinal permeability, thus aggravating the food reaction to reach anaphylaxis [37].

Iodinated Radiocontrast Media

The general incidence of iodinated radiocontrast medium reactions is ≈4.5%–8.5% of procedures [210]. It is relatively rare in pediatrics, involving above all patients aged >20 years. About 68% of reactions occur in atopic subjects and 56% react positively to SPTs vs 30% and 24% of control patients, respectively [120]. Furthermore, atopics are predisposed to experience reactions to conventional compounds of higher osmolality compared with those of lower osmolality that are nonionic with a 3.5:1 ratio [120], corresponding to 4:1 of non-atopics in a study on 337,647 cases, with a reciprocal risk (RR) of 5.5:1 [100]. The results of a meta-analysis show a RR of 6.3:1 [33]. A study in children aged >10 contests that lower osmolality radiocontrast media are better tolerated [100]; however, *a 15-month-old-girl* has experienced a reaction [17]. In asthmatic patients, 12% exhibit reactions vs 4% of controls [188]. The pathogenesis is reported in Chap. 19. These media can also contribute to anaphylaxis, via histamine and tryptase release, inhibition of platelet activity, serotonin release by platelets, enzyme inactivation, activation of the prekallikrein-kallikrein system, hypocalcemia, alterations in myocardial conductivity and contractility, and lesions of the vascular epithelium [84, 120].

Others

Additives

A severe anaphylactic reaction occurred in an 11-year-old girl with AR (allergic rhinitis) a few minutes after eating a slice of mortadella that contained Na glutamate to which the girl reacted in a DB challenge [145]. With the increasing use of additives in commercially prepared foods [81], it is likely that the prevalence of severe food-induced anaphylactic reactions will continue to rise. Chapter 10 reports the recent introduction of additives in foods for infants, toddlers and young children and three anaphylactic reactions in children to fluorescin, sunset yellow, and tartrazine.

Aeroallergens

A 6-year-old girl, with a history of atopic dermatitis and signs of respiratory allergies, presented an episode of anaphylaxis after 10 min of snow sledding. Her

symptoms included sneezing, runny nose, blushed skin, edematous lips, dyspnea. Clinically, the girl had tachypnea, tachycardia (110/min), blood pressure (BP) of 80/50 mmHg, and wheezes and crackles in the lungs. Both SPTs and RAST were positive to horse, cat and dog dander. Repeated exposure to horse allergen when the girl visited a stable elicited early asthmatic response, as confirmed by spirometry [80]. A pollen-sensitive boy we have seen experienced a severe laryngeal edema when entering a home where a dog was present or had gone outside before his entrance.

We have seen uncommon cases of anaphylaxis triggered by pollens in highly pollen-allergic children including a boy touching a blessed olive-branch on Palm Sunday: he needed an urgent ED admission. The cross-reactivity between foods and aeroallergens finds its most surprising example in the mite-snail cross-reactions (Table 1.73). Similarly, peanut- and Bet v-sensitive children should strictly avoid soy ingestion.

Clinical Presentation

Anaphylactic reactions have a broad spectrum of possible clinical pictures and are almost always alike, regardless of specific causes in the background. Characteristic symptoms may manifest in different organs or organ systems; however, the degree of involvement of target organs can vary from one child to another, from mild to moderate intensity to severe manifestations, from a simple pruritus to an irreversible shock and to fatal respiratory insufficiency [103, 188] (Table 20.9 [28, 57, 136, 185] and Table 20.10 [55, 177]). The macroscopic findings of 56 cases included signs of asthma (mucous plugging and/or hyperinflated lungs) (26.8%), petechial hemorrhages (17.9%), pharyngeal/laryngeal edema (41.1%) [160], at variance with [55]. The most common reported finding was nonspecific pulmonary congestion and edema, which was present in 41 (73%) cases [160]. Anaphylaxis often produces signs and symptoms within a few minutes of allergen exposure, but late-phase reaction can occur 2 [171], 14 [212], 24 [171], and up to 32 h after onset [103, 194]. The more rapid the onset, the more severe the episode. Once started, the reaction evolves in a dramatic way, the latency time varies from a few seconds to 1 h, commonly <10 min [157]. More precisely, the time needed was <5 min in 21.2%, 5–59 min in 37.7% and 1–4 h in 8.2% of cases [28], 15.4±27.5 min [145], 19 min [171] and 59 min [57]. All of the organs or organ systems can be involved, both singly or in combination [129].

Before the onset of full-blown features of anaphylaxis, some patients complain of *early prodromic symptoms*, which may warn of impending severe reactions, including deep asthenia, malaise, anxiety and/or psychomotor unrest, profuse sweating, etc., or warmth sensation, pruritus, tingling and a metallic taste in the mouth followed by development of rhinorrhea, hoarseness, dysphonia, dyspnea, cyanosis, beginning from the head (scalp, external auditory meatus, lips), with vertigo, headache or from the trunk, spreading centripetally down to the genital region and the tips of the toes [179]. Usually, initial symptoms progress rapidly, associated with extensive cutaneous flare, urticarial manifestations, angioedema, nasal congestion, aggravated with nausea, abdominal pain, vomiting, agitation, loss of consciousness, tachycardia, bradycardia, and hypotension. *Food anaphylaxis* manifests with oral pruritus, a sensation of swollen lips and tongue and throat constriction, urticaria, angioedema, nausea, abdominal pain, vomiting, diarrhea, laryngeal stridor, dyspnea and wheezing [28].

In terms of their spread, reactions may be local and systemic [44] (see Table 17.5):

- *Local reactions* often affect the first site of exposure to the offending antigen, or the gut with angioedema in case of food anaphylaxis.
- *Systemic reactions* affect one or more organ systems with frightening rapidity.

According to statistics, urticaria-angioedema occurs in 79% of patients, dyspnea or wheezing in 70%, and hypotension and cardiovascular reactions in 24%. Respiratory complications are associated with most fatal cases. The most frequently involved organs are the skin and respiratory and cardiovascular tracts, less often the gastrointestinal tract [57].

The clinical signs of full-blown anaphylaxis, in accordance with *severity*, can be mild or severe [129, 136, 179]:

- *Mild systemic reactions* (usually with late onset) include urticaria with or without swelling, limited to the area of antigen exposure; other manifestations such as nasal obstruction, rhinorrhea, etc., are absent or are present in mild form, which does not always remain mild [187].
- *Severe symptoms* are generalized, affect organs or systems, often accompanied by hypotension or respiratory obstruction. Such polymorphous features express the contemporaneous and tumultuous compromise of varying localizations with involvement of several target organs.

Clinical features related to the organs or organ system involved [44, 57, 106, 129, 136, 179, 185] (Table 20.9) are discussed in the following sections.

Skin and Soft Tissues

The skin is the most common target organ and usually the earliest involved. An initial pallor may become flushing (cutaneous vasodilation); often a discoloration to deep red or purplish may herald impending shock. The skin is cold with cyanosis of limbs, if respiratory obstruction coexists. Urticaria (increased vascular permeability) and pruritus affect the lips, nose, periorbital region, ears, hands and feet, whereas angioedema is common in the periorbital areas and mucosa of the oral cavity, up to glottis edema.

Table 20.9. Symptoms and signs of anaphylaxis related to target organs involved

System/target organs	Clinical manifestations
Cutaneous (93%)	Cyanosis (5.9%), pruritus (54.1%), flushing (48%), urticaria-angioedema (88%), urticaria (56.5%), angioedema (51.8%), erythema (44.7%)
Eyes	Lacrimation, periorbital pruritus (4.5%), conjunctival injection (7.1%), edema
Nasal	Sneezing (3.5%), rhinorrhea (8.2%), pruritus, congestion
Oral	Pruritus of lips, tongue, and palate, edema of lips and tongue, metallic taste
Upper airways	Pruritus, dysphagia, dysphonia, hoarseness, stridor, glottis edema (3.5%–56%)
Lower airways	Dyspnea (55.3%), wheezing (47%–48.2%), tachypnea, bronchorrhea, respiratory arrest
Cardiovascular (21.2%–26%)	Tachycardia (9.4%), arrhythmias, hypotension (9.4%–33%), chest pain, cardiac arrest
Gastrointestinal (13%–22.4%)	Nausea (9.4%), vomiting (10.6%), heartburn, cramping (7.1%), diarrhea (1.2%), abdominal pain and/or distension, fecal and urinary incontinence
Neurological (26%)	Headache (15%), dizziness (33%), seizure (1.5%), syncope (4.7%–33%)

(%) = incidence of systemic symptoms in children from [26, 57]; respiratory symptoms = 93% or 88.2%.
Data from [136, 185].

Table 20.10. Pathological features in two series of fatal cases

System/target organ	43 cases [55] (%)		113 cases [177] (%)
Lower airway		Respiratory tract	88.4

Upper airway			
Laryngeal edema	37.5	Gastrointestinal tract	26.5
Mild	12.5		
Moderate	15	Serosae	23.8
Severe	10		
Spleen		Apparent absence of lesions	4.4
Eosinophilia	22.5		

Respiratory System

Respiratory manifestations along with the skin account for an earlier onset of anaphylaxis and are more common than the gastrointestinal and cardiovascular manifestations in children (78% and 79% vs 24% and 25%, respectively) [145] and are responsible for the majority of fatal cases (≥50%) (Table 20.10). It is likely that such cases occur for both pre-existing hyperreactivity and lacking response of β-receptors. Nasal congestion caused by edema and hyperemia of nasal mucosa, watery and profuse rhinorrhea and nasal and palatal pruritus may mimic an acute episode of AR. Laryngospasm, laryngeal edema, marked bronchospasm, bronchial obstruction, or status asthmaticus can lead to hypoxemia, hypercapnia, acidosis and death. With a partial obstruc-

tion of the upper airways, the patient may complain of fits of choking, hoarseness or repeated cough, stridor and glottis edema heralded by a choking sensation, as well as of retrosternal constriction and difficulty talking with hoarseness, of such a severity that a mechanical asphyxia is envisaged, while obstruction of the lower airways is characterized by bronchospasm, dyspnea and incoercible cough simulating an asthma attack. An obstruction by mucus hyperproduction may lead to respiratory insufficiency; however, if bronchospasm is exacerbated during the reaction, reversing the episode will be more challenging [171].

Cardiovascular System

Several of the mediators of anaphylaxis can adversely affect the vascular system by dilating arterioles and capillaries and increasing vascular permeability, so that it is the second most common cause of fatal events. The drop in BP (in hypertensive patients, the values drop to normal levels) makes patients tachycardic, agitated, anxious, and even a severe collapse may follow. An exceedingly elevated tachycardia (>140 beats/min), often accompanied by dysrhythmias, is an extremely reliable sign. The pulse may be weak, rapid and very soon imperceptible (a sign of hypovolemia). Pallor is followed by intense cyanosis. Hypovolemic shock with diminished left-sided heart filling, stroke volume and cardiac output may result in a severe hypotension and thus in a further decline of coronary perfusion. Generalized arteriolar vasodilation and an increase in vascular permeability appear, with blood shifting from the circulation to extravascular spaces, a consequent decrement of peripheral resistance and reduction of blood flow. The frequent appearance of acidemia and hypoxemia aggravates the alterations already present. By activation of the intrinsic coagulation pathway, a disseminated intravascular coagulation and depletion of clotting factors may occur. Hemoconcentration and hemostasis troubles, signs of associated cardiorespiratory involvement, lead to irreversible shock and death [160].

Gastrointestinal and Urogenital System

The symptoms and signs, more frequent in children with FA [145], are less common and never occur alone, but are not life-threatening. The most common clinical manifestations depend on contraction upsurge of smooth muscles and mucosal edema. They include nausea, vomiting, abdominal or uterine cramps, colic and diarrhea, which turns bloody, or progresses to fecal and urinary incontinence. Spontaneous abortion in pregnant patients and an increase in fetal or perinatal death have been reported [204].

Nervous System

Loss of consciousness (in some instances the initial manifestation of anaphylaxis), psychological and sensorial disturbances including anxiety and motorial unrest or torpor, with hyporeflexia or areflexia, have been more frequently reported. A sense of anguish may occur, not rarely intense headache, tinnitus, vertigo, and paresis. Convulsions, with or without shock, have been sporadically reported [129]. A cohort of 44 children, aged 2 months to 15.5 years, 32% presenting hypotension, 86% severe edema, and 66% respiratory distress were admitted to a pediatric ED [128].

Idiopathic Anaphylaxis

IA is characterized by one or more severe reactions which can even be life-threatening, characterized by urticaria and/or angioedema, associated with airway obstruction, hypotension and/or bronchospasm, or with intestinal colic [83]. In six children aged 5–10 years, cutaneous, respiratory, gastroenteric symptoms and syncope were observed [63, 64], and were thus wholly polymorphic. The reported pediatric IA population, with an incidence of 6.4% [128], is made up of 12 patients aged 6-16 years (including a 24-year-old) who had urticaria, angioedema, diarrhea, and wheezing [154], ten adolescents aged 11–19 years with similar symptoms, but a low level of compliance [59] as well as eight aged 17 months to 20 years (including a 39-year-old) who had cutaneous reactions, either urticaria, angioedema, or generalized flushing, and seven were noted to have wheezing or angioedema of the airways, causing respiratory difficulties. Diarrhea was noted among five children. Clearly many had life-threatening events [88].

The manifestations of anaphylactic shock are in turn classified into [63]:

- *Life-threatening,* compromising the airways by extending to bronchi and to the cardiovascular system
- *Not life-threatening*, preferentially compromising the skin

Moreover, based on their course:

- *Monophasic or diphasic* based on the occurrence of one or more episodes
- *Protracted* based on more or less long-term course [63]

IA features are categorized as life-threatening and not life-threatening based on frequency of symptoms [64] (Table 20.11) [47, 108, 220].

Classification of Episodes

IA-generalized: systemic manifestations of wheezing, hypotension or syncope with or without upper airway obstruction.

IA-angioedema: angioedema of larynx or tongue with airway involvement as the only life-threatening feature.

Table 20.11. Features of idiopathic anaphylaxis

Disease	Clinical manifestations
1. Idiopathic anaphylaxis generalized frequent	Urticaria and/or angioedema with wheezing, hypotension, shock, gastrointestinal symptoms with or without airway compromise with frequent episodes, ≥6/year
2. Idiopathic anaphylaxis generalized infrequent	Urticaria or angioedema with upper airway compromise such as laryngeal edema, or tongue edema but with ≤6 episodes/year
3. Idiopathic anaphylaxis angioedema frequent	Urticaria and/or angioedema with upper airway compromise such as laryngeal edema, or massive tongue edema without other systemic manifestations, with frequent episodes, ≥6/year
4. Idiopathic anaphylaxis angioedema infrequent	Same manifestations as 3, but with ≤6 episodes/year
5. Undifferentiated somatoform idiopathic anaphylaxis	Patients whose history mimics idiopathic anaphylaxis but lacks correlated objective physical symptoms, shows no response to the therapeutic regimen
6. Corticosteroid-dependent idiopathic anaphylaxis	Steroid-dependent patients, but unable to completely discontinue treatment

Data from [47, 108, 220].

Frequency of Episodes

- *Frequent:* > six episodes a year or ≥ two within a 2-month period
- *Infrequent:* < six episodes a year or ≤ two within a 2-month period [64]

Symptoms may aggravate very rapidly, the patient becomes unconscious. Death occurs suddenly if treatment is not initiated immediately, but even an aggressive treatment may be unsuccessful in particularly severe cases [18, 157, 214]. We believe that the outcome can almost always be transformed into a positive one by a timely and appropriate treatment. Several factors may influence the outcome: the briefer the onset of the anaphylactic reaction, the faster death may occur; in such a case death may occur within 10–30 min of the initial exposure [55]. The nonfatal forms are self-limited, subsiding usually within 48 h [204]. The great majority of reports concern muscle relaxant and IV anesthetic-induced fatalities, with a rate varying between 4% and 6% of cases; atopics are clearly more at risk than nonatopics. The share of food-induced anaphylaxis is unknown: death is more frequent in public places than in private homes [171, 228]. Unfortunately, 5 victimes aged 2–16 died at home or at a friend's home because they received no epinephrine, or received it late [27].

In more severe forms, cardiorespiratory and neurological symptoms prevail, while in other organ systems, these symptoms are attenuated or absent, whereas severe symptoms are preponderant instead in less severe forms or with protracted progression. The initial findings in 43 cases of drug-induced anaphylactic death, including four children (Tables 20.9, 20.10) were respiratory distress in 16 cases and circulatory collapse in 15; laryngeal edema in 15 cases was considered severe enough to be the primary cause of death in 4/15 cases [55]. Some manifestations may predominate over others: more evident digestive symptoms *may mimic a surgical urgency* or acute intoxication; others simulate status asthmaticus, or epileptoid crisis, or deep coma, etc., which in certain cases appear to be neurological in nature [44].

Diagnosis

Although anaphylaxis generally causes no diagnostic problem, successful treatment of anaphylaxis emergencies requires the ready availability of a more immediate possible diagnosis, which depends upon the observation of specific signs and symptoms. History remains an indispensable tool in the diagnosis of anaphylaxis, in identifying responsible allergens and/or another related precipitating agent, factor, or event. The points able to yield valid indications are both history-based and clinical:

- History data

Past history: enquiry into previous reactions since in all fatal cases of food anaphylaxis and in half of the cases by insect sting, there is a previous reaction to the same allergen [188, 229]. Drug allergy history was significant in hospitalized children, and asthma history in outpatient children [57]. Patients with repeat episodes of unidentified etiology, despite appropriate investigations [220], may be atopic and/or asthmatic [225].

Present history: ingestion of foods or drugs, Hymenoptera sting, EIA, or parenteral administration of a drug or vaccine or biological product, have occurred ≤1 h before the onset of symptoms were fully indicative.

- *Clinical features*

– The presence of characteristic *prodromal symptoms,* hypotension, urticaria-angioedema, and laryngeal or bronchial obstruction, are symptoms indicative of initial respiratory insufficiency or of cardiovascular collapse, isolated or associated. When symptoms consist

only in hypotension and loss of consciousness, the diagnosis is more difficult.
– It is more probable that cutaneous symptoms are associated with nonlethal anaphylaxis [170, 171].

If a patient has experienced more than one episode, the responsible allergen should be unmasked: a 4-week-old baby admitted because of pallor and hypotonia lasting 25 min after breast-feeding was subjected to EEG and endoscopy and only at 8 months of age was a severe egg allergy diagnosed [52].

In IA, despite a careful history, including diary products and detailed lists of drugs, no specific agent was identifiable, nor were laboratory tests conclusive [83, 150].

Laboratory Diagnosis

Often no time is left for deeper investigations; however, a number of indications can be detailed.

- *Complete blood counts* (CBC) reveal a hematocrit rise and a neutrophil and platelet decline for a trapping phenomenon.
- *Blood exams* including glycemia, azotemia, creatinemia, uricemia increases as well as hyponatremia and hypokalemia.
- The *possible myocardial changes* are documented by an increase in ASAT (aspartate aminotransaminase), creatinine phosphokinase, SGOT (serum glutamic-oxaloacetic transaminase) and lactic dehydrogenase concentrations.
- The *increase of serum tryptase levels,* released selectively by mast cells, may be related to histamine release by degranulated mast cells and indicate either protracted anaphylaxis or mastocytosis [176, 212]; however, results are more helpful for systemic allergens [171, 229].
- A *chest roentgenogram,* in the case of respiratory tract impairment, shows hyperinflation, which may or may not be accompanied by atelectasis. In some cases, it shows pulmonary edema.
- *ECG:* unless a myocardial infarct has occurred, an ECG frequently shows an S-T segment flattening with T-wave inversion, bundle branch block, atrial fibrillation, etc.

Immune Diagnosis

As seen in Tables 20.1 and 20.2, the task is not easier, the causative agents of anaphylaxis and of anaphylactoid reactions being countless. The identification of specific allergens may become critical, because a reaction to CM may be caused by penicillin contamination [183], egg embryo-based measles vaccine [18], reactions aroused by agents with a high anaphylactic potential, or meals based on highly allergenic foods [22].

Zomepirac

Modified from [204].

SPTs and in vitro tests may establish IgE-mediated responses to allergens. Likewise, all children with spina bifida should be investigated to uncover a latex allergy before any operation [21], a prerequisite generally not essential for the diagnosis, important for the correlation with history [227] and for prevention. In case insect stings are suspected, see Chap. 17.

SPTs are as always the most reliable procedure to establish the diagnosis; however, three children aged 7–10 had SPT+ to normally ingested foods [64] and in 78% of patients, food challenges disproved SPT+ [196]. SPTs are very effective in the diagnosis of sensitization to anesthetics and related compounds, while a negative test can exclude sensitization. SPTs to latex are unreliable when done with glove extracts, as they differ from lot to lot [227], nor are they usually recommended for certain drugs (Table 20.12) [204], which in some cases provoke anaphylactoid reactions also in healthy subjects [204]. During administration of such procedures, serially increasing extract dilutions are applied [18] since the test potentially stirs up severe reactions in hypersensitive subjects; moreover, the equipment and drug needed for office treatment of severe reactions should be available (Table 13.13).

RAST is reliable for foods and Hymenoptera stings [229]; however, false-positive results might follow nonspecific IgE bindings, such as [101] blood sampling done too early after reaction onset, unsuccessful antigen coupling, presentation of a mistaken epitope in the insoluble phase. In vitro tests give tangible positive results, but negative results fail to exclude a propensity to anaphylaxis, because the high IgE affinity to mast cell receptors may make serum IgE levels too low to be recognized by RAST; several cases of cross-reactions revealed by RAST

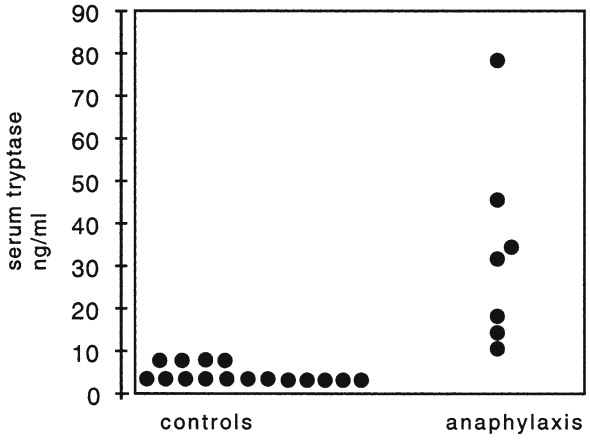

Fig. 20.2. Effect of anaphylaxis on serum tryptase levels as measured by monoclonal antibodies. (Modified from [175])

do not appear to parallel clinical conditions [192]. Positive RAST to soybean and wheat should be confirmed by a food challenge (Chap. 6).

The definitive and specific diagnosis of idiopathic anaphylaxis [201] is made by measuring serum *tryptase levels* within 60 min after anaphylactic events, which have a half-life of 1.5–2.5 h, and normal levels <1 ng/ml, which during an acute EIA are as high as 8 ng/ml [228] (Fig. 20.2) [175]; a value >10 ng/ml is considered to be high [229]. The serum mast cell tryptase, 1 h after the onset of an anaphylactic shock due to cefuroxime, was >200 µg/l (normal range, 10–16 µg/l) [158]. However, even elevated tryptase levels are inconsistent after food-induced anaphylaxis and may have no significant value when evaluating suspected food reactions [171]. Histamine plasma levels peak instead at 5–10 min after an insect sting and then decline, showing a half-life of few minutes from both immunological and non-immunological stimulations [176]. Tryptase levels may be effective, whereas histamine levels could be falsely increased by basophil stimulation during the coagulation [225]. The determination of tryptase levels allude, in case of elevation, to a near-fatal mast cell activation [225] or, as reported in a hospitalized patient with diagnosis of heart attack, who was correctly identified as a case of anaphylaxis only several days later when the blood sample taken at admission was re-examined [176]. The diagnostic complications were paradigmatic in the case of a girl who was very sensitive to peanuts and died after eating a sausage and cheese pizza and french fries; strangely enough, tryptase levels were minimally elevated. The girl had positive RAST to the soybean found in the sausage pizza but not to soybean oil used to cook the french fries; however, neither CM nor chicken proteins, frequent constituents of both cheese and sausage were tested [229].

In conclusion, as soon as a diagnostic clue arises, it is vital for the attending physician to institute the most appropriate treatment as swiftly as possible: this concept is strengthened by the disclosure that underreporting also affects these aspects: only in 4/17 patients (23.5%) was anaphylaxis diagnosed, perhaps due to imprecision of ICD9 International Classification of Disease, 9th edition, where a worldwide accepted definition appears to be lacking [105].

Differential Diagnosis

A few syndromes masquerading as anaphylaxis are considered in children and adolescents [34, 113]:

- *Vasovagal reactions* and collapse, which often occurs with injection of local anesthetics in dentistry, for example: a sudden appearance of pale, clammy skin, slow pulse, diaphoresis, nausea, vomiting, usually bradycardia (tachycardia in both anaphylaxis and insulin reactions), cutaneous symptoms and respiratory obstruction is observed.
- *Insulin reactions* have connotations such as asthenia, pallor, diaphoresis and unconsciousness, there is no occurrence of airway obstruction and respiratory distress, and BP is only somewhat depressed.
- *Reactions to other drugs* are clarified by side effects.
- *Systemic mastocytosis* is characterized by mast cell accumulation and possible presence or absence of cutaneous manifestations: sometime patients elicit anaphylaxis, but in their history there are episodes of maculopapular lesions (Chap. 8), flushing, and headaches, there is no upper airway obstruction and bronchospasm is infrequent and transitory. Diagnostic points are gastric hypersecretion and/or diarrhea, lymphadenopathy, hepatosplenomegaly, leukopenia and/or platelet dysfunction.
- *Hereditary angioedema* (Chap. 8) is considered if laryngeal edema is the prominent symptom; the diagnosis requires the demonstration of C1-INH deficiency. A rapid screening test is C4 reduction [108].
- *Cold urticaria* may occasionally occur as generalized urticaria, bronchial obstruction, cardiovascular collapse. The iced cube test in a localized and cooled room is resolvant in systemic cold urticaria (Fig. 8.8).
- *Laryngospasm* possibly due to asthma and vocal cord dysfunction.
- *Respiratory failure* can be caused by foreign body aspiration, or a severe asthma attack if the airway is obstructed, which may be mistaken for an anaphylactic reaction.
- *Epileptic seizures,* sepsis, dehydration, etc.
- *Reactions to additives* (monosodium glutamate, in other words Chinese restaurant syndrome), and/or toxins in certain fishes, etc.
- *Scombroid fish* (Chap. 10) and snake venom poisoning [32].
- *Pseudoanaphylaxis* is used to describe patients developing symptoms after injections of procaine penicillin. These reactions are of short duration and subside without the need of any intervention. Typical symptoms are

hallucinations, fear of death, anxiety, and other neurological symptoms [219].

IA should be differentiated by several the conditions mimicking it (Table 20.13) [108], including [83, 153, 217]:

- *Münchausen stridor,* a term coined after Münchausen syndrome [8], describes patients who intentionally adduct their vocal cords and present to emergency department (ED) with self-induced manifestations of dyspnea depending on laryngeal edema and with paroxysmal attacks of choking mimicking those of angioedema with glottis edema. IgE-mediated episodes have been reported after ingestion of nuts, peanuts or eggs in patients sensitized to these foods [219].
- *Anxious attacks* in children with upper airway obstruction, with anxiety, globus hystericus, in the absence of cutaneous and respiratory symptoms (except hyperventilation) and hypotension.
- *Somatoform anaphylaxis* [47], fictitious forms (such as panic attacks), however simulated [219].

Additional conditions not to be underestimated include food inhalation [13], serum sickness, hypovolemic shock and others, objectively rare in children [153].

Table 20.14. Differential diagnosis between exercise anaphylaxis and cholinergic urticaria

Exercise anaphylaxis	Cholinergic urticaria
10–15 mm urticaria	1–3 mm urticaria
Stridor with laryngeal edema	Bronchospasm and wheezing
Hypotension common	Hypotension uncommon
Occurs only with exercise	Provoked by heat, stress, exercise, anxiety, etc.

Modified from [213].

The differential diagnosis of *anaphylactoid reactions* matches that of the true anaphylaxis.

Specific Differential Diagnosis

EIA and cholinergic urticaria (Table 20.14) [213]. The ultrastructural aspect of EIA is consistent with a form of "anaphylactic" degranulation [180], which in cholinergic urticaria is instead "zonal" [91].

Immediate Treatment

The immediate treatment of anaphylaxis is the same for idiopathic and anaphylactoid forms [109, 136]. We distinguish general and specific measures related to the reaction severity [36, 87, 136, 188]: in an emergency, little time exists to consider fitting treatment, or to consult medical textbooks or other colleagues, therefore physicians, nurses and medical personnel must at all times be prepared to treat anaphylaxis [136].

The goal of initial evaluation is to assess airway patency, systolic BP, breathing, and vital signs [36]. Fatal cases occurred independently of the use [18, 214] or not [27, 171] of epinephrine. *Two out of six fatal cases* [171] received epinephrine within 1 h of the onset of symptoms also because *none of them had the emergency kit* (Table 20.15) [27, 171, 208], similarly to a 16-year-old boy [30] and two children reported in the press. The other seven, who were at home, received epinephrine within 5–55 min [171], thus proving that a medical emergency is resolved more rapidly and effectively *at home rather than in public places.* Anaphylaxis may materialize in a multiplicity of places, the most common site of occurrence of nonfatal pediatric cases was at home in 24%–57% of cases. (Table 20.16) [27, 57, 65, 145]. An analysis suggests that parents may hesitate to use the autoinjectable epinephrine (EpiPen) and seek ED treatment when indicated. The 11 (27%) children given EpiPen were taken to the ED; however, also 16 of 30 children not given EpiPen went to the ED [58]. In another cohort 32% of episodes of anaphylaxis were treated with epinephrine [187] or the first treatment was

One fatality occurred in the youngest of the 17 subjects, a 2-year-old child not known to have FA, or asthma, or other atopic conditions [27].

self-administered or given by a parent (57.1%) or a physician, or an emergency team, or by a teacher, or a caregiver in *91.8% of cases* [60]. In some reports, most of 17 [27] children and adolescents did not have EpiPen [30, 171], despite a regular prescription [171], and an 11-year-old child was in such a severe condition that even 50 mg of epinephrine (and resuscitation) were insufficient [18]. Two children died despite receiving epinephrine before admission to hospital [124]. However, 4 of 17 children and adolescents died at home and *only one received epinephrine, but late,* and of the remaining 13, only one received epinephrine [27]. Of the nine children whose reactions occurred in non-hospital settings and who had had at least one prior episode of anaphylaxis, only five had EpiPen available for use, which were successfully used in three children. Of the 11 children with known FA who had reactions in a non-hospital setting, eight had known histories of asthma and only three of these children had EpiPen available for use, and only in two cases was it administered [57]. Also it has recently been reported that epinephrine for first aid use by parents and other caregivers and the EpiPen autoinjector device are infrequently used in children with recurrent episodes of anaphylaxis [82]. In a diverse field, the great spectrum of critical situations faced by parents of children with FA is illustrated by a 2-year-old peanut-allergic child who experienced a severe reaction in a store after a woman in the check-out line quickly popped a *peanut-butter candy in the child's mouth* while the mother turned her head away to pay [65].

General Treatment

In the initial phase the treatment includes the following steps [64, 103, 136, 151, 188, 219, 226, 231]:

- *Stop child exposure* to the offending allergen if present, even based on a simple suspicion.
- *With hypotension,* place child in recumbent position (Trendelenburg) and elevate lower limbs: this favors venous return to the heart; modification of the Trendelenburg position may be necessary if the child is wheezing.
- *Secure and maintain airway patent;* to secure adequate gas exchanges, in an equipped center endotracheal intubation or cricothyrotomy may be required.
- *Frequently assess vital signs,* especially at the onset of symptoms and assess level of consciousness.
- *Place a venous tourniquet* above the injection, SIT and insect sting site; this may decrease absorption of the residual allergen, which should be released every 5–10 min for 1–2 s, thus insuring tissue oxygenation.

Initial Treatment

Primary drug of choice in pediatric therapy is *epinephrine,* because it reduces mediator release by metachromatic cells and acts directly to regress vasodilation, edema and bronchoconstriction [36]. The β-adrenergic property of epinephrine produces bronchodilation and increases both inotropic and chronotropic cardiac activity. Epinephrine administration must be immediate, *at first sign of danger,* including throat pruritus or tight-

ness, lipedema, laryngeal edema, nausea cyanosis, wheezing and *before airway compromise* with stridor, dyspnea, wheezing, etc. [36, 170]. In children, epinephrine is always the drug of first choice, according to 63%–81% of cases in the US (Table 11.48), to be administered even before symptoms become aggravated [36]. In a large study of children [28] epinephrine was given in 78.8%, parenterally administered antihistamines in 50.6%, CSs in 34.1% and bronchodilators in 27.1% of cases (compare with Table 11.48) or epinephrine in 75.7% of severe cases [65] or 84% of children received epinephrine, CSs, and an H_1 blocker [57]. We stress that epinephrine often *goes unused,* even in hospitals and doctors' offices, employed only in 18% of cases of anaphylaxis [145]. However, as 87% of children had only one anaphylactic attack, parents or babysitters were unprepared to deal with this situation, in part because 57% of cases occurred at home and 62% of children were treated in an ED or hospital [145]. Pay attention to *peanut oil,* which may be used as an excipient of epinephrine [138]. Initially, epinephrine inhalation was not recommended as an alternative to the parenteral route [36], and the inhaler was withdrawn worldwide in 1998, due to the chlorofluorocarbons (CFCs) of the spray and the supplier's inability to guarantee long stability of the product [221]. This inhaler delivered 150 µg/puff: an indisputable advantage was its easier and immediate utilization, since it allowed a more rapid and constant absorption compared to the SC route [221].

Reactions of Intermediate Severity

- First of all, *administer inhaled epinephrine.* An alternative method for epinephrine inhalation consists in the administration of an aerosol including a 1:1,000 aqueous epinephrine vial/10 kg bw (body weight) and normal saline, up to a maximum of three epinephrine vials, possibly *by a three-way connection,* to administer at the same time epinephrine, O_2 and if required beclomethasone dipropionate (G. Taranto, G. Giarratana, pers. comm., Nov 5, 2002).
- Alternatively, *racemic epinephrine* (Racenephrine HCl) (doses in Table 11.16) may be administered for 5 min *by a nebulizer* with continuous flow of O_2 of 4–6 l/min (Nellcor PB Raindrop medication nebulizer). It should be stored in a cool, dark place. Discoloration is an indication for discarding epinephrine. *Additional epinephrine preparations* include:
- *Epinephrine bitartrate:* metered dose inhaler: 0.35 mg/inhalation
- *Epinephrine hydrochloride:* solution for inhalation: 1:100, 1:1,000 (Community Pediatrics Committee, Canadian Paediatric Society, May 2002)

Pay attention to the content of *metabisulfites* [123], present in levo-epinephrine preparations as a preservative (racemic), or in epinephrine acid tartrate as a vehicle,

Table 20.17. Epinephrine body weight-based dose

Body weight	Dose
3 kg	0.03 ml
5 kg	0.05 ml
10 kg	0.10 ml
15 kg	0.15 ml
20 kg	0.20 ml
30 kg	0.30 ml

The dose may be repeated q 15 min if necessary q 10–20 min ×3–4, not >0.3 mg per dose. Epinephrine acts within 5–6 s and its action persists for 30 min (ml and mg are equivalent).
Data from G. Taranto, G. Giarratana, pers. comm.

which may be the case of failure of two studies referred to in Chap. 11 in the treatment of bronchiolitis. Interestingly, the two positive studies employed epinephrine diluted in normal saline, as we do, and suggest doing, in other cases, as do G. Taranto and G. Giarratana (pers. comm.)

- *IM epinephrine.*
- *IV epinephrine.* Note that a 1:1,000 aqueous epinephrine solution in 10 ml of normal saline produces a 1:10,000 solution; in addition 0.01 ml of a 1:1,000 aqueous epinephrine solution yields 10 µg and 0.1 ml yields 100 µg; for example, adding 0.5 ml of a 1:1,000 dilution to 100 ml of normal saline at 5%, a solution at a 5 µg/ml concentration results.

A recent study stresses that the mean maximum plasma epinephrine concentration was achieved at a mean time of 34±14 min by 6/9 children and only 2/9 children achieved maximum plasma concentrations by 5 min. In 8/9 children who received IM epinephrine, the mean maximum plasma concentration was achieved at a faster mean time of 8±2 min [188]. Thus, even when SC epinephrine is injected promptly, it may not always be effective [22, 188, 228]. Therefore, *in severe cases, IV, or IM, or inhaled epinephrine should be preferred*.

It necessary, continue as follows:

- Administer SC 1:1,000 aqueous epinephrine, 0.01 ml/kg bw, repeat epinephrine twice q 10–20 min as needed (maximum dose, 0.2–0.3 ml/kg), or terbutaline in children <12 years of age, 0.005–0.01 mg/kg per dose (maximum dose, 0.4 mg) to be repeated in 15–20 min, in children ≤12 years, 0.25 mg/kg per dose to be repeated in 15–20 min, as needed. Table 20.17 shows a body-weight-based epinephrine dosage.
- In case of *injections and insect stings* in the absence of contraindications, infiltrate site of inoculation or puncture with one-half dose of epinephrine, 0.1–0.2 ml unless the puncture is not localized on the head, neck, hands or feet.
- To modulate possible *late-phase sequelae,* give diphenhydramine: 1 mg/kg per dose q 4–6 h IV or IM with maximum daily dose of 300 mg (5 mg/kg).

• All children should be monitored up to 24 h [170, 204]. However, satisfactory treatment should be continued *until symptoms improve sufficiently or subside,* so the child can be released from the hospital, with precise instructions to take the child immediately to the ED if a relapse occurs, an unexceptional event that cannot be prevented by CS administration along with the emergency treatment [136] (Tables 17.7 and 17.8).

Shock (Severe Reactions)

Anaphylaxis must be treated with IV therapy. Many children should be rehydrated due to excessive insensible loss from respiratory effort, abundant diuresis, and vomiting. Initial therapy must include intravascular volume repletion with normal saline, correction of electrolyte imbalance, and fluid and electrolyte maintenance

First Aid Treatment (ED)

[64, 103, 151, 155, 170, 188, 219, 226, 231]

1. *Immediately give IM epinephrine* into the arm every 5 min in case of hypotension. However, IM injection into the anterolateral thigh (*vastus medialis*) produces higher and more rapid peak plasma levels compared with those of IM injections administered into the arm; otherwise the absorption is too slow. The time to peak plasma epinephrine concentration (t_{max}), accompanied by prompt physiological effects, was 8±2 min after IM injection, significantly shorter than the t_{max} of 34±14 min (range, 5–120 min after SC injection [187]).
2. Alternatively, administer *inhaled, or racemic, or IV epinephrine* (1:10,000), also *by continuous flow,* or use EpiPen (0.3 mg), or EpiPen Jr (0.15 mg) may be injected *through clothing* into the anterolateral thigh.
3. *Monitor vital signs* including blood gas, BP, ECG; measure or estimate bw to calculate proper drug dosage.
4. *Start peripheral IV line.* Request CBC with differential, electrolytes, blood gas analysis, base excess (BE), etc.
5. *Place child in Trendelenburg* position (if not done previously), with head elevated in case of laryngeal edema.
6. Before any question arises about the adequacy of cardiopulmonary function, *give supplemental O_2 humidified* to 30%–40% (4–6 l/min) by nasal cannula or mask or if necessary by Ambu bag to prevent tissue hypoxia, which fosters vascular collapse; be ready for a possible intubation.
7. Secure and *maintain adequate airway* (mucus aspiration, application of Mayo tongue depressor).
8. (a) If the response is slow or inadequate, or BP is <60 mmHg, the recommended initial resuscitation dosage in children is *epinephrine 1:10,000 dilution for slow IV infusion* (over 5 min) at the dose of 0.1–0.2 ml/kg repeated every 3–5 min for ongoing arrest [103].
(b) For initial resuscitation, a commonly used sequence in children is *a continuous infusion* started without delay at the dose of 1 µg/min, with increments depending on the response; increasing to a maximum of 10.0 µg/min for adolescents.
(c) Inhaled epinephrine, repeat as above, if necessary.
9. *Check pH and BE, correct acidosis* by measuring BE: if the result is <–5 mEq/l give $NaHCO_3$ (sodium bicarbonate) 1 M ml is = to BE × kg bw/3.
10. Otherwise, *give enough IV fluid,* administer an IV solution as follows:
• *Normal saline,* 5% glucose, children should receive 20–30 ml/kg IV in the 1st h; *if hypotension persists*:
• *Plasma* or 5% human albumin at a dose of 10–15 ml/kg IV.
11. If needed, antihistamines IM *to prevent urticaria recurrence:* chlorpheniramine may be given by IM or slow (add to 5–10 ml of NaCl, sodium chloride) 0.9% and K^+ chloride (25–40 mEq/l) and give over 1 min IV injection at a dose of 2.5–5 mg to 1- to 5-year-olds, or 5–10 mg to older children [151].
12. *H_1 and H_2 antihistamines IV* such as ranitidine in 25 ml of normal saline (50 mg/2 ml) over 5 min at the dose of 12.5–50 mg (0.01 ml/kg) or 1–2 mg/kg up to 50 mg, or diphenhydramine as above [224].
13. *CS IV to prevent biphasic anaphylaxis* or late or persistent sequelae: hydrocortisone, 5–10 mg/kg (caution in subjects with past ASA-induced anaphylactic shock), up to 500 mg q 4–6 h, or methylprednisolone, 2–4 mg/kg in 25 ml of normal saline over 5 min by the peripheral IV line, max 100 mg q 4–6 h [224].
14. Continue to *administer fluids,* antihistamines, CS, etc., even once the child has sufficiently recovered.

Pay attention to the *potential relapses of anaphylactic symptoms* (cases of biphasic or persistent anaphylaxis are frequent). Because of delayed effect of CSs and the possibility that acute symptoms fail to abate wholly after ED treatment, children should be kept in an observation area up to 12–24 h before dismissal. If necessary, the child should be immediately taken to the nearest medical facility [171] and monitored over a 24-h period [22].

There is a deplorable tendency to rely only on CSs (72%) or antihistamines (20%); in anaphylactic cases noted to date, only 18% have been treated with epinephrine compared to CSs [145], also because epinephrine may be *underused by the medical staff* [128]. However, epinephrine use in the treatment of anaphylaxis should be promoted because, even among hospitalized children, the first drug used in the ED was CSs, although it is well known that epinephrine is the first choice of treatment during anaphylaxis [145]. *CSs may have no effect for 4–6 h* and *antihistamines have a much slower onset of action* compared with SC or IV epinephrine [103].
• *Angioedema and acute urticaria* generally respond to H_1 and H_2 antihistamines, which are not adequate epinephrine equivalents [36]. Systemic CSs are usually

Table 20.18. Home and out-of-hospital fixed-dose of self-injectable epinephrine by subcutaneous route

Brand name	Dose (mg)	Comments
Ana-Kit[a]	0.30	Appropriate for infants weighing less than 12 kg[b]
Ana-Guard	0.30	Syringe ready with needle dispenses 4 doses = 1 ml epinephrine for 12–25 kg and >25 kg body weight
Anahelp[a]	0.25	
Epi-Pen[a]	0.30	
Epi-Pen Jr[a]	0.15	With a shorter needle
Fastjekt junior	0.165	IM, for children weighing no more than 45 kg[c]
Fastjekt for adult use	0.330	IM
Min-I-Jet[a]	0.5[d]	IM, see notes for adult use

Data from [36, 142, 190].
[a] Kit available in two monodose preparations.
[b] Relatively low priced; however, it is more difficult to self-administer than Epi-Pen.
[c] Dose for *children weighing about 16.5 kg*.
[d] Costs only 15 % of Epi-Pen and consists of a cylinder predisposed with a needle which acts as a plunger.
Epi-pen and Fastjekt emergency kits contain a spring-activated concealed needle. Ana-Kit allows separate delivery of two doses like Ana-Guard, but contains sterilizing swabs, tourniquet and chlorpheniramine tablets (optional). Anahelp's separate plunger has four small position wings allowing four doses of 0.25 mg if broken away. Min-I-Jet consists of an injector with a mounted needle and a separate vial, which acts as the syringe plunger [142]. The preparation should be stored in dark and cool repositories. Checking the expiration date, which for Epi-Pen, for example, is 24 months. Ana-Kit may remain for 24–30 months at ambient temperature [142]. Fastjekt preparation should be checked every 15 days and discarded if the solution shows staining and/or precipitates. Ana-kit is no longer available in the USA. The Epi-Pen auto-injector is supplied in light-resistant packaging, and each 0.3 ml dose contains 0.3 mg epinephrine, 1.8 mg sodium chloride, 0.5 mg sodium metabisulfite, and hydrochloric acid to adjust the pH from 2.2 to 5.0. The Epi-Pen Jr contains epinephrine 0.15 mg and the same additional ingredients in the same amounts as in the Epi-Pen [187].

not employed acutely but may be helpful in refractory and/or prolonged reactions and in asthmatics treated with oral or topical CSs [151].

- *If wheezing does not respond* to epinephrine, add inhaled albuterol (0.1–0.15 mg/kg per dose up to 5 mg q 20 min over 1–2 h) in 3 ml of saline and/or IV theophylline (22 mg/ml, 2.5 mg/kg over 15 min) at a dose of 3–6 mg/kg depending on whether the child has received oral theophylline over the previous day (Table 11.45). Pay attention to children on current use of long-acting theophylline (the toxicity of theophylline with a level of >20 µg/ml).
- *Epinephrine is the best medication* to treat even the most severe form of anaphylaxis [221]. It is contraindicated only in coronary heart disease, an issue usually unknown in pediatric patients [104]. Self-injectable epinephrine is available in a kit with tourniquet and a preloaded syringe, containing epinephrine 1:1,000, an antihistamine tablet and a single-dose alcohol applicator. Alternatively, a spring-loaded, pressure-activated system is available [142]. A limited number of these formulations are available for out-of-hospital use [190] (Table 20.18) [142, 36, 190]. However, since the available doses vary between 0.15 and 0.30 mg, it is impossible to treat all infants, children, and adolescents from birth to the 17th birthday within this narrow range [190]. Recently, five children with a mean weight of 18 kg received the 0.15-mg dose, and five children with a mean weight of 25.4 kg received the 0.3-mg dose. In those who received 0.3 mg, systolic BP was significantly higher, but adverse effects were also more common (palpitations, headache, nausea). The authors concluded that the beneficial and adverse pharmacological affects could not be dissociated, and premeasured doses would facilitate more precise therapy for infants [191]. However, in a nonemergency setting, parents took a mean of *142 s* to draw up the medication, and half of them were >30 % off the requested dose [189].

The symptoms of *epinephrine overdose*, or inadvertent IV administration include tachycardia, vomiting, pallor, chills, cyanosis, blurred vision, irritability, sweating, ventricular arrhythmia, further pulmonary edema, respiratory failure and death. The antidote is phentolamine IM at the dose of 0.15 mg/kg; in case of no response an immediate admission is crucial. In addition to restoring the circulating cell mass, it is necessary to correct, if present, metabolic acidosis, hypoglycemia and/or hypocalcemia.

With no improvement, or subsequently to resolution of anaphylactic symptoms, the child should be admitted to an *intensive care unit (ICU),* or at best within the hospital, to prevent the risk of late forms of shock. Every effort should be made to prevent future reactions, especially to foods and drugs. Therefore first aid management should be as early and effective as possible including, if needed, *cricothyrotomy* [167], because a life-

threatening crisis may occur regardless of a pertinent and timely treatment. Since the complications of an anaphylactic shock and its management are very challenging, it should be handled in an individualized manner in accordance with the clinical features of the child and symptom severity. Management is not always appropriate: 3/7 patients were initially treated with oral drugs [228]. Dibs et al [57] point out striking differences when comparing in- and out-of-hospital sites of occurrence. In-hospital reactions were elicited by latex (n=15), IV medications (n=6), IVIg (n=1), and radiocontrast material (n=1). Surprisingly, reactions occurring out of the hospital with identifiable agents were triggered by foods (n=14), insect venom (n=8), and oral medication (n=2). Oral and SC agents were seen exclusively in the out-of-hospital group, whereas IV agents were responsible for all but two of the in-hospital reactions. The former group also had a greater prevalence of FA, atopy and asthma during their reactions.

Once emergency care has been provided, the basic management should treat the prominent symptoms (urticaria, wheezing, etc.), which is more demanding in CS-dependent children [64].

Prognosis

Prognosis varies greatly and is certainly very challenging when anaphylaxis is very severe and proteiform [225]: the briefer the interval between exposure to an allergen and onset of clinical manifestation, the more severe the reaction tends to be [55]. Therefore, prognosis depends on the route of administration, sensitivity of the recipient, duration of the latent period, time required for the recognition of an adverse reaction, and medical management within reach [179]. In the majority of cases, an allergic reaction occurs in a typically sudden and unpredictable way and with symptoms in some cases that make the earlier and more appropriate treatment ineffective [18]. Fortunately, cutaneous signs, urticaria, or angioedema are present in 80%–90% of reactions. In IA, recovery is reported in 65% of frequent and in 91% of infrequent cases [109]; two fatal cases are known [110, 153] in addition to near-fatal ones [153].

Prevention

The superlative treatment of anaphylaxis is prophylaxis, which requires first and foremost a recognition of the risk for fatality. The most pressing guideline in preventing anaphylaxis is a thorough food and drug allergy history and use of related substitutes [224]. The best control of allergic reactions should consist in their anticipation and prevention: the more severe the reactions, the more likely the attack is to be fatal or near fatal in a substantial proportion of cases. Table 20.19 [113] outlines and amalgamates the basic principles of drug anaphylaxis prevention. Specific recommendations for young victims of anaphylaxis can be summarized as follows:

Table 20.19. Prevention of drug-induced anaphylaxis in drug-allergic children

1. Identify causes of anaphylaxis and at-risk children
2. Avoid exposure to those agents whenever possible
3. Give drugs orally and slowly rather than parenterally, where appropriate
4. Ensure that children wait in office 30 min after drug administration, under observation
5. Provide instruction on proper, thorough reading of medication labels
6. Provide children at risk of anaphylaxis with warning identification
7. Provide instruction of predisposed children in proper use of self-injectable epinephrine
8. Use human serum preparations when antiserum is essential
9. Use skin tests when applicable
10. Use supervised preventative protocols for the following drugs:
Local and IV anesthetics Skin testing Occasional challenge testing
Radiographic contrast material Prophylactic pretreatment
Blood and blood products in selective IgA-deficient patients Washed erythrocytes Autotransfusion IgA-deficient blood used
Special drugs (ASA, penicillin, insulin) Short-term desensitization
Insect venom Long-term desensitization

Modified from [113].

- Allergic or intolerant children and adolescents

– Prospective and true sufferers of *past anaphylactic episodes*: a careful family and personal history is mandatory, and existing concerns on the possible association between atopy in allergic children or only with positive FH, and these children should be examined before prescribing any medication included in Tables 20.1, 20.9, and 20.10. In 46 of 76 (61%) children who had been enrolled in the previous study [145], 14 (30%) had experienced a recurrence of anaphylaxis [46]. Nine children out of 44 (20.5%) had a relapse during the following months [128]. In either case, physicians should provide these children (or their parents) with a list of foods causing anaphylaxis. The lists of incriminated foods and drugs should also include those responsible for cross-reactions.

Table 20.20. Prevention of food-induced anaphylaxis in children

1. Take a thorough food-allergy history
2. Identify cause of anaphylaxis and the children and adolescents at risk of future attacks
3. Educate children, adolescents, parents, day-care providers, caretakers, school personnel, and restaurant, pizza-shop, fast food managers, and other public institutions about potential food-induced anaphylaxis
4. Educate pediatricians, GPs and nurses on the danger of partly hydrolysate formulas in children with CMA
5. Provide emergency kits containing epinephrine in spring-loaded self-injectable syringes to at-risk children; parents, day-care and school personnel
6. Educate parents and older children on proper reading and interpreting lists of ingredients on packaged foods (careful attention to biochemical terms or technical jargon) where appropriate
7. Parents and children over 7 years old must be trained to use such kits
8. Predisposed children should carry warning identification, MedicAlert bracelets or chains at all times
9. Food manufacturers should provide unambiguous ingredient listings on prepackaged food labels, identify the potential for contamination during food processing, take steps to eliminate contamination during food processing

Data from [167, 171].

– For children *sensitized to specific foods* (Table 20.20) [167, 171], hints can be found in Tables 20.4 (foods and additives most frequently involved), 20.5 and 20.6 (hidden sources), and Appendices 9.9 (hidden sources of several foods) and 10.1 (foods and non-food products potentially containing vegetable gums). The role of ingredient labels and undeclared allergens in purchasing prepackaged foods should not be overlooked [96, 140, 211].

- Special Issues

– *Is the allergic child safe at home?* The anaphylactic event occurs at home (Table 20.14) in 25% [65], 57% [145], or 78% of cases [140], sometimes because of a lack of parental surveillance [140]. The first reactions to peanut and/or tree nut occurred primarily in the home (72%) [185]. The use of colored stickers to mark forbidden foods clearly, such as those provided by lay organizations, might diminish the risk of giving a food inadvertently [65].

– *Is the allergic child safe at school?* As discussed in Chap. 9, school personnel, the child's teachers, day-care providers [3], and all people in contact with the child should be informed.

– *FA reactions are common in schools* and preschool, as almost 20% of children experienced such reactions in school in the past 2 years [147]. The mere presence of an information pack and action plan decreases the incidence of allergen exposure in school and day-care facilities [140]. The reactions took place at school in 22% [140] or in 38% of cases [148], the meal was at school but prepared by parents in 8.8% [140], 50% [147], or 69% of cases [148].

– *Moneret-Vautrin et al encountered the refusal of a member of the teaching staff,* and of a school physician in two cases [140]. On the contrary, in the cohort of 100 subjects [186] in 55% of the teachers, in 10% of cases school nurses and even school secretary or cafeteria workers took charge of the situation. In 60% of cases parents were notified about the emergency. In one report, 66% of children with anaphylaxis did not have emergency medication available at school, an emergency action plan, or a teacher on site able to administer epinephrine for first aid use [29]. In another 77% had the medication available in school, and 81% stated that the school knew the indications for administration [184]. Otherwise, the medications were kept in the health room in 71%, the classroom in 26% [147], the nurse's office in 46%, with the teacher in 23%, in the child's bag in 18%, and in the front office in 15% of cases [148]. The emergency kit was stored in the classroom (51.3%), in the infirmary of the junior high school (23%), or in the director's office (25.7%) [140]. An emergency plan was in place for 53% of the reactions, but it was followed only 73% of the time [186]. Active parents provided schools with protocols and medications for treatment of acute allergic reactions in 91% and 93% of children, respectively, but 50% of schools utilized their routine medication forms for instructions for treatment of allergic reactions, whereas 50% used specific forms [148]. The use of Epi-pen will help to overcome the reluctance of staff members [140]. A positive prevention was accomplished by 71% of schools that made available special accommodation for children with food allergies: restricted peanuts from the classroom (25%), alternative meals (21%), separate eating areas [221], peanut-free tables in the cafeteria (8%), and other means (17%) [148].

- *Is the allergic child safe in public places?* Public venues are becoming increasingly common sites for unattended reactions. Such locations include stores, malls, sporting event sites, transportation vehicles, airlines, railways, and restaurants [185].

– *Eating away from home* (bakeries/doughnut shops, cafeteria, ice-cream and confectioner's shops, etc.) should be forbidden, parents should be instructed to request lists of ingredients from restaurant personnel [226].

– *Parents of children allergic to peanut and tree nuts* altered their approach to restaurants and other food establishments as in two CM- and nut-allergic children in a variety of ways, including always carrying medications (91%), avoiding specific types of restaurants (89%), asking more questions (84%), and 19% reported that they would reduce their frequency of eating out [77].

– In France, *a personalized care project* (PCP) has been instituted for children presenting IgE-dependent FA. One-third of children with PCP or an integrated care plan had an allergic reaction compared to five out of six children without such a plan [140].
– Epinephrine should be included in the *emergency medical treatment kits of schools, restaurants,* rail and bus carriers, airlines, other public facilities and other trained personnel in a position of responsibility for public safety, such as teachers, sport instructors, camp counselors and scout leaders [4]. We would also suggest that persons in designated position of public safety, who may be called first on the scene of accidents, including policemen, firemen and traffic policemen, etc., be correctly trained so that they can administer epinephrine as needed [226]. However, babysitters were unprepared [145].
– Not all parents were sure of entrusting the responsibility of first aid *to a nonmedical adult,* even though fully trained, who should judge the need for injection. Some teachers have argued that it is not their responsibility to make such decisions [151].

- Additional issues for children who have a history of previously suffering from reactions: objective SPT investigations should be requested, possibly with an in vitro test based on history clues (see "Diagnosis"), with the target of unmasking responsible agents, particularly the foods responsible for EIA [165], or a latent sensitization to muscle relaxants [139].
- When there is foreseeable *long-term contact* with these agents that are particularly necessary (a life-saving drug), the physician should evaluate the prospect of a desensitizing treatment [18].
- When there is foreseeable immediate or short-term contact, a prevention program with antihistamines and CSs should be started.
- In cases of *absolute urgency,* it may be medically necessary to administer *a radiocontrast agent,* particularly IV, to a child in whom it previously caused an anaphylactic reaction: the child should take as prevention prednisone (13 h, 7 h and 1 h before) + diphenhydramine (1 h before) ± epinephrine (1 h before) [119]. Alternatively the patient could be provided with a kit containing EpiPen (Table 20.18).

The Achilles' heel is that epinephrine autoinjectors are underprescribed in the pediatric population at risk of anaphylaxis [190], and many doctors provide parents with preloaded epinephrine syringes *without training parents in their use* [18]. Indeed, often patients do not receive a prescription of self-injectable epinephrine, nor are preventive measures suggested, nor are they sent to a specialist for the necessary assessment in 58.8 % of cases [105].

As has been suggested in similar cases, children at risk should permanently wear a *Medical Alert bracelet* listing the food allergens that may cause an anaphylactic reaction and carry a *cellular phone,* which for younger children will be that of the accompanying parents. This is a necessary precaution because three patients with near-fatal reactions did receive epinephrine within 15 min of developing symptoms but still went on to develop respiratory collapse requiring mechanical ventilation and vasopressor support [171].

Cold-Induced Urticaria

For patients with cold-induced urticaria, a non-stop prevention with antihistamines is suggested, as well as the above-mentioned kits [136].

Exercise-Induced Anaphylaxis

Children with EIA should avoid all activity for 2 h (even better, 6 h) after a meal, especially if consisting of shrimps and certain vegetables, stop exercise as soon as a sensation of even mild pruritus is perceived and for all eventualities, be accompanied by an *adult capable of administering epinephrine*. We also suggest that these subjects be provided with a *cellular phone.* Taking cromolyn before a meal and exercise was crucial for all parameters. In an epidemiological survey, only 31.1 % of teachers had ever heard of EIA [200].

Sulfites

Tables 10.3 and 10.4 list foods containing these additives for subjects with past *reactions to sulfites*.

Tomorrow's Treatment of Anaphylaxis

TNX-901, a humanized IgG1 anti-IgE mAb, recognizes and masks an epitope in the CH3 region responsible for binding to the high-affinity FcεRI on basophils and mast cells. A DBPC, randomized, dose escalation trial was conducted with 84 patients with a history of peanut allergy. Allergy was confirmed by a DBPC oral food challenge (OFC) and patients were randomized 3:1 in three dose groups to receive either TNX-901 (150, 300 and 450 mg) or placebo SC every 4 weeks for four doses. They underwent a final OFC within 2–4 weeks after the last dose of study medication. From mean baseline values of 178–436 mg in the three treatment groups, the significant mean increases in the OFC threshold were 710, 913, 1,650 and 2,627 mg for the placebo, 150, 300 and 450 mg for TNX-901 dose groups, respectively. The well-tolerated TNX-901 at a dosage of 450 mg significantly *increased the threshold of sensitivity to peanut* by OFC from a level of about half a peanut (178 mg) to almost nine peanuts (2,805 mg). Thus anti-IgE therapy may be an effective long-term approach for management of food-induced anaphylaxis [118].

Pediatricians and Anaphylaxis

A very challenging task is the search for the responsible food allergens, only secondary to the hunt for the hidden substances: their recognition is critical to issue specific instructions for the immediate administration of epinephrine. This should be closely considered by *pediatricians*, who should be informed of the wide spectrum of ASA or sulfite-containing medications, capable of causing or aggravating asthma, or of provoking anaphylactic reactions. High-risk groups predisposed to fatal or near-fatal food hypersensitivity reactions include children and adolescents with asthma, especially when they do not receive epinephrine immediately following onset of the reaction, and children and adolescents having presented previously with a serious anaphylactic reaction (Table 20.21). Above all pediatricians should gain the confidence of children and their parents, to be advised of all medications and over-the-counter products they take, notwithstanding the invitations to disregard them, including cold and cough preparations, eye drops, ointments, antihistamine/decongestant preparations, injectable drugs, analgesic and antipyretic preparations, etc. Families should be provided with every variation of therapeutic regimen, highlighting clearly and without fear of causing dismay that even the more severe and/or potentially fatal reactions can be successfully prevented. Only delay in spotting the signs and symptoms of anaphylaxis can result in unforeseen complications. But anaphylaxis may present without these hallmarks, especially in the perioperative circumstances where anesthesia can mask certain signs and symptoms. The task becomes hazardous when foods are on the scene (Table 20.16), above all if we consider that:

- In so many cases of *peanut-allergic children* who suffered from anaphylaxis [9, 18, 24, 27, 30, 54, 67, 68, 74, 161, 171, 185, 228], several of them were victim of hidden peanuts [9, 18, 30, 67, 74, 130, 134]. The most frightening case is that of deodorized peanuts, reodorized and sold as almonds [170].
- In 11 pediatric fatal cases, *nobody had the prescribed Epi-pen* [30, 171, 228], as is the case with most children and adolescents [27].
- The foods with *highly suspected ingredients* were regularly eaten away from home or came from uncontrolled purchases [171, 228].
- *All seven children* experienced previous allergic reaction to the incriminated food and all unknowingly ingested the food allergen [171].
- Symptoms developed *within minutes of ingestion* [171] as in the two press-reports.

In conclusion, pediatricians should inform children and adolescents at risk of anaphylaxis to food, drugs, and stings, and their parents, as soon as they are encountered for the first time, that in the office they have epinephrine and resuscitation equipment ready for use. When history is positive to such reactions, an epinephrine kit should be prescribed [36, 190].

Table 20.21. Points to cover in the medical history of anaphylaxis in infants, children, and adolescents

1. Food, drugs, and stings suspected of having provoked the reaction
2. Quantity of the ingested food or drug
3. Length of time between sting or ingestion and development of symptoms
4. Description of the symptoms
5. Similar symptoms developed on other occasions when the food or drug was taken
6. Other factors (such as EIA) inducing serious reactions
7. Length of time since the last reaction

Autoimmune Diseases

Dysregulation of the Immune System

It is difficult to fulfill Koch's postulates when considering the etiology of autoimmune diseases (AIDs), which are multifactorial diseases where a primary role is played by genetic factors associated with environmental factors responsible for their clinical expressions [359]. Direct evidence is restricted to transplacental transmission of IgG pathogenic autoantibodies (Aab) from the affected mother to her fetus, such as in neonatal myasthenia gravis, polychondritis and Graves' disease. Indirect evidence comes mainly from AID reproduction in animal models and/or development of genetically determined AID models, and from the isolation of Aab or reactive T cells [359]. In this chapter, a multiplicity of abnormalities associated with systemic AIDs in different organs and systems will be examined.

Definitions

Autoimmunity is a condition that triggers an immune response to autologous body constituents, called autoantigens (Aag). The immune response may become manifest through humoral (Aab) or cellular mechanisms. This activity is generally prevented by control mechanisms, in particular by CD8 T cells. Normal healthy subjects possess T cells with the potential to cause organ-specific AIDs, but regulatory T cells play a dominant role in maintaining self-tolerance. Autoimmune responses are not always harmful; on the contrary, they are physiological to some extent (Table 18.1) [286, 402]. Actually, all individuals show low concentrations of Aab and autoreactive T and B lymphocytes controlled by regulatory mechanisms, which act by deleting autoreactive immature cells or inactivating peripheral mature cells [286]. When these mechanisms which safeguard the nonreactivity or tolerance to the self fail, an AID, for example, a damaging, severe and persistent autoimmune process, develops [402].

Table 18.1. Comparison between natural and disease-associated autoimmunity

Normal autoimmunity
Interaction between CD4 T cells, HLA class II molecules and APC
Interaction between CD8 T cells, HLA class I molecules and APC
Anti-idiotype antibodies
Anti-idiotype T cells
Cell–cell interactions mediated by interaction of adhesion molecules with ligands
Interaction between lymphocytes and epithelial cells
Disease-associated autoimmunity
Several factors contribute to AID pathogenesis:
a. Quantitative features of the immune response (antibody levels, size of T-cell response, IL-produced
b. Qualitative features of the immune response (antibody affinity, isotype, specificity)
c. Genetic basis (multifactorial) Genes increasing susceptibility Augmenting factors: antibody, ILs, cells of innate immunity Immunodeficiency
d. Environmental factors Infectious agents, including superantigens Physical: UV light Pollutants: cigarette smoke Iatrogenic: drug exposure Nutritional: foods, caloric intake, nucleotides, fatty acids, vitamins, minerals (Zn)
e. Random factors Underproduction of suppressive ILs Overproduction of inflammatory ILs Exposure of sequestered antigens (by trauma or infection) Somatic recombination of antibody variable regions Recombination of T-cell TcR genes Hormonal fluctuation Stress

Data from [286, 402].

Table 18.2. Organ-specific and systemic AIDs

Organ	Proven AIDs	Uncertain AIDs
Organ-specific AIDs		
Gastrointestinal tract	Ulcerative colitis Crohn's disease	
Joints	Rheumatoid arthritis	
Heart	Rheumatic fever	
Skin	Pemphigus Pemphigoid Vitiligo	Psoriasis
Liver	Primary biliary cirrhosis Acute hepatitis Chronic hepatitis	
Endocrine glands	DM Hypoparathyroidism Addison's disease Basedow's disease Hashimoto's thyroiditis	Some hypogonadisms
Eye	Sympathetic ophthalmia Uveitis	
Kidney	Goodpasture's syndrome	
Blood	Autoimmune hemolytic anemia Autoimmune neutropenia Thrombocytopenic purpura	Biermer's anemia Pernicious anemia
Brain	Myasthenia gravis Guillain-Barré syndrome	Multiple sclerosis
Spermatozoa	Some male sterility	
Systemic AID		
Dermatomyositis, polymyositis		
Lupus erythematosus, systemic		
Rheumatoid polyarthritis		
Scleroderma		
Sjögren's syndrome		
Vasculitis		

Data from [18].
DM diabetes mellitus.

Classification

AIDs include a group of diseases with different incidence, characteristics and severity, which share a common denominator: relevant immune alterations attributable to immune pathogenesis. Since AID etiology is unknown, and genetic factors are multifactorial, in most cases AIDs are preferably classified according to their tissue distribution. Those involving one or a few tissues are called organ-specific, whereas those involving many tissues are called systemic. Table 18.2 [18] summarizes the main AIDs.

Etiopathogenesis

Genetics

The role of genetic predisposition is unquestionable. Interestingly, New Zealand black mice (NZB), an AID model, develop a disease similar to systemic lupus erythematosus (SLE), whereas the white variety (NZW) remains untouched. Crossbreeding both types of mice, the hybrids (F1) develop an earlier and much more severe form of SLE. The fundamental anomaly, however, can be traced to the immune system [359]. Solid evidence has been collected by studies on family AIDs – regardless of their specificity – where, without any clinical manifestation, the proband's parents and/or siblings show higher concentration of Aab [474], and by their resolution after bone marrow transplantation (BMT) [243, 457]. Studies on homozygote (HZ) twins affected by different AIDs have shown a 15%–50% rate of concordance, thus confirming the genetic relevance in their pathogenesis, but suggesting that a large component is environmentally determined [482].

Different models have been proposed to explain the major genetic factor in AIDs [6].

Polymorphic HLA Sequences

Most AIDs show statistically significant associations with specific HLA haplotypes [359], which thus represent a relative risk (RR) for their carriers (Table 18.3) [18, 80, 125, 141, 352, 431]. Studies have also revealed associations with inflammatory bowel diseases (IBD), such as ulcerative colitis (UC) and Crohn's disease (CD).

Immunoglobulin Genes

Some pathogen Aabs have been shown to prefer V_H or V_K gene families. Actually, antibodies with different specificity may have identical sequences and idiotypes common to several individuals. For instance, public idiotype 16/6 is associated with anti-DNA codifying genes found in active SLE, and 20% of patients with SLE or rheumatoid arthritis (RA) show V_H gene deletion of their germinal repertoire, which could be a genetic predisposing factor [507]. Subsequent studies have not found such deficits in SLE-affected individuals [420]. Nevertheless, the HLA molecule and T-lymphocyte role in humoral AIDs remains undisputed. A major role is also played by clonotype convergence after isotype switching from IgM to IgG and by restriction of somatic mutations to complementarity determining regions (CDRs) [420].

TcR Genes

Predominant $CD8^+$ and $CD4^-$ $CD8^-$ have been seen in normal subjects, TcR-αβ/γδ have been found in the ileal mucosa of patients with CD [75], and γδ in patients with early-onset multiple sclerosis (MS) [386].

Interleukin Genes

Defects in IL gene structure, transcription and function and/or their receptors have been observed in several AIDs, for example, DM (diabetes mellitus) and IBD [465]. Studies on animal models show that ILs and/or their inhibitors may influence both positively (IFN-α and -β, TGF-β) and negatively (TNF-α, IL_2) the AID development; in particular IL_{12} [134, 225, 301, 433] especially in NOD (nonobese diabetic) mice [434]. IFN-γ has a positive action on experimental autoimmune encephalomyelitis (EAE), and a negative action on MS and DM [301].

Apoptosis Genes

Fas/FasL defects have been suggested to cause inadequate clonal deletion during B or T tolerance development, with consequent availability of a higher number of autoreactive lymphocytes [286]. In light of current knowledge, Fas/FasL deficit can be considered an autoimmune process accelerator, but not the only one [391]. Some cases of human SLE may have symptoms in common with experimental SLE in mice with lymphoproliferative mutations [469].

Complement Deficits

Especially C2, C4 or CR1 (CD35) deficits predispose to AID: a C2 heterozygous (HET) defect is shown in 0.3% of population, but 40% of these subjects are affected by systemic SLE and SLE-like syndromes. As for C4 allotypes, C4B3, C4AQ0 and C4BQ0 associations with DM, and C4B2 association with RA have been reported. The obvious association between complement defects and autoimmune manifestations in immune deficiency (ID) can explain ID development in different types of AID such as in autoimmune hemolytic anemia (AIHA), idiopathic thrombocytopenic purpura, etc. Even though the basic mechanisms of the ID/AID association are not fully understood, Aab presence in these patients seems to be relevant, despite the severe deficit of antibody synthesis against foreign antigens [357].

Table 18.3. Association of HLA alleles in autoimmune disease

Disease (reference)	HLA allele	Relative risk [18]	Relative risk [141]

Etiopathogenetic Mechanisms

Loss of Self-Tolerance

AID could be an expression of a tolerance deficit consequent to qualitative and quantitative abnormalities. Recent findings clarify the concept shown in Fig. 18.1 [106]: during lymphocyte maturation in the thymus, unlike Figs. 1.22b and 1.22c, specific T cells whose TcRs have high affinity for HLA–Aag complex are clonally deleted because they are autoreactive, whereas lymphocytes lacking this affinity fail to be rescued from apoptosis, as they are useless (anergic) [106]. However, cells with low affinity for HLA molecules do not attack the self, and populate the periphery, where they can recognize the pertinent Aag. Consequently, clonal deletion of T lymphocytes specific for high-affinity epitopes of self proteins promote low-affinity epitopes to a position of apparent immunodominance [106]. Control mechanisms can be escaped: for instance, directly activated T lymphocytes become resistant to suppression, or Aags bypass T lymphocytes and stimulate T or B effector cells (Fig. 18.2). Figure 18.3 shows additional models of T lymphocyte avoidance.

Molecular Mimicry and Shared Epitopes

Molecular mimicry [6] has been used to describe a spectrum of cross-recognition of non-self and self peptides thought to underlie AIDs [25] based on the necessity of escaping the host's specific immune responses [6]. Researchers found amino acidic sequences identical to those discovered in self antigens in various microorganisms [420]. Self and non-self antigens, for instance, can share a sequence of five amino acids, with a 3% probability that human and exogenous proteins contain this type of pentapeptide. Since there could be 20,000 human genes, the incidence of this could be higher [402]. There are numerous examples in nature. Mimicry in specialized endoparasites could facilitate invasion of host tissues or avoidance of host defense mechanisms [25]. Immunization with these peptides prevents T lymphocyte tolerance to Aags, thus eliciting an AID [25]. Most CD4 of transgenic mice have a TcR specific for the 1–11 peptide of major basic protein (MBP). This has led to the conclusion that EAEs develop only in animals bred in nonsterile environments [145]. Similarities between non-self antigens and host features can facilitate antigenic cross-reactivity supported by B or T lymphocytes, which elicit transient autoimmunity (TAI) or a chronic AID [25]. Researchers focused their interest on this subject, and recently they have proven that a single TcR can recognize both the immunodominant peptide MBP and a distinct viral peptide [484]. A TcR from an MS patient

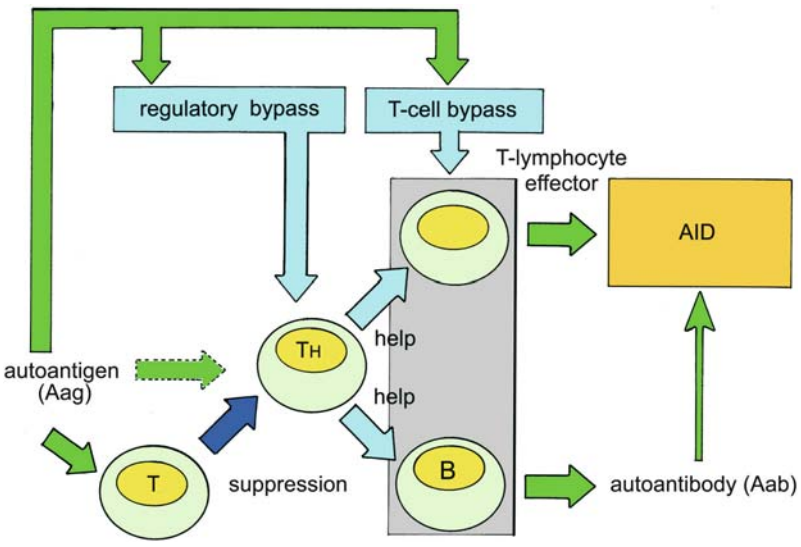

Fig. 18.2. Autoimmune disease (*AID*) may result from evasion of controls. Self-reactive B cells, effector T cells and Aag are normally present but Th cells able to induce autoimmune responses are functionally absent, because of anergy or clonal deletion, or apoptosis (Fig. 1.22), or the action of suppressor T cells. Autoimmunity may arise by a regulatory bypass, which either activates directly Th cells or indirectly T contrasuppressor, thus making T lymphocytes resistant to suppression. Aag could also bypass the Th cells by directly activating T effectors and B cells, especially if in adequate concentrations

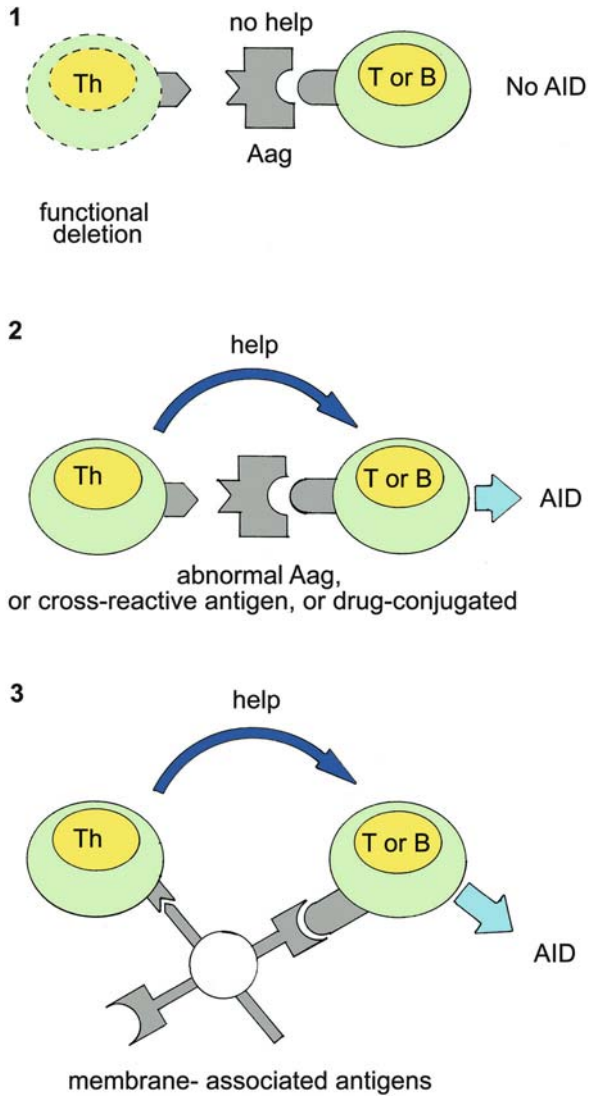

Fig. 18.3. Induction of autoimmunity by T-lymphocyte bypass. Usually AIDs do not occur because T cells reacting with Aag are functionally deleted (*1*). In the presence of cross-reactive antigens, a new T-cell subset may recognize processed antigens on the B-cell surface (*2*).The drug binding to an Aag may also be recognized by T cells as a carrier epitope, or the Aag may be structurally altered by defects in synthesis or by abnormalities in lysosomal processing. The new carrier could arise on a molecule also bearing the Aag epitope as in *2*, or may be on a different molecule, associated with Aag on cell membrane (*3*). The issue is further complicated, since the simplest viruses may express several different antigens, and each of these molecules may contain several distinct epitopes

recognized both a DRB1*1501-restricted MBP and DRB5*0101-restricted EBV (Epstein-Barr virus) peptide. The DRB5*0101–EBV peptide complex revealed a marked degree of structural equivalence to the DRB1*1501–MBP peptide complex at the surface presented for TcR recognition [219]. This provides evidence to identify homologous peptide sequences in micro-

Table 18.4. Homology between microorganisms and HLA molecules

Modified from [357].
[a] T-cell epitope.

organisms and body components as potential TcR cross-reactive epitopes, even among specific HLA proteins correlated with human AIDs (Table 18.4) [357]. Reactive arthritis following urethritis from *Chlamydia trachomatis* or gastroenteritis from *Yersinia*, *Salmonella*, etc., is an apt model for studying the molecular mimicry of these germs with HLA molecules [200]. The association between HLA-B27 and spondyloarthritis has been explained assuming that HLA-B27-derived peptides are presented by self-HLA class II to CD4 arthritogenic T cells, tolerance having been broken by mimic peptides from the triggering bacteria [388]. For instance, HLA-27 and *Klebsiella pneumoniae* share six consecutive amino acid residues (Fig. 18.4) [244]. Studies on shared epitopes fall under RA pathogenesis. In these patients, a protein from EBV shares homologous sequences with all three HLA alleles linked to juvenile rheumatoid arthritis (JRA) and uveal antigen S, and a protein of unknown function mimics part of the hypervariable third region. This would explain the frequent association between JRA and iridocyclitis [6]. A similar model may be suggested for DM [25]. These studies confirm the hypothesis that common pathogens can elicit an anti-self response, thus contributing to AID pathogenesis. However, there is still a lack of convincing evidence to extrapolate data to human pathology [474].

Cryptic Epitopes

The corollary hypothesis for the mechanism of AID infective pathogenesis is crypticism, which concerns epitopes unable to produce tolerance in conventional immune responses as they are unexpressed, expressed at a subliminal level, or hidden by dominant epitopes. This can happen because of:

- *Increased antigen degradation,* which occurs when surface receptors decrease because of high-affinity antibody or ligand inflow [369]
- *Processing modulation* when the antigen is bound to these antibodies or ligands [395]
- *Increased synthesis of HLA class II molecules* or increased expression of the adhesion and/or costimulating molecules (Fig. 18.5) [220]

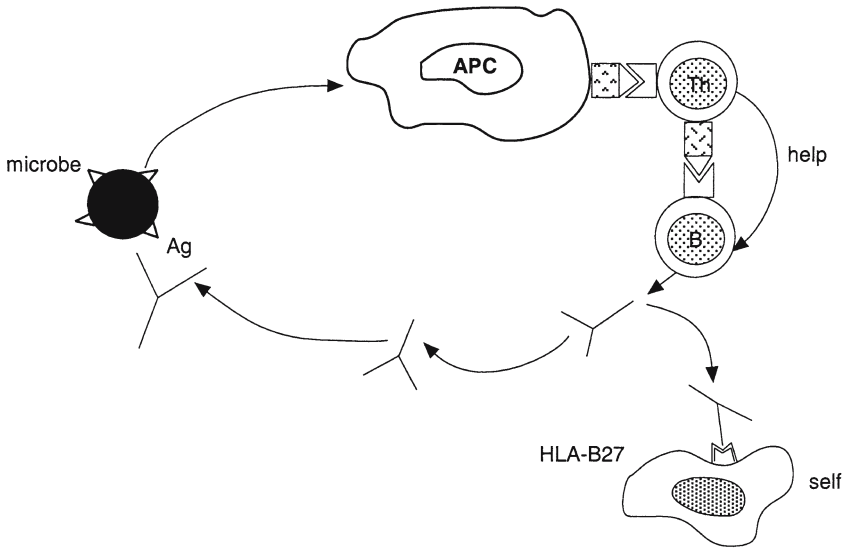

Fig. 18.4. Molecular mimicry. Microorganisms may display surface antigens very similar in structure to a particular HLA molecule. Th cells recognize processed microbial antigen and prime B cells to switch into antibody-secreting cells that react with intact antigens on the microorganisms, thus binding to HLA molecules. Following an alternative mechanism, T cells may be converted into effectors and recognize processed antigens expressed on the cell surface and complexed with HLA molecules

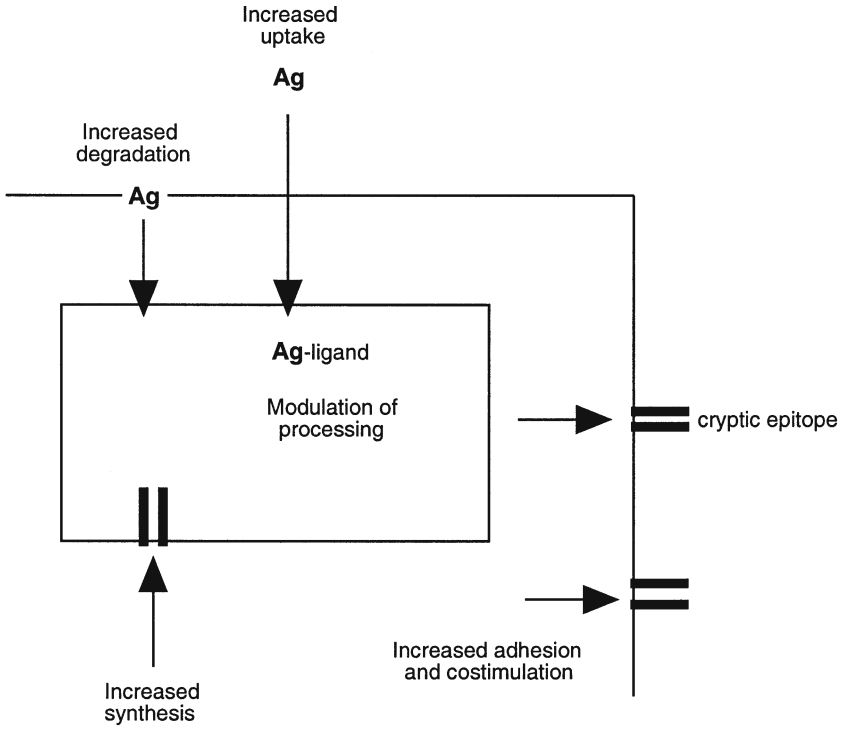

Fig. 18.5. Mechanisms possibly leading to a presentation of cryptic epitopes. *Ag* antigen. (Modified from [220])

What is the first event that activates the *autoimmune spiral?* Induction may occur through the same immune response to foreign antigens. It is also possible that cryptic epitopes are presented to nonprofessional APCs of peripheral organs such as quiescent B lymphocytes or epithelial cells [220]. Much attention has been focused on heat shock proteins (HSPs), which may provide a facilitated peptide binding to normally absent HLA molecules and an efficient presentation of cryptic epitopes [223]. In this context, T cells may also be activated by antigens presented by nonprofessional APCs or stimulated by recognized cross-reactive antigens presented by professional APCs following molecular mimicry, or by a second TcR with different antigen characteristics [220]. According to a third hypothesis, the activation of self-reactive B lymphocytes is facilitated by T-independent mechanisms, foreign cross-reacting antigens with self antigens on B lymphocytes, or by direct activation from a highly organized self antigen (Fig. 18.6) [220]. A recent study has shown that antiendomysial antibodies (EMAs) were detected in the culture supernatants of all 16 untreated celiac disease patients irrespective of gliadin challenge, as well as in 17 of the 23 biopsy samples from treated patients challenged with gliadin. The authors hypothesize that the self antigen, against which EMA are directed, are hidden, or cryptic,

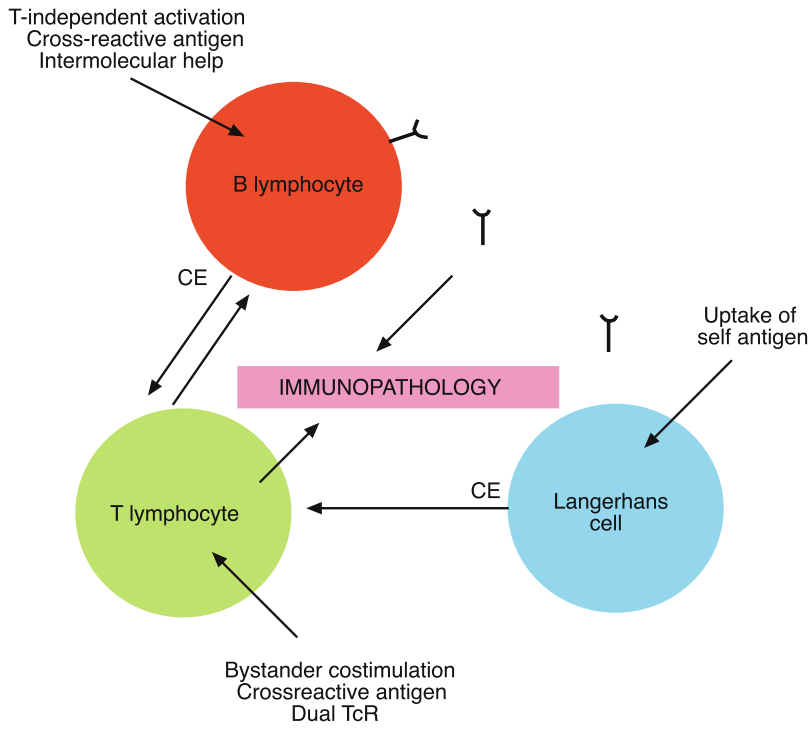

Fig. 18.6. Mechanism that may start and continue an autoimmune response to a cryptic epitope (*CE*). (Modified from [220])

and are recognized only after gluten ingestion, and preferentially recognized in the context of HLA DQ2 [330]. Celiac disease, where the trigger is well known and the pathogenic cascade is relatively well defined, is a situation that is not common in autoimmunity [239]. The relevance of crypticism appears more clearly by assuming that a first response against a cryptic epitope triggers a second wave of intramolecular and intermolecular cryptic epitopes via epitope spreading [223], which along with antigen-independent inflammatory mechanisms elicits a chronic autoimmune inflammation in RA [7] and in other chronic AIDs mediated by self-reactive T cells [455].

Modified Antigen

Sometimes, drugs induce Aab production, often persistent, even after the therapy has ended. The interaction between drug and tissue protein may induce some alterations on sites far away from the drug–protein reaction. Thus, the cells modified by the self can be recognized as non-self by the immune system and become immunogen. Antibodies or cytotoxic T cells can recognize both the native protein and the cells modified by drug–antigen action. This occurs, for instance, in autoimmune hemolytic anemia [470] AIHA. Further knowledge recently acquired in this field has shown a large number of possible applications for modified peptides, from specific immunotherapy to AID therapy. As a matter of fact, it has been observed that the replacement of just one amino acid modifies the peptide so as to prevent EAEs [297]. Studies on ligands from these modified peptides have shown new bonds to the HLA antigens headed for Th1/Th2 production [297]. It is thus possible to influence the differentiation of T cells with the most eligible HLA alleles [410] by manipulating the peptides forming complexes with HLA.

Polyclonal Activation

Recent findings observed in humans point to polyclonal activation of B and T lymphocytes as a major cause of AIDs, especially in systemic AIDs. The existence of self-reactive B cells eluding anergy and/or deletion, and thus the induction of tolerance, is confirmed by the action of a number of microbial or viral molecules (EBV; LPSs, lipopolysaccharides) (Fig. 18.7), which are polyclonal activators of B lymphocytes eliciting the Aag synthesis [420]. $HgCl_2$ injection in susceptible strains of mice and rabbits leads to polyclonal activation and an autoimmune syndrome. In the best studied model (BN rats), IL hyperproduction is induced through stimulation of CD4 Th2, whereas CD4 Th1 and CD8 are mostly stimulated in other rats. Such results could also depend on drug reactions [139]. Chronic forms of GvHDs (graft-vs-host diseases), by T lymphocyte induction in adult hybrids, are characterized by the presence of nonspecific organ Aab and the development of a syndrome similar to SLE or juvenile scleroderma (JSD). Aabs are produced by the receiver's B lymphocytes, whereas HLA class II molecules stimulate donor's Th2, leading to IL_4 and IL_5 synthesis with preferential stimulation of self-

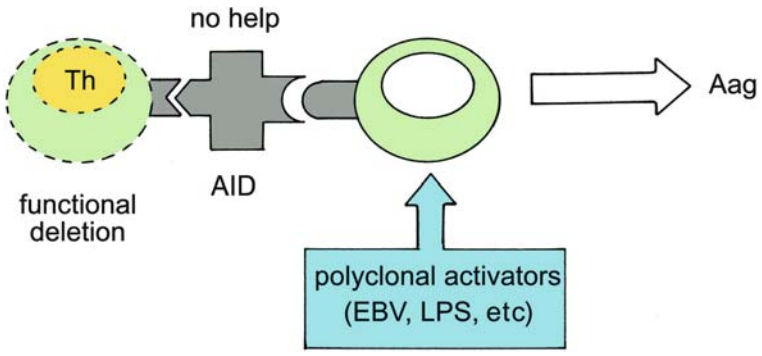

Fig. 18.7. Induction of autoimmunity by polyclonal activators

reactive B lymphocytes [139]. A similar mechanism occurs in GvHD against semiallogenic splenic cells. This protocol is used to elicit allograft tolerance in newborns. In this model, there is deletion of cytotoxic T lymphocytes (CTLs) and alloreactive Th1 T cells, while alloreactive Th2 T cells are spared, since they recognize HLA class II molecules of the receiver B cells [139]. This mechanism seems to be arguable, since Aab responses are primarily of the low-affinity IgM type, whereas tissue damage in SLE is caused by high-affinity IgG Aabs produced by T cells. In addition, IgG Aabs are antigen-dependent, though not all of them show consistent somatic mutations. Although EBV and LPS increase Aab titers in mice, either normal or SLE-susceptible, the most severe lesions are observed only in the latter. The effects of these activators can be attributed to the aggravation of SLE, but in the final analysis their impact is quite modest [420].

Idiotypic Determinants

Idiotypic determinants are seen as normal self–self interactions. In B and T lymphocytes, the idiotype consists of a set of cells with receptors that recognize only epitopes on antibody molecules produced by other B lymphocytes; T cells have similar receptors recognizing epitopes on T cells or on antibody molecules . In general, molecular mimicry may help idiotypic determinants to integrate autoimmunity mechanisms [402]. Several viruses use normal host receptors to adhere to host cells and subsequently penetrate host cells. These viruses must have equal structure, and presumably cross-react like antigens with a normal ligand for the relevant receptor. If the host develops an immune response to those viral structures, it will mount an autoimmune response to the normal ligand. Similarly, the production of anti-ligand antibodies may elicit an anti-idiotype response to that antibody; such an antibody reacts with the viral receptors [357] (Fig. 18.8). This mechanism could trigger anti-receptor conditions: myasthenia gravis, Graves' disease, etc. Broadly speaking, anti-idiotype Aabs could represent the natural outcome of a normal immune response [357]. Aab production will be constant or intermittent, depending on the infective agent consistency or intermittency. The same mechanism has been suggested for T lymphocytes [402].

Microorganisms

In principle, several mechanisms may be concerned:

- *Cross-reaction* with microbial antigens: some microorganisms have epitopes also present in self molecules. Thus, an immune reaction against these antigens could cause T lymphocytes to react with the pathogen and support antibody B production. This occurs, for instance, in RA.
- *Polyclonal activation:* some infective antigens, such as those of malaria, and EBV induce B-cell polyclonal activation, while the generated antibodies involve several self molecules.
- *Immune dysregulation:* different causes could come together, such as abnormal processing and presentation of self molecules because HLA or pathogens are more inducible, lower levels of inhibiting ILs (TGF-β), and increased sensibility and/or prolonged response to activating ILs (IL_2).
- *Possible hyperproduction of ILs:* the immune system would be by-passed by activating potentially self-reactive anergic T cells.
- *Tissue damage* can be induced via sequestered antigen release, ectopic expression of molecules, redistribution of intracellular molecules to cell surface, cryptic antigen release via increased HLA molecule expression and bystander T lymphocyte activation [420]. Bacterial DNA stimulates macrophages to release IL_{12} and TNF-α, which act in synergy to stimulate IFN-γ from T lymphocytes [286].

The predominant environmental bacterial load is demonstrated by the high variations of diabetes incidence among synergic colonies of NOD mice of both sexes, which were bred in 22 different centers [340]. On the other hand, some physiopathological conditions, especially during acute and chronic infective diseases, can cause TAI in which Aab increase is not associated with any clinical manifestation.

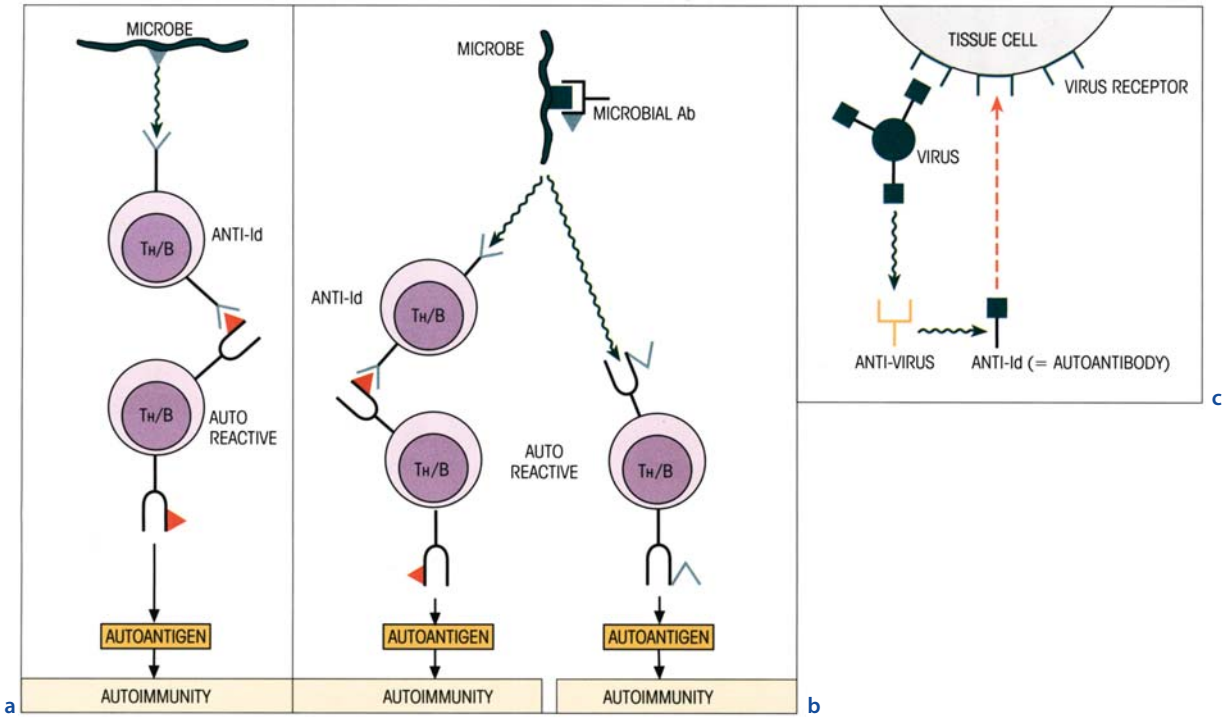

Fig. 18.8 a–c. Idiotype mechanisms leading to autoimmunity. **a** Microbial antigens cross-react with the corresponding idiotype (*Id*) on autoreactive lymphocytes. **b** Microbial antibodies either share Ids with or are anti-Id to autoreactive lymphocytes. **c** Anti-virus generates anti-id, which is Aab to viral receptors

Superantigens

Superantigens (SAs) are bacterial or viral antigens, which can activate several T and B lymphocytes and directly bind to TcRs and HLA class II molecules, without resorting to transport and intracellular processing [210]. As shown in Fig. 1.41, SAs, by binding TcR variable (v) regions and HLA class II molecules, act as a bridge between TcR-expressing T cell Vβ regions and APC HLA. In this way, T lymphocytes are activated directly without an antigen being present [210]. SAs have been suggested to intervene in the pathogenesis of Kawasaki disease (Chap. 8) and RA.

Th1-Th2 Alternation

A large body of Th1- and Th2-like T cell IL abnormalities have been associated with systemic AIDs and models; however, the Th1/Th2 paradigm (hygiene hypothesis) has no application [385]. Some occur late in illness and are probably not causal, while others may be actively involved in regulation and dysregulation of immune responses. There is not a clear demarcation line between Th1 T cells and Th2 T cells involved in cell- or antibody-mediated AIDs. However, Th1 T cells represent a significant mechanism for eliciting EAE, whereas Th2 T cells inhibit encephalithogenous T, and thus provide protection without preventing the development of EAE [231]. In view of what has been said about potential IL defects, it appears that if pro-Th2 ILs are lacking, in EAE as well as in other AIDs, the parenteral administration of IL_4 could prevent diabetes in NOD mice [231].

X Chromosome

X-chromosome inactivation and resultant tissue chimerism may explain the female predisposition to systemic autoimmunity. For example, autoreactive T cells may fail to be tolerized by self antigens encoded by one of the two X chromosomes. In the periphery, these autoreactive T cells may stimulate B cells expressing the target X-encoded antigen, so the conjecture can be extended to explain how systemic autoimmunity may be induced [406].

Hormonal Mechanism

Sex and growth hormones directly stimulate the immune response, whereas estrogens depress it. Furthermore, the close correlations between immune system and neuroendocrine system increase susceptibility to AIDs [263].

Juvenile Rheumatoid Arthritis

Definition

JRA (also called juvenile idiopathic arthritis and juvenile chronic arthritis) is characterized by chronic inflammation, synovial cell proliferation and progressive joint damage. Both terms are usually considered synonyms; however, they are characterized by arthritis persistent for at least 6 weeks in JRA. Psoriasis and ankylosing spondylitis, and other known conditions are excluded from JRA [331]. We classify RA (rheumatoid arthritis) as a general term encompassing JRA; others prefer juvenile idiopathic arthritis (JIA). According to general knowledge, JRA comprises a group of diseases of unknown etiology, which becomes full-blown before 16 years of age and peaks at 2 and 9 years in males, and at 1–5 years in females [109].

Epidemiology

Table 18.5 [112, 262] indicates frequency, male/female ratio and mean age of onset. Table 18.6 [15, 29, 30, 89, 95, 117, 158, 169, 250, 255, 323, 392, 409, 463, 483] indicates number of children, their age, subtypes of JRA, and frequency. A meta-analysis of 34 epidemiological studies of JRA since 1966 reports an annual prevalence of 0.07–4.01 × 10^3 children and an annual incidence of 0.008–0.226 × 10^3 children [254]. The mean age of onset of disease may be at 11.7±3.39 years (range, 2–15) [288], with children aged 0.2–0.7 years [250], two children aged 2.1–3 [117, 458], two girls aged 1–5 [458], and one 1.5 [95]. In Greek children, the peak ages of JCA onset were between 2 and 5 years and between 9 and 12 years, with a high female predominance in pauci articular, poly artuclar [95], and in the systemic groups [250]. Two studies [392, 483] found a male:female ratio of 1.8:1.

Classification

A classification of JRA is shown in Table 18.5.

Etiopathogenesis

Genetics

JRA, like other polygenic diseases, shows genetic anticipation, that is earlier onset and worsening conditions from one generation to another [329]. The disease gene was localized to *16q12–21* by using members of consanguineous Saudi and Arabian families for a genome-wide search for homozygous-by-descent microsatellite markers [258]. JRA-like syndrome may also be a component of the *del(22q11)* spectrum [84, 458]. In rats, RA development is linked to chromosomes 10, 12, 14 and to two *loci* at the telomeric end of chromosome 12 and APR2 (acute-phase response 2) on chromosome 5 [303], in addition to quantitative trait *loci* on chromosomes 5, 10, 17, and 18 [1].

Susceptibility to developing JRA is linked to the presence of specific immunogenetic markers such as the HLA alleles summarized in Table 18.7 [119, 343] showing that the *DQB1*0402* allele contributes most of the HLA-associated risk, although alleles at other loci contribute independently [293]. JRA is associated with both HLA class I and class II genes. Since the *E. coli* HSP DNA specifically binds within the groove of HLA class II alleles known to be associated with pauci JRA [6], the class II associations are consistently less limited than those for class I. There are some differences in the JRA

Table 18.5. Clinical forms of JRA

Clinical forms	Frequency (%)	M/F (%)	Mean age[a]
1. Systemic	34.5	19/15.5	5.0
2. Polyarticular (poly) (≥5 joints involved)			
RF (IgM) positive	3.5	3/0.5	9.6
RF (IgM) negative	12	7.5/4.5	6.8
3. Pauciarticular (pauci) (″4 joints involved)			
Type I: early onset associated with iridocyclitis and ANF	34.5	26/8.5	4.2
Type II: early onset with polyarthritis	7.5	1.5/6	10.1
Type III: with none of the above characteristics	8	3.5/4.5	6.6
4. Juvenile spondyloarthritis (see Table 18.7)			

Data related to 200 children (Department of Pediatrics, University of Pavia, Italy).
Data from [112, 262].

The incidence of spondyloarthropathy was 2.9[a] and 2.0[b]$\times10^{5}$.

subgroups (Table 18.8) [15, 46, 112, 119, 331, 343, 428, 468]: significant associations with HLA alleles can be found mostly in pauci forms, and less frequently in systemic ones [112]. Specifically, some alleles (Appendix 1.1) are shared by several forms of JRA, such as *DPB1*0201–0202* [6], *DRB1*0801* and *TAP1*0201*, whereas others are specific, such as, *DRB1*1301* and *DQA1*0101* [120]. Commonly associated with JRA are *DRB1*0404*, which implies a 47 RR, and *DRB1*0401* with a 26 RR [119]. It is significant that the alleles and *DRB1*0405* are associated with JRA, both seropositive and seronegative, in 93% of cases. However, the *DRB1*0401* allele dominates in 71% of seropositive cases, whereas one of three alleles can be equally expressed

Table 18.7. Significantly positive associations between HLA alleles and JRA subtypes

JRA subtype	HLA association	Relative risk	Confidence intervals (95 %)
Pauci	*DRB1*01*	1.41	1.06–1.90

The most recent HLA nomenclature is in Appendix 1.1.
Data from [119, 343].

Table 18.8. Forms of JRA

Systemic (a, b, c, d)
No gender predominance, no typical age of onset, from 6 months onward
Arthritis associated with fever, rash, serositis, hepatosplenomegaly, pleuritis, pleurocarditis (25%), neurological symptoms (20%), and abdominal pain (10%)
Variable characteristics of children:
Linear growth retardation, osteoporosis
Arthritis may develop long after systemic features with luxation of large and small joints and joint destruction
Late Rx changes may reveal fractures, marginal erosions
25% of children develop severe, chronic arthritis
Poly: type I (a, b, c, e)
Marked predominance of females aged ≈8 years
RF (IgM)+ : more unfavorable outcome (arthritis 50%)
Five or more large and small joints in upper and lower joints rapidly and severely involved
Chronic uveitis
Plane Rx show erosive changes as early as 6 months after onset of JRA
Poly: type II (a, b, c, d, e)
RF (IgM) – less unfavorable outcome (arthritis 10–15%)
Mostly young males
ANA+ in females aged <3 years, *HLAB27*+
Enthesitis, hips, knees, and ankles involved
Chronic uveitis
Pauci: type I (a, b, c, d, e)
Most common in young girls aged <5 years, with a girl-to-boy ratio of 1.5:1 [15]
≥5 involved joints
50%–90% of children ANA+
Frequency of iridocyclitis: 30%
No systemic manifestations

Pauci: type II (a, b, c, d, e)
Most common in male adolescents
May have a polyarticular course
≥5 involved joints
Clinical overlap with juvenile spondyloarthropathies
Enthesitis-related arthritis (a, d, e)
Arthritis and enthesitis, or arthritis or enthesitis with at least two of the following:
Sacroiliac joint tenderness and/or inflammatory lumbosacral pain
HLA-B27 antigen
Onset of arthritis in a male over 6 years of age
Acute (symptomatic) anterior uveitis
History of ankylosing spondylitis, enthesitis related arthritis, sacroiliitis with IBD, Reiter's syndrome, or acute anterior uveitis in a first-degree relative
Juvenile onset spondyloarthropathy (JOSA)
Male predominance
FH+
Later onset ≥9 years
Frequent enthesitis and arthritis affecting heel, feet, knee
Urethritis, cervicitis, or acute diarrhea within 1 month before arthritis
Acute uveitis ±10% of children
High frequency of HLA
ANA and IgM RF
Clinical forms:
Arthropathy associated with AIDs
Juvenile psoriasic arthropathy
Entheso-arthropatic syndrome or undifferentiated spondyloarthropathy
Juvenile ankylosing spondylitis JAS

See also Table 18.6.
JOSA is a term for a group of HLA-B27-related disorders. The letters a–e stem from the recent ILAR (International League of Associations for Rheumatology) classification, which has introduced five variable exclusions: a) Psoriasis or a history of psoriasis in the patient or first-degree relative, b) Arthritis in an HLA-B27-positive male beginning after the 6th birthday, c) Ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with IBD, Reiter's syndrome, or acute anterior uveitis, or a history of one of these disorders in a first-degree relative, d) The presence of IgM rheumatoid factor on at least two occasions at least 3 months apart, e) Children may not necessarily belong to the expected subgroup for enthesitis-related arthritis (ILAR) and juvenile ankylosing spondylitis (European League Against Rheumatism, EULAR) [29]. The ILAR classification system does define genetically distinct groups of patients [428] and has been recently updated [330].
Modified from [46, 112, 119, 331, 343, 468].
ANA antinuclear antibody, *RF* rheumatoid factor.

in 33% of seronegative cases [475]. In *DRB1*0405*-positive RA patients, type II collagen reactive T cells might play a pivotal role in the development of RA through IFN-ɣ production [301]. Studies on TcR genetic polymorphism have shown the *Vβ-6.1β* allele association with some forms of JRA, especially when it is characterized by pauci onset and poly course, and especially with the *DQA1*0101* allele, thus suggesting the existence of a genetic interaction between HLA and TcR genes in this particular form [57]. In contrast, a candidate disease-

associated TcR polymorphism was not identified in pauci-onset JRA [293].

Since *DQ/DR* haplotypes may influence the susceptibility to developing JRA, a pathogenetic role is suggested for the *HLA-DQ locus,* and a protective role for the *HLA-DRB1 locus.* Thus, JRA could be caused by *DQ* alleles presenting arthrogenous antigens, which start the autoimmune reaction, and by nonprotective *DRB1* [501]. Studies on genetic predisposition have shown that *DQB1*0301* (*DQ7*) and *DQB1*0302* (*DQ8*) are in linkage disequilibrium with several *DR4* haplotypes, and many *HLA-DR4* RA patients express one of these alleles. Therefore, *DQB1*0302* can be found in subjects both susceptible and resistant to RA [501]. In this case, the *HLA-DR* protection seems to prevail over the *HLA-DQ*-mediated susceptibility. Overall, an excess sharing of two *DR* alleles was found among affected sibling pairs with JRA; however, evidence was established for linkage between poly JRA and the *HLA-DR* region [341]. A less severe form of JRA is caused by the heterozygosity between *DRB1* alleles, both protective and nonprotective, while the homozygosity of two nonprotective *DRB1* increases the risk and severity of RA [88]. This explains the increased severity in *DRB1*0404 HZ* or *DRB1*0404/DRB1*0101* [474] HETs, and the reason why the homozygosity for shared epitopes implies the highest concordance for RA in monozygotic twins (MZ) [182]. As for the strong association with *HLA-DRB1*0401* or *DRB1*0101* molecules, the latter have a five-amino acid sequence in the 3rd hypervariable region of the β chain, QKRAA, which is found in many HLA-associated alleles (*HLA-DRB1*08*, *HLA-DRB1*11*, *HLA-DRB1*13*) correlated to RA. This shared epitope is predictive of a progressively destructive illness, which is dose-dependent and at high risk for these HZ genes [7, 474]: in fact, it is associated with *HLA-DRB1*1040* and *DRB1*0404* [474].

Interestingly, *HLA-DRB1*1104* was the allele most significantly associated with susceptibility to JRA [131], as well as three other haplotypes (*DRB1*08-DQA1*0401-DQB1*0402*; *DRB1*11-DQA1*05-DQB1*03*; *DRB1*1301-DQA1*01-DQB1*06*) [428]. Moreover, the pair of *DQA1*0501/DQB1*0301* alleles corresponds to the *DQ* molecule *DQ7* on the cell surface, which has been described to be strongly associated with JRA [114]. Alleles significantly participating in JRA protection were *DRB1*04-DQA1*03-DQB1*03* [428], *HLA-DRB1*1602* associated with a lesser degree of susceptibility [131], and *HLA-DRB1*1501* and *HLA-DRB1*1402* also with JRA protection [131]. An association between *HLA-DRB1*0701* was found in those ANA+ [131]. An interesting finding is the presence of both *DRB1*0307* and *DRB1*0308* in significant proportion in children with JRA and their absence in the controls. *DRB1*0307* was present in 15%–16% of children with pauci and poly JRA. *DRB1*0308* was only detected in children with pauci JRA, none of the children with poly JRA or the controls had this allele [10]. The most commonly expressed alleles were *HLA-DRB1*1104* in the pauci subset, *HLA-DRB1*0404* in the poly group and *HLA-DRB1*1602* in patients with systemic JRA [131]. In the early onset pauci subtype, positive-HLA associations with *DR11* and *DR8* alleles were shown. In the late onset pauci group, only the *B27* allele was increased [95]. Recent data suggests that a gene in linkage disequilibrium with *D6S265*5*, but distinct from *HLA-A*02* and a *locus* near the *D6S2447* microsatellite, which is flanked by *DQB1* and *DRB1* [363], could be markers for an additional susceptibility gene in JRA [363, 394]. *HLA-A* and *HLA-DRB1* were confirmed as independent susceptibility *loci* for pauci disease. Linkage of the HLA *loci* seemed to be attributable to maternal preferential transmission of alleles [503]. Twins show concordance for the type at onset, JRA course, etc. [179]: for instance, JRA developed in two 1-year-old MZ twins, with a lapse of 5 months between the first and the second [86]. Analyzing 71 affected sibling pairs, 63% were concordant for gender and 76% for onset type [283]. In an analysis of 118 affected sibling pairs, 14 pairs of twins were identified in which both twins had arthritis. One pair comprised a girl with poly and a boy with persistent oligo pauci. The other 13 pairs (11 MZ, two DZ and two of unknown zygosity) were concordant for gender (nine female, four male), disease onset (ten pauci, three poly) and disease course (eight pauci, five poly) [342]. In Finland, 41 JRA multicase families with 88 affected siblings have been collected over a period of 15 years. This study estimated the RR of JRA to be nearer 20 [377]. Within this set of families there were eight sets of MZ twins, two of which were concordant for JRA. Both sets of twins were concordant for disease course but were unexpectedly different for disease onset [368].

Immune Factors

JRA immune mechanisms, which are associated with HLA haplotypes (Table 18.7), require mast cell recruitment [193]. These are present in the synovia, localized on the microvascular endothelium, and are quantitatively correlated with activated CD4 [249], which under the action of IL_3 continue to grow and are activated along with B cells [126]. Mast cells degranulate and release mediators and ILs, thus contributing to clinical flare-ups [274] and, together with other inflammatory and adhesion cells, to the development and persistence of symptoms [476]. The role played by DCs in this and other AIDs is shown in Table 18.9 [423]. Early stages of JRA can be summarized in this way: T lymphocytes from thymus, which recognize self-HLA molecules, go through positive selection, whereas those unable to recognize endogenous Aags avoid deletion and enter the circulation. DCs, both at rest and circulating, in the SF (synovial fluid) express a relatively low number of HLA molecules with self peptides. They produce CD80 and CD86, localized in the SF near T cells, but they do not

Table 18.9. Features of dendritic cells (DCs) in autoimmune diseases (*AIDs*)

Features of DCs in diseased organs	AIDs
Enrichment of DCs	RA, CD, psoriasis, autoimmune thyroiditis
Infiltration of DCs early in disease	RA, autoimmune thyroiditis with perivascular distribution
Differentiation and expression of CD86	RA, psoriasis
More potent APCs than parenchymal cells of inflamed organ	RA (synoviocytes, fibroblasts, autoimmune thyroiditis (thyrocytes, psoriasis (keratinocytes), diabetes (islet cells)
Enhanced AMLR stimulation by DCs from inflamed tissue	RA (DC of SF) psoriasis (dermal DCs)

Data from [423].
AMLR autologous mixed lymphocyte reaction, *APCs* antigen-presenting cells, *CD* Crohn's disease, *DCs* = dendritic cells, *SF* synovial fluid.

express CD80 [423]. DCs are reinforced through differentiation when GM-CSF and TNF-α are present and induce autoreactive T cells that escaped thymic deletion to mature in lymph nodes so that TcRs can be primed through DC presentation of self peptides differentiated in the SF. This model suggests how an autoreactive response to self peptide can trigger JRA without the requirement for a synovial antigen that initiates JRA [423].

The pathogenic role played by *microbial SAs* is suggested by the Vβ-14 T lymphocyte decrease in the bloodstream, but they increase, both in number and in quality, in the SF of RA patients [210]. Normally, the exposure to a microbial SA can cause the deletion of most Vβ-14 T cells, whereas in susceptible subjects surviving lymphocytes can migrate to the synovial tissue, recognize an antigen *in loco,* proliferate oligo-clonally, and mediate the joint damage, which is a JRA characteristic [210]. Highly differentiated SF T cells expressed early and late markers of activation with little evidence of *in situ* proliferation. CD25 and CD71 significantly increased in the SF T-cell subset, but the differences between SF and peripheral blood were not as remarkable as for CD69 or HLA-DR. CD8 T cells expressed significantly higher levels of CD69 and HLA-DR than did CD4 T cells, whereas CD25 and CD71 expression was higher on CD4 than on CD8 T cells [34]. In addition to all activated, potentially pathological T cells, the SF from RA patients may contain $CD25^{bright}$ $CD4^{+}$ T cells with a regulatory capacity [49]. SF lymphocytes also proliferate in response to IL_{15}, showing their enrollment and activation in the synovial membrane, thus concurring to the pathogenesis [269].

T-cell activation may result in an overflow of events, including TNF-α release, possibly under the control of specific genetic markers. The frequency of polymorphisms at the –1031, –863 and –857 positions of the TNF promoter was shown to be significantly higher in a group of Japanese systemic-onset JRA patients compared with those observed in controls. [82]. Particular alleles of a microsatellite marker in the TNF-α gene were found to be strongly associated with early-onset pauci JRA in German patients [102]. In UK patients the association of several TNF single-nucleotide polymorphisms was detected and linkage of the *locus* to pauci JRA was established [504]. The TNF –308 and –238 polymorphisms were studied in Czech and Turkish JRA patients, but no association with either polymorphism was found [312]. In contrast, a positive association with TNF polymorphisms was reported in a large panel of UK Caucasian pauci JRA patients [502].

Another pathogenetic hypothesis involves *Enterobacter proteoglycans,* with the release of the relative IgA antibodies, whereas CMI responses are more difficult to prove [326]. Despite inconclusive evidence [453] and considering the large digestive system thin epithelial walls, one can hypothesize that a bacterial attack colonizes the intestine, with the microorganisms or their degradation products released into the bloodstream [326]. Recently, the use of an HSP antigen, which is equivalent to *E. coli*, has proven that sera from JRA patients challenged with the antigen, and all the more with SF cells, react significantly more than normal controls, or children suffering from rheumatic diseases different from JRA [6]. This data shows that JRA can represent a chronic form of RA, whose pathogenesis is in common with other disorders such as acute rheumatic fever, Reiter's disease and ankylosing spondylitis [6].

Recent developments of JRA pathogenesis introduce *bcl-2, Fas, NF-κB, and the status of apoptosis.* They show that a distinctive phenotype of RA fibroblast-like synoviocytes, that is persistent activation, proliferation, and resistance to apoptosis, is related to the autocrine activation of $IL_{15}R$ by fibroblast-like synoviocyte-derived IL_{15} [215]. IL_{15} levels in systemic JRA were higher than in controls. An increased apoptotic index correlated with raised IL_{15} [396]. However, blocking IL_{15} biological activities using $IL_{15}R\alpha$ chain substantially reduced endogenous expression of bcl-2 and bcl-x(L), and RA fibroblast-like synoviocyte proliferation that was reflected by increased apoptosis [215]. NF-κB appear to be activated in vivo, both Fas and FasL being expressed by synovial cells [391]. Apoptosis is ongoing in synovial tissues with significant patient variations, which could

be in part due to the level of Bax expression [393]. The role of galectin-1 (Gal-1) and galectin-3 (Gal-3) proteins with pro-apoptotic and anti-apoptotic properties, respectively, has been clarified. Thus, Gal-1 expression is down-regulated in patients with pauci JRA, accompanied by low Bcl-2 expression and low proliferation rates, and Gal-3 expression is up-regulated in synovial tissue from those with poly JRA [156].

Immunopathology of Joint Damage

The study of pathogenetic mechanisms is gathering an ever growing body of experimental evidence, with T cells, RSs (rheumatoid synoviocytes) and vitronectin (VN) as the major causes of damage. The damage worsened by the targeted migration of CD45 with all its ILs and integrins [74]. T lymphocytes have a clear dominant position in the synovial pannus, where *CD8 lymphocytes are mostly localized in perivascular areas,* while *CD4 cells infiltrate the stroma* (Fig. 18.9) along with B lymphocytes. Significantly, there are APCs, like the DCs [423], at the synovial level. The key role played by T lymphocytes in the progression of articular damage is demonstrated by the expression of activation marker cells such as the IL_2R and transferrin receptor (CD71), the RA improvement after total lymph node irradiation, the use of immunosuppressors, etc., or in patients with AIDS and cytopenia [382]. The CD4 population seems to be activated by the presence, on the cell surface, of cellular activation markers such as HLA class II and β1 integrins. T lymphocytes have the phenotype of memory cells (CD45RA and CD45RO), with CD25 and CD102, which cause their proliferation and activation. There is also prevalence of lymphocytes with Vβ TcR [210], not in serum, and γδ with preponderance of Vδ1 cells [468]. It is also possible that memory cells have greater ability in binding to endothelial cells and migrate to synovial tissues [74]. T lymphocytes activated by CD25 are thus highly responsive to IL_2, as proven by the presence of IL_2 mRNA in the SF [496]. Eventually, a wide spectrum of proinflammatory IL is generated: type A RSs express high IL_6 concentrations, whereas IL_1 and TNF-α present in the SF increase CD54 expression (ICAM-1) 496]. Inflammation is also caused by high-molecular-weight SF IgG stimulating $IL_{1\alpha}$, IL_6, IL_8, TNF-α and GM-CSF from PBMCs (peripheral blood mononuclear cells) [181]. Recent data have shown that these ILs also interact with IL_{13}, with potentially negative consequences for C3 synthesis in the inflamed joints [190]. Similarly, IL_{10} plays a significant role in immunity by regulating/inhibiting IL production by PBMCs and T lymphocytes [189]. The intra-articular production of rheumatoid factors (RFs) that are Aabs reacting with epitopes on the Fc fragment of Ig, mostly the IgM type, may reveal the *in situ* release of IL_6, a well-known primer of B plasma cells [382]. IL_6 levels, a well-known pro-inflammatory IL, were correlated with the degree of knee joint vascularity in 28 children with active JRA or JOSA, which may stress the role of IL_6 as an inducer of neoangiogenesis in JRA [383]. SF CD62E levels accurately reflected intrasynovial inflammation and soluble CD54 (sCD54) the effects of disease-modifying agents [35].

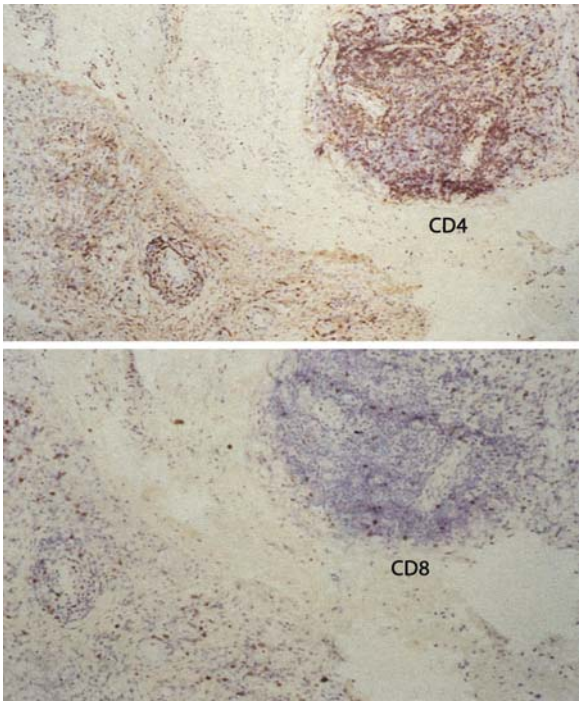

Fig. 18.9. Immunoperoxidase staining of RA synovial membrane

RSs bind to circulating immune complex (CIC) deposited on the cartilage, and since they have no FcγR (Table 1.3), they use complementary components as a go-between with CICs. The latter bind the complement and consequently VN, whose receptor is present on the RSs, which in turn can reach the cartilage surface. The following invasion front is marked by local alterations to collagen, fibronectin and other proteins from the matrix [79]. The fibronectin peptides, by interacting with synovial cell-specific receptors, can induce metalloproteinase expression in type B synoviocytes. A number of receptors for fibronectin, laminin, collagen and fibrinogen products – resulting from β1- and β3-integrin combination – have been described. The action of these superficial structures ensures a close link to the matrix. Thus, SRs are able to migrate through basal membranes and invade tissues. Cathepsins B, D and L as proteinases play a major role in destroying synovial tissue and cartilage matrix [413]. In this respect, it should be noted that SRs express large amounts of CD106, whose ligand $\alpha_4\beta_1$ is present in the rheumatoid cartilage [79]. The pathogenesis of structural modifications is summarized in Fig. 18.10. The histopathology shows the cells in action and the articular lesions: see Figs. 18.11–18.13 [357].

Additional Factors

An association with food allergy (FA) has been theorized over recent years [28, 320, 321].

Changes to diet have not always improved the symptoms consistently [319]. The theory expressed by the US Arthritis Foundation, which affirmed that there was no convincing evidence on the efficacy of these manipulations, has been disproved by further research [319]. It would be strange if FA would not imply any arthritic disease such as that seen in gout and lupus [320]. As for the pediatric age, only three cases involving the connection between joint complaints and FA in children have been described in the literature [380]. This concept, however, should be further clarified in order to avoid any disappointment for families, who might sustain higher expenses only to have simple dietary changes, which would aggravate a nutritional situation already compromised.

RA can frequently be associated with IBDs: 12% in UC, and 20% in CD. The lesion severity depends on the disease activity (see below).

Clinical Presentation

Figure 18.14 shows the disease may have an early onset. Clinical presentation in JRA includes symmetrical joint inflammation early in the course of the disease and findings of joint destruction with chronic disease. Warmth, swelling, pain, reduced range of motion possibly restricted in deeper joints, and palpable effusions characterize active synovitis [41]. Musculoskeletal pain was the most common reason for referral to a pediatric rheumatology clinic [268]. Back pain in 3.1% and neck pain in 0.6% of children were not diagnosed, perhaps because they were associated with affective disorders [250]. Clinical polymorphism appears clearly from

Fig. 18.14. Juvenile rheumatoid arthritis (JRA) in a child. Severe swelling of the proximal interphalangeal joints causing typical spindle-shaped fingers

Table 18.6 and Table 18.8, with relative frequencies for pediatric JRA. Systemic onset disease (subtype 1) is characterized by very high fever, which is characteristic, quotidian, with spikes to >39°, rarely intermittent, mostly at night, associated with one or more of the following: faint erythematous rash, generalized lymph node enlargement, hepatomegaly and/or splenomegaly, and serositis [330]. Arthritis is usually defined as palpable

swelling or effusion of the affected joints, with loss of range of motion, pain on palpation or mobilization in one or more joints, and loss of grip strength in the hands, leukocytosis, pleuropericarditis, and extended joint involvement [41]. JRA symmetrical presentation is often associated with a positive RF; manifestations are poly articular (≥5 inflamed joints), which are required as a criteria for classification of this type of onset, although as many as 20–40 distinct joints may be affected, and JRA may persist into adulthood (subtype 2 ≤5 inflamed joints). RF-negative children have joint involvement and probably less severe disease. An early-onset group typically occurs in young girls with a positive ANA (anti-nucleus antibodies) and an increased risk for iridocyclitis (subtype 2). Children with ≤4 joints involved may be defined as having a pauci articular disease. The joints most likely to be affected are the knees, elbows, wrists, knees, feet and ankles. The most important feature of JRA is joint erosion, which leads to deformity and, in severe cases, to severe disability [506]. In the subtype 3, arthritis affects the spine as well as other joints, although spinal involvement may not occur until children reach their late teens. Children may be HLA-B27-positive and suffer from musculoskeletal features of a JOSA [506]. The swelling associated with restricted movement, notably during or after periods of immobility, leads to the typical symptom of early-morning stiffness and to the easy fatigability after school in the early afternoon [343]. JRA also affects the cervical spine, shoulders, and hips, and hydrarthron of the knee or dactylitis of both the hand and foot may be found at onset [506]. Pain alone is not sufficient to make the diagnosis of arthritis [331]. The form characterized by early onset and poly progression is strictly connected to the JOSA, to which it belongs nosographically [262].

Uveitis (Chap. 14) complicates several forms of JRA. It was observed in 5.7% [483], 8% [506], or 8.6% of children during the first 6 months of the disease [30]. Mean age at uveitis onset was 4.39 [29] or 5.4 years [323]. In 158 children with JRA who had eye examinations, 39 (25%) developed uveitis, 16 of them (41%) had uveitis on the initial eye examination, and 23 (59%) developed uveitis within 4–81 months [205]. Pauci onset, ANA+, young age, but not gender are risk factors for developing uveitis in children with JRA [30]. Other authors observed no correlation between prognosis and sex, age at the onset of uveitis or JRA, pattern of JRA, or positivity for ANA or HLA DR11 [323]. Children with suspected uveitis should be slit-lamp examined, every 3 months if positive, and every 6 months if negative [323]. ANA should be viewed as a significant determinant for uveitis in JRA children [30].

Diagnosis

There is substantial uniformity among most major clinical variables that have been suggested for an objective definition of articular involvement, with discrepancies between subjective perception and objective assessment of joints [136]. Among 124 children with micrognathia, short stiff neck and short stature were noticed among poly and systemic onset JRA. Seventy percent of oligoarthritis group developed inflammatory low back ache. Bony ankylosis of tarsal and carpal bones were seen in eight cases [288]. Figures 18.15–18.22 show a wide range of diagnostic imaging (interphalangeal and temporomandibular joints, cervical spine, hand and wrist, knee, tibiotarsal joint and foot) in children aged 7–19 [63]. X-ray evident joint space damage was seen within 1 year of onset in poly children, and by 5 years 2/3 of poly and systemic children had damage [39], but magnetic resonance imaging (MRI) and ultrasound are now providing a more effective and safer alternative [184]. The major elements of the differential diagnosis are summarized in Table 18.10 [378]. They include the inflammatory seronegative spondyloarthropathy, or pauci onset juvenile psoriatic arthritis, occurring in symmetric distal *osteoarthritis-like* joint disease, symmetric proximal *JRA-like* joint disease, and *ankylosing spon-*

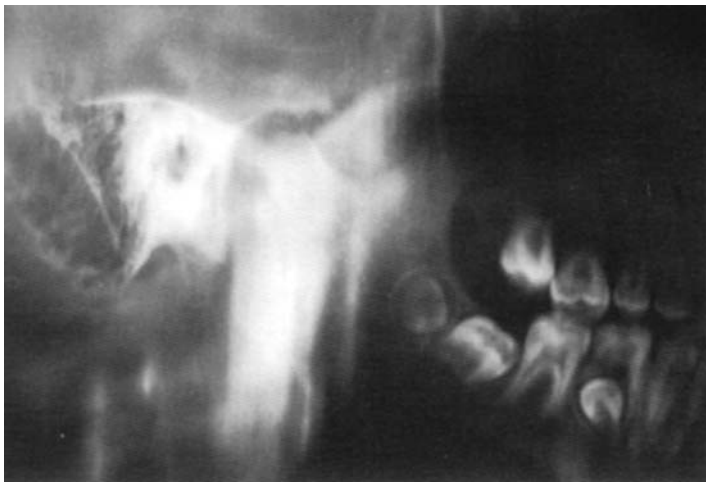

Fig. 18.15. Temporomandibular joint (TMJ). Stratigraphy in a 19-year-old boy affected with pauci JRA since the age of 18 months. Widespread ulcerations of both articular heads have provoked the destructive changes of the anterior tubercle of the temporal bone and of the proximal part of the mandibular condyle; closing the mouth, the mandibular condyle is subluxed forward and proximally

Table 18.10. Differential diagnosis of rheumatic disease

Characteristics	RA	JRA	SLE	Dermatomyositis
Sex	No predilection	Dependent on subgroup	F>M	F>M
Age at onset	≥3 years	≥1 year	Usually >8 years	≥2 years
Pathogenesis	Poststreptococcal	Unknown	ICC disease	Unknown
Manifestations				
Joint	Transient, migratory, arthritis – large joints	Pauci- or poly-articular chronic (≥6 weeks)	Arthralgia, transient or chronic arthritis	More frequent contractures occasional arthritis
Extra-articular	Fever, chorea, cardiac disease, rash, nodules	Dependent on subgroup: systemic JRA: fever, rash; pauciarticular: iridocyclitis	Occasionally systemic: nephritis, rash, CNS and hemato-logical involvement	Muscle weakness, rash, gastrointestinal pain, respiratory involvement
Diagnosis	Clinical (Jones criteria)	Clinical (JRA criteria)	Clinical (LES criteria)	Clinical: rash + myositis muscle biopsy
Laboratory	Prior streptococcal event	May have ANA, RF	ANA, low comple-ment titers, anti-DNA antibodies	Abnormal muscle enzymes, EMG, muscle biopsy
Natural history	Arthritis – transient carditis may cause permanent damage	Chronic arthritis may be destruens	Chronic or recurrent, potentially fatal	Chronic, interstitial lung disease, potentially fatal
Treatment	Prophylaxis against group A streptococcus	Anti-inflammatory, physical therapy	Anti-inflammatory, CSs cytotoxic medication	CSs, cytotoxic medication, methotrexate, alendronate

Modified from [378].
CSs corticosteroids, *EMG* electromyogram.

dylitis-like disease. Small joint disease or wrist disease within 6 months of disease onset were much more suggestive of psoriatic arthritis than those of pauci JRA [170]. Differential diagnosis of JRA also includes spondyloarthropathy, infectious arthritis, and IBD. Certain vasculitis syndromes, including Schönlein-Henoch syndrome, Kawasaki syndrome, and Takayasu arteritis (Chap. 8) should also be differentiated. Neither ANA nor RF evaluations were useful in evaluating children with musculoskeletal complaints [268]. Sex differences are not useful since girls were ANA+ in 83 of 197 (42%) and boys in 40 of 118 (34%) cases [29]. ANA should be taken into account in the diagnosis of several JRA children according to Table 18.8.

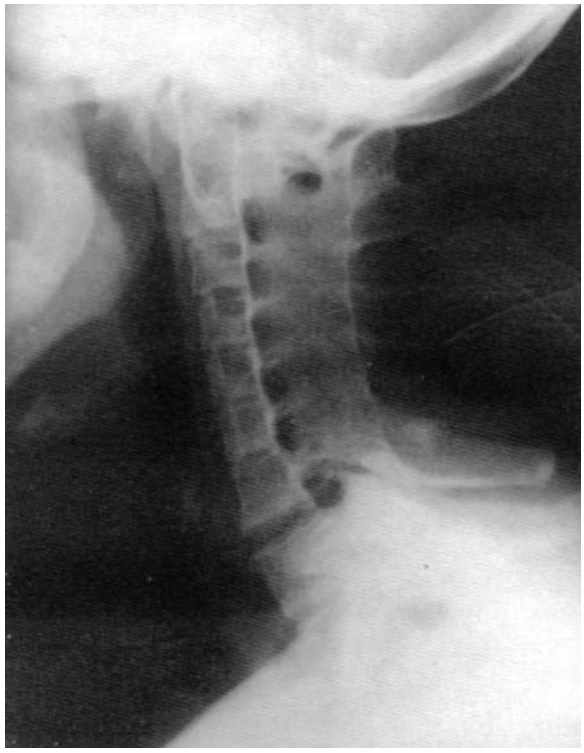

Fig. 18.16. Cervical spine. Latero-lateral projection in a 16-year-old girl affected with seronegative polyarticular JRA since the age of 12 years. C2–C7 synostosis of apophyseal spaces with consequent atrophy of intervertebral disks, hypoplasia of vertebral bodies, and loss of normal lordosis

Fig. 18.17. Hand and wrist. Anteroposterior projection in a 7-year-old girl affected with pauciarticular JRA since the age of 3 years. Reduced ulnar development with ulnar subluxation of the carpal bone; fractures by compression of the radial distal epiphysis, metacarpal heads especially laterally, and phalangeal epiphyses; tumefaction of articular soft tissues; phalangeal periostitis, and destruction and fusion of wrist bones

Fig. 18.18. Pelvis. Anteroposterior projection in a 12-year-old girl affected with pauci JRA since the age of 3 years. Widespread osteoporosis, cotyloid tectum thoroughly destroyed by confluent ulcerative foci; markedly hypoplastic femoral heads and with cranial intracotyloid luxation; striking narrowing of joint spaces; rough femoral heads in marked valgus by protracted load absence

Fig. 18.19. Knee. Anteroposterior projection in an 8-year-old girl affected with systemic JRA since the age of 2 years. Symmetric metaepiphyseal hypoplasia of femoral heads with consequent genu valgus, which contrast with hypoplastic diaphyses; epiphyseal fracture by compression of internal tibial condyles; osteoporosis; result of mean diaphysis of left femur; light narrowing of joint space, negligible erosions

Treatment

The goals of treatment in JRA are to control inflammation, prevent progressive joint destruction, preserve and improve the activities of daily living, and alleviate pain [41]. Medical treatment remains a challenge [109]. The therapeutic aspects are listed in Table 18.11 [22, 137, 263, 506]. Current recommendations are to initiate treatment with disease-modifying antirheumatic drugs (DMARDs) within 3 months of diagnosis. Commonly utilized DMARDs include methotrexate (MXT), leflunomide, sulfasalazine, and hydroxychloroquine. While some children respond to treatment with NSAIDs and intra-articular or pulsed CSs, others require further treatment. There is evidence that MXT is an effective second-line drug for such children, and it is increasingly used earlier in the course of the disease, with the aim of preventing long-term joint damage. Some children, however, have disease that does not respond adequately to MXT or they cannot tolerate MXT treatment. These patients are treated with other DMARDs.

Fig. 18.20. **a** Tibiotarsal joint and foot. Latero-lateral projection in an 18-year-old girl affected with seronegative polyarticular JRA since the age of 4 years. Secondary astragalotibial arthrosis with hollow foot and dorsal subluxation of the first phalanx of toes II–V. **b** Right forefoot. Anteroposterior projection in a 14-year-old boy affected with B27-positive JRA Para-articular ulcerative changes of the third metatarsal phalanx with narrowing of joint spaces; modest osteoporosis

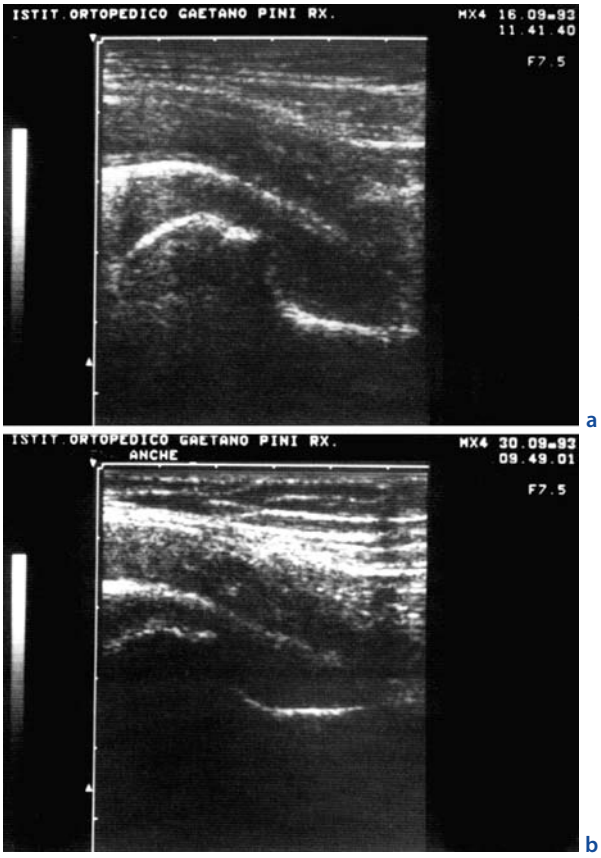

Fig. 18.21 a,b. Pelvic echography. **a** A 4-year-old boy with systemic JRA. Synovial hypertrophy and marked hydrarthrosis. **b** Same boy. Reduction of hydrarthrosis after topical corticosteroid treatment

Among US and Canadian pediatric rheumatologists, NSAIDs were the most commonly used medicines for all forms of JRA, and intra-articular CS injection was the second most common therapy for pauci JRA, but MXT was second for poly and systemic onset forms of seronegative enthesopathy JRA and arthropathy syndrome [71]. However, continuous systemic CS usage for <1 year does not affect attained adult height in JRA patients; however, prolonged CS treatment for >1 year can lead to irreversible growth impairment [464]. Chronic inflammation and prednisone therapy may adversely affect growth in patients treated with long-term CSs during childhood for systemic JRA and final height may be closely dependent both on the severity of growth retardation during JRA's active phase and on linear growth after remission [389]. It has recently reported that treatment with recombinant (r) human growth hormone (GH) restored linear growth without inducing catch-up growth, significantly improved body composition, and prevented further bone loss. Prolonged follow-up is needed to assess the benefits of GH and long-term consequences of hyperinsulinism [390]. IgG, IgA, and IgM levels fell significantly by 26%, 21%, and 17%, respectively, while on MXT, up to a in IgG to below the normal range [346]. chapter 18 reports two girls suffering from JRA who were severly worsened by unconventional remedies. It could be useful to assess whether introducing dietetic manipulations such as adequate amounts of fatty acids during the perinatal period (via breast feeding) may prevent JRA, as well as other autoimmune disease [81].

Rehabilitative cures should be provided to JRA children as soon as possible.

Magnetic resonance scan of left knee in intermediary sagittal plane before IV injection of paramagnetic contrast medium. **a** A 17-year-old girl with poly JRA since the age of 5 years. Huge distention of the bursa either of quadriceps or of medial head of gastrocnemius secondary to hydrarthrosis associated with notable synovial thickening appearing as exuberant synovial pannus, and vegetating aspect with nodules. **b** After IV injection of paramagnetic contrast medium, remarkably dense signal in the synovium representing inflammation

Table 18.11. Nonsteroidal anti-inflammatory drugs (NSAIDs) and immunosuppressors for the treatment of JRA

Drug	Half-life (h)	Daily doses (mg/kg) (PO)	No. of doses	Max dose (mg daily)	Side effects
Salicylate					
Acetylsalicylic acid	9–16	<25 kg: 70–100 mg	3	1,500	Pseudoallergy, nausea, vomiting, polypnea,
		>25 kg: 2.5–3 g (Salicylemia: 20–25 mg/dl)	4		Increased transaminase levels, irritability or sleepiness, hearing disorders
Diflunisal		7–21 mg	2–3	1,500	Gastrointestinal and auditory effects
Propionic acid derivatives					
Flurbiprofen	5–6	5 mg	3–4	300	Gastrointestinal effects
Ibuprofen	2	40–50 mg	4	2,400[a]	Gastrointestinal effects
Ketoprofen	2	3–5 mg	4	300	Gastrointestinal effects
Naproxen	13–14	10–15 mg	2	1,500	Gastrointestinal effects
Indolacetic acids					
Etodolac	7	100–200 mg	2	1,500	Gastric toxicity
Indomethacin	2–5	2.5–3 mg	3–4	200	Gastrointestinal effects, headache
Sulindac	7	2–3 mg	2	400	Gastrointestinal effects. Abdominal pain
Tolmetin sodium	2–6	15–30 mg	3–4	1,800	Gastrointestinal effects
Phenacetic acid					
Diclofenac	1–2	2–3 mg	3	200	Gastrointestinal effects
Diclofenac extended release	12	2–3 mg	2		Gastrointestinal effects
Oxicam					
Meloxicam	24	7–15 mg	1		Unknown
Nabumetone	24	0.5–1 g	1		Unknown

Table 18.11. (Continued)

Drug	Half-life (h)	Daily doses (mg/kg) (PO)	No. of doses	Max dose (mg daily)	Side effects
Immunosuppressors					
Methotrexate (MXT)	6–7	10 mg/m^2 week PO, SC, IV escalate as tolerated			Hepatotoxicity, bone marrow suppression, interstitial pneumonia, decreased transaminase levels, nephrotoxicity, especially at high doses
Cyclosporine	3				
Initial dose		2 mg	2[b]		Nephrotoxicity, hypertension, hyperlipidemia
Maintenance		4–6 mg	2		Hirsutism, gingival hyperplasia
Penicillamine		5–10 mg	1		Nephrotoxicity, bone marrow suppression
Sulfasalazine[c]					
New drugs					
Etanercept		0–4 mg SC	2 weekly		Infections, use with MXT
Infliximab		3–5 mg IV	q 8 weeks		Infections, use with MXT

Data from [22, 136, 263, 506].
[a] 20–30 mg/kg daily for children >6 months. [b] Continual infusion. [c] See Table 18.16, also for azathioprine dosage.

New Drugs and Treatments

Etanercept (enbrel), a dimerized version of the soluble TNF receptor II, is a fusion protein linking the extracellular ligand-binding portion of a human TNF-αR to the Fc portion of human IgG, is a therapeutical agent related to infliximab (anti-TNF-α therapy) [251]. Etanercept was administered at a dosage of 0.4 mg/kg (maximum 25 mg) subcutaneously (SC) twice a week. Children with severe, long-standing, MXT-resistant poly JRA demonstrated sustained clinical improvement with >2 years of continuous etanercept treatment. Etanercept was generally well tolerated, a remarkable result, considering that 83% of those receiving placebo flared at a median of 28 days, whereas only 28% of those still receiving etanercept flared, and at a median of 116 days [242]. However, children taking etanercept should be monitored closely for infections [242]. The response rate to etanercept was significantly lower in patients with systemic-onset JIA than in those with pauci- or poly-onset JRA. This treatment may be associated with a wide spectrum of severe side effects in 19.75% of cases [345]. However, during etanercept treatment of systemic-onset JRA one child developed SLE and a second DM. For children with JOSA, *infliximab,* a chimeric, human-murine anti-TNF monoclonal antibody, may confer similar benefits [45]. Treatment of three children with infliximab was started at 3 mg/kg at weeks 0, 2, and 6, followed by infusion every 8 weeks, with effective and well-tolerated results in two children, but in the third child no effects were apparently noted [31]. In a nonrandomized, prospective, open-label study, 24 children (mean age, 10.2 years) with poly JRA were treated with either infliximab or etanercept, and both TNF-α inhibitors provided a significant rapid and sustained reduction in disease activity [216].

Drugs of Tomorrow

In a multicenter, blinded, placebo-controlled (PC) safety trial the addition of the rIL1 blocker *anakinra* (r-metHuIL-1ra) to a stable background regimen of RA medications introduced no important safety risk in patients with RA [417]. A multicenter randomized double-blind (DB) PC trial significantly reduced the clinical signs and symptoms of RA when used alone or in combination with weekly MTX [63]. In another trial, patients in whom RA was active despite MTX therapy were treated with a combination therapy with etanercept and anakinra with no added benefit and an increased risk compared with etanercept alone [133].

Adalimumab, another human anti-TNF monoclonal antibody, was investigated in a multicenter DBPC trial and was more effective than placebo at inhibiting the progression of structural joint damage, reducing the signs and symptoms, and improving physical function in patients with active RA unsuccessfully treated with

MTX [197]. In a DBPC phase III trial, patients with RA for whom previous antirheumatic drug treatment had failed achieved significant, rapid, and sustained improvements in disease activity and improved physical function by adalimumab monotherapy. It was safe and well tolerated [450].

Another promising strategy is to inhibit the formation of IL_6–IL_6R (receptor) complex to block the binding to gp130 receptor, a biologically active receptor for IL_6. Yokota [494] performed recent trials of anti-IL_6R antibody, temporarily called MRA, for children with acute systemic JRA intractable to long-term high-dose CS therapy.

ASCT (*autologous stem cell* [SC] *transplantation*), proposed as a possible treatment for severe AIDs such as JRA, MS or systemic, and SLE [485], has unique issues in pediatric JRA [23]. In a study started in 1997, ten children with systemic JRA and four with polyarticular JRA, all with progressive disease activity despite previous treatment with CSs, NSAIDs, MXT up to 1 mg/kg/week, and CsA (2.5 mg/kg/day), were treated with ASCT. Follow-up to 36 months showed a marked decrease in JRA severity as expressed by the core-set criteria for JRA activity [23]. During the follow-up of 3–40 months, there was a recovery of CD4 and CD8 subsets, and of CD45RO T cells, later replaced by the CD45RA phenotype. The clinical improvement was evident, with younger children reaching a catchup growth of 1–2 SDS (standard deviation score). MAS (macrophage activation syndrome) was the cause of death in two children [23]. However, these children remain at risk for severe viral infections due to a prolonged lymphopenia [485]. A third fatality resembling MAS, shortly after auto-SCT, was reported in Paris and was caused by a disseminated toxoplasmosis infection [344]. Allogenic transplantation (Chap. 22) certainly has a theoretical advantage of replacing the entire lymphocyte population, and could overcome the complications associated with the ASCT [485]. To ≥40 children treated with ASCT since 1997, an extension is reported, including 18 children with JIA treated in the Netherlands and 13 children from other European pediatric centers, with a follow-up of 8–60 months. At 5–9 months after ASCT, the numbers of circulating T cells were normal with normal in vitro mitogenic responses at 6–18 months after ASCT. In all, 17 patients showed a drug-free follow-up of 8–60 months with a marked decrease in the scores of the child health assessment questionnaire (CHAQ). During the 36 months of follow-up, the first patient showed a catch-up growth of 22 cm (and a corresponding increase in shoe size), in contrast to the minimal gain of only 2 cm in the three preceding years. The second patient also showed a rapid drug-free remission of the disease that persisted at 30 months of follow-up. Since ASCT, she has grown 18 cm in 30 months. She is on a physical therapy program to improve muscle strength after years of immobilization and prednisone-induced obesity. A relapse was noted in seven children 18 months after ASCT. These relapses have so far been mild, pauci forms and sporadic fever, which could be controlled easily with a 3-month course of low-dose prednisone and NSAIDs [486]. A US woman affected with a severe form of RA interesting 38 joints was able to discontinue all medication after having received a *stem cell transplant* from her healthy sister (Reutershealth, 9 September, 2004).

Outcome

The early onset of ankle and/or wrist disease, symmetric joint involvement, and an elevated ESR in a child with pauci JRA may be predictive of extension [9]. The prognosis varies significantly according to the different forms of JRA. More than 50% of patients, in fact, develop severe articular lesions with seropositive poly forms, 25% develop systemic forms, and 10%–20% have seronegative poly forms. In pauci forms, with adequate treatment, the remission is complete in 50% of cases. Some type I forms, however, may evolve with severe poly involvement [343]. In 703 children, at 5 years after onset >25% of poly and nearly half of systemic JRA children had functional limitations that required modifications in their school schedule [39]. Pauci JRA occurring in older boys had the best functional outcome, but growth abnormalities and Rx changes were more common in poly and systemic onset JRA [288]. However, a number of patients with type II pauci forms can develop ankylosing spondyloarthritis in adult age [263]. One should also consider the numerous problems caused by daily and/or social activities, and the psychological problems as well, especially for their impact on the child and parents and on *quality of life* [354]. Because chronic inflammatory eye disease in children in JRA is usually asymptomatic until visual loss occurs, it is vitally important that all children with JRA undergo an eye examination every 6–12 months by an ophthalmologist.

Since pain, peer rejection, and problematic social behavior are strongly associated with depressive symptoms, health care providers should assess the social functioning of children with JRA to identify those socially vulnerable who may be at increased risk of internalizing problems [372].

Inflammatory Bowel Disease

Definitions

The two major IBDs, UC [478] and CD [72] are correlated with autoimmunity (Table 18.2), UC is limited to the large bowel and pathologically is a relatively superficial, ulcerative inflammation, whereas CD can involve any part of the gastrointestinal tract and is characterized as a transmural granulomatous inflammation.

Epidemiology

These affections are characterized by an ever-growing frequency in pediatric age (data $\times 10^5$). in Great Britain, CD incidence in cases begun <16 years increased from 1.3 to 3.1, UC incidence remained at 0.7, and their prevalence was at 16.6 and 3.4, respectively [67], over the last 10 years. In a retrospective study done in Australia, the incidence of CD in children aged ≤16 rose from 0.128 to 2.0×10^5 per year over three decades, from 1971 to 2001 [331]. The incidence of IBD in Wisconsin children was 7.05×10^5, whereas the incidence for CD was 4.56, 2.13 times the rate of UC (2.14) [213]. In Norway, the rates were inverted (2.5% for CD, and 4.3% for UC) [302]. The mean annual incidence of CD in the child population was 2.5×10^5/year, whereas the incidence of UC in the child population was 4.3×10^5/year [302]. UC incidence in Spain reaches a mean value of 3.8×10^5. CD figures reach an average rate of 1.9×10^5, half of UC [318]. The average age of onset was 1.0–17.5 years in 55 German children [407]. The IBD incidence rate was 5.2 new cases $\times 10^5$ Danish children per year [451]. In other Danish children, the mean annual incidence of IBD was 4.3 (1.8 for UC, 2.3 for CD) $\times 10^5$ children <15 years. The mean annual prevalence of IBD was 15.8×10^5 children <15 years (UC 8.3; CD 6.7). A total of 152 children were diagnosed with IBD, corresponding to an overall incidence of IBD of 7.4×10^5. The incidence of CD was 4.9 and UC 2.2 The marked increase in CD incidence, while UC incidence was almost stable, led to a net increase in the overall occurrence of IBD [165]. UC has a bimodal distribution among children: its prevalence is higher between 11 and 15 years, with a peak between 16 and 20 (2.3×10^5) [201]. However, children aged <10 represent 0.5%–15% [150] of that peak. In 29% of Gryboski's cases [150], UC onset occurred during the first 2 years of life. CD is affecting a growing number of children and adolescents. According to estimates, there are 9.5–10 cases $\times 10^5$) in children <15 years, so CD is more frequent than UC among children. As a matter of fact, at least 20% of CD cases have their onset in childhood or adolescence [172]; however, CD is not rare at 6 years [208].

Genetics

The increased number of cases, at least within families, could depend on genetic anticipation. This is supported by the study of parent-son pairs. In 78.8% of cases, fathers developed the disease >5 years before their sons [374]. Genetic predisposition is likely, because these affections have higher incidence among first relatives of affected subjects [311], and among MZ twins rather than DZ twins [437]. The concordance ratio between twins seems to be more significant in CD than in UC [437]. However, no model of Mendelian inheritance has been shown in these disorders, so they could reasonably represent a heterogeneous group with multifactorial inheritance [374]. The heterogeneity of UC is confirmed by the presence of antineutrophil circulating antibodies (ANCAs) (Table 8.26). According to evidence, parents and sons, either with CD or UC, have the same disease in 100% cases, and the same symptoms in 75% cases on average [374]. First relatives are at risk of developing the same illness 5–10 times more than the general population [338]. In this respect, the familial risk is 5% for UC and 9% for CD [50]. Relatives of an individual with CD or UC have a tenfold increase in the risk of having the same disease as the patient, whereas in the relatives of an individual with UC, the risk of acquiring CD is not significant; the two diseases may occur in the same family, thus suggesting that IBDs have a genetic cause [311]. This divergent genetic behavior suggests a greater relevance for environmental factors in UC [437]. However, the development, with a lapse of a few months, of CD and UC in two sisters shows that both affections depend on the interaction of genetic factors with environmental factors [51], including smoking [374]. Some genetic markers have been studied using molecular techniques to typify DNA. Table 18.3 reports UC and CD associations with HLA molecules, UC with HLA-DR2 specificity, and CD with *HLA-DR1-DQ5* allele (more with the *DQB1*0501169*). CD has been associated with the *HLA-DRB1*07* allele as well, especially in subjects <35 years of age [352]. While the association with *HLA-DRB1*03* is significantly decreased [352] or makes CD more resistant [80], other studies suggested that UC is susceptible to *HLA-DRB1*1502* [129, 266]. These data confirm that HLA-B27 is associated with both CD and JRA. However, none of the four family members, including one daughter with CD and another with UC, presented JRA, even though all members had HLA-B27 antigen [51]. The HLA region on chromosome *6p*, referred to as IBD3, showed evidence of male-specific linkage with a max lod score of 5.9 in CD and UC male-affected families. Regions on chromosomes 11, 14 and 18 showed strong evidence of linkage also in male-affected families [121]. In UC families, the most significant lod scores were observed on chromosome *2p11* (D2S2333) and a second at proximal *12p13* score was observed, also with a high lod score [313]. A susceptibility to CD, but not to UC, was associated with homozygosity for a common haplotype, H2 ($p(c)$=0.002; RR 2.0). Genotype–phenotype analyses demonstrated that this association was very strong in patients with perianal disease ($p(c)$=0.0005; RR 1.7), mostly in individuals HZ for this haplotype ($p(c)$=0.0005; RR 3.0) [16]. Two genome-wide searches have identified suggestive linkages at chromosomes *5q33-q35 14q11.2*, *17q21–q23* [246], *2p13–11*, *11p12–q13*, *12p13–12*, *12q23*, *19q13* [313], but the linkage at 3, 7, and 12 [375] was subsequently excluded [459]. Another potential susceptibility locus for IBD2 was localized at *12q13–14* near the deoxyribonucleic acid marker D12S83 by linkage analysis [439]. *The IBD1 gene was mapped to the proximal region of the long arm of chro-*

mosome 16 (16q12) in the white population, utilizing genome-wide scan linkage strategies [171], contains the susceptibility gene encoding *NOD2*, also referred to as CARD (caspase activation and recruitment domain), has been linked to CD in different populations [37, 53, 73, 161, 313, 505] or not in French [508] and Japanese patients [490] and several more in PubMed (March 2005).

Confirming the importance of NOD2, Hampe et al have provided evidence of linkage to *loci* at chromosomes *1q*, *6p*, and *10p* and replicated linkages on chromosomes 12 and *16p* [154]. Additional *loci* with suggestive significance for IBD in a meta-analysis affected relative pairs were *2q*, *3q*, *5q*, *7q* and 16 (*CARD15* region); CD, *2q*, *3q*, *6p*, 16 (*CARD15* region), *17q*, *19p*; and UC, *2q* [454]. A group of pedigrees that contained one of the three *CARD15* variants had two suggestive linkage results occurring in *6p* (lod, 3.06 at *D6S197*, IBD phenotype) and *10p* (lod, 2.29 at *D10S197*, CD phenotype). Moreover, at *16q12* where *CARD15* is located, the original genome scan had a peak lod score of 2.18 at *D16S415* (CD phenotype) [384]. Carriage of *NOD2/CARD15 risk* alleles is associated with ileal location, earlier disease onset, and stricturing phenotype [36]. In 55 German children with CD, the genotype–phenotype analysis showed that those who had at least one of the six *CARD15* disease-associated mutations had a high risk of inflammation located in the terminal ileum and ascending colon. In ten of 19 patients with two mutations, intestinal resection surgery was necessary because of stricturing [476]. A significant association of ileal involvement was shown with *CARD15* variants, *HLA-DRB1*0701* and *DRB1*04* alleles and the capacity of combined *CARD15* and *HLA-DRB1* genotyping to predict ileal disease in CD patients was demonstrated. By contrast, the *HLA-DRB1*0103* allele was associated with later age of diagnosis and pure colonic disease [295]. Other IBD genomic regions include *IBD2* on chromosome *12q* (observed more in UC), and *IBD3*, containing the HLA region [36]. Three major coding region polymorphisms within *NOD2/CARD15* have been highly associated with CD among patients of European descent: *R702W*, *G908R* and *L1007fs* [37, 53, 161] with allelic frequencies of 0.11, 0.02 and 0.07, (or 3.3%, 0.6%, and 4.8%), respectively [53]. The *G908R*, *R702W*, and *L1007fs* variants share a common signaling defect in response to bacterial components, providing evidence for a unifying molecular mechanism whereby *NOD2* mutations contribute to disease susceptibility, while *R702W* is not associated in Ashkenazi Jews [37]. Having one copy of the risk alleles confers a two- to fourfold risk for developing CD [36], or no increased risk [505] and double-dose carriage increases the risk 20- to 40-fold [36] or 5- to 15-fold [505]. All three major CD variants exhibit a deficit in NF-κB activation in response to microbial components [36]. In CD patients, six more variants (*5 UTR-33 GT*, *S178S*, *P268S*, *R459R*, *R587R*, *V955I*) have been reported [227]. The penetrance of the *NOD2/CARD15* mutations is estimated at <1% [505]. *CARD* is expressed in macrophages and may serve as a so-called pattern-recognition receptor for bacterial LPS, perhaps regulating macrophage apoptosis [338].

Etiopathogenesis

According to new pathogenetic theories, *SAs could play an active role in cell-mediated immunity* (CMI) *for CD* by inducing autoimmune phenomena [175], while *UC could be caused by atypical type 2 helper T cells* [338]. Moreover, the mucosa in patients with UC may be dominated by $CD4^+$ lymphocytes with an atypical type Th2 phenotype, characterized by the production of TGF-β and IL_5 but not IL_4. In contrast, the mucosa of patients with established CD is dominated by $CD4^+$ lymphocytes with a Th1 phenotype, characterized by the production of IFN-γ and IL_2 [128]. In murine models, the effects of the activation of Th1 cells may be enhanced by the concomitant decrease in subgroups of suppressor T cells, which produce the down-regulatory IL_{10} and TGF-β [427].

The most reliable data to clarify the pathogenesis of chronic inflammation are as follows. *The inflammatory reaction* is triggered by macrophage activation and spread by local IL release, particularly $IL_{1\alpha}$, IL_2, IL_2R, IL_6 and IL_8, and other chemotactic factors such as LTB_4, PAF and C5a [149, 278, 304, 473]. IL_8, mediating neutrophil infiltration of the gut wall, starts and prolongs the inflammation, also correlating well with the neutrophil numbers in mucosal tissue, while IL_1 and TNF-α represent the releasing factor on the inflammatory site [278]. This interesting paradox remains to be explained, especially why serum levels are not correlated [278]. Certainly, neutrophil infiltration is a histopathological characteristic of active forms. PBMCs scattered among the crypts and interstices synthesize TNF-α and $IL_{1\alpha}$, which in turn increase their concentrations [304]. TNF-α is involved in the development of granulomas [40], which were found in 11.4% of 88 children [276].

- *Serum IgG increased* 10- to 100-fold, including IgG_1 subclasses with pro-inflammatory action and complement activation, and IgG_2 with regulatory activity, mostly in CD (Table 18.12) [28, 43, 151, 195, 196, 400]. As for IgA, the different expressions of J chains seem to have no specific meaning, nor is the secretory system involved [196]. IgG-mediated immunoinflammatory responses can damage the intestinal mucosa since they activate the complement and the cascade of inflammatory mediators [152].
- *Complement activation* is a mechanism which can induce and amplify inflammatory processes independently [474].
- *Some patients with ANCA*$^+$ CD and $ANCA^-$ UC are associated with the rare allele *R241* from CD54 [492], as well as with high levels (reduced, however, in patients with UC only) of an antierythrocyte Aab (AEA-15) in

Table 18.12. Differences in the mucosal and systemic immune response between Crohn's disease and ulcerative colitis

Immune response	Crohn's disease	Ulcerative colitis

Antitropomyosin or P40 levels	–	+

Data from [28, 43, 151, 195, 196, 400].

the *VH3–15* [28] gene (Table 18.12). The two diseases, on the contrary, show no differences in CD44 levels [242, 272].

- *Hyperproduction of O_2 and NO radicals* is evident [38, 148]; however, antioxidant vitamins have low levels [398], with consequent oxidative stress and mucosal lesions.

The pathogenesis thus is characterized by the following major aspects:

- *Primary or secondary dysfunctions* of the immune response in IBD mucosa are caused by IL_4, able to disrupt the intestinal epithelial barrier, thus increasing intestinal permeability and macromolecular transport [92]. These changes facilitate the indiscriminate access of luminal antigens (alimentary and/or microbial and viral) [201] and the intestinal epithelial cells (IECs) ready as APC in mucosal immune responses [430]. T lymphocytes already activated and ready to react with microbial antigens reside in the lamina propria [334], which are also responsible for HLA class II antigen expression on colonic epithelial cells [473]. In addition to producing the key ILs that stimulate Th1 (IL_{12}, IL_{18}, and macrophage MIF), macrophages produce a mix of inflammatory ILs, including IL_1, IL_6, and TNF, which target a broad variety of other types of cells [338]. Increased levels of IL_4 have been shown in the early phase of relapse in the intestine of CD patients [177] and in the UC active phase [91]. T cells activated by IECs are $CD8^+$ suppressor and dependent on $CD8^-$ associated $p56l^{ck}$ activation. In this process, a 180-kD glycoprotein (gp180) has been shown to be important in $CD8^+$ T cell activation. However, gp180 expression by IBD IECs appears to be altered, and correlates with a functional alteration of $p56l^{ck}$ activation [430]. Thus, this defect may be reflected in IBD pathogenesis.
- *The inflammatory reaction* is started and propagated by the local IL release by Th1 IL_2, IL_2R, IL_6 IFN-γ [149, 473] and by PBMCs, especially TNF-α [304]. IL_2R, mostly present in CD, plays a significant role in the expansion and differentiation of CMI responses [42]. IFN-γ is the major evocator of HLA antigen expression on the epithelium, by stimulating the mucosal damage continuation and amplification [147] by an increased APC activity [357]. The damage is also caused by TNF-α, a powerful inflammatory protein activating endothelial cells, which express β2-integrins, selectins, chemokines and other molecules involved in lymphocyte and neutrophil adhesion [304]. IL_1, IL_2 and the factors activating PBMCs have a similar action on the epithelium, by inducing lymphocyte and macrophage activation and migration in the inflammatory lesions [42, 473]. When environmental antigens activate the intestinal immune system the response is modulated by the genetic makeup of the host. Usually, both IFN-γ and TNF-α inhibit the TGFβ/Smad signaling pathways. In normal individuals the TGF-β enhanced intestinal production is followed by an increase of phosphorylated Smad3 (p-Smad3) and a concomitant decrease of inhibitory Smad7 thus allowing the expression of TGF-β anti-inflammatory activity, and maintaining IFN-γ and TNF-α within the limits of a physiological intestinal inflammation. In susceptible individuals, activation of the immune system leads to increased production of TGF-β signaling, but also to inappropriately *high levels of Smad7* which inhibit p-Smad3 resulting in *defective TGF-β signaling*. Consequently, excessive amounts of IFN-γ and TNF-α are produced resulting in chronic intestinal inflammation clinically manifested as IBD [120].
- The *protective mechanism failure* consequent to inadequate metabolism of the PG/leukotriene (LT) system [400] and the generation of a legion of inflammatory and destructive molecules [473] such as IL_4, PAF, proteases, etc. underlie the chronic progression of lesions [40], facilitated by a continual involvement of inflammatory cells. Intestinal mucosa disturbance, mostly from abnormalities involved in the immune adaptation to intestinal antigens, may be explained as hyperreactivity of T lymphocytes to microbial antigens [326, 334]. Especially in CD, the mucosal destruction is similar to that caused by experimental activation of T lymphocytes in the human fetal small intestine, consequent to increased expression of HLA-DR, $IL_{2α}R$ and macrophages [247] in the lamina propria. This suggests that the primary activation of T lymphocytes is an important effector mechanism. The release of IFN-γ from T lymphocytes can lead to the expression of $IL_{2α}R$ on macrophages [247], as in CD. However, the continuing Th1 activation from bacterial microflora stimulates Th1 to release the above-mentioned ILs [326]. In UC as well, the enteric microflora can cause a major event: HLA-B27 transgenic mice do not develop UC as usual if bred in a sterile pathogen-free environment. However, when maintained in a non-

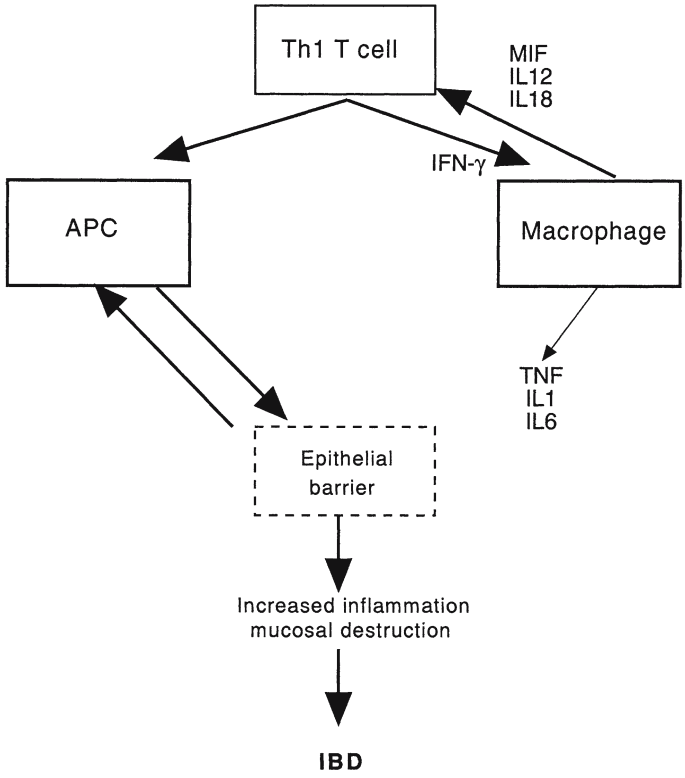

Fig. 18.23. Pathogenesis of IBD. Activation of classic APCs, such as DCs or direct stimulation through pattern-recognition receptors promotes the differentiation of Th1 T cells in CD patients or, possibly, atypical Th2 T cells in UC patients. (Modified from [338])

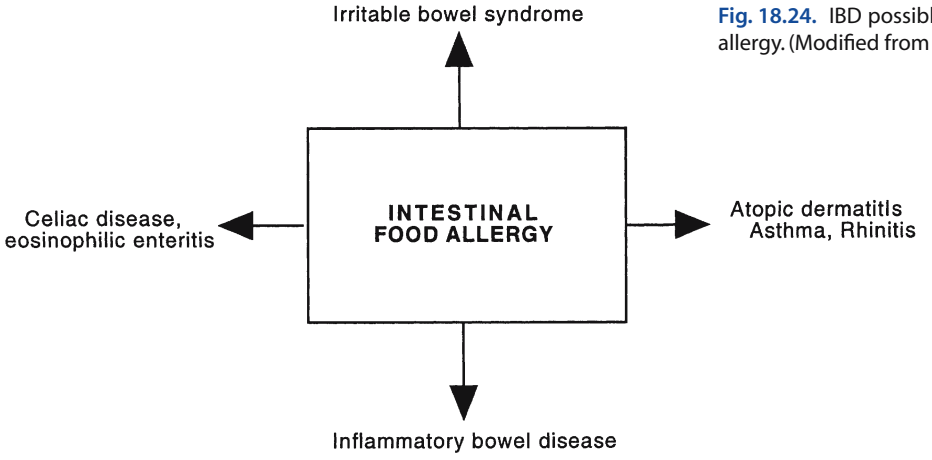

Fig. 18.24. IBD possibly related to intestinal food allergy. (Modified from [32])

sterile facility, they develop inflammatory phenomena within a few weeks [414]. Microflora have important and specific metabolic, trophic and protective functions, based on evidence obtained by the above studies [152]. Thus, the pathogenetic process should be referred to as an increased activity of the inflammatory processes and/or the absence of mucosal standard protective mechanisms, so that the inflammation goes on indefinitely [338], as shown by Fig. 18.23. Therefore, IBD patients show an impaired tolerance toward commensal bacteria of the resident flora [152]. The barrier integrity may be compromised by inappropriate and ongoing activation of the mucosal immune system, a reduced reparative response to injury, or exogenous agents, or

products of commensal bacteria in the lumen [338]. A nonspecific repair function of the colon cells to compensate for damage to barrier function, including a reduction in the number of goblet cells and a decrease in the number of sugar residues may be present in children with both CD and UC by MUC5AC (faveolan cell mucin) and TFF1 (gastric trefoil factor) expression in goblet cells [379]. Antigens from dietary sources may also contribute [338]. The most important differences are as follows: UC DRB1*15, ANCA$^+$, AEA-15$^-$, CD DRB1*01 and DRB1*07, ANCA$^-$, AEA15$^+$.

The relationships with FA are also important for pathogenesis (Fig. 18.24) [32], though they are little known for a number of reasons (Table 18.13) [32].

Ulcerative Colitis

The major symptoms are summarized in Table 18.14 [150]. The characteristics of AID are obvious, with antibodies in the serum, activation of the complement by CICs, and lymphocytes aimed at colon epithelium. This could cause T-mediated damage to the mucosa, suggesting a type IV reaction. The presence of IgG among the complement activation products in the colon epithelium could be interpreted as an IgG-mediated autoimmune process. The accumulation of complement is directly correlated with the level of inflammation [40]. Histopathological studies have shown that the primary lesion is on the epithelium, thus the inflammation is only secondary. These phenomena, however, are not observed in all patients, and they are not correlated with clinical manifestations, whereas CS effectiveness in managing UC may be due to an immune-mediated suppression of IL production by macrophages and T cells [40]. The significant association with HLA alleles [431], with high familial prevalence of atopic diseases (22%) and minor prevalence of extraintestinal symptoms [150] (Table 18.14), supports the theory that autoimmune immunological factors could be involved in etiopathogenesis, even though it is unclear if these mechanisms play a primary or secondary role. CM has been considered the provoking factor in 14% [150] to 21% [138] of cases, since UC develops at an earlier age (6.7 years) compared to subjects with a negative history (10.6 years) [138]. It should be noted that CM ingestion causes flare-ups, while its elimination rarely leads to the resolution of stabilized forms. These data suggest that nutrition does not play a prominent role in pathogenesis. Likewise, there is no scientific evidence of a psychosomatic etiology, even though emotional and psychosocial factors can affect UC development [201]. The specific diagnosis is made based on p-ANCA (Table 18.12), which are present in 66% of children (median age 13 years), with 66% sensitivity and 84% specificity compared to CD [400]. If ANCAs are matched to a technique based on immunofluorescence and ELISA, specificity reaches 97% [480]. ANCA specificity has led to dividing patients into ANCA$^+$ and ANCA$^-$ [431] according to familial background. Treatment is essentially similar to CD therapy [400]. Experimental data show the utility of ketotifen [98]. Recently, the derivatives of 5-aminosalicylic acid (5-ASA) have been widely used, since they have both antioxidant and superoxide-dismutase-like activity [398], while sulfasalazine reduces the production of PGs/LTs [400]. Surgical therapy provides satisfactory results: the speculation that a more aggressive surgical approach to treatment could reduce the growth retardation [116] is intriguing.

Table 18.14. Symptoms in children with ulcerative colitis

Symptoms at onset	%	
Abdominal pain	92	
Diarrhea	84	
Rectal bleeding	84	
Weight loss	74	
Fever	11	
Arthralgia	8	
Arthritis	5

Arthralgia	8	3.6
Eye lesions	3	5.4
Skin lesions	2.6	6.4
Failure to thrive	5	13.8
Colectomy	5	20.4

The extracolonic manifestations are compared with five pediatric studies (mean) reported by Grybowski, including 537 children aged 1–20 years.
Data from [150].

Crohn's Disease

CD is a painful, chronic inflammation of the GI tract, which also causes social and emotional problems in children [20]. The pathological mechanisms behind the disease are definitely different. According to the most widely supported theory, CD is a genetically determined disorder [352], immune-mediated, whose major risk factor is a positive family history (FH) [147]. The cause of immune dysregulation is still controversial, while reduced antigenic stimulation on the intestinal wall through dietotherapy appears more relevant. In CD pa-

Data from [147, 172].

tients carrying at least one of the three *NOD2* variants, the ileum was affected more often than in noncarrier CD patients (90% vs 73%); they had stricturing or penetrating disease more often than noncarriers (88% vs 56%), and they had an increased need for bowel surgery [161].

Dietotherapy can help correct nutritional deficiencies and growth deficits, apparent both in children and teenagers [366]. *The major pediatric symptoms* are listed in Table 18.15 [147, 172]. A different case is that of a 5-year-old child with CD who developed eosinophilic gastroenteritis [415]. The pathophysiology is different, depending on the bowel region involved, the degree of inflammation, and the presence of complications such as stricture or fistula. Systemic signs and symptoms are more common in CD than in UC [172].

As a remedy to dietary factors generally considered as primary causes, consequent to unbalanced nutrition with excessive consumption of refined carbohydrates and/or sulfites – with insufficient bulk – a pediatric study has suggested reducing – during remissions – the consumption of vegetables, rich in fibers susceptible to cause postprandial pain, and increasing sweets with a higher content of refined sugars (less harmful in this regard) [422].

In some cases, a simple diet could improve symptoms, but with frequent relapses. When diet was followed by refeeding under control (one food/day, excluding food causing relapses), after 2 years remission was significantly longer (7.5 months compared to 3.8), and relapses clearly lower (62% vs 79%) compared with CS-treated controls, suggesting a new therapeutic strategy [355].

A group of children – divided into two subgroups, one treated with CSs, the other with a simple diet – has shown good results irrespective of treatment [422], whereas in 19 other groups, also randomized, the best result was obtained with medication [364]. A successful experiment was based on a 4-week discontinuation of drugs and diurnal solid feeding, which was replaced with night nasogastric feeding based on amino acids or oligopeptides. The night tube was accepted by almost all patients (7–17 years), their linear growth improved, and clinical scores significantly diminished, with no relapses during 12 months in 30% of cases. The rate reached 50% when subjects agreed to continue the night diet and reduced to 50%–60% with restoration to normal diurnal diet [479]. With severe, acute disease, children with active CD were treated for 6 weeks with exclusive enteral feeding; then treatment was cycled to overnight infusion at home. Significant improvements occurred by day 3 in inflammatory parameters and by day 7 in growth-related changes, preceding any significant changes in nutritional parameters [21]. Improved growth and development, without the side effects of CS therapy, make *enteral nutrition a better choice for first-line therapy in CD children.* Children can participate in normal daytime activities. A major disadvantage of this approach is similar to that of other therapies: early relapse on discontinuing treatment [163]. Especially in children with poor nutritional status or growth impairment, this approach may be ideal. Children and adolescents with active CD who continued nasogastric supplementary feeding after resumption of an otherwise normal diet remained well longer than those who discontinued nocturnal supplements completely. Furthermore, continued use of nasogastric supplements before completion of puberty was associated with improved linear growth [460]. However, the improvement in disease activity seems to be associated with improvement in lean body mass irrespective of the type of diet used to achieve it [198].

In children aged a mean 14.4 years, a *percutaneous endoscopic gastrostomy* was more acceptable than nasogastric feeding, with a net reduction of CS dosage and a significantly improved height score 1 year after the procedure [68].

Diagnosis

Diagnosis depends on the combination of clinical history, physical findings, and endoscopic, X-ray, and histological features, as well as the results of routine laboratory tests. Clinical, X-Ray, and endoscopic (type of lesions, distribution) examinations unequivocally confirm the diagnosis of either UC or CD [338]. CD patients positive to p-ANCA (19%) [400] are characterized by a special

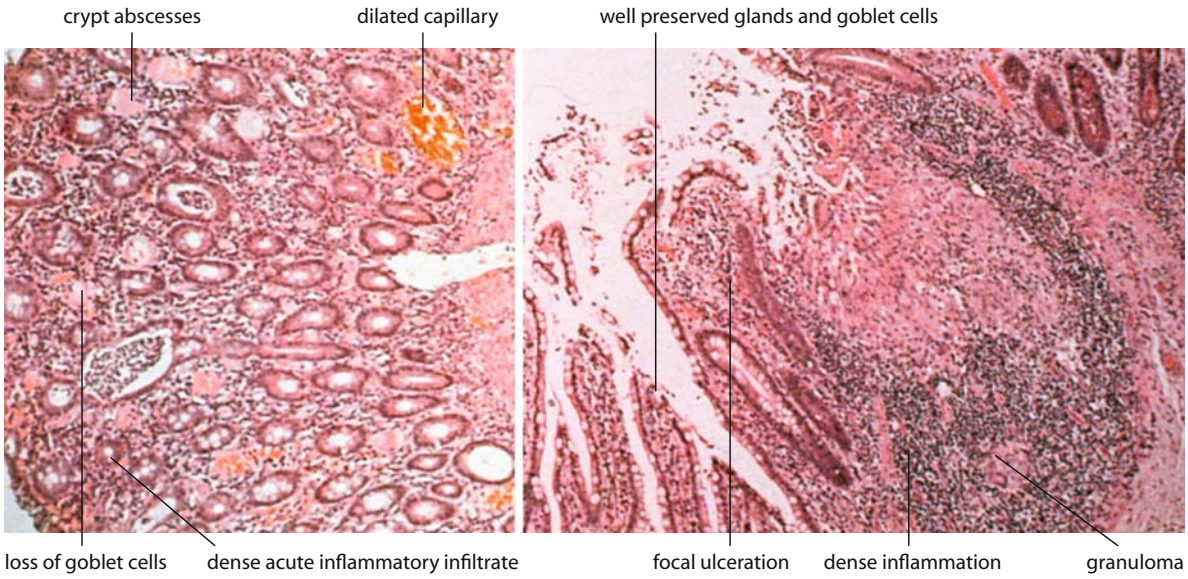

Fig. 18.25. Inflammatory bowel disease. *Left:* UC histological appearance. *Right:* CD histological appearance.

clinical phenotype [456]. The differential diagnosis of both conditions is based on the data shown in Table 18.12: IgG_1 is as specific for UC as IgG_2 is for CD, thus allowing us to make a precise diagnosis for 15% of patients (4–19 years) for whom the parameters generally used are insignificant [151]. The clinical comparison of UC (Table 18.14) and CD (Table 18.15), shows that rectal bleeding is 4.2 times more present in UC, and failure to thrive four times more present in CD. The extraintestinal manifestations, if common, are more frequent in UC; however, CD children have particular extraintestinal manifestations. Additional studies are focused on IL_6 level determination, which is useful to differentiate pediatric patients with CD [43], as well as the $CD25^+$ mucosa cells in CD, mostly T lymphocytes, whereas in CU they have the macrophage phenotype [175]. Colonoscopy in the two IBDs is highly specialized [338], and the histological test gives different results (Fig. 18.25).

Treatment

Medical treatment is summarized in Tables 18.16 [172, 201] and 18.17 [252, 371]. Pediatric CD requires prolonged pharmacological management, but the side effects of current treatments are problematic. The aim of CD therapy is to relieve symptoms and prevent complications of chronic inflammation (anemia, growth failure), prevent relapse, and, possibly, effect mucosal healing. Apart from dietetic recommendations for CD, we suggest for children special formulas that may be useful and palatable (see Appendix 9.7). The nutritional approach may be useful to reduce acute inflammation, but it rarely leads to long-term remittance; however, simple diets or, more commonly, liquid diets can give good results, especially in children [366]. Elemental diets have also been advocated as a primary treatment for CD: a nutritional approach can induce clinical remission and improve the growth failure associated with pediatric CD [362]. The best strategy is to tailor treatment to the clinical pattern [366]. Immunosuppressants have been experimented for both diseases in adults. Immunosuppressants, including cyclosporine, a powerful inhibitor of T cell activation, provide significant results in UC, but disappointing results in CD among a sample of children. Results improve with CS-based therapy [296]. The possible involvement of TNF-α and $IL_{1\alpha}$ in chronic IBD [304] has led to searching for a new therapeutic module based on the inhibitors for these ILs [232].

New Drugs and Treatments

The decisive action of anti-TNF-α has been proven on a 14-year-old girl by the total endoscopic remission of lesions for 3 months after two 10-mg/kg IV infusions of anti-TNF-α antibodies, cA2 (*infliximab*), followed by improved symptoms, a 3.2-kg weight increase in 10 weeks, and a decrease in the activity index for pediatric CD from 77.5 to 10 [90]. After a single dose of infliximab (either 1, 5, or 10 mg/kg), all 21 children (100%) aged 11–17 achieved a clinical response, and ten children (48%) achieved clinical remission. There were no infusion reactions in any child [20]. In children and adolescents, infliximab has been found to be safe and reduces the CS need, both in CD [20, 173, 404] and UC [259, 381]. The results of a two-year follow-up [253] have shown a short-term improvement in 14 of 17 (82%) patients, and sustained improvement in 10 of 16 (63%) patients followed up for >9 months. Eight additional UC children with infliximab were seen and 7/8 were consid-

Table 18.16. Medication doses for children with IBD

Drug	Daily doses (mg/kg)	No. of doses	Maximum dose	Side effects
5-ASA				
Sulfasalazine initial dose	25–40	3–4		Fever, hemolytic anemia, hepatitis, pancreatitis
Sulfasalazine maintenance	50–75	3–4	3 g	Neutropenia, rash, thrombocytopenia
Mesalamine	40–60	2–3	3 g	Nausea, dyspepsia, headache
Mesalazine	30–50	2–3	4.6 g	Headache, abdominal pain, nausea, vomiting
Corticosteroids				
Prednisone, initial dose	1/2		40–60 mg	Fluid retention, fat redistribution, hypertension,
Prednisone, maintenance[a]				Hyperglycemia, psychoneurological disturbances
Methylprednisolone, IV	1–1.5 g			Adrenal suppression, growth failure
Metronidazole	10–20	2	1 g	Nausea, metallic taste,. peripheral neuropathy
6-Mercaptopurine	1–1.5			Pancreatitis, bone marrow suppression
Azathioprine	1.5–2			Pancreatitis, bone marrow suppression
Cyclosporine (for highly selected cases)				Nephrotoxicity, hypertension, headache
Initial dose[b]	2	2		
Maintenance	4–6	2		
Methotrexate	5–25	Once weekly		Leukopenia, hypersensitivity pneumonia, hepatic fibrosis, hepatotoxicity, bone marrow suppression

ered responders. The use of infliximab for the maintenance of remission in pediatric CD and UC, as well as its long-term safety, needs to be further assessed before its extensive use can be recommended [381]. Infliximab may be safe and effective as short-term therapy of medically refractory moderate to severe CD in a pediatric population [20]. CDP571, the second anti-TNF-α, is a humanized monoclonal antibody in which only the small number of residues necessary to confer antigen specificity remain from the original murine antibody. The overall usefulness of CDP571 in a clinical trial involving adults with active CD appears to be generally similar to that observed with infliximab [399]. It is necessary to monitor the arthritic symptoms (Tables 18.14, 18.16, 18.17), especially in children who tend to develop ankylosing spondylitis with consequent disability, irrespective of the therapy for IBD [378]. Newer inhaled CS preparations offer potential for targeted therapy and fewer CS-related adverse effects [401]. Wide-spectrum antibiotic therapy reduces bacterial load and mitigates intestinal inflammation in human CD but not in UC [152]. Table 18.17 details treatment with IL_{10}, an IL that generally down-regulates the activation of Th1 cells, and IL_{11}, an IL that enhances the epithelial barrier and inhibits inflammatory ILs (Table 1.5). A large-scale study of patients with CD who were treated with a monoclonal antibody directed against the $\alpha_4\beta_7$ integrin produced promising results [142]. *Probiotics* appear to be one promising approach: *Lactobacillus GG* may improve gut barrier function and clinical status in children with mildly to moderately active CD [1531]. Other therapies have been suggested such as the psychosomatic or immune deletion therapies, but they have not been consistently confirmed by clinical studies [400]. If the method chosen is surgical resection, frequent relapses follow, especially when the involvement is widespread [147], even though more severe lesions can be prevented for at least 1 year. The clinical advantage of postsurgical prophylaxis with 5-ASA seems more permanent [366].

Drugs of Tomorrow

CDP571 binds to the free TNF-α and neutralizes it. In a 24-week PC trial CDP571 at an initial dose of 10 or 20 mg/kg was safe and effective for treatment of patients

Table 18.17. Biological agents with clinical trials in IBD

Drug	Doses × kg	Regimen	Response rate (%)
Infliximab (anti-TNF-α antibody)	8 mg	Single IV	81
	10 mg		50
	20 mg		64

	3.2 µg	SC 5 times/week	42
	15 µg	SC once/week for 6 weeks	37
	15 µg	SC once/week	37

Only the most positive studies have been included.
Data from [252, 371].

with moderate-to-severe CD [370]. Also, patients with mild or moderate UC were treated openly with a single IV infusion of 5 mg/kg of CDP571. In these patients, a consistent improvement in disease activity was seen in the initial 2 weeks after infusion and the treatment was well tolerated [104]. A Cochrane Database review concludes that evidence suggests that a single infusion of infliximab may be effective for induction of remission in CD, so we can recommend a dose of 5 mg/kg. There is also some evidence that CDP571 may be effective in inducing remission in CD. However, no evidence was found that supports the use of etanercept in CD [5].

Newer biological (natalizumab) or IL-based therapies (monoclonal antibody to IL_{10} and IL_{11}) have shown preliminary evidence of efficacy in controlled trials of adults, but neither have yet been approved by the US FDA. Natalizumab, a recombinant humanized monoclonal antibody against $\alpha_4\beta_7$ integrin was effective in CD in a phase II DBPC trial. The highest remission rate was 44% and the highest response rate was 71%, after two infusions of 3 mg or 6 mg of natalizumab administered 4 weeks apart [135]. In a recent trial [371] patients were randomized to 4 weeks of SC injection with rIL_{11} 15 µg/kg or placebo weekly, or rIL_{11} 7.5 µg/kg or placebo twice weekly, which turned out to be safe and effective in inducing remission in a subset of patients with active CD.

Outcome

Reduced growth has been observed, especially in CD [164, 257], in connection with protein-energy malnutrition with multifactorial origin [400], stressing the need to guarantee early diagnosis and therapy. Despite a number of contrasting factors, the improvement of nutritional conditions, irrespective of the methods used, can foster the resolution of IBDs, especially CD. Certainly, the new diets based on amino acids with a palatable taste – as we have stressed – are useful in pediatric cases, in order to avert CS resistance or dependence, or when it is desirable to discontinue or significantly reduce CSs. An improved nutritional condition will counter the effects of malnutrition, including trace elements – especially Zn (Chap. 21) – resulting in improving the retarded growth, which is a typical aspect of pediatric IBDs.

Autoimmune Hematological Disorders

AIHA is discussed in Chap. 19.

Autoimmune Lymphoproliferative Syndrome

Genetic defects in proteins that mediate lymphocyte apoptosis caused by Fas gene mutations can result in the autoimmune lymphoproliferative syndrome (ALPS), a rare inherited illness occurring in a number of kindreds [176]. Heritable mutations in Fas or Fas ligand genes, which regulate lymphocyte survival by triggering lymphocyte apoptosis, are the most frequent causes of ALPS. In vitro studies of eight new HET *Fas mutations* suggest a second defect, because some Fas missense mutations leading to a truncated Fas product were associated with variable (instead of high) clinical penetrance [354]. Histological sections of a cervical lymph node of a 3-year-old child demonstrated a marked paracortical proliferation of occasional small and intermediate-sized lymphocytes with numerous large immunoblasts, the majority of which displayed a $CD3^+$, $CD43^+$, $CD45RO^-$, $CD4^-$, $CD8^-$ phenotype, with a $CD2^+$, $CD3^+$, $CD5^+$, $CD5^-$, Td^- ($CD4^-$, $CD8^-$) DN (double negative) profile [211]. Children develop these $CD4^-CD8^-$ DN T cells expressing the αβ TcR, hypergammaglobulinemia [310], a marked paracortical over accumulation of occasional small and intermediate-sized lymphocytes [240]. About 100-fold higher IL_{10}, but not IFN-γ or TGF-β was detected in DN than in single-positive T cells. IL_{10} was exclusively expressed in DN αβ but not γδ T cells [299]. Specifically, IL_{10} antagonizes the development of Th1 cells and indirectly enhances Th2 development. The Th2-oriented lymphocyte profile generated by IL_{10} may promote B-cell antibody production, including Aabs [240]. Currently, three genetically distinct subtypes of ALPS are recognized, caused by a mutation of the *TNFRSF6* (TNF receptor superfamily 6) gene (*ALPS type Ia*), of the FasL gene (*ALPS type Ib*), or of the caspase-10 gene (*CASP10*) (*ALPS type II*). In one subpopulation of patients, no mutations have been identified as yet (*ALPS type III*) [451]. Although these forms of ALPS differ genetically, they share defects in crucial homeostatic apoptotic mechanisms for controlling mature lymphocytes, leading to the features of ALPS [240].

Some children exhibit lymphoproliferative features during the 1st year of life and most children are well before the 5th year of life [33]. Some patients with ALPS have relatives with these same apoptotic defects who are clinically well [240]. ALPS, especially at young ages, is usually associated with lymphadenopathy, moderate to massive splenomegaly, and hepatomegaly resulting from abnormal accumulation of lymphocytes. AIHA, neutropenia, and idiopathic thrombocytopenic purpura are the most common features to diagnose autoimmunity in children with ALPS. These features have important diagnostic and prognostic value in avoiding expensive and time-consuming studies and unnecessary treatments [310]. However, the appreciation that manifestations of lymphoproliferation usually subside over time has allowed a wait-and-see approach in many patients who might previously have been treated aggressively. [33], although immunological disorders persist [354].

Autoimmune Neutropenia

Primary autoimmune neutropenia (AIN) is caused by increased peripheral destruction of neutrophils as a result of antineutrophil Aabs [47] and occurs predominantly in infants and toddlers between the ages of 6 and 24 months [435]. Primary AIN was mainly diagnosed at the average age of 5–15 months [47, 292, 412] and resolution of neutropenia was 20.4±4.9 months [412]. AIN was observed as early as day 33 of life [47], and two cases of congenital AIN in premature neonates indicate that AIN can have *a prenatal onset* [48]. Secondary AIN occurring in collagen vascular diseases such as JRA and SLE often shows more severe infectious complications [487]. In 90% of cases, AIN is associated with mild infectious symptoms (88.9% of children) [435], despite severe neutropenia, including skin abscesses, otitis media, and upper respiratory infections, only 12% have pneumonia; sepsis and especially meningitis are extremely rare in AIN [47]. One child had primary AIN associated with endocrinopathies [487]

Neutropenia is the sole abnormality, and neutrophil counts are generally <500/μl [44, 487], virtually always <10%, and usually <5%. CBC with differential usually reveals a selective, profound neutropenia with an otherwise normal CBC, often including a normal WBC. Both platelet and red cell counts are normal, although monocytosis and/or lymphocytosis may be seen. If neutrophil antibody testing in AIN is complicated, repeating testing as many as three times is recommended, to detect antibodies in clinically suspected cases if the initial test results were negative [47]. Examination of BM biopsies may reveal an increase in B lymphocytes and myeloperoxidase-positive cells with a maturation arrest at the myelocyte stage [48], with a markedly reduced number of neutrophils beyond the band stage [487]. The diagnosis of AIN depends on the demonstration of Aabs directed against neutrophil-specific antigens such as CD16 [487]. Primary AIN is usually associated with NA (neutrophil antigen)-specific antibodies, whereas secondary AIN seems to be associated with pan-FcγRIIIb antibodies [28]. Antibiotics are indicated for prophylaxis of infections. For severe infections, G-CSF, CSs, and IV IgGs are administered, resulting in increased neutrophil counts in 100%, 75%, and 50% of the children treated, respectively [47]. If the neutrophil count rises substantially to >1,000/μl (87% of children), the response con-

firms the diagnosis of AIN and provides therapeutic benefit [292]. See "Cyclic and Severe Congenital Neutropenia" in Chap. 22.

Diabetes

Definition and Classification

Diabetes is caused by inherited and/or acquired deficiency in production of insulin by the pancreas, or by the ineffectiveness of the insulin produced. It is an immune-mediated, but heterogeneous disease including both primitive forms: type 1 DM, and NIDDM (non-insulin-dependent diabetes mellitus) or type 2 DM, is characterized by progressive destruction of β-cells in Langerhans islands, with consequent total insulinopenia and hyperglycemia [353]. In 1%–2% of cases, NIDDM is transmitted as autosomal dominant (AD) inheritance (MODY, maturity-onset diabetes of the young), which can show itself during childhood or adolescence (<25 years) [426]. A case is transient neonatal diabetes: most newborns are growth-retarded at birth, present at a median age of 3 days, and recover at a median age of 12 weeks, and may be predisposed to diabetes later in life [416].

Epidemiology

The annual global incidence of pediatric DM ($\times 10^5$) in Europe is exceptionally high in Finland (35.2%) [441], with a high increase from 12×10^5 per year in 1953 to 45×10^5 per year in 1996) [335], and in Sardinia (33.2×10^5) [397]. In Denmark, Norway and Sweden, incidence is >20% [241]. In Poland the increase was significant in children aged 0–4 and 5–9 years in the Wroclaw province [96]. In Liguria, Italy, the incidence rate was higher in the 10- to 14-year-olds (15.01×10^5) than in 0- to 4-year-olds (9.01×10^5) and in the 5- to 9-year-olds (13.03×10^5) [69]. In Germany only 70 children were identified in a nationwide diabetes survey out of >5,000 (1.4%) young people who would meet DM diagnosis [199]. In the US, by 1994 it represented up to 16% of new cases, and by 1999, this incidence ranged between 8% and 45%, primarily in African, Asian, Mexican, and Native American children and youths [192], much less in the native population of Canada [498]. A report based on 24,423 children found during the period 1989–1998 an annual increase in incidence of 3.2%, highest for children in the 0- to 4-year-old age group: 4.8%. Central and Eastern Europe showed the highest increase, whereas Sardinia and Northern Europe (except Finland) showed no evidence of an increase [146]. In France during 1988–1997 there was an increase from 7.41×10^5 to 9.58×10^5, with a similar shift toward the same young group, higher in males than in females [56]. DM incidence has increased in Thai children and adolescents from 5% during 1986–1995 to 17.9% during 1996–1999 [233], was 0.7×10^5 per year in Peru [238], and increased in pediatric populations in several countries [307]. In a meta-analysis of 37 studies in 27 countries, the overall increase in incidence was 3.0% per year; however, the incidence of Type I DM is increasing worldwide to such an extent that by the year 2010 the incidence will be 50×10^5 per year in Finland and in several other populations it will exceed 30×10^5 per year [307]. A meta-analysis in 100 populations worldwide found that the overall age-adjusted incidence of type 1 DM varied from $<0.1 \times 10^5$ per year in China, Pakistan, Paraguay, Peru and Venezuela to the above-mentioned highest rates in Sardinia and in Finland. This represents a >350-fold variation in the incidence among the populations examined. A very high incidence ($\pm 20 \times 10^5$ per year) was also found in Sweden, Norway, Portugal, the UK, Canada, and New Zealand [188]. Among 303 diabetic twins, 81.5% had type 1 DM and 9.25% type 2 [174]. The incidence was the highest among children aged 10–14 [188]. For type 2 diabetes, recent prevalence estimates were 3.6% for Cree and Ojibwa girls aged 10–19 living in Manitoba [87] and 5% (CI 3.2–6.9) for Pima Indians aged 15–19 living in Arizona [76]. There, from 1966–1976 to 1987–1996, the prevalence increased fourfold for children aged 10–14 and sixfold for children aged 15–19 [76]. Instead, prevalence estimates were 2.7% for children aged 4–19 living in Manitoba [87]. The wide variation in geographical distribution has been related to different impacts of environmental factors [93], while its lower incidence in densely populated areas with many cohabitants in any single accommodation suggests that very early infections may play a protective role [300]. DM onset even during the neonatal period, and with 0.22×10^5 incidence [241], matches the higher number of new cases diagnosed at neonatal age [441]. There are no substantial differences between sexes as for the onset [241]. A disproportionately higher prevalence in the incidence of type 2 DM in children and adolescents has been highlighted recently, which underwent a greater than tenfold increase over the past decade [105, 361, 419]. The increase has been primarily attributed to the epidemic proportions of childhood obesity [497] in children with type 1 [192, 199, 233] and type 2 DM [105]. A study of the prevalence of childhood asthma and type 1 diabetes in 28 different countries found a strong positive correlation of the prevalence of these two conditions, suggesting that the immune processes underlying childhood asthma and autoimmune diabetes might be similar [403]. Until recently, most children with DM had type 1; however, type 2 diabetes is being reported in children from the USA, Canada, Japan, Hong Kong, Australia, New Zealand, Libya, and Bangladesh [105]. The prevalence of type 2 DM in children ranges from 4.1% of 12- to 19-year-olds in the US to 50.9% of 15- to 19-year-old American Indians [11, 105]. Between 8% and 45% of recently diagnosed cases of diabetes among children and adolescents in the US is

type 2, and the magnitude of this disease may be underestimated [11, 105].

Genetics

Twins provide a powerful tool to investigate relative importance of genetic factors on traits by comparing of concordance in MZ and DZ twins [348]. Significant deviation from 50% sharing was observed. MZ twins of patients with type 1A diabetes have a diabetes risk higher than that for HLA-identical twins ordinary siblings, suggesting that non-HLA genes contribute to diabetes risk [348]. MZ twins are also discordant (only one twin affected) for type 1 DM. More precisely, since the concordance rate among identical twins of whom one has type 1 DM is only 30%–50%, discordance for disease between such twins implies the postnatal participation of environmental triggering factors or other genetically or nongenetically determined factors, but could also be influenced by a decreased load of diabetes susceptibility genes [273]. The concordance rates for DM in MZ twins were very high: 70% in DR3/DR4 HET twins, but only 40% if they were not. If a sibling shares both HLA-D haplotypes with an index case, the risk for type 1 DM in that proband is 12%–20%; for a sibling sharing one haplotype, the risk is 5%–7%; with no haplotypes in common, the risk is only 1%–2% [357]. It can be assumed that in whites, the overall risk to cotwins is 50% within 7 years if the entrant is <10 and 23% if the he is >10 at the time of diagnosis [174]. The risk to offspring of a diabetic parent is 2%–5%, with the higher risk occurring in the offspring of a diabetic father. DM can be observed after BMT, thus confirming the immune nature of the disease [218]. The family incidence of DM (Fig. 18.26) is well known. There is a difference concerning the parents, since the number of children with DM having mothers with DM is lower than the number of children having fathers with DM. The incidence is 6% of fathers and 2.5% of mothers of children <15 years, with a total risk for children <20 years of 5.4%–7.6%, if their fathers are diabetics, and 2.1%–3.5%, if their mothers are diabetics [8, 97, 440, 466]. Of 243 children with features of type 2 DM, 76% had no known diabetic parent, 7% had a diabetic father only, 15% had a diabetic mother only, and 2.5% had two diabetic parents [308]. The risk of diabetes in offspring was significantly higher if the parent's DM was diagnosed before age 11 than if it was diagnosed later (9.3% vs 4% for the offspring of DM fathers [8]. Early onset affects the last-born child, who has a 1.75-fold risk compared to older siblings [440], who have a 10% risk before reaching 20 years of age [8]. It has been observed that DM is directly proportional to the father's age at onset, and inversely proportional to the mother's age at delivery [466]. Thus, the impact of imprinting is still unclear. Apparently, it is correlated with the maternal allele preferential expression [144]. However, if DM is correlated with the paternal allele, the neonatal DM is transitory [415]. MZ twins have a much higher risk of progressing to DM and expressing Aab than do DZ twins [348]. Studies on twins have shown a higher concordance in MZ [216], corresponding to a consistency rate of 35% in the late onset type, and 60%–100% rate in the common type [493]. In addition, carrying the high-risk insulin genotype increases the likelihood of identical twins being concordant for DM and the load of both HLA and non-HLA susceptibility genes having an impact on DM penetrance [273].

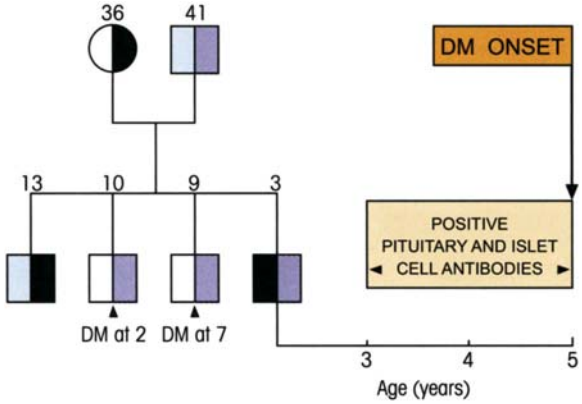

Fig. 18.26. Prospective study of a family with DM. The 3-year-old sibling had complement fixing antibodies to the islet cell surface before developing frank DM

Children at risk may develop type 1 DM through a dysfunction of HLA class II in the expression of Ii (invariant chain) p35, which may result in the impairment of antigen presentation [491]. Type 1 DM has a substantial genetic component, with consistent evidence for susceptibility *loci* in the *HLA-DR/DQ* region on chromosome *6p* and the insulin gene region (DM2) on chromosome *11p* [446]. The gene with strongest susceptibility is localized on the HLA-DQ *locus,* in linkage disequilibrium with HLA-DR [447]. Genome-wide scans for linkage have identified 18 chromosome regions showing some evidence of association with DM [83], with 10 susceptible *loci* confirmed. Each *locus* is linked to a type of DM (DM1 to DM18) [65, 118, 281, 425]. Others are correlated with MODY and type 2 DM, with late or common onset, and to neonatal DM (Table 18.18) [26, 62, 64, 65, 70, 83, 118, 144, 168, 259, 271, 280, 281, 348, 426, 446, 488, 489]. MODY 1–7 are known [280], MODY1–3 cases are transmitted by an AD trait [493], but types 1 and 3 are linked to HNF-4α and -1α mutations (4α and 1α hepatocyte nuclear factors), respectively. HNF is a transcription factor also present in Langerhans islands, which belong to the superfamily of thyroid/steroid hormones [488, 489]. Glucokinase-related MODY (MODY2) is frequent in children, mutations in the genes encoding IPD1 (insulin promoter factor 1), HNF-1β and NeuroD-1 (neurogenic differentiation factor 1) are the

rare cause of MODY4, MODY5, and MODY6, respectively [107].

Molecular biology methods have proven that the strongest relative and absolute risks were observed for *DRB1*0401*, *DRB1*0402*, *DRB1*0405*, *DQA1*0301-DQB1*0302* and *DQA1*0501-DQB1*0201* alleles [348] or for *DQB1*02-DQA1*0501/DQB1*0302-DQA1*0301* HZ, or the simultaneous presence of both *DRB1*03* and *DQB1*0302* alleles. An additive risk is suggested: *DRB1*03 is more strongly associated with DM than DQA1*0501-DQB1*02* and that *DRB1*0401* has an additive effect to *DQB1*0302*, thus the association between type 1 DM and HLA results from a complex interaction between *DR* and *DQ* haplotypes [204]. In children with type 1 DM, the frequency of risk-related alleles *DQB1*0302*, *DQA1*0201*, *DR4*, and *DR3* was more prevalent among Swedish than among Lithuanian subjects. Transmission rates of *DR4-DQB1*0302-DQA1*0301* and *DR3-DQB1*0201-DQA1*0501* alleles *from parents were higher than expected. DQB1*0302* and *DR4* were significantly more frequently transmitted *from both parents,* but *DR3* was transmitted more frequently *only from mothers* [367]. It may be related to age, since no child with early-onset DM had either of the protective *DRB1*1501* or *DQB1*0602* alleles [160]. Less common haplotypes such as *DQA1*0401-DQB1*0402* and *DQA1*0101-DQB1*0501* are also associated with high risk for DM [204]. It was hypothesized that the *DQB1*0302* either as HZ or HET encoding for aspartic acid (AA) at position 57 of the *DQ* α chain conferred protection, while the presence of arginine (Arg) at position 52 on the *DQ* β chain determined susceptibility to type IA DM, as observed in diabetic subjects and first-degree relatives as compared to controls [306], even though this predisposing factor is less relevant (Table 18.19) [348, 353]. Among the patients, 92.78% carry *DQa1* alleles that have Arg in position 52 of DQ α chain, and 78.2% are AA^- in DQβ at 57. The RR for HZ is 32.8 and 5.6, respectively [143]. A significant enrichment in *DQB1* alleles encoding for an amino acid different from AA in position 57 and *DQA1* alleles encoding for Arg in position 52 was observed in diabetic subjects and first-degree relatives as compared to controls [306]. *DRB1*1401* and *DQA1*0102-DQB1*0602* alleles [348] and *DMA*0102* and *DMB*0101* can provide protection from type 1A DM. *DQ7 is the protective allele* (OR=0.38), whereas *DQ8 is the allele conferring the susceptibility,* which is associated with an OR of 8.07 [372] and a RR of 12–32 [9, 72]. In comparison, the risk is 4 for *DR2* or *DR3* carriers alone, 6 for those carrying *DR4* only, higher for HETs on *loci DR3/DR4*, and equal to the sum of *DR2*, *DR3* and *DR4* alone; 90%–95% of diabetic patients have *DR3* and/or *DR4* haplotypes (Table 18.3), compared with 40%–50% of the general population [357]. This may be a synergistic effect of both genes, since this effect is relative, being linked to the *DQB1*0302* allele as HET in the haplotype *DR4* [353]. The observation that 20% of Americans and Europeans have *DQA1*0102-DQB1*0602*, while <1% of children with type 1A diabetes carry these alleles underlines the importance of genetics in disease development [348]. Recently, the hypothesis of non-HLA genes contributing to diabetes risk is supported by the observation that the

Modified from [348, 353].

diabetes risk for MZ twins of patients with type 1A DM is higher than the diabetes risk for HLA-identical ordinary siblings. Multiple genes, different in unrelated families probably explain this non-HLA genetic susceptibility [348]. Only two non-HLA *loci* are known. *DM2* is a polymorphic region that maps to a variable nucleotide of tandem repeat (VNTR) minisatellite, with three main VNTR classes. HZ for class I VNTR predisposes to DM1 and the longer class III alleles confer dominant protective effect. This *locus* contributes ≈10% toward disease susceptibility. Another *locus* associated with DM1 in some populations is *DM12* (Table 18.18), whose marker is the CTLA-4 (cytotoxic T lymphocyte antigen-4) = CD152 (*2q33*) (DM12). CTLA-4 and GCK may concur to the susceptibility [144] that encodes a receptor expressed by activated T cells involved in the T-cell activation. Studies in Japanese [279] and Polish [212] children have shown that a polymorphism at the *CTLA-4* gene (A → G transition at position 49 of exon 1) called the *G* allele, is preferentially transmitted to the affected siblings. Instead in nondiabetic offspring, the *CTLA-4 49 A* allele confers a protective effect in the presence of maternal *HLA-DRB1*03* and paternal *HLA-DRB1*04* alleles. Segregation analysis supports the hypothesis of a modulation by *CTLA-4 49 A → G* dimorphism of the *susceptibility conferred by maternal HLA-DRB1*03 inheritance* [108]. Recently, it has been stressed that there may be a pathogenetic relevance of genetic factors unconnected to the HLA system and particularly to the genes controlling the production of TNF-α. These are localized on human chromosome 6, and are close to class I and II genes and to the genes of some complementary components. It has been observed that this IL is one of the most important ILs produced in patients with DM; it is associated with *DR4* and is a crucial cytotoxic factor. These data cannot be applied to TGF-β [337].

Autoimmune Diabetes

Remarkable studies on transgenic mice have shown that β-cell destruction occurs via the convergent and synergic action of three genes: a HLA molecule, a TcR specific for this molecule, and increased IL local production, which lead to island inflammation and destruction; a viral infection can trigger IL production [286]. A fourth cause of β-cell destruction is reflected in increased circulating levels of adhesion molecules, supported by the observation of elevated sCD54 concentrations in 29 siblings who progressed to clinical type 1 DM [429]. The SA intervention in DM has been suggested. These SAs, by reacting with a proper TcR, signal the beginning of the destruction to T cells [286]. The most common abnormality at DM onset (60%–90% cases) is the presence of Aabs such as ICA (islet-cell antibodies) and insulin Aab (IAA), evidence of an AID, which can be found in 5% of the general population [157]. These Aabs seem to have a role not so much pathogenetic as supportive of the autoimmune activity after the initial damage, exacerbating the β-islet destruction [286]. Male gender and young age favor positive ICA reactivity, and siblings test positive for high ICA titers more frequently than parents [103]. IAAs were detected in 45% of children with an 85% positive rate in <5-year-old children, GADs (glutamic acid decarboxylases) in 66% and ICAs in 23% of children [140]. ICA and GAD-positive frequencies in type 2 DM children were 71%–76% lower than in type 1 DM children. Among children with type 2 DM, the rates were 34.8%, 30.3%, and 8.1%, respectively [159]. However, the frequency of positive ICA512 and GAD65 antibodies was significantly less in early onset DM (28.6% and 31.6%, respectively) [160]. As for GAD, there are at least two allelic forms from different genes, known as *GAD67* and *GAD65* (based on their respective MW, which might coexist in patients' sera [191], playing a preventive role against DM [472]. Conversely, anti-GAD antibodies are indicative of β-islet destruction [157]. Most peptides derived from GAD65 and islet associated-2 Aags can bind to HLA molecules predisposing to or protecting from type 1 DM [155]. In other twin studies, IL_2 and TNF-α responses to GAD were detected more frequently and at higher levels in diabetic compared to nondiabetic twins [330]. Moreover, T cell responses to a human GAD65 target epitope as a DM-associated Aag present-

Table 18.20. Major DM autoantigens (Aag) and autoantibodies (Aab)

Antigen	Localization	Clinical significance
ICA (glycolipid)	All islet cells	Main immune marker of recent-onset and preclinical DM insulin Aab in over 50% of subjects with late preclinical and recent-onset DM; especially in younger children are an index of remarkably faster β-cell destruction
IAA	β Cells	
64K/GAD	β Cells, all islet cells, neurons, ovary, testis	Aac to 64K or GAD in about 80% of subjects with preclinical DM, their titers remain more elevated than ICA during DM progression
37 kD/40 kD Tryptic	Secretory vesicles of β cells	Aab in up to 60% of preclinical fragment of 64K and recent-onset DM subjects and in 2%–3% of their relatives
38 kD (Protein from insulin secretory granule membrane)	Neuroendocrine secretory cell granule	Aab in about 30% of recent-onset DM subjects, it is identified as the target of T-cell lines from peripheral blood of recent-onset DM subjects
52 kD (PTP)	Neuroendocrine secretory cell granule	Aab in 25% preclinical and 0% control subjects. True prevalence and disease specificity unknown
Islet polar antigen	Vascular pole of β cells	Aag in up to 25% of preclinical DM subjects
GLUT-2 (glucose transporter protein)	β Cells, hepatocytes	Aag in up to 75% of recent onset DM subjects
Pro-insulin	β Cells	In preclinical and recent-onset DM subjects and in full-blown DM; usually correlated with IAA

ed on HLA-DR4 molecules are experienced by a majority of DR4-positive DM patients aged 14–25, indicating that this epitope represents one of the epitopes recognized by $CD4^+$ T cells during the autoimmune events associated with DM [294]. Table 18.20 [59, 157] summarizes the main characteristics of these Aabs and Aags, and of another immunological marker, the PTP (protein tyrosine phosphatase) [59, 157]. GAD and PTP are present in 55%–60% of diabetic patients at onset and in 8%–9% and 2%–3% of relatives, respectively [59]. Glima 38 is recognized by Aabs in 20% of patients with type I DM, its biochemical properties define glima 38 as a new Aag in type I DM, able to bind *Triticum vulgare* and *Ricinus communis* I lectins [358]. Aabs to human HSP60, HSP70 and HSP90 proteins evaluated in children with newly diagnosed type 1 DM showed heightened T-cell autoimmunity to HSP70 and HSP60, but not to HSP90 [1].

Some models point to the molecular mimicry between PC-2 proteins of the *Coxsackie* B4 virus and GAD antigen [353], the enzyme catalyzing the glutamic acid conversion into GABA (γ-aminobutyric acid) [157]. Furthermore, the primary viral infection may decrease the expression of some viral genes inside β cells. It is likely, however, that cross-reactive epitopes evoke a chronic immune response specifically aimed at β cells [353].

Immune Dysfunctions

Type 1 DM is associated with immunological dysfunctions such as B-cell and related Aab dependency, and CMI deficits and the phagocytic system: type I develops after a period of autoimmunity against pancreas β cells. Multiple immunoregulatory T cell defects such as low numbers of resting $CD4^+$ $CD25^+$ T cells underlie islet-cell autoimmunity, leading to immune-mediated diabetes in humans with these lesions possibly part of a broad T cell defect. Moreover, a defective production of IFN-γ and IL_4 deficiency in NK T-enriched cells were reported [214]. T-cell recognition of insulin-secretory granule antigens is associated with the immune-mediated process of β-cell destruction, thus showing that T cells have a role during the disease process [356]. The level of lymphocytes with surface markers consistent with recent primary activation (CD45RA/CD45RO) was higher than that in the other diabetic children, who had higher levels of CD45RA/CD45RO cells than the nondiabetic controls [260]. Whether or not B cells are activated, Aabs to pancreatic β-cell antigens can be produced, such as GAD65, insulin, or the tyrosine phosphatase-like Aag IA-2, and they are able to take up and present autoantigen to T cells [351, 356]. In a 14-year-old boy with X-linked agammaglobulinemia (XLA) DM1 (immune-mediated) developed [260]. Since XLA is charac-

terized by a blocking of B-cell differentiation that results in an arrest in the progression of pre-B1a cells, it is obvious that neither Aabs nor B-cell function is critically involved in the pathogenesis of type 1 DM.

The development is also possible without HLA class I cytotoxicity, thus suggesting the pathogenic contribution of a killing factor through PBMCs, macrophages, activated CD4 and endothelial cells [207]. Secondly, the insulitis is caused by SAs or other immunostimulating products expressed by β cells. It is rather the balance between mediators and IL released by Th1 and Th2 that may cause the destruction of β cells [207]. Data obtained from studies on NOD mice stress the preferential activation of IL_{10} and IL_{12} by macrophages and resident DCs. IL_{10} plays an anti-inflammatory role by inhibiting IFN-γ and Th1, thus favoring Th2 and sparing islet cells. The same occurs with macrophages and their APC function [433]. The opposite occurs when IL_{12} prevails and Th1 are produced. Th1 along with NK cells produce high levels of IFN-γ, which in turn amplify the IL_{12}-mediated Th1 response [434]. Thus, the prevailing response is Th1, with a preventive role played by the Th2 response. This is confirmed by the Th1 of transgenic mice for diabetogenic TcR, which can transmit the disease to healthy NOD mice. Moreover, when the IFN-γ action persists, macrophages are activated to carry on cytolytic activities and secrete $IL_{1\alpha}$ and/or TNF-α, potentially cytotoxic for β cells [434]. It has been observed that IFN-γ and IL_2 cause CTLs to destroy β cells and secrete TNF-β and more IFN-γ [433]. Its damaging action is confirmed by experiments on transgenic mice developing DM when it is expressed on β cells [447]. In contrast to what has been said, NOD mice expressing IL_{10} seem to develop a severe and early form of DM instead of being protected by it [481]. This can be explained by the protective effect played by TGF-β [58]. The break in the Th1/Th2 balance is consequent to the CD28/CD80 block. This prevents the differentiation of Th2 and triggers DM [224]. The comparison of mature DCs between patients and controls showed significant differences for CD80 and CD83; no difference in T-cell stimulatory capacity was seen [500].

Recently, it has been shown that the incidence of atopic diseases in DM is not higher than the incidence among controls. There are, however, specific differences concerning late responses [405]. As for specific foods, even without direct evidence, the epidemiological data seem to corroborate the protective role of exclusive breast-feeding [462], and the close relationship between early CM ingestion and the onset of DM [78]. This hypothesis, however, is not supported by all studies [248]. Apparently, some children with DM have IgG antibodies against ABBOS, a specific peptide from bovine serum albumin (BSA), which cross-reacts with a 69-kD protein (p69), possibly induced by β-cell IFN-γ in Langerhans islands. Thus, CM ingestion, failing any symptom of CM allergy (CMA) can trigger DM if the nursing child is susceptible [186]. It is revealing that almost all diabetic patients have anti-ABBOS Aabs, triggering a T response against them, vs only 2% among normal subjects [136]. Not all researchers agree on BSA immunogenicity for subjects with DM [17]. It must be stressed, however, that in children with CMA, BSA is a powerful allergen, even though it is weaker than other CM proteins (Table 1.75), and DM seems to be linked to a cellular, not humoral, reaction. CM protein immunogenicity has been further proven in children and teenagers with early onset DM [100, 376]. It is significant that both CM and hydrolyzed casein, administered to prevent DM, induce both humoral and cellular reactions [445]. α-Casein has a five-amino acid sequence identical to the protein GLUT-2 [52], which transports glucose inside β-cells. Thus, CM exposure and/or its derivates may induce a gut cross-response to the carrier protein. This data implies inadequate regulation of oral tolerance and stresses that GALT is fundamental for immune DM pathogenesis [207]. To solve this problem, and the analogous problem with JRA, large-scale international studies, both prospective and randomized, should be elaborated.

Additional Factors

Among strictly etiological factors there is the association with viral infections [495]. The intervention of environmental factors is also possible such as ethnic and/or climatic factors, caloric excesses, social well-being, etc., but without any definite results [241]. According to some authors, all these factors rely on genetic factors [499]. As for the onset age, there are no substantial differences in a wide range of anamnestic, genetic and immunological data among children whose DM appeared at 3–6 years, except for significant differences concerning the IgA deficit and Aab presence, which are lower in younger patients [54].

Diagnosis

Since <10% of patients have previous cases of DM among relatives, screening the illness appears problematic [59], but it is possible to dose tissue transglutaminase C for diagnostic reasons, also to screen for celiac disease, found in 3%–5% of type 1 DM children [217]. ICAs and IAAs are very useful for the identification of asymptomatic subjects at the preclinical stage, especially ICAs with 100% sensitivity vs IAAs with 33% sensitivity. Above all, there is a direct correlation between HLA heterozygosity, high and persistent levels of ICAs, and a high risk (>100-fold) of contracting the disease [187]. Persistent ICA positivity associated with IAA positivity defines the actual risk (47% and 70%), while the combination of HLA and high ICA titers has the highest predictive value (77%), since it is a risk factor 73-fold higher than in general population [187]. It must be stressed that when ICAs are at low levels, high-risk HLA

markers do not lead to DM, whereas the opposite correlation is a sign of actual risk [187].

Treatment and Prevention

Insulin is the mainstay of treatment. Continuous insulin infusions administered by insulin pumps provide multiple advantages over manifold insulin pump therapy in toddlers and young children [237]. Table 18.21 shows the classification and the preventive measures [339].

Table 18.21. DM prevention

Classification
Primary prevention
Intervention at birth in at-risk children by removal of etiological factors
Diabetogenic virus or with molecular mimesis
Other environmental factors, including dietary restrictions or changes
Secondary prevention
Intervention during the latency phase in children with positive specific markers
Tertiary prevention
Protective intervention at early DM diagnosis of residual β cell mass and function
Intervention
Primary prevention
Breast-feeding
Cow's milk exclusion
Secondary prevention
Insulin
Nicotinamide

Data from [339].

Table 18.22. Therapeutic and preventive approaches for DM under investigation in the animal model of DM

Analogous of vitamin D_3
Anti-oxidants
Immune deviation using autoanalogs
Islet cell vaccination
Monocyte and lymphocyte adherence inhibition
NO inhibitors
T-cell vaccination
Thymic injection of β-cell antigens
Vaccination with specific insulin peptides

Modified from [339].

The most important measures are breast-feeding for newborns at risk [136, 498] and the use of insulin or nicotinamide in secondary prevention. The administration of low-dosage insulin to children at high risk proved to be highly effective, so much so that it could delay or prevent the DM onset [136]. It may be impossible to eliminate CM from the diet of nurslings and children at risk for DM without having more data on the possible presence of anti-ABBOS antibodies in their healthy parents as well [248]. A meta-analysis shows that there is no convincing evidence relating type or intensity of diabetic treatment to the prevention or management of cognitive impairment in MODY [14]. Therapeutic and preventive perspectives have been studied in animal models (Table 18.22)] [339]. Children with DM treated with modern regimens attain a normal height [86]. There is also the possibility of inducing tolerance by administering GAD65 to NOD mice, through the activation of Th2, which blocks autoreactive Th1 [424]. It should be noted that provoking an anti-Th1 response via Th2 may destroy the protective immunity against intracellular microorganisms, or induce allergic reactions [231]. One of the environmental factors that should be stressed is the monitoring of viruses with molecular mimicry, which can have amino acid sequences in common with GLUT-2 and/or p69 [25]. A therapeutic approach to β-cell salvage was tested in new-onset DM by means of anti-CD3 antibodies, which ensures that endogenous insulin secretion remains stable and improves metabolic control during the 1st year of treatment. Clinical responses were associated with a shift from $CD4^+$ T cells to $CD8^+$ T cells 30 and 90 days after treatment [162]. Phase 2 studies should follow.

It is also likely that supplementation of appropriate amounts of LCPUFAs (long-chain polyunsaturated fatty acids) and ω-6 and ω-3 fatty acids *in utero*, and first year of life protect against atopy, AIDs, *type 1 and type 2 DM* [81].

Systemic AIDs

Based on Table 18.2, systemic AIDs include two types of vasculitis (Table 8.17), SLE and dermatomyositis, whose characteristics are summarized in Table 18.10, and juvenile scleroderma.

Systemic Lupus Erythematosus

Definition

SLE is an autoimmune disease in which the body's own immune system is directed against the body's own tissues. SLE is a form of diffuse vasculitis caused by CICs, of which the best example is glomerulonephritis characterized by fibrinoid necrosis of vessel walls, which pro-

duce a systemic inflammatory damage to target organs. Defined by clinical criteria, SLE is a chronic disease with protean manifestations.

Epidemiology

SLE occurs in 0.6 children $\times 10^5$; the female/male ratio is 1:1 until 10 years of age, and 10:1 afterwards [13], for an incidence of 1.4% [250]. The onset of SLE before the age of 5 is uncommon [124]. Two girls aged 6 weeks and 3 months were seen with diffuse proliferative glomerulonephritis, anti-double-stranded (ds) DNA and infantile SLE [265]. Two additional infants aged 2.5 and 6 months were reported [265]. Other children may be as young as 3.2 years [250]. In 39 children with a median age at onset of 12 years, the female/male ratio was 18.5:1 [178] and 6.4:1 [250]. In 204 children, the SLE diagnosis was made before the age of 16 (19.1%) or after the age of 16 (80.9%). [438]. The trial on 1,742 children found a SLE incidence of 6% [89] and two other studies a 0.28 [250] and a 0.48 incidence $\times 10^5$ [169].

Genetics

A genome-wide linkage study of NZB x NZW F2 mice revealed 8 loci designated Lbw1–8, that were located on chromosomes 17, 4, 5, 6, 7, 18, 1, and 11, respectively. They were linked to mortality, nephritis, IgG antichromation Aab production and splenomegaly. In particular, Lbw1 was linked to mortality, nephritis and antichromatin Aabs and mapped to the HLA region. Heterozygosity at Lbw1 (H-2d/z) conferred the greatest susceptibility. Lbw2 was dominantly transmitted and associated with accelerated mortality, nephritis, and splenomegaly [421]. Four major *loci* were additionally identified, designated Lmb1–4, on chromosomes 4, 5, 7 and 10, respectively. All 4 QTL (quantitative trait loci) were linked to lymphoproliferation, Lmb1–3 were also linked to antidsDNA antibodies and Lmb4 was also linked to nephritis [461]. In a cohort of 115 multiethnic nuclear families containing 145 SLE-affected sibpairs, haplotype sharing at *1q23* increased concomitantly with increased haplotype sharing at *16q12*. Analysis of sibpairs sharing two alleles at *16q12* also showed increased allele sharing at *1q23*. No evidence supporting an interaction between *16q12* and *20p12* was observed. These data support the presence of SLE susceptibility genes at *1q23* and *16q12*, particularly in non-Caucasians [436]. In a Chinese cohort, chromosome *16q12* is a likely susceptibility gene for SLE, which was found in linkage disequilibirum with the marker D16S409 and D16S517 [115]. In 94 extended multiplex pedigrees, four genes for SLE (*20p12*, *1p13*, *1q42*, and *4q28* with lod scores ranging from 2.62 to 1.46) were identified in combined African-American and European-American families, with an effect for the FcγRIIA candidate polymorphism at *1q23* (lod, 3.37 in African-Americans) [284]. In a study in 105 SLE sibpair families, the strongest evidence for linkage was found near the HLA locus (*6p11–p21*) and at three more regions: *16q13*, *14q21–23*, and *20p12* (lod scores ranging from 2.62 to 3.90). Nine additional regions (*1p36*, *1p13*, *1q42*, *2p15*, *2q21–33*, *3cent–q11*, *4q28*, *11p15*, and *15q26*) had lod scores ranging from 1.00 to 1.68 [130] and seven additional regions had significant linkage (lod ≥3.3 or $p \geq 0.00005$) at *1q22–23*, *1q41*, *2q37*, *4p16*, *6p21–11*, *16q13* and *17p13*. Putting the pieces together, these linkages can be reproduced ranging from outright independent confirmation (*1q41*, *4p16* and *6p21*) to additional suggestive evidence in the genomic region of the purported linkage (*1q22–23* and *2q37*) [194]. Linkage analysis with covariates uncovered linkage at *13p11*, *17q11–25*, and *20q12* and greatly improved evidence for linkage at *1q22–24*, *2q37*, *12p12–11*, and *17p13* [305]. With 417 microsatellite markers, suggestive linkage in regions on chromosomes *6q* and *14q* as well as HLA on *6p* were detected, also showing evidence for excess sharing of a haplotype on *14q* and excess transmission of a haplotype on *6q* [209]. In a study on Icelandic families, five regions showed lod scores >2.0, which were located on *4p15–13*, Z=3.20; *9p22*, Z=2.27; *19q13*, Z=2.06, on *19p13* (*D19S247*, Z=2.58) and on *2q37* (*D2S125*, Z=2.06), while in Swedish families two regions showed lod scores >2.0: on chromosome *2q11* (*D2S436*, Z=2.13) and *2q37* (*D2S125*, Z=2.18). Notably, both family sets gave a highly significant lod score at *D2S125* of Z=4.24 in favor of linkage for *2q37* [236]. Recently the Oklahoma group has found evidence ($p<0.004$) of linkage at *16p13* and *16q12–13* with SLE in a genome scan based on 37 Hispanic families. [289], linkage at *11p13* for SLE identified in 27 African-American families [290] and linkage at *12q24* that may cause SLE in Hispanic and European American families [291]. In Chinese children, the haplotypes *HLA-A9B40/DRB1*15* and genotypes *HLA DRB1*09/DRB1*15*, *HLA-DRB1*03/DRB1*15* were correlated with SLE [228]. *The HLA-DRB1*1501* (protective for JRA and DM) *greatly enhanced the risk of developing lupus nephritis* conferred by the *DQA1*0101* allele (OR, 65.96), whereas *DQA1*0102 demonstrated a significant protective effect* (OR, 0.31) by suppressing the nephritogenic effect of *DRB1*1501* [256]. *HLA-A24* may confer additional risk of more severe disease expression in female patients with SLE and SLE patients carrying 39-kD *sHLA-I* have increased risk of developing renal disease [2]. *HLA-DMA*0104* may be *a novel allele of susceptibility* to SLE [282] and *TAP2*Bky2 may be a susceptible gene* not only to the disease of SS but also to SS-A/Ro Aab production [185]. Infants of SS-A/Ro- and SS-B/La-positive mothers bearing *HLA-A1*, *B8*, *DR3*, *DQ2,* and *DR52* are at greater risk of having neonatal lupus [221]. Thus multiple genes, including one in the *HLA* region, may influence susceptibility to human SLE [130]. Amazingly, mannose-binding lectin (MBL) variant alleles may confer a 1.6-fold overall increased risk of severity and infection for definite SLE [132].

Classification

The presence of a wide spectrum of clinical forms, from the most benign to the most severe, has triggered the hypothesis that SLE could be a syndrome rather than a well-defined illness [13]. Its major characteristics are summarized in Table 18.10.

Pathogenesis

SLE pathogenesis is not completely clear. However, a number of different factors seem to influence the expression of SLE. In 12% of patients, close relatives are affected, showing a *strong hereditary component* [378]. Studies on *HLA* haplotypes show a significant association with *DR3* (Table 18.3), clinically linked to subacute cutaneous SLE, neonatal SLE, and Sjögren syndrome. MZ twins show higher SLE concordances than HETs. The level of genetic contribution can be measured by comparing the concordance rate between MZ and DZ twins. MZ twins show higher SLE concordances than HETs. The MZ twin concordance rate for the clinical expression of SLE has been found to be 25%–69%, whereas that of the presence of serum Aabs can be as high as 92%. For comparison, only 1%–2% of sibs and DZ twins are concordant for SLE [180, 235]. Children show a relatively higher incidence of familial cases than adults. Furthermore, some children's relatives or family members are affected by other immune diseases, which suggests that SLE develops mostly in patients whose families are susceptible to immune-mediated diseases [18]. In 10%–15% of cases (vs 2% in the general population), there is HZ deletion of the *C4A* allele, which can reach 50%–80% peaks, almost doubling the normal value, when it is HET [378]. Complement deficits are most often associated with SLE-like syndromes [420] as well.

Immune dysregulation appears to underlie the development of SLE, where dysregulated $CCR2^+$ T cells and the CD4/CD8 ratio are also switched to the left [12], with clear stimulation of T-like ILs. Such ILs participate in the activation and differentiation of B cells into Aab-producing cells: as both purified T and B cells express FasL as well as several foreign infectious agent-derived proteins may share the epitope (aa – aminoacids 161–170) with human FasL [275]. This *aberrantly expressed FasL* may facilitate escape of the autoreactive B cells from the immune tolerance system and may contribute to the sustained Aab secretion in patients with SLE [287]. A major cause of Aab production is molecular mimicry which stimulates the development of Aab secreting lymphocytes [275]. Increased apoptosis and decreased clearance of apoptotic cells as observed in SLE might be a contributory factor in systemic autoimmunity [4]. Dysregulation of cell death rates in SLE may lead to self-reactive lymphocytes that normally undergo apoptosis before birth, which suggests that the aa 162–169 region is important for Fas/FasL interaction [275]. A synergistic effect between susceptibility alleles of both *bcl-2* and IL_{10} genes increases the odds of developing SLE by >40-fold [205]. Not only *bcl-2* [110, 277] and IL_{10} [77, 277], but also Fas and TNF-α [277] may interfere with the apoptotic process, promoting lymphocyte hyperactivity secondary to increased IL levels, thus denoting their role in disease activity. IL_{10} was a genetic susceptibility factor significantly associated with SLE in Italian patients [77]. Overexpression of bcl-2 was strongly correlated with SLE activity, thus suggesting an alteration of apoptotic regulation in patients with juvenile onset SLE [110]. Fas levels possibly secondary to TNF-α action, bcl-2 antigen expression and IL_{10} serum levels were shown to be related to the maintenance and progression of SLE [277]. The overexpression of Fas antigen may be associated with the reduction of bcl-2 expression in the basal cells, which correlates directly with the extent of apoptosis in the epidermis [19]. Efforts to characterize SLE as a Th2 or Th1 disease based on CD4 T-cell phenotype have met with difficulty, but IL_{10} seems to be increased in human and murine SLE, along with IL_6. The ratio of IL_{10} to IFN-γ-secreting cells in SLE peripheral blood is increased, thus implying *a Th2 cell predominance* in the circulation [62]. B lymphocytes are stimulated by T cells, with consequent polyclonal hypergammaglobulinemia, possibly caused by alteration of regulating mechanisms, or exogenous factors such as viral infections producing IFN-γ or bacterial infections stimulating the expression of HLA-DR on macrophages, etc. [13]. The marked Aab production leads to CIC formation with antigens and complement, CICs bind to C3b receptors, CR1 (CD11a), which, by interacting with erythrocytes, carry them to RES, in particular to the hepatic sinusoids, for the transfer to CD11b–CD11c-positive cells, mostly macrophages, which removes them from circulation [18]. Consequently, conditions like SLE with high CIC levels are characterized by a CD11a deficit [378]. Similarly, the lack of C1, C2 or C4 markedly reduces the link between complement and CICs, which become larger and less soluble, and, moving in peripheral plasma, deposit in tissues [378, 420]. The correlation of sCD62L with C4 in SLE may indicate that down-regulation of shedding of cell surface CD62L is involved in continued leukocyte adherence to endothelium, probably causing supplemental damage and CIC deposition in SLE children [35]. Clinically, Aab titers are closely related to the degree of inflammation. Anti-DNA antibodies may combine with circulating antigen and contribute to CIC deposition in renal glomeruli [7]. CIC-derived DNA of SLE patients reinforces the evidence that reactive O_2 species may be involved in its pathogenesis [7].

Clinical Presentation

The most frequent clinical manifestation of pediatric SLE, summarized in Table 18.23 [55, 178, 261, 378] and

Table 18.23. Main clinical manifestations of pediatric SLE (%)

Reference	[378]	[55]	[178]

Table 18.24. Common SLE cardiac, renal and CNS manifestations

Cardiac manifestations
Pericarditis
Valvular vegetations (Libman-Sacks endocarditis) most commonly in the mitral valve
Myocardial dysfunctions, including heart infarction
Subacute infectious endocarditis
Lupus nephritis
Class 1: normal
Class 2: mesangial
2a: minimal lesions
2b: mesangial glomerulonephritis
Class 3: focal segmental proliferative glomerulonephritis
Class 4: diffuse proliferative glomerulonephritis
Class 5: membranous glomerulonephritis
(WHO classification)
Neurological disorder
Aseptic meningitis
Behavioral changes
Chorea
Coma
Cranial nerve palsy
Headache
Infarction of nervous tissue
Mental deterioration
Peripheral neuropathies
Pseudo-tumor cerebri
Psychosis
Seizures
Transverse myelitis

Data from [222, 468].
WHO classification, accessed at http://www.mcl.tulane.edu/classware/pathology/medical×pathology/New×for×2004/renal/who.html. The WHO classification has recently been modified as follows: **class I**, mesangial immune deposits without mesangial hypercellularity; **class II**, mesangial immune deposits with mesangial hypercellularity); **class III** for focal glomerulonephritis (involving <50% of total number of glomeruli) with subdivisions for active and sclerotic lesions; **class IV** for diffuse glomerulonephritis (involving ×50% of total number of glomeruli); **class V** for membranous lupus nephritis; **class VI** for advanced sclerosing lesions. Data from [471].

Table 18.24 [222, 468], are not significantly different from the diagnostic criteria defined by ARA [411]. Symptoms are typically variable, as is their natural history (Table 18.10), with alterations in different organs (Table 18.24; Fig. 18.27). The clinical features are atypical, the symptoms are aspecific and heterogeneous. From Table 18.23 we see that malaise, weight loss, failure to thrive, and skin changes are present in 81.5% of cases, and fever in 72.5% of cases [55, 178, 378]. In addition, children exhibit nephropathy (20%), and lymphadenopathy (6%) as presenting clinical features. During the progression of SLE, the children had an increased prevalence of malar rash (79%) and chorea [124]. Arthralgia and arthritis are also present [178]. *The butterfly rash* (Fig. 18.28) is characteristic, whereas the discoid rash is rare in children, lesions that are scarring and occur either alone or in association with SLE. The malar rash is a fixed or raised erythema, over the malar eminences, tending to spare the nasolabial folds, which may be the initial presentation and must be distinguished from other causes of a so-called red face. *The discoid rash*

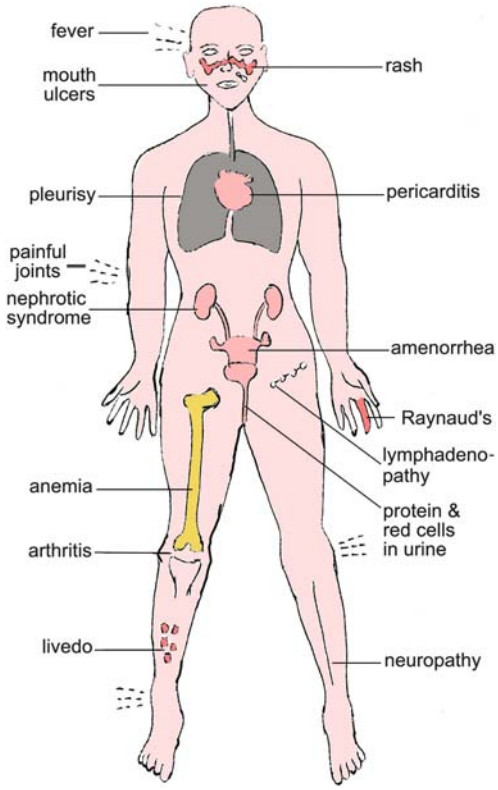

Fig. 18.27. The classical SLE patient

Fig. 18.28. SLE: "butterfly" rash

Fig. 18.29. Neonatal lupus

consists in erythematous, hyperkeratosic, scaly atrophic telangiectatic plaques on sun-exposed skin, with adherent keratotic scaling and follicular plugging, which remain unchanged for months, in regions such as the face, especially if exposed to sunlight, which frequently heal with scarring and dyspigmentation. Alopecia, despite being present in 34% of cases, is not part of the diagnostic criteria, in view of the obviously poor reliability and quantification of observations [178, 261]. Photosensitivity, causing oral and nasopharyngeal ulcers, Raynaud's phenomenon, and systemic complaints, is important. *Multiorgan involvement* is particularly characteristic, probably because of diffuse CIC deposition in vascular structures [41]. Hypocomplementemic urticarial vasculitis may be frequent [85]. A hematological disorder may include pancytopenia, leukopenia (<4,000/ml), lymphopenia (<1,500/ml), or a platelet disorder. A possible *neurologic disorder* (Table 18.24) may include behavioral changes, seizures, psychosis resistant to treatment, hallucination, autolesionism, possibly caused by a cerebral vasculitis (S. Cioschi, personal communication). There are also cases of *neonatal lupus* (Fig. 18.29) caused by transplacental passage of Aabs from mother to fetus between the 12th and 16th week of gestation, explaining the infant disease, as well as its spontaneous resolution, which is coincident with the disappearance of maternal antibody. Cutaneous lesions are rare features (annular, erythematous, scaly plaques typically on the head, neck, and upper trunk) (16%) often associated with thrombocytopenia (27%), hepatosplenomegaly, mild elevation of liver enzymes (26%), and atrioventricular block (1.6%) [61], and wane by 6 months, generally resulting in clearance of the rash. An incidence of 0.3% was found [250]. Since 50% of the mothers of babies with neonatal lupus do not clinically have SLE but carry the Aabs, it is not uniformly manifested in all offspring

of SS-A and SS-B Aab$^+$ mothers. In addition, other contributing etiological factors are being explored given the wide range of clinical manifestations associated with it [41, 221].

SLE course should be followed with particular care, as the progression is often unpredictable. The outcome is potentially dangerous because of sudden relapses, including frequent infections to which these children seem susceptible. Renal involvement should also be taken into account. Renal involvement (proliferative mesangial glomerulonephritis) is present in up to 75% of patients with other SLE features, which, if not aggressively treated, progresses to renal failure. This is a most common complication of proliferative glomerulonephritis.

Diagnosis

The diagnosis is based on the data from Tables 18.25 [166, 412] and 18.26 [178]. Table 18.24 [222, 468, 471] completes the list of symptoms.

The Major Laboratory Abnormalities

The excretion of >500 mg of urinary protein/24 h (>0.5 g/day) or >3+ proteinuria on dipstick testing), the presence of casts (including RBCs, hemoglobin, granular, tubular, or mixed), hematuria (>5 RBCs/hpf) or pyuria (>5 WBCs/hpf), or a protein-to-creatinine ratio >2.0 is evidence of renal disease and should prompt the

Table 18.25. SLE diagnosis, 1982 revised ARA criteria for clinical and laboratory SLE diagnosis

Criterion	Definition
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions.
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	a. Pleuritis – convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion OR
	b. Pericarditis – documented by ECG or rub or evidence of pericardial effusion
7. Renal disorder	a. Persistent proteinuria >0.5 g/day or greater than 3+ if quantitation not performed OR
	b. Cellular casts – may be red cell, hemoglobin, granular, tubular or mixed
8. Neurological disorder	a. Seizures in the absence of offending drugs or known metabolic derangements, eg, uremia, ketoacidosis, or electrolyte imbalance OR
	b. Psychosis – in the absence of offending drugs or known metabolic derangements, eg, uremia, ketoacidosis or electrolyte imbalance
9. Hematological disorder	a. Hemolytic anemia – with reticulocytosis OR
	b. Leukopenia– <4,000/mm^3 total on two or more occasions OR
	c. Lymphopenia– <1,500/mm^3 on two or more occasions
10. Immunological disorder	a. Anti-DNA: antibody to native DNA in abnormal titer OR
	b. Anti-Sm: presence of antibody to Sm nuclear antigen OR
	c. Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) false-positive serological test result for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
11. Antinuclear	An abnormal titer of antinuclear antibody by immune fluorescence, antibody or an equivalent assay at any point in the time and in the absence of drugs known to be associated with drug-induced lupus syndrome

Note the classification is based on 11 criteria: if any four or more of the 11 criteria are present simultaneously or progressively during the course of disease, the diagnosis of SLE is made with 98% specificity and 97% sensitivity.
Data from [166, 412].

Table 18.26. Laboratory diagnosis (including immune ARA criteria)

ESR	Elevated
Hemoglobin	Low
	a. Chronic inflammatory anemia
	b. Autoimmune hemolytic anemia in some patients
Leukopenia	In particular lymphocytopenia
Thrombocytopenia	In some patients
CRP	Often normal unless in case of infection
C3, C4 and CH50	Commonly decreased
IgG	Often elevated
IgM	Can be elevated
IgA	Sometimes absent
Rheumatoid factor (IgM)	Can be positive
Anticardiolipin antibody, lupus anticoagulant	Sometimes present
ANA	≥1:80 in 97% of children
	≥1:640 in 70% of children
Anti-Sm antibodies	in 45% of children
Anti-Ro (SSA)	In 33% of children
Anti-La (SSB)	In 18% of children
Anti-dsDNA	In 95% of children
Double helix anti-DNA antibodies (native DNA)	Often present
Evaluation of renal involvement	
Azotemia	
Creatininemia	
Creatinine clearance	
Quantitative proteinuria (24 h)	
Cellular casts	
Urine culture	
Renal biopsy (where suitable)	

Data from [178].

clinician to a more thorough investigation of renal status and referral to a specialist [222]. CPK (creatinine phosphokinase) levels should be monitored: a constant increase is an unfavorable sign. In addition to urinalysis, blood urea, nitrogen, creatinine, CBC (complete blood count), and complement levels (CH 50, C3, and C4), specific assays for the presence of SLE are anti-Sm, anti-SSA, and anti-SSB. Only 40%–50% of patients with SLE have anti-dsDNA antibodies, although 99% are ANA-positive (see the pediatric data in the Tables 18.23, 18.25, 18.26).

Treatment

Treatment is multifactorial, thus it cannot follow strict protocols, but it should be adapted to each patient, paying special care to the disease and its course. The drugs of choice are CSs, their doses should be gradually tapered once partial remission is reached, with normalization of both blood complement and levels of anti-DNA antibodies [13]. Low CS doses (<10 mg/day) did not affect FasL expression of lymphocytes, whereas in patients taking high CS doses the circulating lymphocytes were dramatically reduced [287]. If necessary, CS can be alternated with NSAIDs in milder forms without renal involvement [378]. Hydroxyquinoline as well as other DMARDs are successfully used in forms with prevalent cutaneous and arthritic manifestations, but it could be effective for preventing relapses in patients with latent disease, or scarcely reactive to treatment [468]. The initial dosage is 6–7 mg/kg/day for almost 3 months, to be reduced to 5 mg/kg/day. If therapy continues >6 months, periodic ophthalmological tests [13] are required. Cytostatic drugs are used when high CS dosage fails to control the disease. They are potentially useful, even when IV administered, if renal involvement is particularly severe [468]. Always monitor the drugs administered in order to prevent any possible adverse effect. Adequate measures for seriously ill children are controlled nutrition, hydrosaline balance, early diagnosis and treatment of infections, and congestive heart failure and arterial hypertension therapy [13]. We suggest avoiding excessive exposure to UV rays during central hours of the day, adopting convenient measures (sun glasses, barrier creams, hats, etc.). Children should have a normal life and take measures for physical fitness. A leg ulcer was treated with a skin graft (S. Cioschi, personal comunication). In severe, life-threatening cases of renal insufficiency, dialysis may be necessary. SLE neonates may need blood transfusion, and IV immunoglobulin (IVIg) (dose of 1 g/kg for 1–2 days), especially when CS is contraindicated [60].

New Treatments

Etanercept is absolutely not recommended in children with SLE. *ASCT for SLE is recommended* [183], but not yet applied in children. In a first study, the conditioning regimen used was cyclophosphamide, antithymocyte globulin, and methylprednisolone. The median follow-up of 15 patients with severe SLE after ASCT was 36 months (range 12–66 months). All patients demonstrated a gradual, but marked, improvement. Of the 12

patients followed up for >1 year after HSCT, ten have discontinued immunosuppressive medications, only two patients have demonstrated clinical evidence of recurrence of active lupus. No deaths occurred following treatment; however, of 20 originally screened for ASCT, three died after being deemed unsuitable for ASCT and two died after stem cell harvesting [432]. Data collected from 53 patients with SLE treated by ASCT in 23 centers show that disease duration before ASCT was a median of 59 (range, 2–155) months, and median age was 29 (range, 9–52) years. At the time of ASCT, a median of 33 (62%) had nephritis. *Ex vivo* CD34 SC selection was performed in 42% of patients. Conditioning regimens employed cyclophosphamide in 84%, anti-thymocyte globulin in 76% and lymphoid irradiation in 22%. The mean duration of follow-up after ASCT was 26 (range, 0–78) months. In conclusion, this registry study demonstrates the efficacy of ASCT for remission induction of refractory SLE in 33/50 (66%) evaluable patients by 6 months, of whom 10/31 (32%) subsequently had a relapse after 6 (range, 3–40) months, which was associated with negative anti-dsDNA antibodies before ASCT. Mortality appeared high: there were 12 deaths after 1.5 (range, 0–48) months associated with a longer disease course before ASCT, of which seven (12%) were probably influenced by the procedure. The safety of this procedure is likely to be improved by patient selection and choice of conditioning regimen. The return of disease activity in 33% of patients might be reduced by long-term immunosuppressive therapy after ASCT [183]. LCPUFAs modulate Th1 and Th2 cell generation, their IL production, and suppress the production of TNF-α and of OX40 (CD134) that belongs to the TNFR superfamily and the expression of bcl-2, suggesting that these fatty acids introduced *in utero* have the ability to *prevent or suppress SLE* [81].

Prognosis

Prognosis depends not only on symptoms and response to treatment, but also on the compliance to treatment [18].

Juvenile Dermatomyositis

Definition

Juvenile dermatomyositis (JDM), polymyositis and inclusion body myositis are the major forms of the idiopathic inflammatory myopathies (IIM) [41], which affect skin and striated muscles. If the lesion is localized to the muscles, the disease is called polymyositis. JDM is by far the most common inflammatory myopathy in children. The central lesion is a vasculitis affecting capillaries, venules and small cutaneous and vascular arteries [314].

Epidemiology

Incidence is 1×10^6 year, onset is after 2 years of age, with a peak at 10 years, and females are more affected than males: the initial ratio 1.7:1 increases to 6:0.7 in the second decade [468]. For children aged 2–17, recent US data report that the 4-year average annual rate (1995–1998) ranged from 2.5 to 4.1 JDM cases $\times 10^6$ children, and the 4-year average annual rate was 3.2×10^6 children. Estimated annual incidence rates by race were 3.4 for white non-Hispanics, 3.3 for African American non-Hispanics, and 2.7 for Hispanics $\times 10^6$ [272]. The female to male ratio was 2.3:1 [272] or 1.5:1 [250]. Two nationwide trials estimated the JDM incidence of 0.8% [250], or as 1.9×10^5 children aged <16 years, with a median age at onset of 6.8 years and a median delay in diagnosis of 4 months. The female to male ratio was higher 5.0:1 [408]. A trial on 1,742 children found a 0.4 JDM incidence $\times 10^5$ children at risk [89] and another study a 0.15 incidence $\times 10^5$ [250].

Pathogenesis

HLA class I overexpression is an early event in JDM and may occur in the absence of lymphocytic infiltration and muscle damage [229]. The familial occurrence was shown in two sisters, one with classic JDM and the other with amyopathic JDM, who shared the *HLA-DQA1*0501* allele [336]. Among 16 families there were three pairs of MZ twins [354]. Pathogenesis is strictly linked to *HLA-DR3* [97] (Table 18.3) and *HLA-DQA1*0501* haplotypes as in DM, whose incidence is significantly increased compared to controls [349]. The *HLA-DQA1*0501* allele in the mother was associated with the presence of chimerism more often in JDM children than in their unaffected siblings or in healthy controls. These chimeric cells play a direct role in the JDM disease process and the mother's HLA genotype facilitates the transfer and/or persistence of maternal cells in the *fetal circulation* [350]. IgA selective deficit is relatively common. The involvement of a provoking factor such as a virus, especially *Coxsackie* B, is not well supported by experimental data. Recently, a patient with dermatomyositis, polyarteritis nodosa, and recurring infections sustained by *Streptococcus* presented molecular mimicry between skeletal myosin and streptococcal type 5 M protein [264]. Thus, a model of antigen (perhaps viral) induction of an apparent AID based on dynamic interaction between muscular, vascular, and immune systems in the genetically susceptible (*DQA1*0501*$^+$) child could be hypothesized [387]. It is also speculated that *DQA1*0501* is associated with JDM susceptibility to an infectious process, eliciting and activating NK cells early in the JDM course [317]. In addition, the increased circulating concentrations of thrombospondin-1 (TSP-1), a potent antiangiogenic factor associated with the *TNF-α-308A* allele, suggest that TSP-1 may play a

significant role in the augmented vascular occlusion observed in JDM children with this genetic marker [245, 330]. A chronic JDM course appears to be associated with the *TNF-α-308G* allele. Untreated children with JDM who had the TNF-α-308A allele had an increased number of TNF-α stained muscle fibers than children with the *TNF-α-308G* allele, thus muscle fiber production of TNF-α could provide a microenvironment in which TNF-α acts synergistically with other mediators to prolong muscle fiber damage [113]. Moreover, new-onset, untreated JDM has four times as many CD56 NK cells in the muscle as in matched peripheral blood, which is associated with a relative increase in $CD8^+$ T cells [316]. Untreated JDM children had a significantly high increase in the proportion of lymphocytes expressing CD19 (B cells) and decreases in the percentage of lymphocytes that were $CD3(^-)$ $CD16(^+)$ and/or $CD56(^+)$ (NK cells) and $CD3(^+)$ $CD8(^+)$. Supposedly, $CD54(^+)$ non-B cells, $CD8(^+)$ T cells, and NK cells are removed from circulation and may participat in the pathophysiology of the disease [298].

The *immune pathogenesis* is still unclear. Cell-mediated functions are abnormal and include circulatory lymphopenia, significant reduction of CD3/CD8, increased CD4/CD8 ratio and CD19 (B lymphocytes) increment [314]. CD4 and B lymphocytes prevail in tissue infiltrates, suggesting that Aabs play an important role in tissue damage. The major role played by monocyte chemoattractant protein-1 (MCP-1) in the pathophysiology is demonstrated by CCR2 isoform expression by different cell subsets in both normal and JDM muscle. CCR2A, a main MCP-1 receptor, was detected in vessel walls and by some mononuclear cells, especially in cells involved in partial invasion in JDM. CCR2B expression was observed in all satellite cells, in the muscular domain of neuromuscular junctions and in some regenerative fibers, but not in inflammatory exudates [24]. Macrophages, IL_6, IL_1, and TNF were found in milk of calcium developed in two children [285]. Serologic studies have disclosed circulating ANAs with different frequencies, up to 50%, but no other Aab [264]. IgG, IgM and C3 in CICs have been shown to deposit in muscles, veins and capillaries. Complement deposition in these microscopic vessels is apparently the earliest pathological alteration. Consequently, vascular obstruction provoking perifascicular destruction, which is the typical pathological lesion of the disease, can be observed [468].

Clinical Presentation

Onset may be acute, with aspecific symptoms, including hyperthermia, asthenia, rash, muscle weakness, etc. More often, however, onset is insidious, with general symptoms like hyperthermia, malaise, irritability, and alternating rash. Symptoms observed in 79 children are reported in Tables 18.27 and 18.28 [261, 315]. An ill-defined, erythematous to violaceous scaly, minimally pruritic eruption occurs in photo-distributed areas such as the face (heliotrope eyelids), upper trunk, and extensor extremities. It resembles the butterfly rash in SLE (Fig. 18.30), a telangiectasia on eyelid borders, and erythematous maculopapular eruptions spread to large joints and over knuckles (Gottron sign) (Fig. 18.31). The periocular involvement of the heliotrope rash may cause the appearance of half-closed eyes, particularly in young children (Fig. 18.32). Papules are present on the extensor surfaces of metacarpophalangeal and interphalangeal joints and become whitish, atrophic, and scaly. Lesions can also extend to neck and torso as a consequence of heliotrope rash. Periungual telangiectasias (dilated capillary loops at the fingernail base) can be visualized with a handheld ophthalmoscope set at +40 diopters [41]; they are not included in criteria, but are present in 48% of children [261]. Skin manifestations are frequent, are associated with the severity of the disease, and are included in JDM diagnostic criteria. However, cutaneous features may precede the systemic illness, reflecting disease activity. New associations of JDM include the findings of pruritus (38%) and a psoriasiform scalp dermatitis (25%) [328]. Muscle weakness is always symmetrical and mostly proximal: it becomes

apparent when children climb the stairs, stand up from a chair, comb their hair, or use their hands trying to stand up from stretched position (Gowers sign) [314]. Arthralgia or full-blown arthritis is observed in 36% of pediatric cases: usually, they are transient and resolve after treatment of primary disease. In early stages, ulcers may be present on oral mucosa, with painful mastication, but they are less extended than those observed in SLE. The medical course of 39 children with JDM followed up for 3–22 years was complicated by respiratory diseases (20%), gastrointestinal diseases (24%), and calcinosis (30%) [276]. Calcinosis is found in 23%–70% of children [122], which despite treatment has remained around 30%. Calcinosis can localize on the cutis, subcutaneous layer, muscular fascia, but not in muscles, and mostly in regions subject to pressure (elbow, olecranon, knee). This is a late complication that becomes evident 3 years after disease onset and tends to spontaneously

Fig. 18.32. Juvenile dermatomyositis: typical heliotrope rash on the face, with a rose-white aspect of eyelashes

regress [314, 361]. Onset of calcinosis is associated with significantly prolonged time to diagnosis and treatment, a longer duration of elevated muscle enzymes, and disease duration [122]. Pathological calcifications are associated with the *TNF*-α-*308A* allele and with increased TNF-α production, which may prolong the inflammatory response [316]. Cutaneous vasculitis, with eschar formation, is a very rare complication (17%). Interstitial lung disease may develop, which is detected by KL-6, a mucin-like high-MW glycoprotein [203]. All segments of the enteric tract may be involved via intestinal vessels, with consequent ulcers, perforations, bleeding, and necrosis [314]. Mesenteric vasculitis may provoke an intestinal perforation: a child from the evening to the night developed this type of perforation, which required an intestinal resection (S. Cioschi, personal communication). The JDM course is shown on Table 18.10.

Diagnosis

Diagnostic criteria, which closely follow the mixed skin manifestations and major laboratory data, are shown in Table 18.29 [468]. Calcinosis is detected by plain X-rays showing the pouring Ca phosphate. Differential diagnosis is mostly with polymyositis, 10–20 times less frequent and without rash [314] and the other IIMs.

Treatment

Treatment is focused on CSs and immunosuppressants (Tables 18.16, 18.17). The former especially have dramatically changed the prognosis: in the US, CSs have reduced mortality rates from 33% in the 1960s to 3% at

Table 18.29. Criteria suggested for the diagnosis of dermatomyositis

1. Proximal, symmetric muscle weakness
2. Typical dermatomyositis rash, also photosensitive (see text for details)
3. Increase of skeletal muscle enzymes, including creatinine phosphokinase (CPK), aldolase, lactate-dehydrogenase (LDH) and SGOT/SGPT
4. EMG results typical of myopathy; the changes of myogenic type are often nonspecific, with denervation potentials characterized by brief polyphasic motor units of decreased amplitude, insertional irritability, spontaneous fibrillations
5. Muscle biopsy may show necrosis of type I and II fibers, with small blood vessels resembling a necrotizing vasculitis

The diagnosis is posed when three or four criteria (plus the rash) are positive, probable when three criteria (plus the rash) are positive, possible when one criterion (plus the rash) is positive. Muscle biopsy is recommended in children with a doubtful diagnosis; a negative result does not skip the diagnosis, since the result may be false-negative in at least 10% of cases. Modified from [468].
EMG electromyography.

present [314]. Pulse CSs should be administered IV, to avoid scarce absorption. With minimal muscle damage, oral CSs (prednisone, 1–2 mg/kg/24 h) may suffice [122]. However, prompt institution of high-dose intermittent IV methylprednisolone therapy may rapidly normalize the muscle enzymes, and additional therapy is used if the indicators of inflammation remain elevated. Pulse IV CS therapy (methylprednisolone 30 mg/kg/daily for 3 days) usually is given initially; thereafter, the frequency of methylprednisolone administration ranges from three times per week to once each week until muscle enzymes or the indicators of inflammation normalize. Low-dose oral prednisone (0.5 mg/kg daily) is given on non-IV methylprednisolone days [105, 122, 314]. MXT can be added if laboratory values fail to normalize as rapidly as expected, but should be given in conjunction with folic acid (1 mg/24 h). Cyclophosphamide, given with bladder protection, is considered for children unresponsive to IV methylprednisolone and MXT. Reports note improved outcome with high-dose CSs, yet the incidence of calcinosis has remained between 14% and 30% [122]. Children who fail to respond within 6 weeks were started on a MXT regimen (65.7%) [122], or alendronate can be an effective treatment [111, 285]. Stepwise, aggressive CS [122], or MXT treatment directed at achieving rapid and complete control of muscle inflammation is highly successful in minimizing the long-range sequelae of JDM, including calcinosis [96]. CSs can cause osteopenia with consequent compression fractures. Thus, bone density should be monitored. If it decreases, vitamin D and a Ca-rich diet should be administered [314]. These patients should also be protected against sun rays by a sunscreen (free of *p*-aminobenzoic acid, PABA) that provides maximal protection against ultraviolet (UV) rays.

Juvenile Scleroderma

Definition

The element in common for many forms classified as JSD is collagen accumulation in the skin and subcutaneous layers, which makes the areas concerned hardened and rigid (scleroderma), with a wide range of lesions.

Epidemiology

The incidence among the general population is 1×10^5, with 3% of all cases in pediatric age; 1.5% of these cases have onset before 10 years of age, and 7% between 10 and 19 years [261, 378]. A trial on 1,742 children found a JSC incidence of 2% [89] and the Canadian trial found a 0.2% frequency of both JSD and morphea [250]. Otherwise the incidence of localized JSD is $0.2–0.4 \times 10^5$ [123]. Approximately 10% of patients with systemic JSD evolve to the disease before the age of 18 years [123]. The female-to-male ratio is between 1.5:1 and 4:1 [443], or 1.3:1 [127].

Classification

JSD is subdivided into a localized form, separated into three major subtypes, morphea, generalized morphea and linear scleroderma, and a systemic or limited form (Table 18.30) [226, 378].

Etiology and Pathogenesis

HLA studies did not reveal either a clear increase of any haplotype or a significantly higher familial incidence. The prevalent hypothesis is based on multifactorial pathogenesis. Similarly to other AIDs, an unidentified antigen, either environmental or self, could interact with the immune system of a genetically susceptible host and activate monocytes and lymphocytes, which in turn release ILs. These agents injure endothelial cells, causing abnormalities in extracellular matrix (EM) and vessels, due in particular to fibroblast proliferation and increased collagen deposit (Fig. 18.33). As shown in Fig. 18.34 [443], the endothelium reacts to these changes by expressing adhesion molecules which entrap platelets and inflammatory cells, which in turn bind integrins to their receptors. Polyclonal hypergammaglobulinemia is common, and ANA and antiendothelial

Table 18.30. Pediatric scleroderma

Characteristics	Localized scleroderma	Systemic scleroderma
Sex	F>M	F>M
Age at onset	≥2 years	≥4 years
Manifestations	Cutaneous fibrosis; patchy (morphea) or linearis, no systemic involvement	Raynaud's phenomenon, diffuse cutaneous fibrosis: face, trunk, extremities, or absent; arthritis; fibrosis of internal organs: heart, lung, kidney, gastrointestinal tract; hypertension
Laboratory findings	Possibly ANA increase, FR increased Ig concentrations	Possibly ANA increase, FR increased Ig concentrations, capillary nailbed changes, cutaneous and systemic fibrosis
Diagnosis	Clinical, biopsy	Clinical
Natural history	Possible progression or remission, occasional crippling	Possible progression or remission, poor, may be fatal
Therapy	No specific medications	No specific medications

Raynaud's phenomenon is practically absent in localized scleroderma, whereas in the systemic scleroderma it arises within 1 year of the onset of cutaneous manifestations and persists for years or decades.
Data from [226, 378].

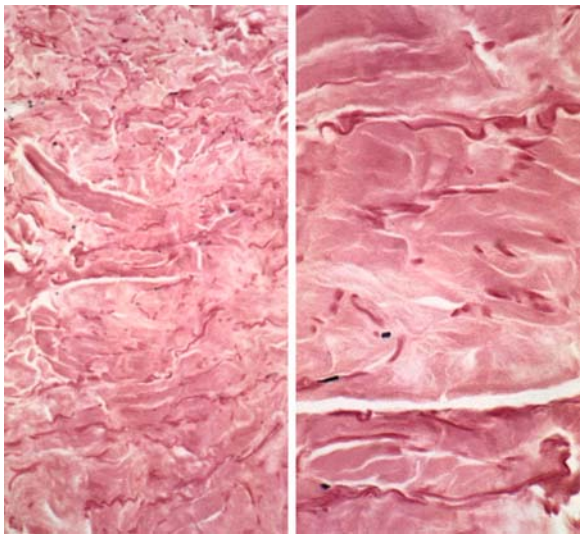

Fig. 18.33. Progressive systemic scleroderma: swollen and eosinophilic dermal collagen fibers

antibodies occur. A high proportion of children have ANA (see "Diagnosis"). The ANA specific for topoisomerase 1 (SCL70) and the centromeres are found in 50% of children with JSD at the onset and during the course of childhood [127], which suggests that autoimmune processes play a role in pathogenesis. ACA (anti-centromere antibodies) positivity was related to the presence of Raynaud's phenomenon in the studied sample, as 86% of children suffering from the phenomenon were ACA-positive, in particular 60% of children with JSD [167]. The presence of vascular lesions is proved by the finding of high levels of von Willebrand factor, which is a marker of endothelial damage, and platelet aggregates. Platelets and inflammatory cells adhere to endothelium and infiltrate tissues. Here they find IL_1-secreting macrophages, which induce platelets to produce PDGF (platelet-derived growth factor). These two ILs stimulate the proliferation of fibroblasts, which react to signals coming from a wide variety of cells and the EM ILs. The presence of IL_2 in the sera may be indicative of disease activity. The prominently frequent incidence of IL_6 in the early stage of disease and in patients with severe systemic involvement indicate a potential role of IL_6 as a parameter of disease activity [230]. The fibroblasts also express integrins, which reach the inflammatory infiltrate already deposited near the small vessels since the first stages [443]. The hyperproduction of connective proteins, especially collagen, generate interstitial and vascular fibrosis associated with widespread obliteration of small vessels (Fig. 18.35) – typical of JSD – along with a relatively modest inflammatory reaction, which leads to the irreversible involvement of many organs [443]. Consequently, one can observe the PDGF in vessels and fibroblasts in skin biopsies of patients with JSD, both localized and systemic, as well as increased CD45RA and reduced CD8, in connection with the stages previously described. This data confirms the activation of T cells, which in turn activate some B lymphocytes. The final result of these signals is Aab production.

It is still unclear if the pathogenesis is infectious. One of the many sclerodermic syndromes reported is the syndrome caused by toxic oil, which is described on Chap. 16.

Clinical Presentation

The mean age of onset of symptoms was 8.0±2.8 years and the age at diagnosis 10.1±3.0 years [127], but onset may be much earlier (Table 18.30). Morphea's early stages are characterized by erythematous and edema-

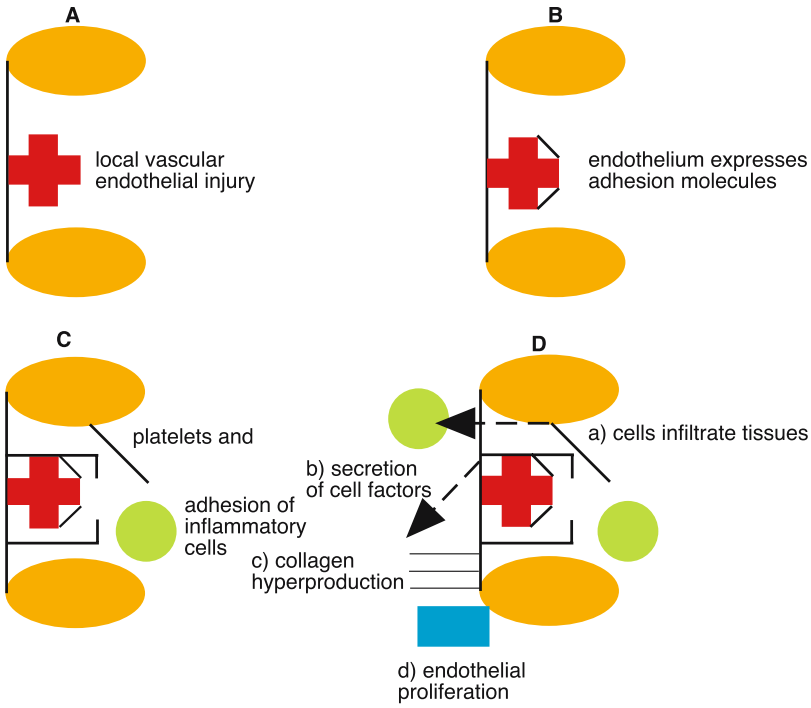

Fig. 18.34. Possible pathophysiological mechanisms in scleroderma (see text). (Modified from [443])

Fig. 18.36. Localized scleroderma: typical aspect of the lesions

tous lesions becoming purplish, with skin thickening and single or multiple patches, and puffiness of the fingers. Later they evolve into a thickened, smooth, waxy, tight lesion, which adheres to underlying strata and cannot be raised in folds (Fig. 18.36). Then the skin tends to soften and becomes atrophic with hypo- or hyperpigmented areas. Linear scleroderma thickening, instead, appears as a linear band, called *coup de sabre* when front and scalp are involved (Fig. 18.37). The changes in a boy with JSD from 10 to 16 years included an expressionless appearance of the face, small mouth with puckering of the lips, pinched nose, and hyperpigmentation of the neck [443]. In some cases, localized scleroderma can gradually involve larger and/or deeper areas, causing relevant atrophy of subcutaneous tissue, striated muscle, periosteum, and bone, along with vascular abnormalities in the head. Out of 30 children, 26 had linear scleroderma, 19 on an extremity and seven on the face, three had morphea, and one had generalized morphea [442]. Thus the two forms largely overlap, and often morphea and linear lesions coexist and appear as a growth deficit, with or without contractures [261]. Among 168 patients were noted 193 extracutaneous manifestations, as follows: articular (47.2%), neurologic (17.1%), vascular (9.3%), ocular (8.3%), gastrointestinal (6.2%), respiratory (2.6%), cardiac (1%), and renal (1%). Other autoimmune conditions were present in 7.3% of patients [509].

Fig. 18.37. Localized scleroderma: linear scleroderma, sabre-cut type

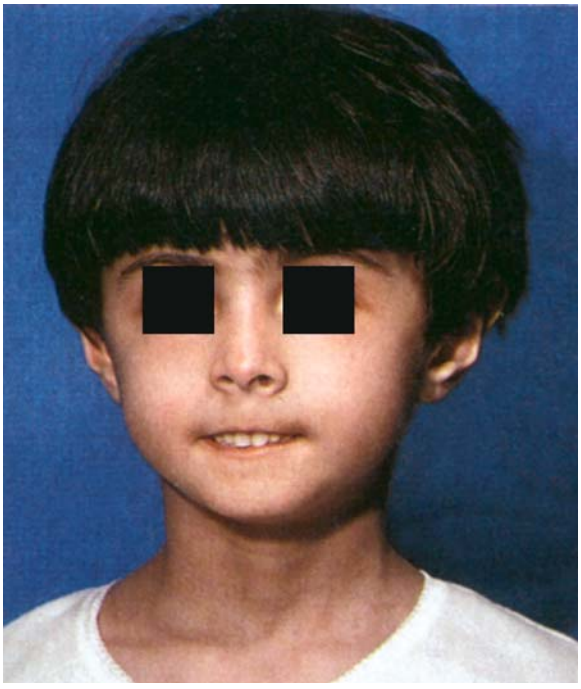

Fig. 18.39. Systemic scleroderma: sclerotic changes of the face and around the mouth associated with severe involvement elsewhere

Fig. 18.38. Calcinosis cutis and sclerodactyly associated with systemic scleroderma

Systemic or progressive JSD may be restricted to the skin, which presents a tense, symmetrical, subcutaneous edema, localized to the fingers and the back of hands and feet, mostly evident at awakening. These stages, often asymptomatic, may persist for some time, and could be followed by a sclerotic stage, with hard, tense, translucent, inelastic and atrophic skin (sclerodactyly), and restricted joint movement [443] (Fig. 18.38). The involved face takes on a typical amimic expression, with loss of normal skin wrinkles, and a reduced opening of the mouth (Fig. 18.39). Atrophy of the frenulum linguae and lung fibrosis are commonly seen [127]. A child with a limited type of systemic sclerosis presented with erythema, tight skin over his face and digits, subcutaneous calcification, telangiectasias, and Raynaud's phenomenon [234]. Raynaud's phenomenon is present in 90% of children and is the presenting symptom in 70% [443] or 89% of cases [127]. One possible variant is known as CREST [calcinosis-Raynaud-esophageal (motility disorders)-sclerodactyly-telangiectasia].

Fibrosis, with evident signs of inflammation, is much more exceptional in pediatric patients with diffuse skin involvement. Fibrosis develops on proximal portions of limbs and trunk, along with vascular alterations and symptoms referable to different organs (Table 18.30). Telangiectasias may be localized on the skin, especially in periungual areas, while the subcutaneous calcifications that develop on fingers, elbows and knees could limit joint mobility. Renal involvement is present in up to 60% of children, and nephropathy develops on average 2–3 years after diagnosis [443]. With time, ischemia may provoke ulcerative and/or necrotic lesions on digital pulp skin and bone reabsorption from ungual phalanges [261]. The gastroenteric tract, which is the third major site of alterations, can be involved in all its segments, from mouth to anus [443].

Diagnosis

The diagnostic work-up of these children should include the several organ systems involved. The immune status investigation should encompass anti-topoisomerase antibodies, ANA, and ACA. Related specialists

should monitor cardiac, respiratory, gastrointestinal, and renal status [41]. Muscle enzymes should also assessed; a muscle biopsy may be necessary [443]. Otherwise it is essentially clinical (Table 18.30). ANA were present in 23%–80% [123, 127, 442] and RF in 25%–40% of children [123, 442] and RF in 39% of 30 children [442]. Approximately 50% of children have anti-Scl-70 (topoisomelase I) antibodies at the onset and during the course of childhood. The clinical symptoms and examination of serological autoimmune antibodies were supportive of an early diagnosis [127]. Differential diagnosis is with the scleroderma overlap syndromes including polymyositis, Sjögren syndrome, scleromyositis and synthetase syndrome [41].

Treatment

It is rarely possible to contain the development of the disease because the disease has various subtypes, each with a different course [443]. Approaches must take into account the therapeutic effect on the child (growth failure and osteoporosis from CSs) as well as the psychosocial impact of chronic illness and physical deformity on children and their family [101]. MXT, 0.3–0.6 mg/kg per week, was given to children with localized JSD. Pulse IV methylprednisolone, 30 mg/kg for 3 days monthly for 3 months, was given to children at the start of therapy, a treatment that appears to be effective and usually well tolerated. Discontinuation causes flare-ups of the lesions [443]. No specific treatment can be suggested. For example, out of 67 children, 27 were taking only NSAIDs, 11 were given NSAIDs and MTX, 15 were also receiving prednisone and 14 were given CSs and alendronate [111]. Dipyridamole, d-penicillamine, colchicine, and nifedipine may be taken into consideration [233]. Combined UVA/UVB phototherapy and PUVA bath are valuable and safe therapeutic options for selected children who do not respond to other treatments [324].

New Treatments

Experience with ASCT for childhood JDM or JSD is very limited [485]. Professor Wulffraat is preparing a transplant for JSC. They will try IV cyclophosphamide pulse therapy first. In London, Great Ormond Street, a girl with JDM has received a transplant, she did well initially but died of respiratory infection. Probably she received ASCT too late (L. Wedderburn, pers. comm., July 3, 2005). As yet the islet of Langerhans transplantation for type 1 DM has not been done in children (M. Markmann, pers. comm., April 19, 2005). A revolutionary and noninvasive cure for JDM could be based in the near future on the transplant of a novel population of fetal cells, the pregnancy-associated progenitor cell (PAPC), which remains in maternal blood and tissue for decades following delivery (D. Bianchi, pers. comm., Mrch 8, 2007). This recalls the sister-to-sister transplant.

Pediatricians and Autoimmune Diseases

AIDs have protean manifestations, and reports of physicians' clinical skills are tested by the assessment of whether or not a patient has this diagnosis [41, 385]. AID therapy is projected into the future. In addition to what has been said on DM, some gene therapies are aimed at treating AIDs characterized by demyelinization with autoreactive T cells that can stimulate tissue regeneration by expressing NGF (nerve growth factor) or producing immunoregulating factors. Examples of this are the primers for MBP or proteolipid protein (PLP), to direct the transgenic expression toward oligodendrocytes, and the primers for insulin, to affect the β-pancreatic cells [267]. Infliximab has been widely used for CD therapy and in JRA as well [99]. In the meantime, pediatric rheumatology centers and pediatric rheumatologists should care for JRA children, since at diagnosis 78% of the polyarticular patients required medication, 98% of the patients functioned in Steinbrocker classes I and II, and 6% of pauciarticular, 27% of polyarticular, and 11% of systemic patients had limitations in school function. Nearly 1/3 of poly patients already had joint space narrowing on X-rays. By 5 years after diagnosis, all pauci, 88% of poly, and 70% of systemic JRA patients were in Steinbrocker classes I and II; but 6% of pauci, 28% of poly, and 44% of systemic JRA patients had limitations in school function. Nearly two-thirds of poly and systemic patients had joint space narrowing [39].

Children with uveitis refractory to other therapies received *infliximab* at doses between 5 and 10 mg/kg at 2- to 4-week intervals, and then were maintained at 4- to 8-week intervals at doses of 5 to 18 mg/kg. After a follow-up of 48 weeks, all children showed reduction in their intraocular inflammation after infliximab therapy was initiated. Only two children reported transient adverse reactions; however, no one has had to discontinue treatment [345].

Malnutrition and the Immune System

Immunological Effects of Child Malnutrition

Although it has long been known that malnutrition, immunity and infection are intricately linked to one another, the study of malnutrition and immunology has been progressing only relatively recently [97]. However, malnutrition and infections in children is a destructive interplay with global dimensions. Human studies and laboratory experiments have confirmed that the alterations of nutritional thymectomy, correlated with kwashiorkor, correspond to deep immune deficiencies [52]. The pioneering studies by Suskind [108] and Chandra [22, 23] have established the relationships between immunity and malnutrition, stemming from a profound knowledge of the endangered functions and the employment of more reliable technologies [52]. It is now common understanding that nutritional deficiencies, either quantitative or qualitative, also during pregnancy, may alter to different degrees humoral and/or cell-mediated immune (CMI) responses [28], thereby representing the most common cause of secondary immunodeficiency (ID) [9] after AIDS [23]. Primitive malnutrition is associated with atrophy of lymphoid organs, with a consequent increase in the susceptibility to pathogens, reactivation of viral infections and the advance of opportunistic infections [22–24, 52, 76]. In the first few days of life, neonates must be prepared to deal with bacterial colonization of the gut and allergenic macromolecules, so malnutrition may reduce mucus secretion and *debilitate the defensive function of the mucosal barrier* (Chap. 2). Until now, in addition to hospitalization (prevalence of 5.1%–6.6%) [82] and prolonged total parenteral nutrition (TPN), and peritoneal dialysis [12], inappropriate elimination diets both for the treatment or prevention of allergic disease may also be considered as causes of malnutrition in children [122]. The connection between the nutritional state and the Münchausen syndrome by proxy has promoted large-scale investigations on iatrogenic causes [52]. A pertinent issue is the recent access of unconventional remedies infantile affections, not prescribed by medical doctors, as far as can be deduced from the report [105].

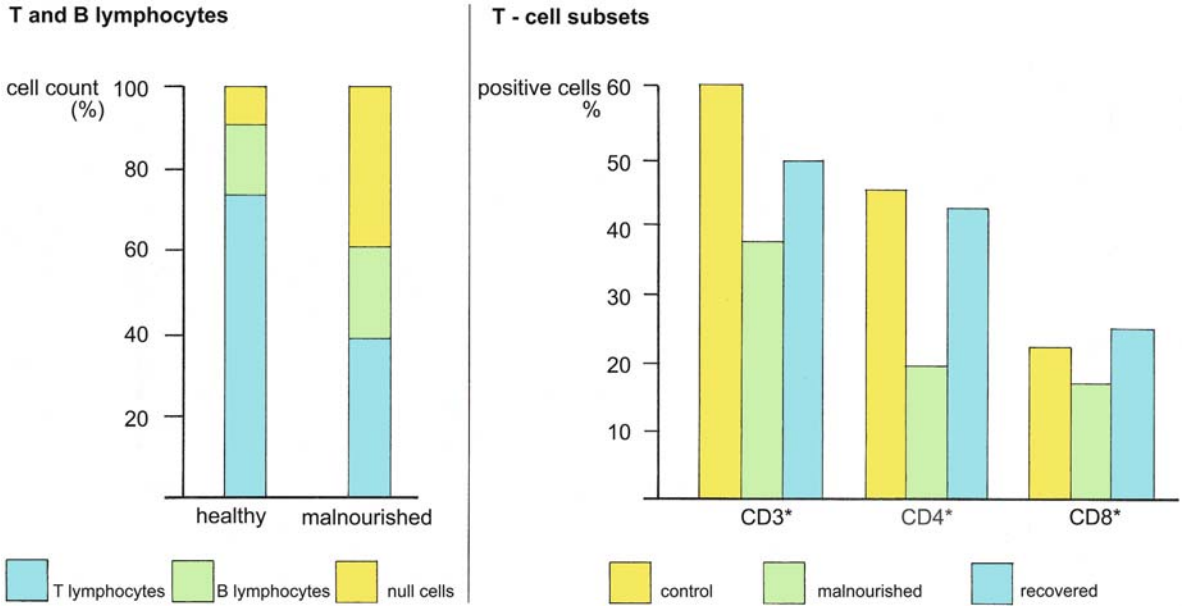

Fig. 21.1. Lymphocyte counts in malnutrition. *Left*: the proportion of circulating T cells is decreased in malnourished patients compared to healthy subjects, the B cell is commonly unaffected and null cells increase. *Right*: profound reduction of CD4 cells, and less of CD8 cells, the CD4:CD8 ratio returns to normal after 4–8 weeks of appropriate nutritional therapy

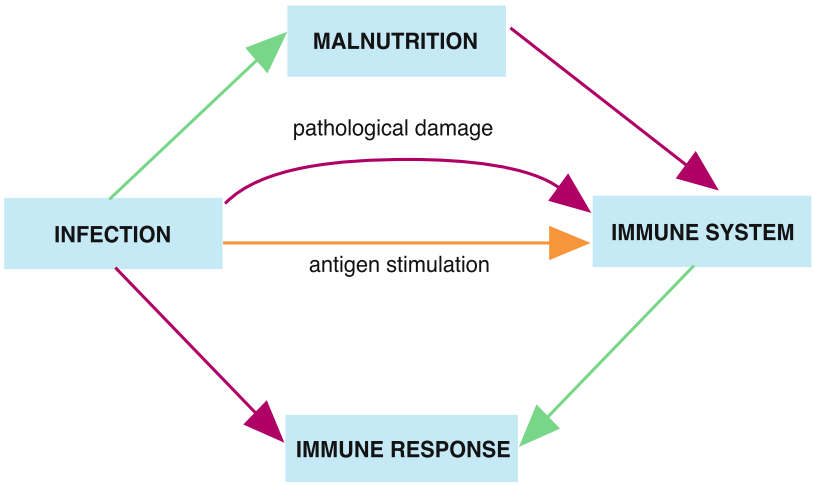

Fig. 21.2. Interactions between nutrition, immunity and infections. (Modified from [23])

Alterations of the functional activity of the immune system are usually caused by protein-energy malnutrition (PEM), but often the type of effect depends on vitamins, trace elements and other nutrient deficiency. Nutritional deterioration is frequently aggravated by a concomitant deficiency in necessary elements such as Zn (zinc) and other trace elements, vitamin B_{12}, folic acid, etc. [34, 42]. Recent research has demonstrated that nutrition is an essential prerequisite of the immune system functionality, which is reflected even in moderate forms of PEM and in apparently healthy individuals, as a consequence of nutritional deficiencies not always pointed out [84]. *Immunotoxic substances* in the diet may in turn impair host defenses, ultimately resulting in a pseudo-ID with a consequent uprising susceptibility to infections [18]. Several studies highlight that infection is the prime mover, and results in the host's nutritional impairment [35, 69], eliciting a closed cycle where infections have the ability to worsen the malnutrition-induced immune alterations (Fig. 21.1) [23], which consequently augments the risk of acquiring infections in undernourished children (Fig. 21.2) [23].

Protein-Energy Malnutrition

The WHO (Word Health Organization) defines PEM as a wide spectrum of pathological conditions ensuing from coincident repeated and prolonged lack of proteins and calories in varying proportions, occurring more often in infants and young children, commonly associated with infections, which find them unprepared, especially if they *were deprived of colostrum* [28]. The terms "primary" and "secondary PEM" refer to malnutrition resulting either from inadequate food intake or from increased nutrient needs, decreased nutrient absorption, and/or increased nutrient losses. Currently, a third disorder, *marasmic kwashiorkor,* which has a number of overlapping features, is recognized [58]. Although dietary factors are known to affect the structure and function of all cells of the body, lymphoid

Table 21.1. Effects of protein-calorie malnutrition on immune function

Cell-mediated immunity
Reductions:
Delayed cutaneous hypersensitivity responses (recall, new antigens)
Skin homograph injection
Thymic size
Thymic hormone activity
Thymic T cells and T cell-dependent zones in lymph nodes and spleen
Lymphocyte proliferation and DNA synthesis
Circulating CD3 subsets
Circulating CD4 subsets
Mixed lymphocyte reaction (MLR)
IFN-γ, IL_1, IL_2 and IL_2R generation
Moreover:
Increased relative proportion of TdT immature T cells
Potential increase of suppressor T cells and/or circulating suppressor factors
Anergy
Response to mitogens (PHA, Con-A)
Humoral immunity
Decreased:
Immunoglobulin production
sIgA
T cell-independent antibody production
Bactericidal power
Nonspecific immune function
Decreased:
Complement components
Phagocytosis, metabolic activation and destruction of bacteria
Macrophages and neutrophils, neutrophil chemotaxis
Lysozyme levels in secretions
Moreover:
Skin and mucosal dysfunctions
Alteration of intestinal flora
Rise in gastric pH

Modified from [24, 111, 125].

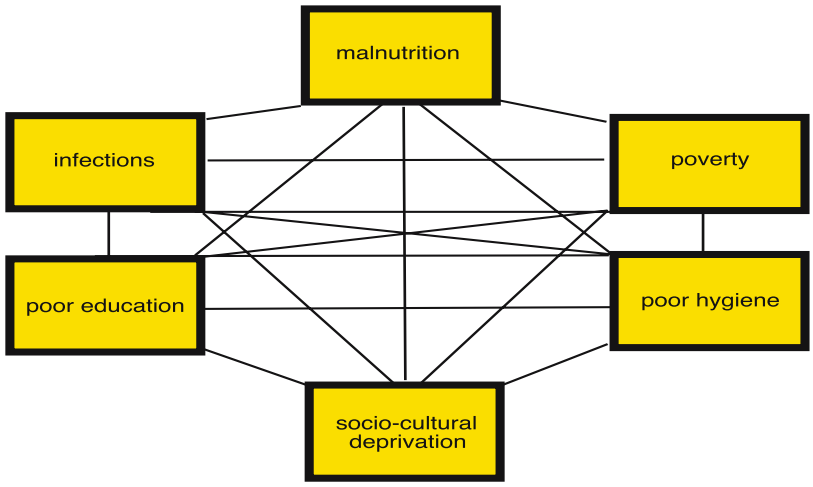

Fig. 21.3. Multifactorial interactions causing malnutrition. (Modified from [23])

Table 21.2. Specific effects of dietary deficiencies on cell-mediated immunity

Food deficiencies
Blunted CD4 levels and not CD8 levels
B cell increase in the circulation
Decreased concentrations of complement components
Calorie deficiency
Decreased Th1 numbers?
Increase in PGE_2
In mice Decreased IL_6 and TNF-α levels Increased TGF-β levels Increased T cell response to mitogens Decreased PGE_2 release by splenic cells
Protein deficiency
Decreased Th1-mediated oral tolerance
Increased Th2-mediated oral tolerance

Data from [97, 111, 125].

tissues are particularly susceptible to their rate of turnover and synthesis of immunomodulating cells. The pioneering studies go back to about 70 years ago, when it was observed that in persons who died of starvation, the thymus underwent an involution, with reduction in both size and number of lymphoid cells. Cell depletion was also found in thymus-dependent zones of the spleen and lymph nodes [42], changes observed in children hospitalized for severe PEM [78] (Fig. 21.3) [23].

Several distinct responses have been observed in the first term of fetal development. In addition to genetic factors, environmental influences such as nutrition play an important role in influencing the developing human immune system [23]. Studies have shown that infants and children with PEM have a *profound depression of several aspects of immunity the world over.* CMI shows the most evident alterations, as indicated in Tables 21.1 [97, 111, 125] and Tables 21.2 and 21.3 [24, 39], and best documented by Fig. 21.4 as compared to Fig. 1.1. Systemic CMI shows varying degrees of impairment: in more severe cases, a thymic hypotrophy, with gross structural alterations on histological examination up to an evident involution characterized by lobular atrophy,

Table 21.3. Humoral and cellular quantitative reduction

	IgA	IgM	IgG	TD lymphocytes	IgA-containing (%)	IEL
Children						
Malnourished	57±6	33±11	10±3			7.4%
Well-nourished	80±5	18±4	4±3			9.5%–40%
Animals						
Malnourished				18.4	0.46	4.3±0.7
Well-nourished				44.5	0.84	18.8±1.8

IgA, IgM, and IgG, mean ± SD; TD lymphocytes and IgA-containing, geometric mean.
Data from [24, 39].
TD, thoracic duct, *IEL* intraepithelial lymphocytes.

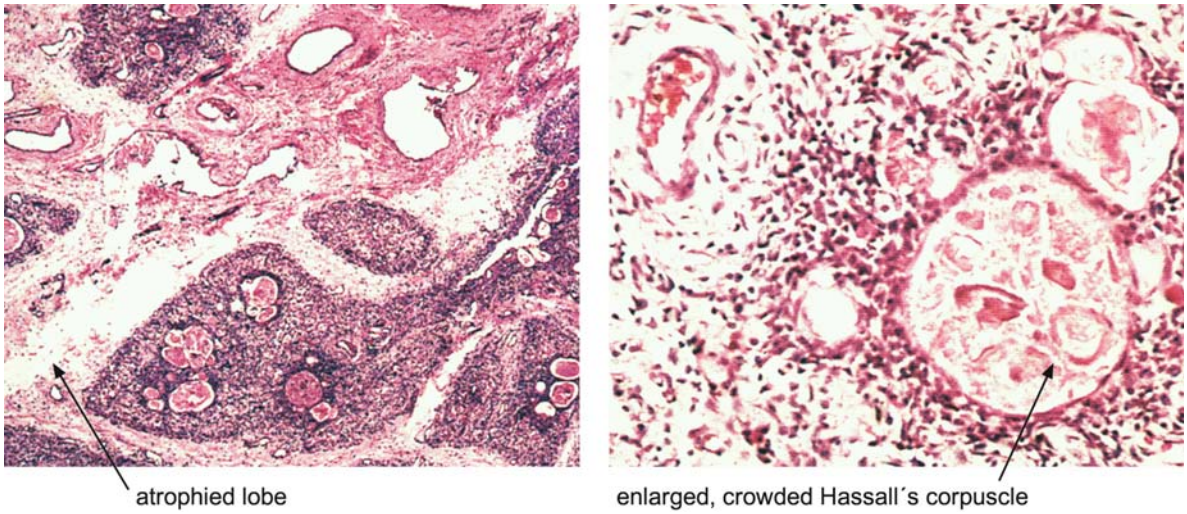

Fig. 21.4. Thymic histology in protein-calorie malnourished (PCM) children. Compared with normal thymus, in PCM there is a tangible involution, characterized by lobular atrophy, loss of distinction between cortex and medulla and lymphocyte depletion, particularly in the cortex. Lower Hassall's corpuscles appear degenerated, hypertrophied, crowded with cells and often calcified

loss of corticomedullary distinction, reduction in the numbers and function of lymphocytes in the cortical zones, depletion of varying degrees of lymph node germinal centers (GCs) and paracortical cells in peripheral lymphoid tissues, whose alterations are proportional to the duration and severity of nutritional deficiency [22, 23, 52]. Significant variations in the number of B and T lymphocytes are reported, associated with distorted proportions of B- and T-cell subpopulations. Malnourished bacterium-infected (BI) children showed significantly lower B lymphocyte values of $CD20^+$ in relation to the results seen with healthy children [72]. The number of total circulating T cells was reduced in PEM children, as well as the CD4:CD8 T cell ratio [23]. Lymph nodes are hypotrophic, the responses to PHA (phytohemagglutinin) and ILs are decreased, NK-cell activity is reduced, as well as delayed-type hypersensitivity (DTH) and macrophage functions [111]. Peritoneal macrophages from PEM mice exhibit significantly *greater levels of apoptosis* at baseline and when stimulated with pro-apoptotic agents compared with controls, a propensity that may be attributable in part to decreased bcl-2 protein expression [87]. CD3, CD4, CD8, the CD4:CD8 ratio, CD45RO, IL_1, IL_2, IFN-γ, lymphocyte circulation and homing (Chap. 1) are altered in number and function [22–24, 84, 111], paralleling the alterations of T lymphocytes with immature phenotype. IFN-γ production is markedly decreased, IL_1 production and functional activity on target cells is depressed, IL_2 production and IL_2R binding are altered [24], the whole proportional to the duration and severity of the nutritional insult. In vitro production of IL_1 and IL_2 was significantly lower in patients when compared to normal controls. The total leukocyte count was significantly higher than in the noninfected controls, thus indicating a *functional rather than numerical* cellular impairment [63].

Similar changes are seen in regions populated by lymphocytes of the spleen, tonsils and lymph nodes, including paracortical and periarteriolar regions, but with preservation of B lymphocyte-rich GC and primary follicles [52]. Underfeeding reduces IL_{10} secretion by anti-CD3-treated cells. Lymphocyte proliferative responses to anti-CD3 ± anti-CD28 antibodies were lower in iron-deficient mice than in controls, IL_{10} levels negatively correlated with lymphocyte proliferation. In addition, iron deficiency has a generalized deleterious effect on cells that secrete IL_{10} and IFNγ [57]. On humoral immunity, T cells do not provide adequate help to B-cell production of immunoglobulins (Ig), so Ig concentrations are reduced compared to a significant increase in IgM levels in well-nourished controls, and there are fewer intraepithelial lymphocytes (IELs) [24]. The mucosal immune deficiency may be more severe, characterized by MALT (mucosa-associated lymphoid tissue) hypotrophy, Peyer's plaques and sIgA level reduction, and secretory component synthesis by epithelial cells, but levels were restored with return to a normal diet [107]; *mucosal IgA levels are remarkably reduced* (Table 21.3), (Fig. 21.5) [23]. Alterations in certain nutrients may have widespread and/or localized effects on the lymphocyte network (Fig. 21.6) [52]. *IEL counts under the lower limit* of normal in malnourished children [39] and animals [24] (Table 21.3) may be a sign of PEM-induced immunological deficiency. PEM also impairs *innate immunity* (Tables 21.1, 21.2), phagocyte functions and neutrophil activity, and the oxidative and glycolytic activity of these cells is quantitatively reduced,

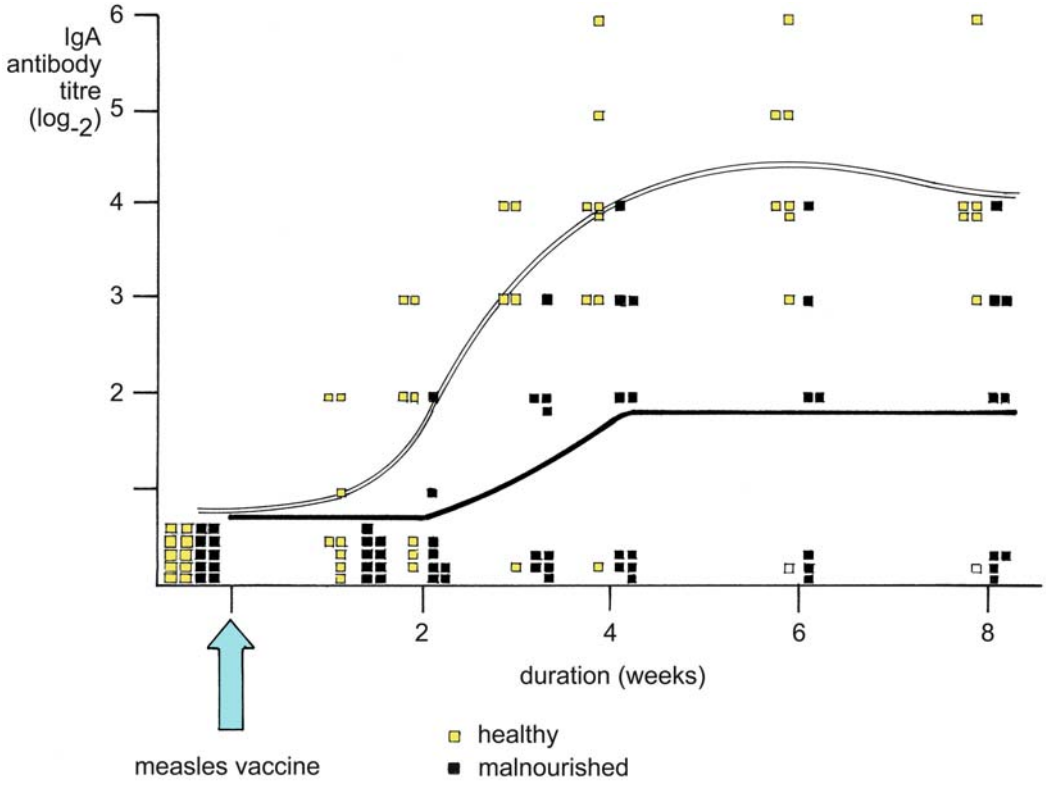

Fig. 21.5. Secretory IgA (sIgA) response in PCM. Two groups of children, one of children who were malnourished with PCM and one group of age-matched healthy children, were given a single dose of live attenuated measles virus vaccine; the sIgA level in nasopharyngeal secretions was measured for 8 weeks. Antibody levels were lower in malnourished children and its appearance was delayed

but processing by macrophages is normal [111]. The levels of complement components, chiefly of C3, are very reduced in PEM acute phases [99], but may return to normal following an adequate alimentation (Table 21.4) [52]. Infections occur as a consequence and are facilitated by the network of interacting factors also causing

Table 21.4. Effects of protein-calorie malnutrition on complement system

Decrease in total hemolytic complement activity of both classic and alternative pathways
No apparent alterations of regulatory proteins
Possibly reduced synthesis of complement proteins and weakened acute-phase proteins
In vivo complement consumption, with complement breakdown products in the bloodstream
Serum concentration decrease of individual complement components
Depression of complement-mediated functions such as opsonization

Modified from [52].

malnutrition. In BI children who do not have PEM, a significant decrease in the proportion of T $CD3^+$, $CD4^+$, and $CD8^+$ lymphocyte subsets was seen compared to the results seen with healthy children [72]. Intestinal infections, possibly occurring because of a reduction in IgA levels as seen in cow's milk allergy (CMA), are frequently associated with malnutrition, which causes mucosal dysfunction, *impairment of digestive function and absorption,* thinning of the gut wall and flattening of villi [109]. Similarly, dysfunctions of both the B and T lymphocyte network have been shown to contribute to *severe and protracted diarrheal disease* in infants with

malnutrition, also enhancing intestinal permeability, as noted in PEM [109]. *Macronutrient titers are also reduced,* for example arginine deficiency, a nonessential amino acid, capable of inducing thymic involution with numeric reduction of thymocytes, a decreased response of lymphocytes to mitogens and poor IL_2 production. Glutamine deficiency, necessary to RNA and DNA synthesis and to cells in the replicating stage [60], involves instead both forms of immunity [3], thus paralleling the characteristics of arginine deficiency [23]. However, glutamine expresses defensive properties: it plays an important role in the gastroenteric tract by improving gut trophism and enhancing local immunity, which reduces the risks of bacterial translocation [3]. In addition, tissues are damaged but inflammatory reactions may be in need of repair, thereby consuming available amino acid substrates. Further studies indicate that PEM-negative effects are also substantiated by micronutrient deficiency such as vitamins, trace elements [24, 80, 89] and nucleotides.

Numerous are the causes of secondary PEM, often enlivened in infancy by alimentary causes (Tables 21.5, 21.6) [11, 38, 112, 122]**;** therefore the issue may have a dramatic corollary [73, 122]. Secondary PEM is often associated with the principal growth disturbances in children. Malnutrition at age 3 years is associated with poor cognition at age 11, independent of psychosocial calamity [62] (Table 21.7) [38].

Micronutrient Deficiency

Dietary micronutrients encompass vitamins and trace minerals that are known modulators of host immune responses against common pathogens. Micronutrients are required for the integrity and optimal functioning of the immune system. The full genetic potential of the child for physical growth and mental development may be compromised as a result of subclinical deficiencies of micronutrients. These children are more vulnerable to developing frequent and more severe common infections, thus triggering *a vicious cycle of undernutrition and recurrent infections* [100].

Vitamin Deficiency

Vitamins have many relevant functions: vitamins A and C increase immune responses, vitamin E increases both humoral and cell-mediated types of immunity if present in abundant quantities in the diet, and B_6 increases the numbers of T lymphocytes [4, 7, 8, 110].

Isolated vitamin deficiencies are rare nowadays; however, studies on experimental animals show that deficiencies of vitamins A and C, pyridoxine and folic acid have deleterious effects on CMI and T-cell-dependent humoral responses [42]. In particular, vitamin deficiencies (Table 21.8) [76, 111, 118, 125] are associated with

Table 21.8. Effects of vitamin deficiencies on immune function

Vitamin A deficiency
Atrophy of thymus and spleen
High infection susceptibility
Higher bacterial adhesion to respiratory epithelium
Decreased: Delayed hypersensitivity (Candida, tuberculin) Number and function of circulating T cells, CD4 and CD45 Number of NK and Th1 cells T- and B-cell responses to mitogens and antigens Antigen-specific antibody response sIgA, IgG_1 and IgG_3 titers
Increased: Th2 cells and IFN-ɣ
Vitamin B_6 deficiency
Prolonged skin homograft survival
Decreased: Thymic epithelial cells Delayed hypersensitivity (Candida, tuberculin) T- and B-cell numbers Antibody-forming cells Neutrophil phagocytic activity
NB: Fetuses of B_6-deficient mothers have hypoplastic thymus and spleen and their neonates have decreased humoral and cell-mediated immunity
Vitamin B_{12} deficiency
Decreased: Delayed hypersensitivity (Candida, tuberculin) T- and B-cell responses to mitogens and antigens Neutrophil phagocytic and bactericidal activity
NB: Pernicious anemia may be associated with autoimmune phenomena
Vitamin C deficiency
Transient decrease of: Antibody and cell-mediated immunity Phagocyte activity Macrophage and neutrophil activity Resistance to infections
Vitamin E deficiency
Decreased: Lymphocyte proliferation DTH reaction T- and B-cell responses to mitogens Immunoglobulin synthesis PGE_2 production Phagocyte function
Increased: Th1 activity
Folic acid deficiency
T-cell responses to mitogens
Reduction of: Delayed hypersensitivity (Candida, tuberculin) Antibody synthesis

Data from [76, 111, 118, 125].

Table 21.9. Pediatric prevalence of dietary vitamin deficiency syndromes

Vitamins	Children at highest risk	Symptoms
Fat-soluble vitamins		
A	Preschool children	Keratomalacia
D	School children	Rickets
E	(Preterm infants)	(E-responsive anemia, lung disease)
Water-soluble vitamins		
B_1	Infants, preschool children	Beriberi
B_6	(CM-formula-fed children)	(B_6-responsive seizures)
Niacin	School children	Pellagra
Folic acid	Young infants	Growth retardation
B_{12}	(Young infants)	(Failure to thrive)
	All ages	Pernicious anemia
Biotin	(Infants)	(Seborrheic dermatitis)
Carnitine	(Infants)	(Carnitine-responsive inborn errors)
C	Infants	Infantile scurvy

The terms in parentheses show associations relatively uncommon, or controversial, or insufficiently investigated.
Data from [6].

quantitative and especially qualitative deficiencies of B and T lymphocytes, and with impairment of antibody production, sIgA and resistance to infections in particular [24, 96]. In vitro studies have demonstrated that vitamin deficiency may be negatively involved in DNA synthesis, regulation of cell proliferation and maturation of immune cells [111]. In this context, a CD8 deficiency correlated with an increase in CD4 T cells with Th2 phenotype may be mirrored by IgE level growth in sensitized subjects, stimulating or aggravating the clinical expression of atopy [111].

Low *vitamin A* titers in mothers with AIDS increase virus transmission from 7% to 32% of cases [96], and in children this causes ID that significantly affects immune functions [71], reduction of $CD4^+$ CD45RA and to a lesser extent CD45RO, reversed along with the CD4:CD8 ratio when subjects were given a dose of 200,000 IU of vitamin A [97]. Such children are more susceptible to acquiring diarrheal disease and acute respiratory infections (decreased sIgA levels) [42]. Studies in vitamin A-deficient animals show enteric mucosal antibody reduction up to 90% in response to cholera toxin [119], aberrant T-cell function and impaired T-cell-dependent antibody response, which could be postulated as both priming of Th1 cells and inhibition of Th2-like ILs [121]. Infection of vitamin A-deficient animals with *E. coli* induced diarrhea with diffusion of the infection to the gut and various peripheral organs, and a greater IgE response compared to deficient animals that were not deficient, even though vitamin A deficiency is normally associated with suppressed antibody production [120]. Vitamin A is a growth factor for Th2 lymphocytes, vitamin D_3 selectively suppresses Th1 functions and related IL_2 and IFN-γ synthesis, but not Th2 and CD8 T cells, at variance with vitamin E, which stimulates Th1.

Vitamin C deficiency inhibits both humoral and CMI responses [125]. *Vitamin D* plays an important role in the impaired functions of T lymphocytes, which may be frequently associated with infection episodes, as in a group of infants with vitamin D-induced rickets: the CD4:CD8 ratios were significantly higher due to both an increase in $CD4^+$ cells and a decrease in $CD8^+$ cells [15]. Table 21.9 summarizes age-related dysfunctions: several variables may influence the peak age of each one for association with deficiency signs and symptoms [6]. An excess of vitamin C may interact with Fe (iron) metabolism, by increasing the production of oxygen-free radicals (FR). *Vitamin K* is most likely the prime example of a nutrient with a peak vulnerability to deficiency materializing at birth [6]. Studies on FR reveal the effective *antioxidant activity* elicited by natural vitamins A, C, E, and enzymes associated with trace elements such as superoxide-dismutase (SOD) (Cu = copper, Mn = manganese; Zn), glutathione-peroxidase (Fe, Se = selenium) [8, 36]: the not unknown pertinent deficiency [9, 33, 71] may foster the imbalance of the oxidant–antioxidant ratio, thus making the cells of the immune system potentially more vulnerable to xenobiotics that may be present in the diet, or environmental contaminants [18], concurrent with increased asthma and rhinitis incidence [95].

Table 21.10. Effects of trace elements and mineral deficiency on immune function

Iron deficiency
Decreased: Total Th1 lymphocytes but not Th2 lymphocytes DTH reaction and graft rejection T cell response to mitogens Activated T-cell cytokine production Cytotoxic activity of phagocytes Antibody production Neutrophil bactericidal power and killing NK cell cytotoxicity
Zinc deficiency
Atrophy of lymphoid organs
Homograft rejection
Decreased: Serum thymulin level Thymocyte count in thymus DTH reaction T lymphocyte development and response to mitogens Macrophage function (phagocytosis, intracellular killing) Monocyte and neutrophil chemotaxis NK cell activity Number and function of T cells, CD4 and CD45 Antibody production
Increased: Monocyte chemotaxis Number of CD8 cells Number of null cells Antibody-dependent cell-mediated cytotoxicity

Manganese deficiency
Depression of cell-mediated immunity
Reduced serum levels of immunoglobulins
Reduced antibody-forming cells
Selenium deficiency
Suppression of T cell response to mitogens and antigens
Decreased: Antibody production Antioxidant activity CD8 T cells, CD4:CD8 ratio (thymocytes) Cell-mediated cytotoxicity IgG and IgM titers Monocyte and macrophage phagocytosis Neutrophil chemotaxis T cell response to mitogens and antigens
Increased: CD4 T cells (thymocytes) Platelet aggregation and leukotriene synthesis Virulence of Coxsackie virus
Copper deficiency
Decreased: Thymus weight Cell-mediated and humoral immunity CD4 T lymphocytes, IL_2 and NK cells DTH reaction Integrity of cell membranes Number of antibody-producing cells Neutrophil counts
Bactericidal power and phagocytosis
Increased: B-lymphocyte numbers

Data from [60, 68, 100, 111, 118, 125].

Trace Element Deficiency

The role played by minerals both in the nutrition and the regulation of immune responses is widely known, as well as the role of their deficiency (Cr, Cu, Fe, Mn, Mo, Se, Zn), which is a source of negative effects on immunocompetence, readily individualized (Table 21.10) [60, 68, 100, 111, 118, 125]. The deficiency is caused by an inadequate supply, as established in the following occurrences [1, 31, 43, 65, 68, 90]:

- Chronic TPN: Fe, Zn, Cu, Se, Cr (chromium), Mo (molybdenum)
- Chronic TPN: Fe, Zn, Cu, Se, Cr (chromium), Mo (molybdenum)
- Congenital deficiency: Fe, Zn, Cu, Mo
- Excessive losses (malabsorption, diarrhea, etc): Zn, Cu, Cr
- PEM and multiple nutritional deficiencies in general, inappropriate diets, diets that are too restricted or restricted for too long [122]: Fe, Cu, Zn, Cr, Se
- Prematurity: Fe, Zn, Cu, Se, Cr
- Synthetic/semisynthetic formulas: Zn, Se
- Unnatural feeding with diets not supplemented with trace elements: Fe, Zn, Cu
- Vegetarian diets: Zn, Cu

Table 21.11 outlines the clinical effects of the trace element deficiency [1], frequent in children aged >6 months, especially of Fe and Zn [65]. Deficiency of only one trace element is sufficient to lead to quantitative and qualitative alterations of the immune system [99].

Fe is transported from extracellular fluids bound to transferrin. This complex, by binding to transferrin receptors, enters the immune cells, and is transported inside the cells via a process of endocytosis, and is critical for important functions in cell division, electron transport and oxidoreductive reactions [65]. Fe is a component of numerous metalloenzymes involved in protein synthesis, including NO synthetase, cyclooxygenase, lipoxygenase and catalase [125]. Fe deficiency

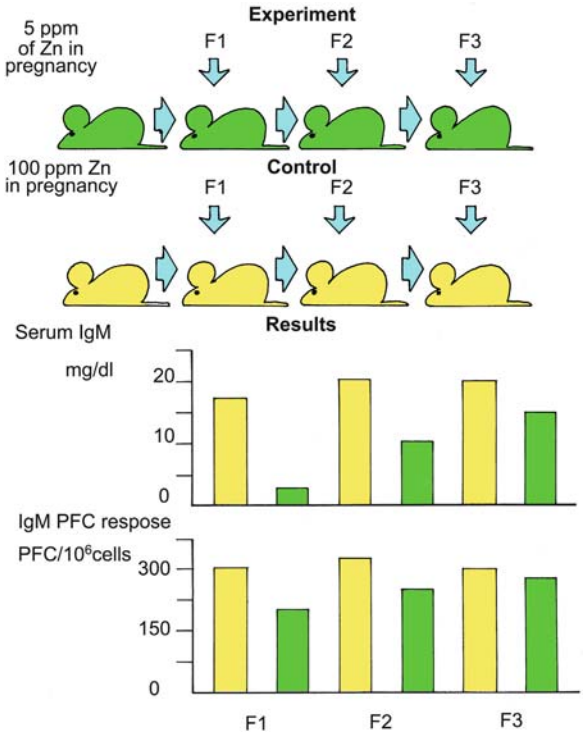

Fig. 21.7. Effects of Zn deficiency on immunity studied in two generations. Experimental animals were fed a Zn-deficient diet (5 ppm Zn) during the later two-thirds of pregnancy and a control was fed a Zn-adequate diet (100 ppm Zn) during the same period. Antenatal Zn-deficiency has severe and prolonged effects on immune functions. *PFC* plaque-forming cells, *SRBC* sheep red blood cells

reduces the bactericidal capacity, since it is necessary for lymphocyte, neutrophil and NK cell function, which is associated with an altered lymphocyte response to mitogens, reduced DTH reaction [84] and production of cytokines, IL_1 or IL_2 [29]. Fe deficiency provokes immune alterations well before the anemia is uncovered [31]. Indeed, patients with PEM-induced Fe deficiency suffer from negative immune responses in addition to having a high incidence of infections [1].

Cu deficiency associated with PEM emphasizes the vulnerability to several microorganisms [81]. The role played as a cofactor of both cytochrome-C-oxydase involved in the electron transport system and SOD, a FR scavenger, may explain in part copper's impact on immunity and the risk of FR aggressions in case of deficiency [45]. Cu deficiency impairs complement functions and Ig structure and has interactions with Fe, thus playing a key role in Fe metabolism and consequently in Hb biosynthesis [125].

Zn is an indispensable trace element, and the effects of its deficiency, both acquired and inherited [118], are impressive. Zn influences all cell subsets of the immune response [118], because it is essential for the stabilization of more than 300 metalloenzymes, and for protein catabolism and energy metabolism, as well as being an important cofactor of a wealth of enzymes, including RNA- and DNA-polymerase and thymidine kinase, which participate in cell replicative processes such as the synthesis of nucleic acids [111, 118]. Zn is determinant for a normal immune system evolution, critical to the biological activity of thymulin and therefore for T cell maturation [30]. The significant role in the activation of immunoregulatory genes is exemplified by production of IL_1, IL_2, IFN-ɣ and related receptors [65], thus elucidating why the cells of the immune system with an intensive replicative activity may negatively react to blunted Zn levels [24], which also lower thymic hormone activity [41] and jeopardize vitamin A transport [24]. As seen from Table 21.10, primitive Zn deficiency is implicated in the pathogenesis of profound ID, by impairing humoral and CMI, especially antenatally (Fig. 21.7), and lymphocyte response to mitogens, and of the inborn disorder *acrodermatitis enteropathica* with an autosomal recessive inheritance, characterized by signs of severe Zn deficiency when weaned, due to a defective intestinal Zn retention [14, 41] (Fig. 21.8). Clinically, Zn deficiency may also lead to a loss of smell [115]. In Egyptian children with atopic dermatitis (AD) and asthma, Zn concentrations were significantly lower than in control children [35], in agreement with possible Zn deficiencies during long-term elimination diets (Table 9.21). Similar alterations of the immune function are recorded in patients assuming excessive Zn doses continued for too long (Fig. 21.9). Human studies have shown that Zn bioavailability in breast milk is significantly higher than in CM and in soy protein formulas. In casein infant formulas, Zn bioavailability is lower than in whey infant formulas [65].

Secondary Zn deficiencies have been reported in [65, 111]:

Fig. 21.8. Acrodermatitis enteropathica with typical combustiform lesions

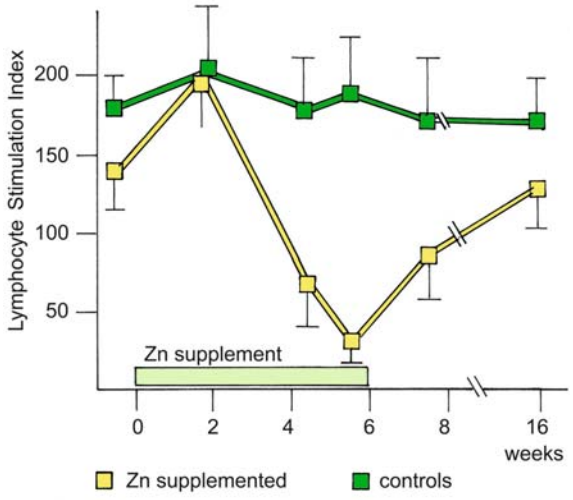

Fig. 21.9. Results of lymphocyte transformation test in subjects fed 300 mg elemental Zn daily for 6 weeks

- Children who are long-term TPN-fed and severely malnourished children living in the Andean regions, which commonly have volcanic soil with low Se content [98], may have dietary Zn deficiency, probably as a consequence of enteric disorders. Zn concentrations not covering basal requirements in the solutions are determinant for TPN.
- Surgical conditions, for example, after jejunoileal bypass.
- Disorders such as cystic fibrosis, essential fatty acid (EFA) deficiency and kwashiorkor.
- Metabolic disorders, such as methylmalonic acidemia, biotin-dependent multiple carboxylase deficiency, MSUD (maple syrup urine disease) especially in infants fed isoleucine-deficient diets and/or branched amino acids [40].
- Intestinal disorders such as IgA selective deficiency, ulcerative colitis, Crohn's disease, celiac disease, diarrheal syndromes [52], etc.
- Acute lower respiratory tract infections [52].

Mn deficiency does not occur in infants and toddlers, Fe deficiency enhances Mn absorption, but Fe medications inhibit Mn [65]. Studies show that Mn deficiency causes depression of CMI (as well as Se deficiency) and decreased serum Ig levels.

Se deficiency is accompanied by suppression of T cell response to mitogens and antigens and by antioxidant effects of the Se-dependent glutathione peroxidase enzyme [103, 106], and clinically is correlated to atopic asthma and to rapid AIDS progression [68]. Children who are TPN-fed over the long term may have extremely low Se levels, and in infants and children the Se requirement is increased to meet growth demands [55].

Essential Fatty Acid Deficiency or Excess

Essential fatty acids (EFAs) represent the major components of cell membrane phospholipids, where they regulate fluidity, conformational changes, enzyme functions and transport and are found in triglycerides as an energy supply. Moreover, being eicosanoid precursors, EFAs may cause immune system dysfunctions: their deficiency induces depression and excess immunosuppression (Table 21.12) [111]. Both heighten the susceptibility to infections, and change humoral and CMI; the reticuloendothelial system functions as well as the neutrophil capacity of migration and phagocytosis [5]. The metabolic cycle of arachidonic acid (AA) is shown in Fig. 1.57; however, the immunosuppressive effects are inadequately known, including the cell membrane fluidity alterations, which are negatively reflected in the distribution and functions of surface receptors. In addition, there is a prostaglandin (PG) excess, whose precursors, AA and linolenic acids, may suppress T lymphocytes and NK cells, as well as their IL_2 primed proliferative phase that follows T cell activation [77]. Various effects of EFA deficiency (Fig. 4.30) have been associated with either exogenous or endogenous causes and show some characteristics of patients with AD [46]. Although in children a severe EFA deficiency is unlikely, subdeficiency states may also occur in this case, following an inappropriate diet. In EFA-deficient, severe PEM children, δ-6 desaturase activity was impaired, and there was a nonsignificant AA decrease. EFA deficiency is a type of malnutrition and is associated with an aggravation of all parameters in severe PEM [104]. In the lung, EFA deficiency has negative effects on O_2 diffusion, surfactant production and PG metabolism [127]. Recently, a new chapter has opened up on trans fatty acids (by a rotation of the molecule across its double-bond, the

Table 21.12. Effect of fatty acid deficiency or excess on immune function

Fatty acids	Effect of deficiency	Effect of excess
Polyunsaturated	Reduced humoral response for both T cell-dependent and T cell-independent antigens	Immunosuppression, delayed rejection of skin grafts, suppressed DTH, reduced T-cell response to mitogens and antigens and reduced neutrophil chemotactic and phagocytic activity
Saturated	Rare	In vitro inhibition of T lymphocyte response to mitogens and antigens
Cholesterol	Rare	Inhibition of humoral and cutaneous hypersensitivity to antigens, reduced lymphocyte and macrophage function

Modified from [111].

Fig. 21.10. (Modified from [69])

–COOH group is on the opposite side of the $–CH_3$ group. So hydrogenated vegetable oils are solid at room temperature), contained in variable concentrations in several kinds of foods [68, 70], which could alter PUFA (polyunsaturated fatty acid) metabolism in infants, by modifying PG and cell membrane function [27]. However, the pertinent problem is at a close end due to clear indications related to infantile food composition [27]. In Denmark, trans acid utilization has been reduced to 5% and will be reduced to 1% [50].

Table 21.13. Immune response modulation in humans via food lipids

Lipid supply	Food	Effects
Eicosapentaenoic acid	Fish oil	Reduction of LTB_4 and free radicals, reduced chemotaxis
α-Linolenic acid	Vegetable oils	None

Modified from [5, 51].

The consequences of EFA deficiency on the infantile immune system are to be evaluated: dihomo-γ-linolenic acid is a PGE_1 precursor and AA of PGE_2, both potentially playing a relevant role in immunoregulation, in particular PGE_1, active in the thymus has elevated concentrations, and thymus-like effects on CD8 maturation (Chap. 7). The PG activity on the immune system might be mediated in part by their capacity to stimulate cAMP synthesis, whose reduced levels are a marker of atopic constitution. Clinically, dietary *linoleic acid deficiency* (Table 21.12) results in failure to thrive, scaly dermatitis, amplified susceptibility to infections, electrocardiographic changes, decreased muscle tone, degenerative changes in kidney, lung and liver tissues, impaired water balance, increased fragility and permeability of cell membrane. *Linolenic acid deficiency* may cause 50% loss of visual acuity due to reduction of the electroretinographic wave primarily related to photoreceptor function [37, 46, 113]. Figure 21.10 [69] shows the consequences of EFA deficiency and that breast milk prevents it [69]. When a δ-6-desaturase deficiency is suspected, the administration of evening primrose oil [124] has yielded controversial results in breast-fed children with AD [94, 124]. On the other hand, EFA (see Table 7.21) or nucleotide balanced supplements may be added to the diets if necessary should breast milk not be available (Chap. 24).

Recent data have emphasized salient characteristics of *EFA excess*, especially of long-chain PUFA, and a dietary excess of these proteins is highly immunosuppressive [37]. PUFA double bonds are the primary target of *FRs*, which start the chain reactions leading to formation of lipid peroxides, able to alter cell functions up to cell lysis [101]. Since EFA is an integral part of cell membranes, and certain ones are PG and LT precursors [127], changes in membrane fluidity caused by lipid peroxides influence immune responses negatively [102], likely reducing lymphocyte ability to respond to immune system solicitations [18]. Furthermore, the EFAs stemming from linoleic acid (ω-6 series) (Fig. 4.30) are metabolized into more immunosuppressant products than those stemming from eicosapentaenoic acid (EPA) (ω-3 series); PGs and LCTs originating from the ω-6 series have an inflammatory effect that mediators from the ω-3 series do not have [42].

PEM directly provokes a reduction in PUFA levels [59], including AA, docosahexanoic (DHA) and EPA acids, proportional to the degree of malnutrition [32], present also in pediatric AIDS [16], with deleterious effects induced by PUFA ω-3 and ω-6 deficiency [32]. Table 21.13 shows examples of immune modulation brought about by alimentation under EFA influence [5, 51].

Other Causes of Malnutrition

Protein and Amino Acid Deficiency

Both lipids and protein are required for cell growth, and a balance between protein and fat is present in all basic foods; thus foods poor in protein are also poor in fat and EFA. Protein deficiency may impair purine, pyrimidine and creatinine synthesis, as well as enzyme metabolism and nitrogen balance; hypoprotidinemia is associated with hypoalbuminemia, and often with hypergammaglobulinemia. Mice experiments indicate that chronic protein deprivation has selective effects on immune functions, qualitatively similar to PEM-induced functions, with negative consequences above all on cutaneous and mucosal lesion repair, lymphocyte proliferation, humoral and CMI, and decreased IgG levels, DTH responses and *oral tolerance* [49]. When protein dietary deficiency was accompanied by induction of ovalbumin tolerance, there was an increase in humoral tolerance, but associated with a parallel increase in DTH responses [49], thus suggesting a prevalent alteration of CMI, without involving Th1 cells priming DTH reactions (Tables 21.1, 21.2). Infections and a protein-deficient diet affect the branched chain amino acids in the same way, but both glycine and alanine have opposite effects [116, 117, 126]: a protein-deficient diet in healthy young adults has no effect on phenylalanine [126], infection brought about an increase in infected individuals [116, 117]. Table 21.14 [116, 117, 126] shows the relative contribution of each influence to the plasma concentration

Table 21.14. Effect of a protein-free diet, infection, or malnutrition on the plasma concentration of selected amino acids

Amino acid	Protein-free	Infection	Malnutrition
Valine	×	×	×
Leucine	×	×	×

of individual amino acids. Clearly, there are major changes to be characterized in protein and amino acid metabolism in malnourished individuals [49].

Nucleotide Deficiency

Ribonucleotides or nucleotides are the basic units of the nucleic acids DNA and RNA, because they can be synthesized endogenously (Fig. 2.20). They are usually labeled as nonessential nutrients, becoming semiessential or essential when the endogenous supply is insufficient for normal function, as during the rapid cell proliferation occurring in newborns [21]. Recent studies show that bone marrow, lymphocytes and red cells are unable to synthesize purines *de novo* and intestinal cells have low, inadequate rates, so these tissues utilize liver-supplied preformed nucleotides. The pertinent deficiency produces in children [20] and experimental animals [83] immune dysfunctions analogous to those described in PEM sufferers (Table 21.15) [20, 83, 125]. Dietary deficiency restrains more immune functions such as resistance to infections and macrophage activation and alters the intestinal architecture [20].

Malnutrition and Immunotoxicants

Recent data have disclosed a relationship between generalized, marginal, or single nutrient malnutrition and the effects of *dietary xenobiotics:* these interactions are schematized in Fig. 21.11 [18], which shows that dietary immunotoxicants and/or malnutrition may cause an ID complicated by susceptibility to infections, autoimmunity and neoplasms, which in turn worsen the initial ID. The French Supreme Council of Public Health has recently revised the studies on the potential toxicity of Se, Zn and Fl and vitamins A, C, D, E, B_6, niacin and folic acid, fixing their limits to a tenth of the dose demonstrated as toxic (Table 21.16).

Immunological Effects of Neonatal Malnutrition

The development of the immune system begins in early intrauterine life (Table 2.4) and continues into the first few months after birth. Malnutrition occurring in early gestation, as epitomized by small-for-gestational age (GA) and low-birth-weight (LBW) infants, is also reflected on fetal ontogeny, all the more severe if PEM interferes with a developing immature immune system (Table 2.1); the effects on CMI are very severe and long-lasting [24]. Infants suffering from malnutrition during fetal life suffer subsequently from numerous and quantitative cellular deficiency, persisting for several months or years; unlike LBW of appropriate GA, who also have depressed immunocompetence, but recover within a few months after birth [23]. Fetuses of B_6-deficient mothers have a dysfunction of both the thymus and spleen, and neonates have comparable CMI deficiencies [111], especially when several immune functions are immature or unprepared (Chap. 2); moreover pyridoxine deficiency causes a reduced lymphocyte response to mitogens [23]. The human fetus is ill-suited to synthesize EFAs, which therefore must be derived from the maternal bloodstream and reach the baby [37]. In the very first days of life, neonates should count on breast milk; however the issue may be more complex.

Malnutrition and Breast Milk

Several foreign substances, especially pollutants, may pass from mother to fetus through the placenta and be found in breast milk, potentially leading to malnutrition [17]. Infants are at great risk from breast milk pesticides because their intake relative to body weight is high [85]. In the study of Koppe et al, 4/14 neonates (28.6%) exhibited hemorrhagic manifestations in the first 4 weeks of life: in their mother's milk, the TCDD (tetrachlorodibenzo-*p*-dioxin) level was significantly higher than in the milk of the other 10 mothers [54]. Besides TCDD, a wide spectrum of halogenated pesticides and industrial chemicals are present in the milk of nursing mothers, such as β-hexachlorocyclohexane (β-HCH) (banned in the majority of industrialized countries), persistent organic pollutants (POPs), polychlorinated biphenyl (PCB), etc. [88] (Table 4.21). Six studies done between 1978 and 2001 [64] in breast-fed children aged 0–12 years have shown high levels of POP, including DDE (dichlorodiphenyl dichloroethylene), DDT, PCB, β-HCH, and β-hexachlorobenzene (β-HCB).

Thirty-two percent of countries report breast milk contamination from chemical exposure, thus raising critical concerns about breast milk safety for nursing infants. In China, breast milk samples from 35 cities were found to have traces of DDT 5–10 times, and in Delhi 12 times higher than permissible limits. While the WHO tolerable daily intake of dioxin is 1–4 pg/kg,

US nursing infants receive 35–53 pg/kg/day and in Japan 100–530 pg/kg/day. In Guatemala, pesticide residues in breast milk are reported to be 250-fold the amounts allowed in CM. Breast milk from Inuit women in Canada had concentrations of PCBs, a fourfold higher metabolite of DDT and tenfold higher metabolite for the pesticide mirex than women in control groups (The '103 Report). Studies in Zimbabwe found that almost all of the breast milk samples taken in some regions showed contamination with DDT [26].

In general, the pollutant levels that pass into breast milk are lower than the levels occurring in maternal plasma, but breast-fed atopic children can have concentrations of immunotoxic compounds 321% higher than nonatopic children [123]. The reported amounts are normally very low and quite distant from the doses considered as harmful and depend on several parameters, such as the POP amount ingested by the mother, its absorption, distribution, metabolism and the elimination of individual substances, either in the mother or the nursling neonate [86]. There is absolutely no positive evidence of hazards posed to infants and of possible toxic effects, although sometimes there were *prenatal exposures* [67, 123], but *breast milk benefits outweigh any possible disadvantages* [53], also because concentrations of chemicals found in breast milk are unquestionably lower than the concentrations detected in maternal plasma [86, 93]. Estimates of prenatal and perinatal PCB exposure of newborn babies in cord blood (CB) and breast milk-negative associations between breast milk PCB and mental and motor development were significant from 30 months onwards. However, prenatal PCB exposure at current background levels inhibits mental and motor development and spreads its effect up to

Abnormal air volume/pressure curves
Decreased elastic recoil

Modified from [47].

Clinical Presentation

It is known that infections that interfere with numerous physiological and metabolic alterations reflect, although transiently, upon the host nutritional status [52]. Detrimental effects on nutritional status are summarized as follows: anorexia, decreased absorption of nutrients, usual food replacement with a hypoproteic and low-energy diet and increased urinary losses of N, K, Mg, Zn, S, P and vitamins A, C and B_2; the loss of trace elements and vitamins further complicate the pattern [1, 6]. Additional effects of malnutrition include increased basal energy expenditure, marked muscle catabolism and depletion of N, glycogen, lipid and EFA deposits [112]. To face the lack of protein substrates, the organism resorts to an increased compensatory uptake of amino acids from the muscles, accompanied by a significant insulin hypersecretion, coming from the dietary carbohydrate intake [52, 112]. The EFA deficiency promotes important metabolic alterations, heralded by hepatic steatosis derangement [49]. When the intestine is involved, it is sufficient to imagine that in CMA with intestinal manifestations, protein absorption can be reduced by 20%–33% and fecal fat loss can approach 40% of fat intake [52]. In the lung mucosa, the reduction of sIgA in bronchial secretions and thymic atrophy in rats are crucial (Table 21.19) [47], with more severe and lasting effects (Table 21.20) [47].

Without taking into account starvation types such as kwashiorkor, the infectious episodes, the inappropriate diet, sometimes with dramatic effects [74] (Table 9.23), and the effects of unconventional remedies are fitting examples [49, 105]. The subject of inappropriate diets has recently been stressed [19]. A 22-month-old male child was started on a rice beverage after weaning because of a history of chronic AD and suspected CMA, while the intake of solid foods was very poor. This rice beverage, fallaciously referred to as rice milk, is extremely low in protein content, thus the resulting daily protein intake was only 25% of the RDA (recommended daily allowance). Consequently the baby developed severe kwashiorkor. A 17-month-old black male was breast-fed until 10 months of age, when he was weaned to a soy health food beverage, which was not fortified with vitamin D or calcium. Intake of solid foods was good, but included no animal products. Thus the child was diagnosed with rickets [19]. In Holland, 24% of 200 neonates and 93 children aged 1.2 admitted to an ICU (intensive care unit) showed signs of acute and/or chronic malnutrition [48]. Allergic children who are the victim of parental attitudes appear to be pale, irritable, with thin and dry hair, succulent subcutaneous edema of lower limbs, hepatosplenomegaly, and weight and height in the 3rd–10th percentile for age, a typical dystrophic aspect explained by unbalanced dietary manipulations with protein deficiency [17, 74, 105].

Table 21.21. Recommended micronutrient daily allowances (LARN 1996)

Category	Age Years	Fe mg	Zn mg	Cu mg	Se µg	Vit C mg	Vit A RE µg
Infants	0.5–1	7	4	0.3	8	35	350
Children	1–3	7	4	0.4	10	40	400
	4–6	9	6	0.6	15	45	400
	7–10	9	7	0.7	25	45	500
Males	11–14	12	9	0.8	35	50	600
	15–17	12	9	1	45	60	700
Females	11–14	12–18	9	0.8	35	50	600
	15–17	12–18	7	1	45	60	600

The Fe daily allowance is of 18 mg for menstruated adolescents, of 12 mg in non-menstruated adolescents. Vitamin A is expressed in µg of RE (retinol equivalent), = to 1 µg of retinol, = to 6 µg of β-carotene, = to 12 µg of other active carotenoids.

Diagnosis

A high priority should be given to the clinical history of admitted children with PEM: documenting multiple deficiencies, investigations to evaluate nutritional parameters (Appendix 9.11) as well as immune background and concentrations of trace elements, vitamins [82], EFA and nucleotides are sometimes needed. A fitting dietary history is necessary and should include inquiry into the use of CM alternatives [17]. The histological examination of intestinal lesions may reveal changes resembling those of celiac disease [13]. The increase in the C18:1/C18:0 δ9 desaturase activity and enhanced lipid peroxidation without any EFA deficiency could be early markers of PEM [104].

Treatment

A large body of epidemiological evidence shows that the often interacting effects of malnutrition (and excess EFA intake) accentuate the need for regular check-ups in case of protracted therapeutic elimination diets [49], either of child growth based on national standards (Appendices 6.1–6.4) or early signs of malnutrition (Appendix 9.12). The management of chronic malnutrition, as seen in pediatric AIDS (Chap. 23) is more demanding and complex. The basic management with Zn (5–10 mg/kg of Zn as Zn sulfate) and breast milk can resolve acrodermatitis enteropathica [14], Zn administration in children with PCM may prevent the related deficiency and improve the immune function [91], and in patients with HIV infection it has the ability to stimulate a CD4 increase, thus reducing the incidence of bacterial infections [118]. When the dosage calculated based on RDA is continued for too long, a reduction in monocyte phagocytosis and an interference in Cu and Fe absorption can result [92]. Similarly, Zn prescription to not Zn-deficient subjects as a nonspecific immunostimulant should be discouraged [118]. In children belonging to disadvantaged population groups, a 2-month period was required for complete immunologic recovery [25]. Six months after the ICU admission, almost all children showed complete recovery [48]. Zn supplements should be prescribed to children with AD undergoing long-term elimination diets or with atopic asthma [35]. However elevating Zn intake from 0.3 to 0.6 mg/kg/d in very LBW infants did not influence serum Zn concentration [66]. If possible, babies with AD should be breast-fed, because Zn absorption is higher from breast milk than from CM [65]. Children with atopic asthma should receive Se supplements, since they are low in platelet glutathione-peroxidase [76]. We believe that formula-fed babies are not as well-provided as breast-fed babies in terms of Se nutrition [55].

Table 21.21 outlines recommended vitamin and mineral dosages according to age and sex. Normally, a well-balanced and carefully prepared diet can ensure an excellent, rapid result as regards micronutrients [41, 43], including vitamins [61] and nucleotides [79] in abundance in breast milk (Tables 2.16, 2.17); a few days are sufficient to normalize liver histology [112]. As regards vitamins, it has recently been ascertained that assuming commercial preparations for preventive or protective purposes has no effect [44, 56, 75], at variance with the vitamins contained in fresh fruits and vegetables [56]. The necessary EFA supplements for the nutrition of term and preterm neonates [37] are to be found in both colostrum and breast milk (Tables 2.14, 2.15); Appendix 7.3 shows the recommended doses. With a rich nucleotide diet, as well as with breast milk (Table 2.16) both the number and functions of intestinal T cells are reversible [79], with positive effects on both humoral and CMI (increase in IgA, CD3, CD4, CD8 levels and CD4:CD8 ratio at 3–3.5 months) [73] and long-chain PUFA levels [21].

Pediatricians, Malnutrition and the Immune System

Assessment of nutritional status and the immune response is new, and our understanding of the mechanisms involved is far from exhaustive. For each of the nutritional deficiencies so far analyzed, such as PEM, vitamin, and trace metal deficiencies, and excess fatty acids, evidence has accumulated that dietary dysfunctions in the nutrients alter immunity and/or susceptibility to infections in infants, children, and adolescents. Some of these deficiencies are reversible with nutritional supplements. In particular, we have included
malnutrition in Table 9.22 among the possible consequences of inappropriate diets. That nutritional deficiencies can provoke alterations of the immune response at various degrees, indirectly aggravating the pediatric allergic affections, is widely understood, without neglecting in this context, trace element deficiency, with Zn in the first place. Pediatricians should thereby ensure that allergic children/adolescents submitted to restricted diets are monitored often, especially regarding their pondostatural growth, to avoid nutritional deficiencies. It is also known that human organisms are unable to accumulate Zn supplies, hence a regular introduction into the diet is needed. To their youngest patients, pediatricians should advise breast milk, in which Zn bioavailability is first-class compared to CM and CM-derived formulas.

Pediatric AIDS

Twenty-Five Years of Science

Never before in the history of medicine have the nosology and etiology of a new disease been defined as quickly as in the case of AIDS (acquired immune deficiency syndrome). The worldwide dissemination of human immunodeficiency virus (HIV) over the past 47 years is one of the most catastrophic examples of the emergence, transmission, and propagation of a virus [248]. AIDS was first observed in the USA in 1981 through the study of young homosexual males demonstrating a high rate of *Pneumocystis carinii* pneumonia (PCP) associated with Kaposi's sarcoma (KS), also at a visceral level [222]. At the time, KS was considered a rare form of cancer that mainly affected subjects over the age of 60. Reports of cases of pneumocystosis and/or KS, often associated with other severe opportunistic infections, rose to such an extent that 159 cases were reported between June and November 1981 [222]. It was soon discovered that HIV infection had spread above all among young adults from already identified risk categories: homosexuals, drug addicts, hemophiliacs, recipients of transfusions of blood or blood products, or natives of Haiti and Zaire, Rwanda and Burundi [61, 87, 182, 455, 555]. The early cases of HIV infection originated in Central Africa, where it was identified in Kinshasa, Democratic Republic of Congo, [555] in a *sample of serum stored since 1959* [599] and then spread outwards to neighboring Tanzania and Uganda in the east, and Congo-Kinshasa in the west [555]. On the basis of the HIV-1 (HIV type 1) sequences obtained from a sample of serum that was stored in 1959 and more recent isolates, it has been estimated that the date of the common ancestor of the main (M) group of HIV-1 is 1931 (1915–1941) [292]. The most recent common isolates of HIV type 2 (HIV-2) have been dated to the 1940s [326]. *As early as in 1983* [477] *several investigators reported AIDS in children* [17, 61, 182, 477], *and especially in infants* [182]. In addition to HIV-1, a second virus, HIV-2, was subsequently identified in West Africa [107, 108], causing a syndrome that was fully analogous to HIV-1 but was different from an antigenic standpoint [82]. HIV infection is characterized by virus replication in a limited number of cells, including T lymphocytes and macrophages, leading to a CD4 depletion and a profound immune deficiency (ID) [31, 202, 205, 442]. In children, the disease is marked by a short incubation period of even <1 year [494], while in adults it can develop in HIV-infected subjects within a decade (or up to even 19 years following HIV-2 infection) [158]; many of these patients remain asymptomatic for long periods of time, with normal CD4 counts [85] and normal-looking lymph nodes, despite persistent virus replication [423].

The WHO estimated that $>40\times10^6$ people worldwide are currently infected, and AIDS has caused $>20\times10^6$ deaths. In the developing world, where the epidemic is most prevailing, the disease's adverse social and economic impact should not be underestimated [438]. Sixty-six percent of infected persons are in Africa, and 20 % are in Asia, where the epidemic has been growing rapidly in recent years. Global statistics have made it clear that at the end of 2003, an estimated 34.6×10^6 to 42.3×10^6 people throughout the world were living with HIV infection, and the AIDS epidemic has claimed the lives of >20 million people [523, 549]. In addition, because HIV-infected mothers are likely to die of AIDS, 10 million children have been orphaned thus far and an estimated 20 million will be orphaned by 2010 [577]. The WHO now recommends quality-assured, fixed-dose combinations of lamivudine (3TC), stavudine (d4T) and nevapirine (NVP) in a single pill as first-line treatment [576] (see "Treatment"). There, when parents die, they leave orphans, most of whom are not HIV infected, thus HIV infection has a disproportionate impact on children, resulting in the loss through illness or death of those persons who can make the greatest contribution to the social support systems and economic vitality of their regions [191, 208].

HIV

HIV-1 and HIV-2 belong to the subfamily of *lentiviruses* (Table 23.1) [139] from the family of retroviruses (Table 23.2) [139], which also includes simian ID virus (SIV), which is most similar to the two HIV types [82]. In contrast to HIV-1 infection, which is spread through all continents, HIV-2 is primarily restricted to West Africa and to population movements from or through this region [326]. HIV-1 is undergoing rapid mutations and recombinations that contribute to its genetic diversity. Three genetic groups, designated M and O (outlier), and N (non-M/non-O), have been identified. M, which

Table 23.1. Main lentiviruses

Classification	Host	Associate pathology	Name
Ungulates	Ram, goat	Encephalitis, interstitial pneumonia	Virus visna
	Goat	Encephalitis, arthritis	CIEV (caprine infectious encephalitis virus)
	Horse	Infectious anemia	EIAV (equine infectious anemia virus)
	Bovine	Bovine lymphocytosis, ID?	BIV (bovine ID virus)
Felines	Cat	Immunodeficiency	FIV (feline ID virus)
Primates	Macaque	Immunodeficiency	SIV_{mac} (simian ID virus)

	Equines	

Data from [139].

is highly prevalent, is further classified into ten established envelope (env) subtypes designated clades, A through J according to their degree of genetic similarity [326]. Subtypes A, B, C and D are known, and they are distinguishable by their genome, while E and G are recombinants with subtype A, and the sequences of subtypes F, H, I and J are not available [367]. Clade B is the most common in the US and Western Europe; clades A, C, D, and E are most common in the developing world [253]. A high heterogeneity of HIV variants is also possible, as seen in Lebanon [435]. Differences in vertical transmission and progression rates have also been reported among these strains [253]. As in other retroviruses, there are cell proteins in the viral preparations, such as the HLA-DR and β chains, β_2-microglobulin, HLA class I and adhesion molecules CD11a/CD18 and CD44, suggesting selective incorporation of these human proteins in the potential host genome [24, 413].

As shown in Fig. 23.1, like other retroviruses HIV is composed of two identical copies of RNA, arranged inside a core of viral proteins [301]. The gene structures in the 9 kb that form the RNA strand are reported in Table 23.3 [214, 456]. The genome includes at least nine separate genes with sequences that partially overlap: these chains are flanked on both sides by long terminal repeats (3′ and 5′ LTR), which contain the set of essential signals to regulate the provirus transcription and become integrated in the cell genes. It must be noted that some LTR regulatory sequences share cell sequences [214]. For a better understanding of the role of these genes, we can theorize that when the cell encounters activation phenomena, this also involves LTR, whose signals include a promoting part activated by cell RNA, an enhancing part, another with a negative regulatory activity and the tat sequence, a positive HIV replicator that is capable of 1,000-fold acceleration of the production of viral proteins [132].

Schematically, the HIV virion is spherical in shape, has a diameter of 100–120 nm, and a basic structure similar to that of other retroviruses [103, 301, 467, 509]:

- *The viral env,* a lipid bilayered membrane, is studded with various host cells (including HLA class I and II) and contains 72 external spikes formed by the two major viral-env proteins gp120 and gp41 [100] (Fig. 23.1). These originate from enzymatic splitting of the larger viral pre-protein gp160; they elicit viral entry and syncytium formation. Gp120 has a variable protein domain containing the V3 loop, which triggers a strong immune response [194, 584]. The cell shows mature and budding particles (Fig. 23.2). Within the virus, structural proteins surround an inner viral core that contains enzymes and proteins required for viral replication including protein p24. In addition to p24, the HIV-1 core contains three nucleocapsid proteins, p17, p9 and p7 [226]. These proteins are proteolytically cleaved from a

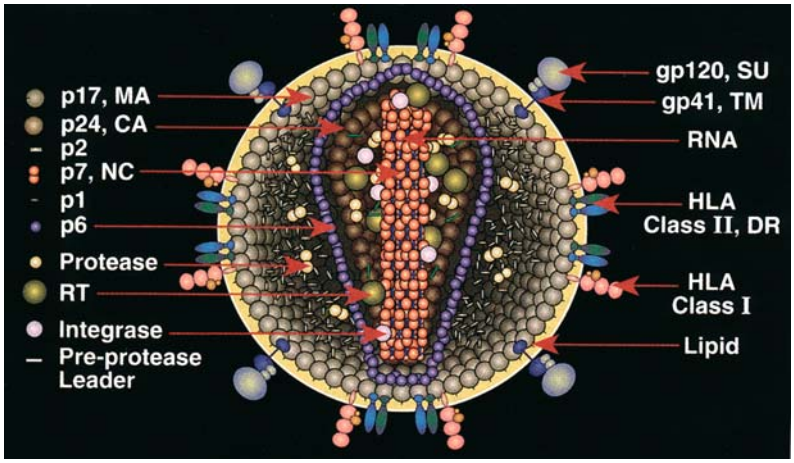

Fig. 23.1. Schematic cross-sectional view of the mature HIV particle. The viral particle is composed of mature gag and pol products. The viral products, two identical RNA molecules, are surrounded by a lipid bilayer with membrane-bound surface proteins of viral (gp 41 and gp 120) and cellular (HLA class I and II) origin. *p* Protein, *gp* glycoprotein. (Adapted from NIH Publication 94–1536)

Table 23.3. HIV genes

Genes	Name, size (kD), functions, localization
HIV structural components	
gag (Group-specific antigen)	p17 Membrane anchoring (MA), envelope interaction, nuclear transport of viral core, virion
	p24 Core capsid (CA), virion
	p6 Binds Vpr, virion
	p7 Nucleocapsid (NC), binds RNA, virion
	p9 RNA-associated nucleoprotein
pol (Polymerase)	p11 Protease (PR), (gag-pol-env cleavage and maturation), virion
	p66/51 Reverse transcriptase (RT), reverse transcription, RNase H activity, virion
	p32 Integrase (IN), DNA provirus integration, virion
env (Envelope)	gp120 External viral glycoproteins, binds to CD4 and coreceptor, plasma membrane, virion envelope
	gp 41 Transmembrane glycoprotein or fusin, fusion protein
Regulator proteins	
tat (Trans-activant)	p16/p14 Viral transcriptional transactivator, activates indispensable transcription for viral replication
rev (Regulator of viral expression)	Codes a 20-kD protein for RNA transport, primarily in nucleolus–nucleus, shuttles between nucleolus and cytoplasm
nef (Negative factor)	p27/25 CD4 down-regulation (myristylated protein), plasma membrane, cytoplasm, virion
vif (Viral infective factor)	p23 Promotes virion maturation and infectivity, cytoplasm (cytosol, membranes), virion
vpu (Viral protein U)	p16 Promotes extracellular release of viral particles, degrades CD4 in the endoplasmic reticulum, integral membrane protein
vpx (Viral protein X)	Encoded only by HIV-2 and SIV appears to be required for viral replication in peripheral monocytes and macrophages
vpr (Viral protein R)	p10–15 Promotes nuclear localization of preintegration complex, inhibits cell division, arrests infected cells at G2/M, virion, nucleus

Data from [214, 456].
gp glycoprotein.

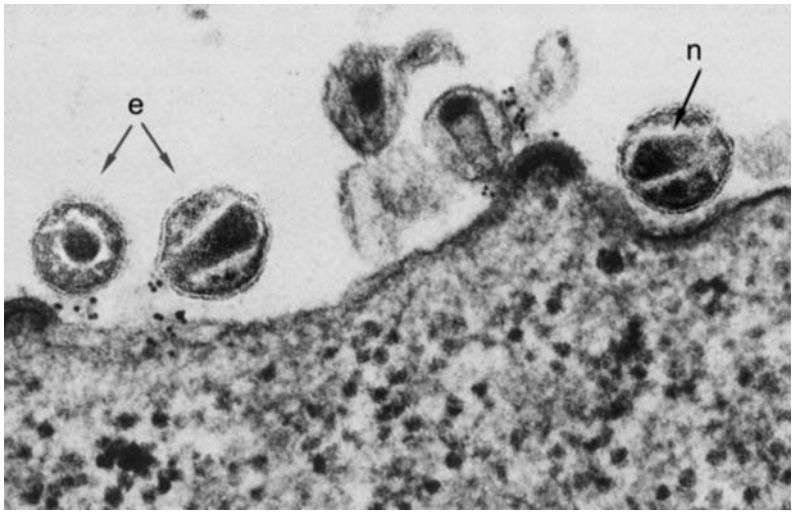

Fig. 23.2. HIV appearance at electron microscopy. At the surface of an infected cell the HIV eccentric nucleus (*n*) appears [p24, p13, reverse transcriptase (RT) and diploid genome], and *e* (*two arrows*) shows the envelope with two small spinous projections (glycoproteins) and internal membrane (p17). In the middle appears a budding viral particle, and others that are mature produced by the same cell: the free HIV-1 virion thus produced from the host cell can initiate the retroviral life cycle by infecting other $CD4^+$ target cells

common 53-kD (p53) gag precursor by the virion protease [226]. The phosphorylated p24 polypeptide forms in vivo the chief component of the inner shelf of the nucleocapsid that encloses two genomic RNA strands and the viral enzymes. The myristoylated p17 (matrix protein) is associated with the inner surface of the lipid bilayer. p9 is a nucleocapsid protein not covalently attached to the viral RNA [343].

- *After attachment,* the next step in the infectious process is *viral penetration.* The viral life cycle begins with the gp120 glycoprotein protruding from the surface, anchored by the transmembrane *env* molecule gp41 (fusin). The viral lipid *env* fuses with the lipid membrane of the target cell, which occurs by a disulfide bridge (S-S-bond): gp120 has a binding site for CD4 and associates noncovalently with gp41 to form a peplomer on the virus surface [58] (Table 23.3). They mediate viral entry and syncytium formation, one way in which infection spreads [459].
- *The main nucleus and virion protein enter the cell* and the single-stranded viral genomic RNA is transcribed into double-stranded DNA by reverse transcriptase (RT): double-stranded HIV DNA, complexed with the viral enzyme integrase, a product of the *pol* gene, travels to the nucleus and is inserted into chromosomal DNA [72]. As HIV virus particles bud from the surface of infected cells, are enveloped by the host cell membrane, and incorporate portions of the membrane and cellular proteins of the infected cell, HIV acquires its outer membrane as the virion exits the cell [23].
- *Binding to CD4* is necessary, but not sufficient for HIV entry into the cell. *CD26 is also necessary,* since it is the enzyme dipeptidyl-peptidase IV (substrate is the V3 loop of HIV-1 and HIV-2). Cell susceptibility to HIV infection is correlated with CD26 expression, and HIV transactivator *tat* and envelope protein gp120 are reported to interact with CD26 [410]. HIV-1 uses two different types of receptors for cellular attachment and viral entry into the target cell. Initial viral attachment occurs through cognate recognition of the env protein gp120 with the cell surface CD4 and a chemokine co-receptor, either CXCR4 or CCR5 (CXC chemokine receptor 4 and 5, respectively) [39]; especially CCR5 serves as the major portal of entry for HIV-1 [103]. Thus HIV enters the CD4 and exposes gp120 on the CD4 surface. As a result, HIV can be transmitted from one cell to another, as gp120 is the key for accessing CD4 [63, 340].

Like all retroviruses, the HIV genome consists of *gag*, *pol* and *env* genes, which code the main structural proteins and virus enzyme activities, and two LTRs at the chain's ends, on position 5′ and 3′ of the viral genome (Fig. 23.3). These gene sequences, which are common to all retroviruses, are implicated in controlling the transcription process [226]. In addition to these essential genes, HIV also contains seven more regulatory proteins: *tat, rev, nef, vif, vpr, vpu, and vpx* that control the proteins with regulatory functions, given that they intervene positively or negatively in its replication and maturation [546]. In the early formation phases of the transcription complex at 5′-LTR, the primary RNA molecule undergoes multiple splicing events that yield the synthesis of these regulatory proteins (Table 23.3). *Both tat and rev* regulate viral gene transcription and *are essential for HIV replication. tat* is a powerful transactivator that binds the TAR (transactivation responsive sequence) region contained in 5′-LTR and amplifies the viral replication transcription phase. Another indispensable gene for replication is the *rev* gene because, by continuing the splicing events, it transmits mRNA from the nucleus to the cytoplasm [467]; the *rev* gene reaches threshold concentrations and codes specific response sequences present in the viral genome [546]. The precise function of the *nef* gene is being debated, as it is required for the dissociation of CD4 from $p56^{lck}$, degradation in cytosol [458] and the progression of AIDS in monkeys with SIV [282]. Its function as a negative regulator in HIV replication has not been confirmed [458] since *nef* favors HIV entry into target cells by the

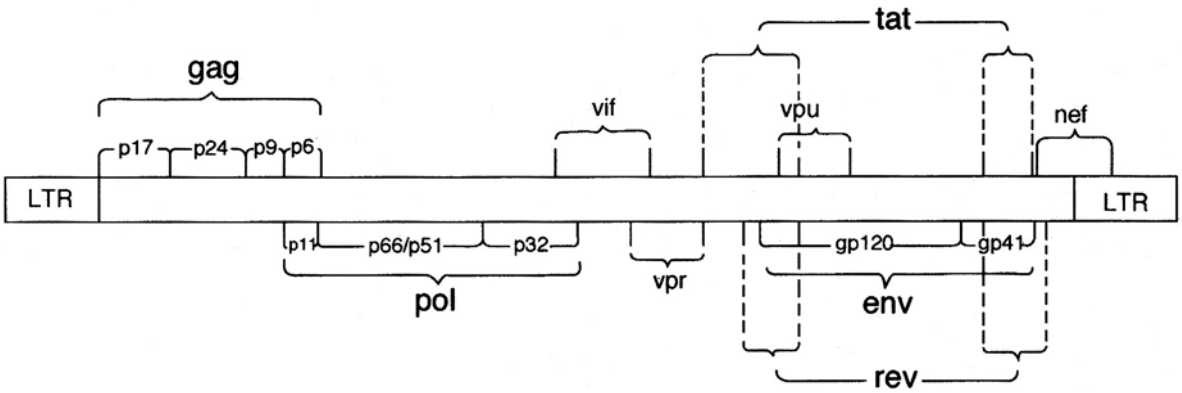

Fig. 23.3. Molecular structure of HIV. The 10-kb RNA genome has two LTRs (long terminal regions) on either end. These LTRs are important for regulating expression of viral genes, and for integrating within the host genome. The HIV genome has three structural genes: *gag* and *env* coding production of constituent proteins, the nucleus and viral envelope, respectively, and *pol* cleaving the precursor *gag-pol*. RT and other enzymes catalyze both transcription and dimension of nucleus and viral envelope proteins. There are seven regulatory genes, *tat*, *rev*, *nef*, *vif*, *vpr*, *vpu* (unique to HIV-1) and *vpx*. Several coding regions are discontinuous and overlap with each other and with other regulatory proteins

CD4 and chemokine-dependent route [491]. In fact, *nef* enhances HIV in unstimulated human lymphocytes [517], while *nef* absence can be associated with the non-progression of HIV infection [287]. The other genes, *vif*, *vpu*, *vpr* and *vpx* [58], could increase replication speed, fostering the spread and cytopathic effect of HIV [456]. *Vpr* and *vif* might participate in this nuclear transport. *Vpr* is thought to enhance the HIV-1 preintegration complex transport to the nucleus [592]. *Vif* increases the efficiency of HIV infection in vitro. *Vpu* intervenes in the assembly process and *vpr* in the nuclear transport of the viral genome [491]. Specifically, the lack of *vif* protein entails the inability to complete the synthesis of proviral HIV, and therefore it seems to be necessary for the viral initial cycle once it has entered the host cell [564]. *Vpr* appears to favor the replication of HIV, transporting it from the cytoplasm of the infected cell nucleus [331].

Etiopathogenesis

Genetic Factors

Genetic susceptibility involves *several HLA genes associated with HIV progression.* HLA genes are divided into three groups: those associated with a rapid progression, those with a slow progression/non-progression over the long term, and those with frequently exposed HIV-negative subjects. HIV-infected patients have a higher percentage of circulating lymphocytes expressing *HLA-DR that, if associated with CD8, are a sign of a poor prognosis* [298]. The class I genes that are considered protective include *HLA-A25*, *A32*, *B18*, *B27*, *B51* and *B57*, which are quite rare in various populations [575]. *HLA-B35* has a direct role in rapid progression, whereas *HLA-A29* and *HLA-B57* are associated with slow progression to AIDS [190]. In American HIV$^+$ children, the *HLA-DR3* haplotype (*DRB1*0301-DQA1*0501-DQB1*0201*) is a risk factor associated with a faster decline of CD4 levels and an increased rate of encephalopathy and death prior to the child's second birthday, whereas *DQB1*0101* is *highly protective* and has an equally marked effect [275]. Instead, in Spanish children, *DQB1*0301 is protective* and *DQB1*0201 is a tenfold risk* factor [276]. The pattern of allelic involvement has been shown to be distinct from that influencing HIV-1 infection outcome. The mothers who transmitted despite low viral loads (48%) had HLA-B1302, B3501, B3503, B4402, or B5001 alleles, vs 8% of nontransmitting mothers. Notably, the expression of *HLA-B4901* and *B3501* alleles inhibited mother-to-infant HIV transmission despite high maternal viral loads [579]. The concept that a person's haplotype plays an important role in determining the susceptibility to HIV infection and clinical outcome may appear incompatible with the characteristics of chimpanzees, which are 98% identical to *Homo sapiens* on a genetic level yet are resistant to HIV infection [242]. Moreover, while HLA class II genes appear to be virtually homologous in both species, there are subtle differences in the HLA-B and HLA-III regions. In particular, chimpanzees lack the homologs for the HLA genes associated with rapid progression, such as *HLA-B8*, as if this absence were due to a prior HIV infection [575]. HZ (homozygotes) carriers of variant mannose-binding lectin (MBL) alleles are at increased risk of HIV infection, also associated with a significantly shorter survival time after a diagnosis of AIDS [204, 351].

Viral Factors

The main receptor of HIV-1 and HIV-2 is the CD4 molecule: the high-affinity interaction takes place between the N-terminal domain D1 of CD4 and a region composed of four constant parts of gp120, situated in areas that are quite far from the primary structure. Infection

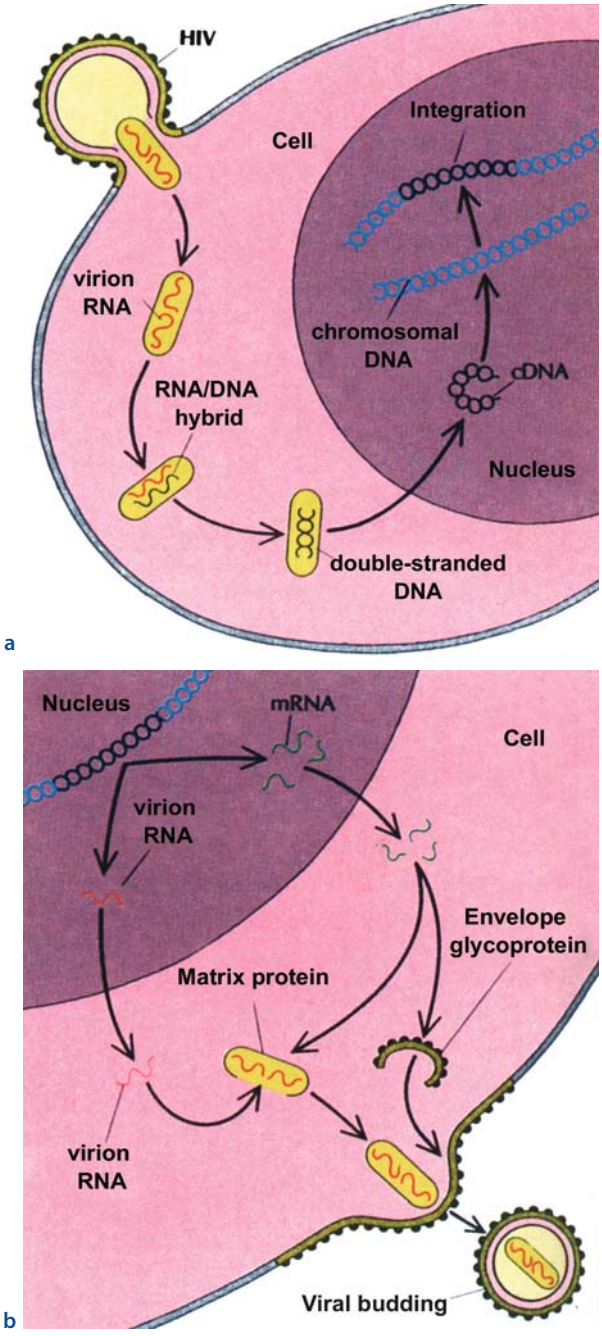

Fig. 23.4 a,b. HIV life cycle. After internalizing and uncoating, HIV fuses with cell membrane (**a**). HIV loses the nucleus and because of interaction of viral gp120 with CD4, enters the cytoplasm, where RT initiates processes inducing production of RNA/DNA hybrids, double-stranded DNA and chromosomal DNA, which integrates as provirus into the host genome. Cell activation (**b**) leads viral DNA to transcriptional production of viral mRNA. Structural proteins regulated by additional genes lead to subsequent rounds of HIV replication, and viral proteins are assembled with virionic RNA to form the viral genome. Free HIV virions are produced by viral budding from the host cell, as depicted in Fig. 23.2

by HIV starts because of this affinity: two gp120 regions show an evident homology with HLA-DR and another homology with the immunoglobulin (Ig) V_H domain [529, 575]. The gp120–CD4 interaction allows the hydrophobic end of gp41 to be inserted in the cell membrane phospholipid *env*. Virus-cell fusion then occurs, allowing the virus to penetrate the cell and start its replication cycle (Fig. 23.4). After penetration, the next step is the viral RNA transcription into a double-helix DNA copy, which is performed by viral RT [420]. More precisely, this enzyme is a dimer of two proteins (p66/51) (Table 23.3). According to some authors, a key that allows HIV to be transmitted from cell to cell is integrin CD11a/CD18 (LFA-1) [421], although others disagree and attribute a marginal role to it [218]. *CD30 and CD8 favor replication* [147]; 88-kD CD30 soluble form (sCD30) is higher in the serum of infected patients [6], whereas CD8 express CD30L (ligand) [147]. HIV can thus start its *reproductive cycle in young children* via other viral enzymes, particularly integrase p32, and the provirus is incorporated into the host cell DNA, where it can remain latent for months or even years [71], probably as a result of regulatory genes [467]. Indubitably, the signals that trigger the physiological T lymphocyte activation also mediate the transcription of the provirus, for example, by promoting the IL_2 (interleukin) gene transcriptions that have not been transcribed yet (Chap. 1); NF-κB (nuclear factor κB) also activates the provirus transcription. This occurs because the LTR and the regions regulating the IL_2 genes share certain nucleotide sequences [420].

Several key conceptual issues regarding the role of host factors in the pathogenesis of HIV-1 infection remain unresolved, in particular the relationship between expression levels of CCR5, the major coreceptor for HIV entry into cells, and HIV-1 pathogenesis [39]. CCR5 is a G-protein-coupled chemokine receptor that is used as a cofactor by macrophage-tropic (M-tropic) isolates of HIV-1 to gain entry into host cells [283]. M-tropic strains (R5) seem to preferentially use the CCR5 coreceptor, whereas T-tropic strains (X4) preferentially use CXCR4, although several dual-tropic strains have been described [102]. Recent studies have demonstrated that CD4 cannot act alone, and neither the galactosylceramide of cerebral and enteric cells nor FcR are adequate alternatives, although this bond can intensify the infectivity of HIV [330]. This is confirmed by studies on genetically manipulated mice that resist HIV, although they express CD4 [331]. This is the reason why a research trend has focused on identifying other coreceptors that permit HIV fusion [64, 136, 444]. These findings have been confirmed with the CD4 of several individuals that were exposed to HIV but were not infected [429]. As shown in Fig. 23.5 [330], the interactions of HIV before it replicates are quite complex, and thus the approach is different. If cell penetration of *T-tropic strains is mediated by CXCR4* [185] (Table 1.57) *that of M-tropic strains is mediated by CCR5* [394]; the

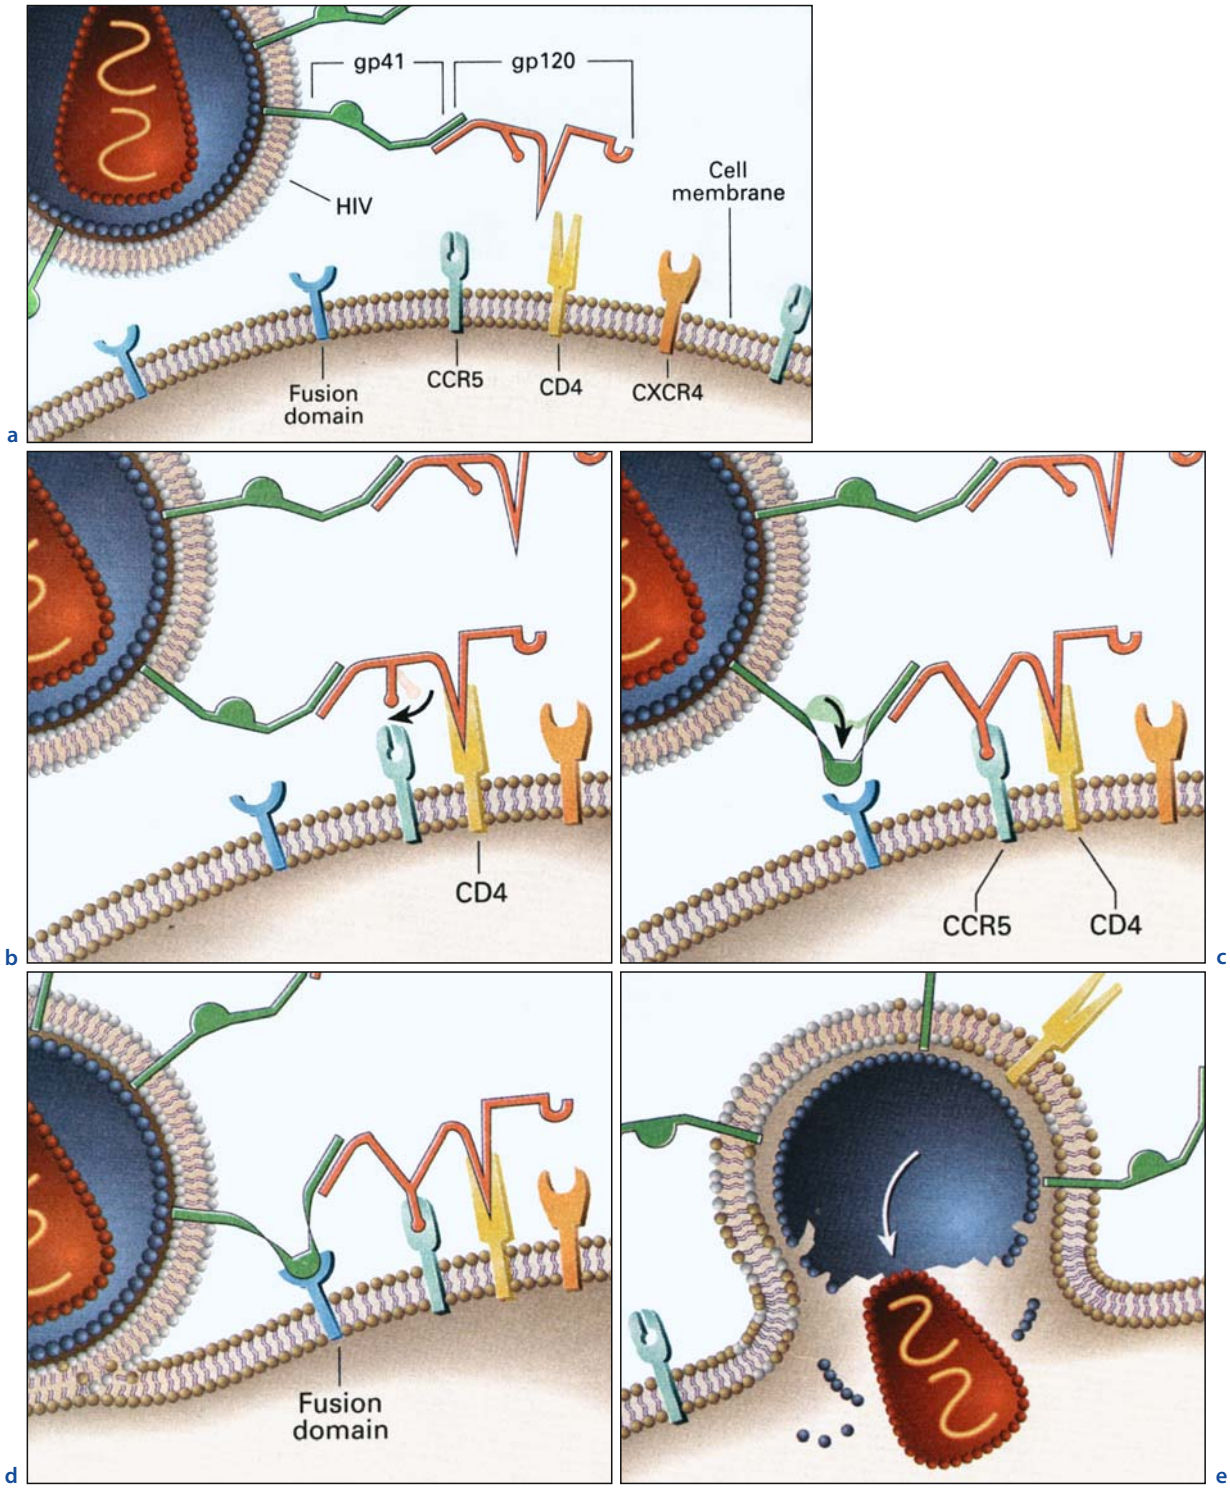

Fig. 23.5 a–e. Interactions between HIV and the cell surface. HIV interacts with a cell-surface receptor, primarily CD4, and through conformational changes becomes more closely associated with the cell through interactions with other cell-surface molecules such as the chemokine receptors CXCR4 and CCR5 (**a**). Alternatively, some viruses, such as certain strains of HIV-2, could attach to CXCR4 directly. The likely steps in HIV infection are as follows. The CD4-binding site on HIV-1 gp120 interacts with the CD4 molecule on the cell surface (**b**). Conformational changes in both the viral envelope and the CD4 receptor permit the binding of gp120 to another cell-surface receptor, such as CCR5 (**c**). This second attachment brings the viral env closer to the cell surface, allowing interaction between gp41 on the viral env and a fusion domain on the cell surface. HIV fuses with the cell (**d**). Subsequently, the viral nucleoid enters the cell, most likely by means of other cellular events (**e**). Once this stage is achieved, the cycle of viral replication starts

β-chemokines MIP-1α, MIP-1β and RANTES (new terminology CCL3, CCL4 and CCL5, respectively) secreted by CD8 were shown to prevent infection with primary, M-tropic viruses by blocking the replication of M-tropic HIV strains but not of T-tropic HIV strains [9, 114]. It may also be true that CCL3, CCL4 and CCL5 are inactive, whereas SDF-1 is a powerful inhibitor of infection by T-tropic HIV-1 strains [407]. See "Future Perspectives". *CCR5 haplotype pairs* associated with enhanced risk of transmission *were the chief predictors of a faster disease course in 649 Argentinean children* exposed perinatally to HIV-1 [351].

Pathophysiology of HIV Infection

It is clear at this point that whatever analytical approach we use, *all HIV-1 strains infect primary CD4 T lymphocytes,* that is, CD4 T lymphocytes directly isolated from the peripheral blood, *and replicate in activated CD4 T lymphocytes.* The predominant consequence is progressive CD4 inactivation, thus *inverting the CD4/CD8 ratio* and inevitably causing ID: to understand this, we simply need to recall that bone marrow can replace only 50% of these lymphocytes [498] and that HIV demonstrates tropism for all cells that express CD4, which the virus sees as physiological receptors [132]. Thus, above all HIV infection reflects an immune microenvironment inability to renew the competent antigen-specific T cells [242]. Moreover, based on more in-depth knowledge of the role played by HIV, we have been able to define the broad range of its detrimental actions: as opposed to what was previously thought, research into CD4 subsets positioned in the lymph nodes has established that *up to 25% of CD4 cells are infected by the virus* [463]. Other studies have made it possible to understand the large number of cells that carry mRNA for CD4: monocytes/macrophages, dendritic cells (DCs) and follicular dendritic cells (FDCs), Langerhans' cells (LCs) and microglial cells. The mRNA for CD4 is also found in certain B-cell clones, in the CNS (central nervous system) capillary endothelium in enterocytes and probably also in retinal cells (Table 23.4) [132]. These cells also appear to act as an HIV reservoir, permitting its spread throughout the body. It has been theorized that HIV can instead dysregulate the FCD precursors, germinal centers (GCs), DCs [230], and mucosal LCs [593]. HIV gp120 produced by infected DCs impairs $CD4^+$ T cell-mediated immune responses in vivo [280].

Another area of increasing interest is *CD8 T-cell depletion,* which is another hallmark of HIV infection. Younger age or a $CD4^+$ T-cell count under 400 cells/μl was associated with poor $CD8^+$ T cell responses and high HIV loads. In contrast, vigorous, broad $CD8^+$ T cell responses against HIV Ags were frequently observed in children >3 years and maintained $CD4^+$ T-cell counts >400 cells/μl [488]. Infants with median $CD4^+$ or $CD8^+$ T cells <25% had a relative risk (RR) of progression to AIDS that was 3.35- or 4.95-fold higher than those with $CD4^+$ or $CD8^+$ above this level, respectively [453]. A greater number of children (81%) from the $CD8^+$ >25% group than from the $CD8^+$ <25% (40%) presented significantly undetectable viral load levels and showed a 4.5-fold higher relative proportion for achieving a viral load <400 copies/ml than the $CD8^+$ <25% group [454].

Table 23.4. Human cells sensitive to HIV-1 infection

Hemopoietic cells	CD4 lymphocytes
	B lymphocytes
	Monocyte-macrophages
	Promyelocytes
	Follicular dendritic cells
	Stem cells
Gastrointestinal cells	Colonic mucosal cells
	Epithelial cells
	Enterochromaffin cells
	Stromal lymphocytes and macrophages
Cutaneous cells	Langerhans' cells
	Fibroblasts
Brain cells	Astrocytes
	Oligodendrocytes
	Macrophages (microglial cells)
	Capillary endothelial cells
Additional cells	Kupffer cells
	Epithelial cells of hepatic sinusoids
	Fetal chorionic villi

Depletion of the Immune System

The immunopathogenic mechanism by which lymphocytes and various other cells are infected, eventually culminating in severe ID, is largely unknown to date. *The depletion of CD4 T cells and disease progression occur more rapidly in children than in adults* and viral replication plays an important role in the depletion of CD4 T cells and disease progression [247, 346]. Moreover, the viral replication dynamics in children may be similar to those in adults, although a large and renewable pool of permissive host cells may contribute to persistently high plasma HIV-1 RNA levels in infancy and early childhood. CD4 T cells and thymocytes might be particularly important substrates in young infants [578]. *Disruption of thymopoiesis occurs during fetal life*; thus the lymphocyte reservoirs never build up to a normal level

ADCC antibody-dependent cell-mediated cytotoxicity.

Table 23.6. The cytopathic effect is not the sole mechanism underlying HIV infection

Human herpesvirus 6 (HHV6) kills CD4 T cells in vitro; however, an infection with this virus is not AIDS-associated
Direct cytopathicity is incompatible with the long latency period observed in AIDS
Noncytopathic HIV strains induce a rapid loss of CD4 T cells in severe combined immunodeficiency mice grafted with human peripheral blood lymphocytes
No correlation exists between cytopathicity of HIV strains in vitro and AIDS pathogenesis in vivo

Modified from [529].

for age [296, 402]. Moreover, HIV infection produces an inhibition of the thymus function in children [128] depending on the ability of T-tropic viruses to infect T-cell precursors using CXCR4 receptors, usually highly expressed in immature thymocytes [127]. Thymus from children progressing to accelerated disease showed severe thymocyte depletion along with a profound disorganization of the thymic epithelial network [48, 272]. An increased influx of $CD34^+$ precursors was demonstrated during primary infection and was followed at a later stage by thymus damage, with DP $CD4^+CD8^+$ thymocytes particularly sensitive to apoptosis [470]. Late thymic failure is reminiscent of the fact that, among patients with advanced disease administered ARTs (antiretroviral therapy), CD4 cell counts often remain below normal, despite long-term suppression of viral load [325]. However, the main hallmark is the progressive CD4 depletion: these cells are destroyed by direct lysis and the formation of multicellular syncytia, preventing lymphocytes from performing their functions (Table 23.5) [422]. Above all, this extends the cytopathogenic effect to the normal cells that have been trapped there. These cells are defined as *dormant cells,* as they do not reproduce [588]. What is certain, however, is that HIV is directly cytopathic for the infected cells and is responsible for their lysis when it is activated and starts to replicate. Moreover, the cytopathic effect cannot be the sole immune mechanism underlying HIV infection (Table 23.6) [529]. High serum concentrations of gp120 and anti-CD4 autoantibodies (Aab) may operate *an autoimmune T-cell response* against CD4 cells. Thus, gp120 (a non-self-antigen), by altering CD4 processing (a self-antigen), can unveil hidden immunogenic self peptides, thus awakening specific autoreactive T and B cells from their lethargy [485]. Therefore more immune pathological mechanisms may be associated. This led researchers to theorize that during the initial stages of HIV infection, there is a strong anti-HIV-1 response and a weak anti-Fab response, pointing to a shift toward anti-HLA class II [485].

The next phase can involve the anti-anti-CD8 Aab, anti-anti-gp120 and anti-CD4 recombinants and, above all, interactions of substances that mimic anti-HLA class I and II, triggering an increase in immune complexes [529]. *Apoptosis* may be a mechanism for the observed depletion of T lymphocytes [77] (Fig. 23.6) [422]. TcR binding by gp120, alone or with an antigen, may set off a series of intracellular events leading to apoptosis, as the HLA class II^+ antigen complex binds to the CD4-TcR complex [382]. In this scenario, the simple activation of a cell that has been prepared for apoptosis by the antigen involved would set off the cascade of programmed death: this would thus explain the destruction of CD4, such as, CD4 lymphopenia, decreased naive phenotype and lymphoproliferation, thus excluding the requirement that a substantial number of these lymphocytes actually be infected by HIV [422]. When apoptosis has been initiated in CD4 subsets by interactions with gp120 and TcR, it can be avoided through degradation and internalization [458]. Infected thymocytes and lymphocytes are protected from apoptosis because of their high capacity to respond to IL_7 and the subsequent high level of bcl-2 [231]. By inhibiting apoptosis, IL_7 favors HIV persistence, converting thymocytes and lymphocytes in viral reservoir [231]. Productive HIV infection kills infected cells but is not sufficient to cause the death of a significant number of uninfected $CD4^+$ T cells, which are by definition bystanders [228]. A mechanism for HIV to directly participate to maintain its production from this CD4 reservoir derives from the HIV *env* ability to induce virus expression from HIV-infected resting $CD4^+$ T cells without eliciting apoptosis [286].

Another possible mechanism is *anergy,* which could be what underlies the functions specific to CD4 and induced by gp120 in humans but not in chimpanzees [242]. In vivo and in vitro studies have led researchers to speculate that a negative signal reaches the CD4 cells following the interaction of their surface receptors with gp120 or with gp120-anti-gp120 complexes. Anti-gp120

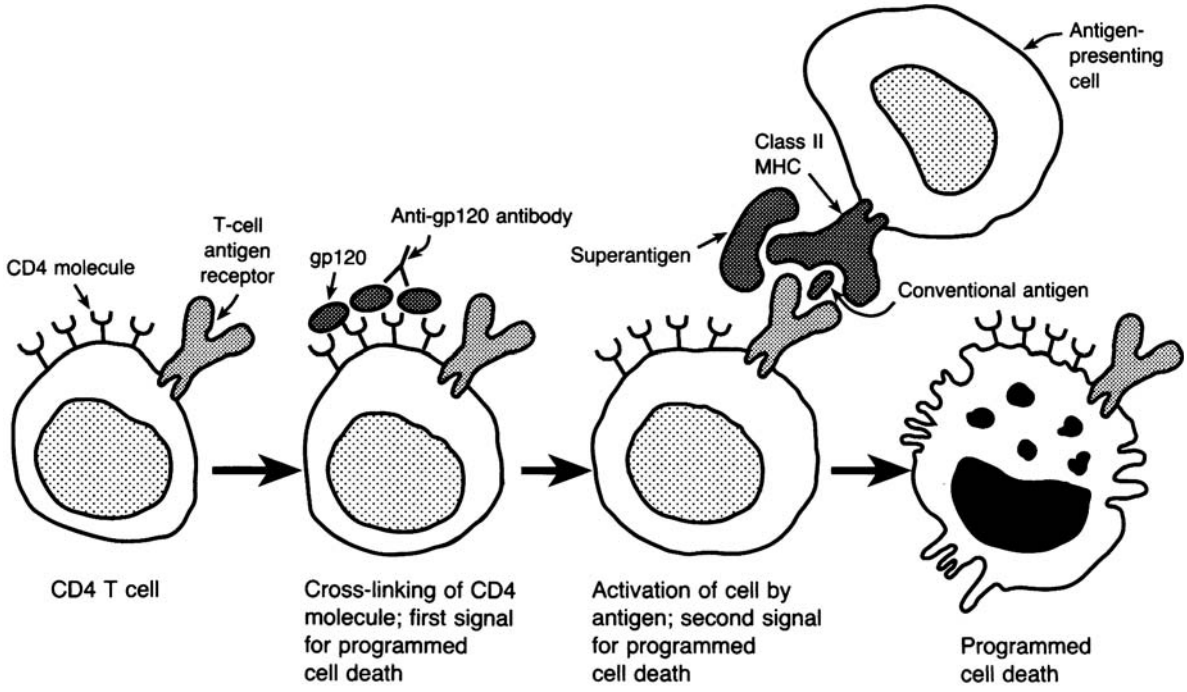

Fig. 23.6. Apoptosis (PCD) in HIV infection. Cross-linking of CD4 molecules to one another by gp120 alone or gp120 complexed with anti-gp120 antibodies provides the first signal required for PCD. Cell activation via TcR by other conventional antigen or superantigen is the second signal

antibodies have indeed been found with the CD4 of HIV-infected patients [12]. In effect, the CD4 lymphocyte count is considered a marker of HIV infection progression or outcome [522], but a marked lymphocyte depletion may also occur late, for example, in children after years of retroviral therapy [510].

It has been postulated that *microbial superantigens* (Table 1.29) can play a significant role in the immunopathogenesis of HIV infection: although there is no direct proof in vivo and preliminary data are available from test animals, it has been observed that CD4 stimulation in mice leads to anergy or to the deletion of a substantial amount of CD4 that have the specific Vβ region of TcR [513]. In keeping with this theory, there have been reports of patients presenting deletions of CD4 subpopulations that have the same Vβ region [513]. However, it seems more likely that if CD4 are active in the HIV infection, the superantigens would activate the CD4 – making them more open to infection – instead of damaging them [422]. We cannot overlook the influence of certain ILs on HIV replication; in particular, a rise in IL_{16} serum levels correlates with progression to AIDS and vice versa (Table 23.7) [97, 331, 422]. ELISPOT (enzyme-linked immunospot) assays suggest that only a fraction of HIV-specific $CD8^+$ T cells are able to produce IFN-γ, which are positively correlated with plasma viral load [75]. Importantly, the serum IL profile at baseline in the progressor group showed *a Th2-like IL profile* (elevation of IL_4 and IL_{10} levels with decreased IL_2 and IFN-γ levels) and inversely correlated in the non-progressor group with a Th1-like IL profile (elevation of IL_1 and IFN-γ levels with decreased IL_4 and IL_{10} levels) [101]. IFN-γ production was impaired in children with a severely depleted and phenotypically altered $CD4^+$ T cell compartment and circulating gag-specific $CD8^+$ T cells [488]. As seen in mice thymus/liver implants, HIV-1 infection can greatly distort the T-cell IL profiles [290]. Thus, HIV progression leads to a progressive decline in the production of several ILs, including TNF-α, IFN-γ, $IL_1Rα$, IL_2, IL_{10}, IL_{12} and $IL_1Rβ$, whose low production was shown to be associated with increased mortality risk in the patients [414].

Table 23.7. Cytokines influencing HIV replication

Stimulator	Inhibitor	No effect
IL_{2-6}, IL_9, IL_{18}	IL_{13}, IL_{16}	IL_1, IL_7, IL_8, IL_{10}
TNF	IFN-α, IFN-β	
IFN-γ	TGF-β	
GM-CSF	CCL3, CCL4	

Data from [97, 331, 422].

Table 23.8 [331] summarizes the immune system alterations that occur during HIV infection. The infection seems to attack preferably the CD4 CD45RO memory lymphocytes; the next subpopulation is that of virgin CD4 cells that express CD45RA, followed by IL_2, critical for T-cell responses. High virus load and advanced

Table 23.8. Cellular immune perturbations during HIV infection

T cells
Defects in IL proliferation and production in response to antigens or mitogens, also due to ineffective IL_2 expression
Inadequate expression of effector functions (reduced intervention of CD4 and CD8 T cells in antibody production and CTL/DTH induction)
Skewed TcR repertoire
Reduced CTL cytotoxicity
Selective loss of memory cells
Transient oligoclonal expansion
Chronic partial activation
B cells
Increased polyclonal activation and antibody synthesis
Increased response to stimulating ILs
Reduced response to antigens and mitogens
Reduced isotype switching
Immature cells in the bloodstream
Autoantibody production
Thrombocytopenia
NK cells
Reduced cytotoxicity
Monocyte-macrophages
Spontaneous IL_1, IL_6, TNF and PGE_2 production
Reduced response to activating signals
Defective phagocyte functions
Reduced ADCC
Reduced expression of HLA class II molecules
Poor APC function
Conclusion
Random depletion
Anergy of non-HIV-infected cells
Immune system breakdown

Modified from [331].
ADCC antibody-dependent cell-mediated cytotoxicity, *APC* antigen-presenting cells, *CTL* cytotoxic T lymphocytes, *DTH* delayed-type hypersensitivity, *IL* interleukins.

immunosuppression correlate with increased perturbations within CD45RA but not CD45RO CD8 T cells: HIV-1-induced disruption of TcR diversity within CD45RA CD8 T cells correlates with disease progression [295]. A selective CD45RO cell loss may be due to their activation following infection, making them a very appealing site for viral replication. Characteristically, HIV preferentially infects memory $CD4^+$ T cells ($CD45RO^+$), whereas naive cells ($CD45RA^+CD62L^+$) are infected at a lower frequency [59]. By this means, HIV-specific memory $CD4^+$ T cells contain more HIV DNA than memory $CD4^+$ T cells of other specificities: thus, by inciting a response in HIV-specific $CD4^+$ T cells, HIV can infect the cells displayed against it [521]. Memory T-cell counts are presumably preserved as a result of chronic stimulation [366]. However, if HIV infects monocytes and other accessory cells, it can further alter the generation of memory cells [331]. The function of cytotoxic T lymphocytes (CTL) is relatively preserved during asymptomatic infection, but is seriously affected in symptomatic patients, due above all to the CD4 cell limited function which has largely been deprived of IL_2. Given that CD8 cells derive from double positives (DP), $CD4^+CD8^+$ (Fig. 2.1), their development can be affected as early as the precursor stage. As HIV^+ children move through stages of HIV disease progression, their $CD8^+$ T cells acquire activation markers (dual expression of DR and CD38), lose CD28, and acquire CD57, in relation to *rapidity of disease progression in pediatric HIV infection* [428]. A maximal $CD8^+$ cell suppression of HIV replication is achieved when the infected $CD4^+$ target cells and the effector $CD8^+$ T cells are syngenic, and thus share the same HLA class I and II genotype [350]. The outcome is a partially activated but chronically aberrant state that prevents these cells from functioning normally [263], ultimately lysing uninfected CD4 cells [594]. Other studies have instead cited a positive albeit incomplete function against HIV and secondary infections [556, 597]. However, these positive effects do not translate into a direct AIDS therapy, as the most effective control of HIV is achieved using noncytotoxic responses that suppress HIV-1 replication (Table 23.9) [332], possibly aided by CAF (CD8 T-cell antiviral factor) (Table 23.10) [332, 590]. Recent data indicate that α-defensins 1, 2, and 3 collectively account for much of the anti-HIV-1 activity previously attributed to CAF [591].

NK, K and LAK cells (lymphokine-activated NK cells), involved as a front-line defense against viral infections, are generally directed against viral antigens gp41 and gp120, and seem to be well preserved during the initial phases: in fact, HIV patients can produce LAK cells *ex vivo*, although less efficiently than normal subjects. It is likely that the ability to participate in ADCC functions gradually becomes altered and reduced, and that the LAK cell defect contributes significantly to AIDS progression. The functional defect can be reduced only in part by adding IL_2 and, consequently, the NK/K lymphocytes of IL_2-deficient patients are able to bind the target cells normally, but not kill them. In addition, the intracellular mechanisms that lead to a NK/K cell dysfunction fail to have a single pathogenic ground and could instead work synergistically with the reduced IL_2 production [507]. HIV infection of primary $CD4^+$ T cells results in a 61%–68% reduction in surface expression of HLA class I molecules, but despite this drastic decrease

Table 23.9. Characteristics of the noncytotoxic anti-HIV response of CD8 T cells

Only observed with $CD8^+$ T cells, not in other cells
Observed with $CD8^+$ T cells, from either lymph nodes or peripheral blood
Dose-dependent
Killing is not involved
HLA compatibility is not required
Exhibited preponderantly by $CD8^+$HLA-DR and $CD8^+CD28^+$ cells
Inhibit HIV replication at the level of transcription
Can prevent HIV replication by a million-fold in vitro and likely by 1,000-fold or greater in vivo
Can suppress HIV replication at low $CD8^+$:$CD4^+$ ratios
Correlates directly with clinical state and the number of $CD4^+$ in peripheral blood
Mediated at least in part by a soluble factor (see Table 23.10)
$CD4^+$ activation and proliferation are not affected
Active against HIV-1, HIV-2 and SIV strains, including cytopathic and noncytopathic variants

Modified from [332].

Table 23.10. CAF (α-defensin 1, 2, and 3) characteristics

Trypsin-resistant
Staphylococcus Vβ protease-sensitive
Different from other known cytokines
HIV replication in naturally and acutely infected $CD4^+$ cells is blocked
HIV replication after virus integration is blocked by inhibiting LTR-driven transcription
$CD4^+$ activation or proliferation is not affected
Stable at high T (30 min at 56 °C, 10 min at 100 °C)
Stable at low pH

Data from [332, 590].
CAF CD8 antiviral factor, *LTR* long terminal sequences. *T* temperature.

the NK cells were unable to destroy autologous HIV-infected T-cell blasts [53]. HIV-induced NK deficiency could be partly mediated by a defect in perforin and granzyme A expression, which could be restored by IFN-α [443].

The deficiency and dysfunction of B lymphocytes (Table 23.8) is particularly evident in pediatric infection. Because *the youngest patients* have not yet encountered a large number of environmental antigens, they have few B- and T-memory cells. As a result, their humoral immunity is still poor in many respects [10]. The result is that these children *are infected by pyogenic bacteria* rather than opportunistic infections. Moreover, in certain settings strong B-cell hyperactivation can be harmful rather than protective [10]. Along with *nef* [463], gp120 acts as a B lymphocyte polyclonal activator, contributing mainly to IgA and IgG isotype hypergammaglobulinemia, and this virtually becomes prominent in HIV-infected children [11], generally preceding the numeric T cell decline [463]. Likewise, IgD levels are high, sometimes as high or higher than IgG and IgA levels, while IgM concentrations remain within normal limits. IgA titers tend to be correlated with the progression of HIV infection [28]. Epstein-Barr virus (EBV) infection is a mechanism underlying hypergammaglobulinemia; EBV rapidly infects B lymphocytes, which, thus altered, escape the T-cell immunoregulatory control and move toward an increased cycle of spontaneous proliferation [28]. B-cell hyperactivity is characteristic of *neonatal HIV infection:* the spontaneous in vitro production of direct antibodies against viral antigens, mainly anti-gp120, is used as a surrogate marker of HIV infection [11]. The dysfunction of B lymphocytes and of humoral immunity plays a key role in pediatric HIV for another reason as well. Two studies [149, 471] have demonstrated that the serum levels of IgG-neutralizing antibodies are inversely correlated with mother-to-fetus transmission: these data suggest that *antibody deficiency* is a factor permitting perinatal infection.

As opposed to the T cells, monocytes/macrophages (Table 23.8) are unresponsive to the cytopathic effects of HIV and can, in turn, become part of the HIV reservoir, disseminating the infection throughout the body. In addition, in their APC function they can present HIV to CD4 lymphocytes, promoting their destruction [378]. However, HIV alters the immune functions of these cells, including APC and IL production, ultimately interfering with antimicrobial activity [378]. Considering that these cells are infected very early in the contagion, during the latency phase of HIV multiplication in their cytoplasm, the latent condition of HIV in these sanctuaries allows them to escape the host's immune system and thus persist in different organs for any length of time [258]. This pathogenic theory does not exclude that syncytial cells are the main cause of AIDS progression, but it seems certain that M-tropic HIV strains are transmitted more readily *from mother to child* [396], especially because IP-10 (interferon-inducible protein-10) may stimulate HIV-1 replication in monocyte-derived macrophages and peripheral blood lymphocytes [317].

In HIV infections, a leading role is played by lymphoid organs, which act as sanctuaries, or the preferential anatomical sites for the propagation of the infection. As we noted, these organs are the CD4 lymphocytes, FDC and monocytes/macrophages, as well as the lymphoid organs and the brain. Persistent generalized lymphadenopathy (PGL) is an early manifestation that can be observed in both children and adults. The main histopathological alterations involve the lymphoid folli-

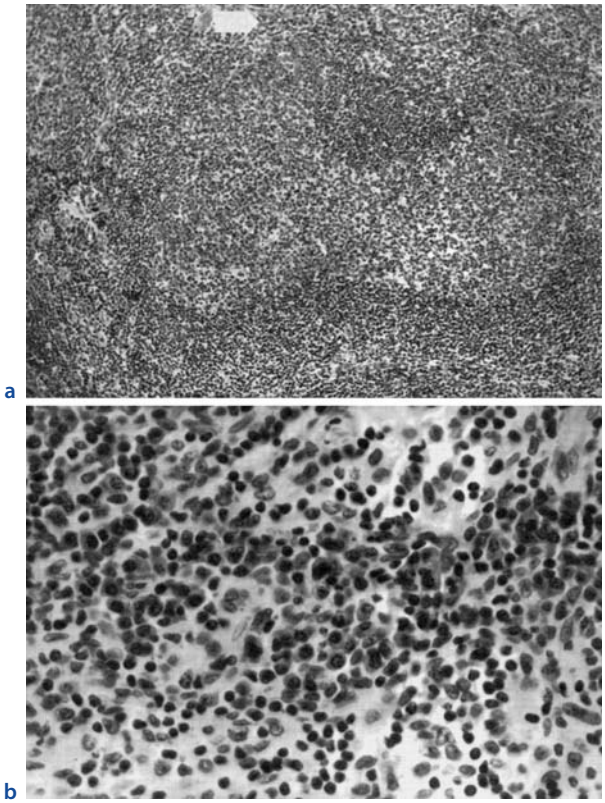

Fig. 23.7 a,b. Cervical lymph node of a child with persistent generalized lymphadenopathy (for details see text)

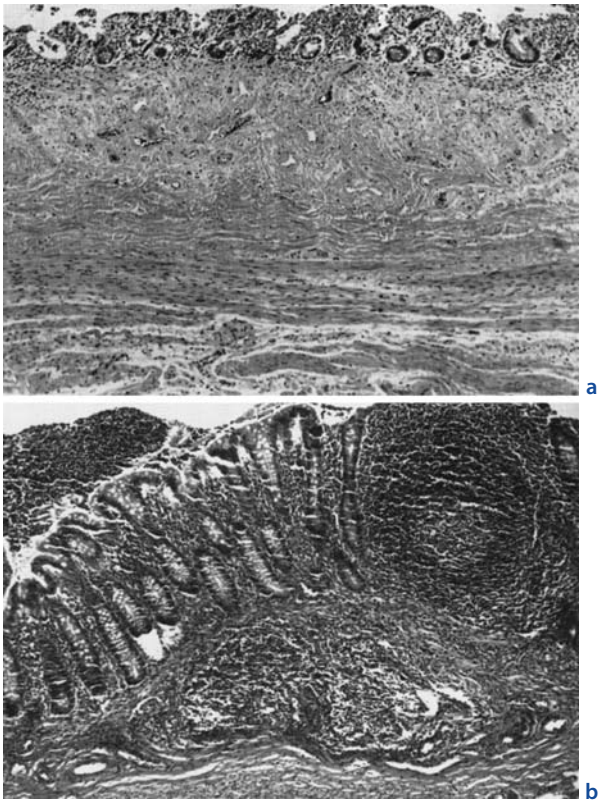

Fig. 23.8. a Normal appendix with an active follicle, and lymphocytes and plasma cells in the lamina propria and submucosa (magnification ×20). b Appendix with severe lymphoid depletion and lack of follicle formation; a few plasma cells and an occasional eosinophil are seen. There is a hypertrophy of fibrous tissue in the submucosa (magnification ×20)

cles: both the primary and secondary are enlarged and are increased in number (Fig. 23.7). In Fig. 23.7, we can see irregular shapes in the paracortical and medullary zones, perhaps the fusion of two follicles. Hyperplasia and the increased cell turnover in the GC are indicated by the increase in cells and mitoses, as well as the presence of numerous "tingible" bodies. The mantle zone, composed above all of CD4, CD8 and B lymphocytes, shows reduced cellularity. In the lower part of the figure, plasma cells are relatively increased in the two indicated zones. The intestinal tract acts as the reservoir for most lymphocytes: Figure 23.8 compares a normal appendix with that of an HIV-infected child.

Pediatric HIV Infection

Children with symptoms reminiscent of those caused by HIV infection have been reported since 1979 [477]. Initially, the possibility that they could have been infected by HIV seemed remote, but starting in 1983–1984 a number of studies have described HIV infection in children, particularly in infants [17, 182, 411, 477]. Doctors took note of this and by the end of 1985, several Centers for Disease Control (CDCs) reported 307 cases in children <13 years old [464]. The main differences between HIV infection in children and adults are summarized in Tables 23.11 [240, 494] and 23.12 [240, 525]. HIV-1 infection in children shows distinctive characteristics from the adult features [453], and these differences may have important consequences for the management of these children. What is striking about these young patients is the greater severity of clinical manifestations, including neurological findings [35, 48, 66, 169, 172, 174, 249, 446, 503, 535, 544]. Before the use of highly active antiretroviral therapy (HAART), distinct patterns of disease progression were seen in perinatally infected children. Some infants rapidly progressed to full-blown AIDS, whereas others maintained immunological control of their infection and had years of slow decline before the development of symptoms indicative of AIDS [41, 265]. The infection in newborns and infants had a bimodal expression of clinical and biological symptoms [41], thus being significantly different than in adults, because after the initial peak at about 2 months of age, a long persistence of viremia was seen prior to attenuation,

Table 23.11. Differences between pediatric and adult HIV infection: clinical differences

	Pediatric HIV infection	Adult HIV infection
Incubation and latency	Shorter (<12 months)	Longer >10 years
Immune dysfunction	Greater and earlier	Reduced, declines slower
Encapsulated bacterial infections	Greater number	Less common
Opportunistic infections	Unusual	Later
Lymphoid interstitial pneumonia	Present	Absent
Loss or lack of gain of developmental milestones	Present, common	Absent
Failure to thrive	Marked, wasting	Less
Lymphoma	Rare	KS, CNS lymphoma
Hepatosplenomegaly	Not in neonates	Yes
Encephalopathy	More frequent	Less frequent
Viral reservoirs in macrophages	Yes	Yes
Dendritic cells and microglia	Yes	Less important

Data from [240, 494].

Table 23.12. Immune differences[a]

	Children <1 year	Children of 1–13 years	Adolescents/adults
Lymphopenia	+	++	+++
CD4 depletion	–	++	+++
Hypergammaglobulinemia	+++	+++	++

[a] According to the Working Group on Antiretroviral Therapy and Medical Management of HIV-Infected Children [240], there are unique considerations needed for HIV-infected infants, children, and adolescents, including:
1. Acquisition of infection through perinatal exposure for many infected children
2. *In utero,* intrapartum, and/or postpartum neonatal exposure to zidovudine (ZDV) and other AR medications in most perinatally infected children
3. Requirement for use of HIV virological tests to diagnose perinatal HIV infection in infants under 15–18 months old
4. Age-specific differences in immunological markers (i.e., CD4 + T cell count)
5. Changes in pharmacokinetic parameters with age caused by the continuing development and maturation of organ systems involved in drug metabolism and clearance
6. Differences in the clinical and virological manifestations of perinatal HIV infection secondary to the occurrence of primary infection in growing, immunologically immature children
7. Special considerations associated with adherence to ARTs for infants, children and adolescents

occurring gradually by the age of 2 [504], as opposed to the rapid drop usually observed in adults [246]. This persistence may partially explain the more rapid progression of HIV infection observed in the youngest patients [504]. In the first few weeks following pediatric infection, rapid increases in plasma HIV-1 load are common, such as plasma HIV-1 RNA copy numbers of 10^3–10^7/ml of plasma [1, 419, 504]. Virus levels may be correlated to the infection severity in the subsequent period: children with mean levels of HIV-1 RNA copies exceeding 299,000/ml of blood showed a 44% probability of progressing toward full-blown disease or death <2 years, but this forecast came true in only 15% of cases if the levels were below this titer (Fig. 23.9) [504]. The progression of HIV infection in women of childbearing age [91, 102, 319] (7% in 1985, 13% in 1993, and

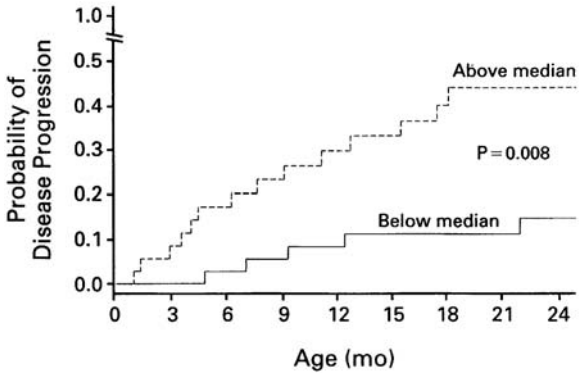

Fig. 23.9. Kaplan-Meier estimates of the probability of progression of HIV infection according to the median number of HIV-1 RNA copies during the first 2 months of life. The median value of 299,000 RNA copies/ml was used as the threshold to predict a rapid progression of disease

23% in 1999) [91] has led to a constant increase in new pediatric cases. Studies of the prevalence of positive blood samples drawn from newborns throughout Italy have made it possible to confirm the rise in births by HIV-1+ mothers, going from 0.085% in 1990 to 0.096% in 1992, reflecting an increase of 89.5% [262]. Considering that the expected annual birthrate is about 560,000, we can estimate that an average of 515 will be at risk: applying an 18% transmission quotient, we can consider that approximately 80–100 infected children are born in Italy every year [262]. All these data contribute to making pediatric HIV infection a priority problem for the public health system.

Definition

AIDS is a lethal multisystem disease that has become a major public health problem since its first description [222]. CD4 cells become depleted since they are the major receptor involved in the binding and entry of HIV into target cells, whereas B cells are polyclonally activated with increased Ig production, but the infection progressively causes overall defects that damage the immune system's two arms. Pathogenesis is almost exclusively by vertical transmission in the perinatal period. Clinically, there is a bimodal curve in which infants infected early have a high mortality rate, within 10–12 months after birth, similar to what is seen with opportunistic infections and encephalopathies. A meta-analysis of individual longitudinal data for 3,941 children from eight cohort studies and nine randomized trials in Europe and the USA concluded that in children >2 years of age, receiving no ART or AZT monotherapy only, the risk of death increased sharply when the CD4 percentage was <than 10%, or 15% for risk of AIDS, with a low and fairly stable risk at a greater CD4 percentage. The risk of progression to AIDS or death for a stated value of CD4 percentage was highest in young children – such as, an approximately threefold higher risk of AIDS in a 1-year-old child than in a 5-year-old child, and a difference of about sixfold for death [161]. Independently of treatment, children with low CD4 cell counts (<15%) and high viral loads (≥250,000 copies/ml median value) had the worst survival rate; children with high CD4 cell counts (≥15%) and low viral loads (<250,000 copies/ml) had the best survival rate [531]. Among 122 infected children tested, 33% were severely immunosuppressed ($CD4^+$ cells <15%), 42% were moderately immunosuppressed ($CD4^+$ cells 15%–24%), and 25% had no immunosuppression ($CD4^+$ cells 25%) [531]. Other children in whom the infection appears later have a higher survival rate >18 months [89], up to 6–10 years of age [265], but there are perinatally infected children who may progress as slowly as many adults [355].

The term *"infected"* refers to people who have been confirmed as HIV-infected, as demonstrated by a direct viral assay and/or by the development of a clinical picture of AIDS. The term *"antibody-positive"* can indicate a person who has tested positive to an HIV antibody assay, bearing in mind that this test does not demonstrate that a newborn is infected but that the baby *may* be infected [324]. Infection is defined as *in utero* when there is a positive HIV-1 culture in the first 48 h, and as *intrapartum* if virus cultures are negative during the 1st week and positive afterwards [504].

Epidemiology

Since 1983–1984, when the first cases were described in children through receipt of contaminated blood transfusions [17, 182, 222, 477], the number of reports grew exponentially until 1986, after which the upward trend leveled off. Above all, this increase involved children infected by vertical transmission in the perinatal period, accounting for >90% of cumulative pediatric cases [15] and virtually 100% of new cases [34, 169]. However, the development of effective preventive and therapeutic strategies may have reduced the number of newly infected infants, therefore changing clinical outcomes in infected children [528]. The number of children in whom AIDS attributed to perinatal HIV transmission that was diagnosed peaked in 1992 at 954 and declined 89% to 101 in 2001 [94]. At the same time, Italian cases (0–19 years) were 0.057% of the total [98]. It was foreseen that by the year 2000 there would be 6×10^6 pregnant women and from 5 to 10×10^6 children infected with HIV [490]. Figure 5.26 shows the current rates of newly infected children <15 years of age around the world; Fig. 23.10 shows the number of children <15 years estimated to be living with HIV as of the end of 2003, with a total of $2.1–2.9 \times 10^6$ children involved while 500,000 children had died [549].

It has been calculated that the rate of HIV-2 infections accounts for 1%–2% of all cases of pediatric HIV infec-

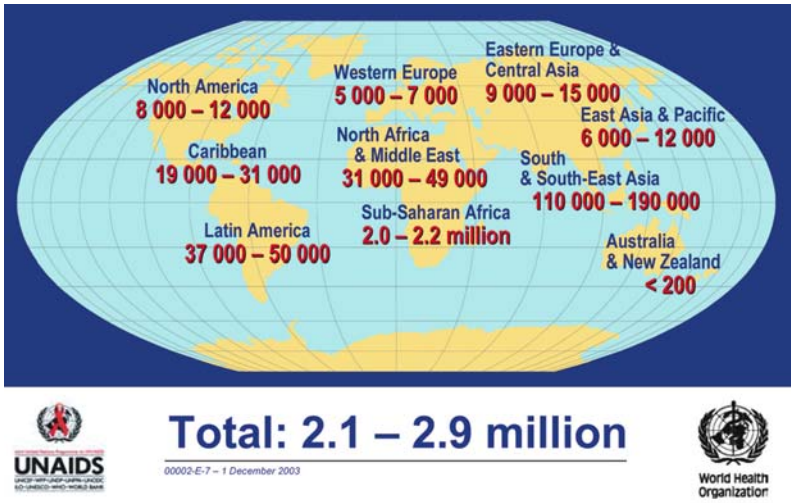

Fig. 23.10. Number of children (<15 years) estimated to be living with HIV/AIDS as of the end of 2003

tion [183]. During the period 1985–1993, pediatric AIDS incidence rates increased in most European countries and leveled off thereafter [138], but perinatal AIDS cases decreased by 75% between 1992 and 1998 [336], and in Italy between 1994 and 2003, the rates dropped to 2.9% [98]. In a few countries (Germany, Greece, Denmark, Austria, and The Netherlands), AIDS incidence rates were $<2 \times 10^6$ children in 1994–1996 [138]. In Romania AIDS has been diagnosed in 40% of enrolled children (a high rate due to hospital HIV transmission) and 52% are receiving antiretroviral therapy (ART) [299]. In Western Europe, where effective treatment is widely available, only 6,000 people died of AIDS in 2003 [549].

Since the mid- to late-1990s, the pediatric HIV epidemic in industrialized countries has witnessed a dramatic decrease in the frequency of mother-to-child HIV transmission, alongside that development and implementation of guidelines for PCP prophylaxis and availability of highly active ART. Fewer children are at risk for clinical progression of HIV disease and other severe manifestations of HIV infection, and most opportunistic infections in children now have lower rates [528]. In children with HIV infection in the UK and Ireland, mortality, AIDS, and hospital admission rates have declined substantially since the introduction of three- or four-drug ART in 1997 [528].

As infected children are living longer, there is an increasing need to address their medical, social, and psychological needs as they enter adolescence [212]. In Italy, in 2004 there were 18 pediatric cases, 12 by vertical transmission and six by undetermined causes [98]. The burden remains greatest in Africa, although it is home to only 11% of the world's population. Eight of the nine countries that have the most HIV-infected people in Africa are South Africa (5.3×10^6), Nigeria (3.6), Zimbabwe (1.8), the United Republic of Tanzania (1.6), and the Democratic Republic of Congo, Ethiopia, Kenya, Malawi and Mozambique (>1). Of an estimated 2.1–2.9 million infected children <15 years of age at the end of 2003 [215], 90% were in Africa, where Nigeria alone had 290,000 infected children and South Africa 230,000. As of the end of 2003, 700,000 (590,000–810,000) children <15 years of age were newly infected with HIV, about 2.5 million (2.1–2.9 million) were living with HIV/AIDS, and 500,000 (420,000–580,000) had died [215], including 440,000 in sub-Saharan Africa. Moreover, despite the availability of effective ART, about 630,000 infants contract HIV infection from their mothers each year, including 550,000 in sub-Saharan Africa [549]. In other parts of the world, the general incidence of AIDS is spreading rapidly in New Zealand [427], Asia [42, 281, 284, 307, 480], Africa [167, 362, 469, 572], Central America [357, 358, 432, 447] and South America [79, 179, 557]. In Brazil the AIDS incidence declined from 14.7×10^5 in 1996–1997 to 9×10^5 in 1998–2000 [376]. The incidence of HIV infection is increasing at an alarming rate in southern and eastern Asia, where large *numbers of children are orphans of parents who died of AIDS* [255] and more than 1 million new infections were expected [191]. The prevalence of HIV-1 is increasing most rapidly in sub-Saharan Africa, where an estimated 4×10^6 new infections occurred in 2001, especially in children [192]. About 2,000 new HIV infections a day in 2002 are in children <15 years of age, 95% of them live in developing countries [549].

Natural History

The information available is scarce: 50% of infected newborns develop symptoms within the first 5 months after birth [122]. Of these, 75% survive to the age of 5 and 6% have not yet developed symptoms at this age [265]. According to other studies, 15%–31% or 29%–59% develop the infection before their first birthday, 79% by 23 months and 27%–40% by the age of 4; 5%–16% die before they are 1 year old and 16%–41%

before the age of 5 [177, 229]. According to CDCs [92], among perinatally infected children aged 0–2 years diagnosed between 1982 and 1977, 60.7% were aged 0–5 months. Of 1,064 pediatric admissions in March 2000, 187 (18.9%) were HIV-infected, and most common in children aged <6 months, 53 of 166 (32%). Almost 30% of HIV-infected children died, compared with 8.9% of uninfected children [466]. Over a 10-year period, 42 children with HIV infection were admitted to an English ICU, mainly for respiratory failure, due either to PCP (45% of cases) or to other respiratory pathogens (32%). Half of the children died, and over 80% of the survivors had good outcomes in terms of growth and development [126]. Recent data demonstrate that Italian children aged 0–19 years totaled 3.7% in 1989, 1.9% in 1993, 0.2% in 2002 and 0.003% in 2004; these decreases, recorded above all in 2004–2005 for both genders, could be attributed to the effectiveness of information and prevention campaigns and, at least in part, to an improved application of guidelines for treating pregnant women [98]. We can also view the reduction in PCP diagnosis along these lines, ascending from 16% in 1982–1992 to 42.9% in 2004–2005 [98]. With regard to HIV-2 infection, 5–7 children reached the age of 8–13 years [183].

Pathogenesis of HIV Transmission in Childhood

Although mother-to-child transmission (MTCT) is the leading source of infection for children (vertical transmission), we cannot omit the fact that the primary modes of transmission of HIV have changed little over the years: unprotected intercourse, unprotected penetrative sex between men, injection-drug use, unsafe injections and blood transfusions, and transmission from mother to child during pregnancy, labor and delivery. Direct blood contact, such as the sharing of drug-injection equipment, is a particularly efficient means of transmitting the virus [523], and a small, residual number is caused by blood transfusions (2%) of the cumulative total from July 1999 to June 2000 [93], or 0 cases since 1998 [98]. As far as MTCT is concerned, HIV-positive mothers who already have an infected child are at a higher risk of transmitting AIDS, and the pregnancy itself seems to aggravate the mother's infection [104].

Vertical Transmission

The possibility of vertical transmission was first reported in 1984 and was confirmed by isolating the virus in cervicovaginal secretions [111, 243], the placenta [244], amniotic fluid [400] and the uterine cervix [441] of infected mothers, and in the gastric aspirates of their children [406] and, as we will see in the next section, in abortuses of different ages. An extreme case is the transmission of *P. carinii* infection to the fetus [395]. The risk of vertical transmission has been calculated to be between 15.3% and 19% in Europe [177, 229, 360], rising to 21% in Africa [195]. Rates of 25.5% [121] involve a particularly selected population, but in the US this is a normal rate [15, 140, 306]. Higher figures can come from samples that are not uniform in age, along the lines of the different sensitivity to the tests (HIV DNA PCR = polymerase chain reaction) [306]. In a US study, 35.7% of vertically infected children contracted AIDS, with a 50.3% mortality rate [140]. Recent Italian data is summarized in Table 23.13 [98], corresponding to CDC data for the cumulative period of 1982–1998 and for 1998 in particular [92]. In the case of HIV-2, the percentage totals 1.2% [183] or a maximum of 2%±4% [195].

Intrauterine Transmission

HIV-1 vertical transmission is thought to take place in utero, at childbirth or thereafter via breast-feeding (BF). We will examine these cases (Table 23.14) [67] (see also "Differential Diagnosis").

The mechanism of intrauterine transmission is assumed to be transplacental: cited as evidence are studies on tissues of fetuses aborted in the first trimester, between the 10th week and the 2nd trimester [274, 319, 518], in which HIV was identified by means of cultures and PCR, which amplifies it and shows the proviral sequences in the DNA of the peripheral blood mononu-

clear cells (PBMCs) [129, 348, 511], even in tissues without material contamination [129]. Studies provide an explanation of the virus passing through the placental barrier during *in utero* HIV-1 vertical transmission, showing that placental trophoblasts could be infected by HIV-1 by a mechanism involving T cells in placental contact. Moreover, placental infection enhanced CD54 (ICAM-1, intracellular adhesion molecule 1) expression and leukocyte adherence, an event which was required to transfer HIV-1 infection to T cells [22]. HIV has also been detected in the fetal thymus [129, 379], where at about the 22nd week proviral DNA was found in 2% of fetuses [65]. Given that there is no entry of HIV-1 in the thymus before the 13th week and that gp120 must bind the CD4 molecule before entering the cell, transplacental transmission does not occur before this period [587]. Further evidence in favor of this theory stems from identification of the virus in blood samples collected at birth from the newborn [73]. The absence of direct infection markers (PCR) in 62% of 271 newborns within 48 h of birth [162], the 4 weeks required for sIgA to develop in 60%–92% of infants (Chap. 2) and the seroconversion with IgG that occurs in 65% of cases at about 2 months of age lead to the conclusion that *60% of newborns acquire the infection at birth and that in the remaining 40% transmission takes place during the last 2 months of intrauterine life* [476]. The observation of infants with severe forms of AIDS in the first few months after birth is assumed to be indirect proof of sensitization during pregnancy [387].

Perinatal Transmission

These data complete the discussion on vertical transmission.

The literature now contains extensive evidence indicating that in a large proportion of children, the infection is acquired at delivery [73, 179, 216, 303], Perinatal transmission was and is *the predominant mode of HIV acquisition for an uncountable number of children,* 649 in one report [351], 944 in another [212], and up to 94.9% of children [179]. A study on twins at risk further demonstrated *intrapartum transmission.* In this case, the infection shows an 80% concordance [141, 159], but the outcome is different: for example, one twin is infected and the other is not, and of them the firstborn is more likely to be infected (Fig. 23.11) [159], regardless of whether delivery is vaginal or by cesarean delivery, as the newborn is the first to encounter the infected barriers formed by contaminated maternal blood and genital secretions [159, 216, 377]. Focus is on preventing virus transmission from an HIV mother to her newborn during the prenatal, intrapartum, and postnatal periods [377]. The differences can be prenatal with 25%–35% of total transmission, occurring mainly in the late pregnancy, or intrapartum: 70%–75% of total transmission. The postulated mechanisms are microtransfusion from the constant massage the placental bed gets from uterine contractions, or exposure of the baby's mucocutaneous surface to maternal blood and cervical secretions [277].

Research has been conducted on the behavior of high-affinity/avidity maternal antibodies directed to neutralizing gp120 or gp41 V3 hypervariable region epitopes [149, 217, 237, 550], but the results differed. Other authors have investigated the mother's condition, documented by immunological impairment, viral load, immune response to the virus, viral phenotype, integrity/non-integrity of the placental barrier and other factors [74, 175, 199, 256, 309, 337, 472, 478, 519], but without reaching definitive conclusions. However, it seems likely that a *high viral load during pregnancy,* regardless of the stage of the expectant mother's illness, *increases the risk of a rapidly progressive AIDS in her children* [312]. It must be pointed out that high autologous levels associated with a very low viral load are also found in

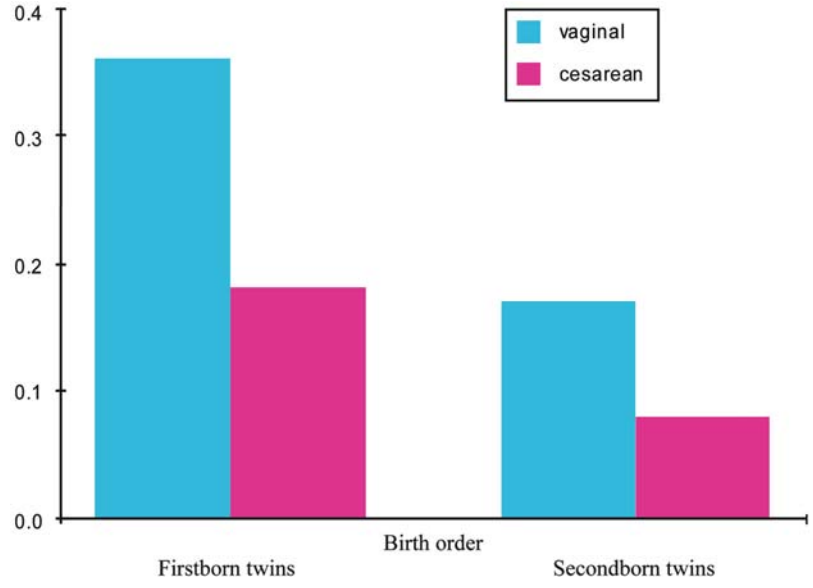

Fig. 23.11. Prevalence of HIV-infected newborns by birth order and delivery route (vaginal or cesarean). (Data from [159])

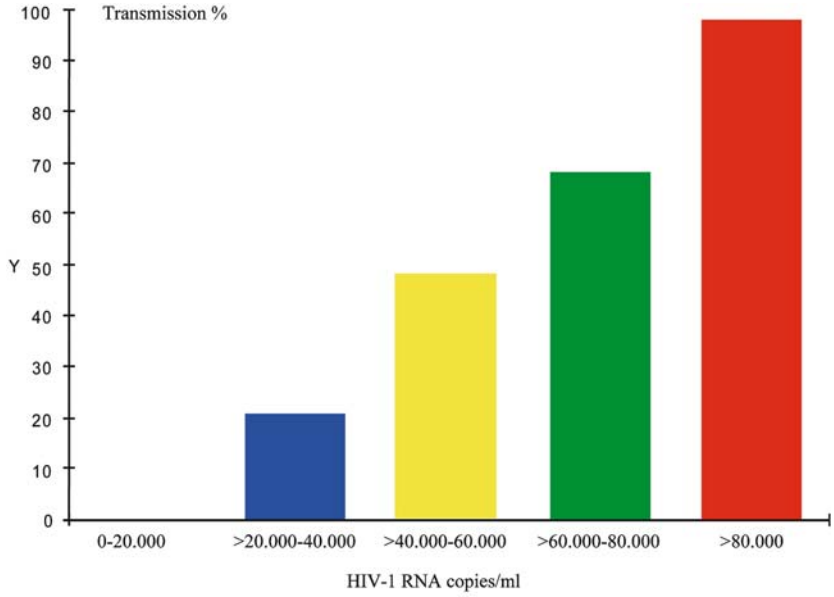

Fig. 23.12. Perinatal transmission rate as based on HIV-1 RNA number of copies at delivery. (Data from [152]

asymptomatic subjects for long periods of time [85, 423]. Relatively few studies have examined the role of factors more closely bound to delivery [74, 176, 305, 315, 383, 519]. The parameters of 525 mother–child pairs significantly correlated with HIV-1 transmission are summarized in Table 23.15, specifically the chronology of membrane rupture [315], which has arisen as a critical factor for mother-to-infant HIV transmission [306]. Based on previous discussions, it seems obvious that the less time it takes to deliver the child, the more difficult it is for the virus to infect the baby. Consequently, *cesarean delivery* should be favored [229]. However, the duration of labor is not correlated with the risk of transmission [315]. There was no correlation in a retrospective study concerning maternal HIV risk factors, mode of delivery, the child's gender, birthweight, gestational age and age at symptom onset [200]. In a prospective study, transmission was lower with ART, cesarean section, greater birthweight, and higher CD4 cell count [260]. What emerges upon examining maternal factors more strictly is the association with an RR of 1.5–1.6 even if the mother's age at delivery is ≥30 years, as opposed to data on the use of alcohol or tobacco [315]. The increased risk of MTCT depends not only on the viral load and its characteristics, but also on the maternal clinical conditions declining during pregnancy, the reduced number of circulating $CD4^+$ cells (RR between 1.6 and 2.1) [315, 519, 541] and malnutrition, including vitamin A deficiency (Chap. 21). It is the increased viral load during pregnancy and/or at delivery that is significantly associated with the risk of transmission [55, 152, 180, 516] (Fig. 23.12) [152], also because people who have recent-

ly been infected have high titers of circulating HIV and can be highly contagious [7, 271]. Although there is no minimum threshold below which one is safe [516], perinatal HIV-1 transmission occurs in only 1% of treated women with RNA virus loads <1,000 copies/ml and may be almost eliminated with ART prophylaxis accompanied by suppression of maternal viremia [260].

Postpartum Transmission

It has been repeatedly hypothesized that HIV can be transmitted from mother to child *through breast milk*. This disregards that BM of both HIV-positive and -negative mothers contains factors that inhibit CD4 binding to gp120 in the HIV envelope [404]. According to data found in the literature, HIV has been isolated from human milk [539] and postnatal transmission of infection has been suggested by two clinical cases [473], but this was not documented [78], since in several cases the mother apparently acquired AIDS from a postpartum blood transfusion [118, 327, 524, 574, 596]. In five other cases, two had the last PCR^+ at birth or at 12 months and another child became positive at the age of 30 months [553]. Aside from this, the low percentage of cases in other studies [25 (1%), 47, 173 (5%), 199 (3.9%), 264 (9.5%)] can lead to a type 2 error. Recently, several studies on larger cohorts have concluded pro [130] or against BM [164, 168, 328, 384, 474], including breastfeeding >15 months [168], mostly in non-European children. Nearly all infants in developing countries are initially breast-fed, and most children continue to receive some breast-feeding until at least 6 months of age but frequently into the 2nd year of life, especially in sub-Saharian Africa and Asia [137]. Recent papers have summarized the current state of knowledge on breast-feeding transmitting HIV infection [270], and highlighted the outstanding issues that will need to be addressed in the very near future before research advances can be translated into public health practice [137], by modifying infant feeding practices [468] and by preventing mother-to-child transmission by passive and active immunization strategies [484], or by means of vaccines studied on newborn and infant macaques [201].

A multicountry African perinatal trial (PETRA) among breast-feeding HIV-1-infected women has shown

that AZT and 3TC administered starting at 36 weeks' gestation, given orally intra- and post-partum for 1 week to both mother and infant, reduced transmission at age 6 weeks by 42% and by 18% at 18 months compared with placebo [433]. In the HIVNET 012 randomized trial with 99% of babies breast-fed (median duration, 9 months), intrapartum/neonatal NVP (200 mg at labor onset and 2 mg/kg for babies within 72 h of birth) significantly lowered HIV-1 transmission risk in a BF population in Uganda compared with a short intrapartum/neonatal AZT regimen (600 mg orally at labor onset and 300 mg every 3 h until delivery, and 4 mg/kg orally bid for babies for 7 days). The absolute 8.2% reduction in transmission at 6–8 weeks was sustained at age 18 months (10.1%) [268]. BM-associated risk may also be of late postnatal transmission [164, 328]. Prolonged breast-feeding by an HIV-infected mother doubles the overall risk of mother-to-child transmission of HIV from <20% to as much as 40% [137]. Exclusive BF carried a significantly lower risk of HIV-1 transmission than mixed feeding (hazard ratio [HR], 0.52 [0.28–0.98]) and a similar risk to no BM (HR, 0.85 [0.51–1.42]) [130]. At 3 months, the difference in HIV transmission between all BM fed or never BM fed was 2.5% [130]. The risk for transmission predicted by the Malawi study was *higher within the first 6 months of life than later:* 0.7% during age 1–5 months, 0.6% during age 6–11 months, and 0.3% during age 12–17 months [384].

We underline that in addition to high viral titers in recently infected mothers [7, 46], following desquamation that starts 24 h after birth, the newborn's *stratum corneum* is just 0.01–0.05 mm thick, as opposed to 0.1–0.9 mm in adults, thus it is easily vulnerable to the virus found not only in BM but also in the blood and secretions of an HIV^+ mother in close contact with her child [112]. If the mother contracted HIV infection during delivery or in the perinatal period, BM can create a higher risk for the newborn compared to the risk yielded by mothers who have had the infection for some time [135, 553], as confirmed by a meta-analysis [387]. Consequently, the risk of infant infection from BF is influenced by an elevated BM HIV-1 RNA, which is highest early after delivery: in BF women, a twofold-increased risk of transmission was associated with every tenfold increase in BM virus load [475]. This is the dilemma to solve, as randomized double-blind (DB) studies are excluded for obvious ethical reasons [324]. Nor can it be settled by a serious statistical analysis, since it is based on an odds ratio (OR) over 1 (1.19, CI 95% 1.10–1.28) [142]. Therefore, we feel that the problem is limited, given that the vertically infected newborns account for only 0.4% in 2005 [98]. However, before current BF recommendations can be changed, the assertion that exclusive BF is associated with a lower rate of perinatal HIV transmission compared to bottle-feeding [130] should be further analyzed. If the test for viral RNA is already positive at birth (39% of newborns), it is clear that infection must have occurred *in utero* (61%) [152]. $HIV\text{-}1^+$ mothers have been advised against BM in the so-called industrialized countries [324], and the CDC, WHO and UNICEF will invest major resources in formula feeding and little in heat treatment of expressed BM to kill the virus, wet nursing, and donation and even sales of BM [320]. More precisely, while <5% of the 2,807 children in four studies from industrialized countries were breast-fed and no HIV-1 infection was diagnosed, by contrast, late postnatal transmission occurred in 49 (5%) of 902 children in four cohorts from developing countries, in which BF was the norm, with an overall estimated risk of 3.2 per 100 child-years of BF follow-up (95% CI 3.1–3.8) [328]. However, this is a massive burden: of the estimated 700,000 children who were infected with HIV in 2003, about *315,000 (45%) were infected through breast-feeding* [549]. Current UN recommendations state that "When replacement feeding is acceptable, feasible, affordable, sustainable and safe, avoidance of all BF by HIV-infected mothers is recommended. Otherwise, exclusive BF is recommended during the first months of life and should then be discontinued as soon as it is feasible." HIV-1-infected women should therefore make a decision regarding formula feeding on the basis of safety, feasibility, and affordability of formula [577]. In South Africa, commercial infant formula is the only replacement milk that meets all nutritional needs of infants aged <6 months. Revisions of WHO/UNAIDS/UNICEF HIV and infant feeding course replacement milk options are necessary [424].

Other Pathogenic Factors

In Italy, the problem of drug addicts continues to be an open issue, as they account for 57.2% of AIDS patients [98]. The impact of this factor is demonstrated by rates of 75% of vertically infected pediatric cases, 52.9% of children of female drug users and 45.5% of children of mothers who acquired the infection heterosexually; 37.8% of the women had a drug-using partner, who may or may not have been infected [98]. Sex was engaged in with an injecting-drug user in 14% of cases [93]. No hemophiliac children were included in 2002, the last of whom were in 1992, as well as one from unspecified causes (0.13%) [98]. In the US, the rates in the 1995–1997 period were 20% for drug use and 37% through heterosexual contact [92]; in the 1998–2000 period, they were 30.5% and 1.8%, respectively [93]. Other data on related problems are summarized in Table 23.16 [46, 179, 225, 411, 416, 464, 540, 545]. Drugs are essentially destructive: in vitro they increase viral replication, can modify the immune response, foster premature birth and can cause placental damage [462]. If drug use continues throughout the pregnancy, the woman presents a higher viral load (expressed as the greater risk to test positive), and she demonstrates a higher probability of transmitting the infection to her child, associated with an RR of 1.5–1.9 [315, 462]. Interestingly, individuals

having multiple sexual partners (78.2%), drug addicts (38.8%), homosexuals (39.2%), commercial sex workers (52.2%) and health care workers (16.2%) were identified as high-risk groups among 600 female college students [181].

Another way of contracting HIV infection, via a blood transfusion, was responsible for a considerable number of cases of AIDS in the early years of this pandemic [80]. Several newborns contracted HIV through a single transfusion of infected blood [318, 489]. It is rare that a child who received a blood transfusion has instead infected the mother [87]. A possible blood transmission has been set mainly in relation to the so-called window period: in fact, it is not always possible to confirm that a subject has recently been contaminated by HIV, such as when the person is viremic but not HIV-positive. The danger dropped substantially following the introduction of more specific measures to reveal the presence of anti-HIV antibodies in donors and in blood derivatives [308, 497], but it may be found in HIV-2 infected children [183]. This transmission rate ranged from 1:450,000 to 1:660,000 according to extensive studies [308, 497], but it can also be 1:2,135000 [153] (Table 23.17) [59, 153, 308, 437, 497]. Italian figures from the end of 1994 indicate that the number of pediatric cases caused by blood transfusions or blood derivatives was over 5% [265], and it is currently zero (the last case was in 1996) [98]. It was estimated that there were 2% [393] or 3% [363] of transfusions of contaminated blood-transmitted HIV, and five cases were reported during a 4-year period [304]. The introduction of NAT (nucleic acid amplification technology) screening [153] and HIV-1 inactivator PEN110, which reduces HIV-1 to the limit of detection by targeting the viral nucleic acids [405], attests that the remaining risk of transfusion-related transmission of HIV could be greatly reduced.

Other potential causative factors demonstrated by multiple logistical regression analysis include birth in regions characterized by a high cumulative rate of AIDS and in metropolitan areas [262]. HIV has also been isolated several times in the tears, saliva, feces and cerebrospinal fluid (CSF) of subjects at risk, even though no association was documented with the horizontal transmission of AIDS [123, 197, 533, 539]. The horizontal route has been suggested by rare pediatric cases, which are not well documented, on transmission, for example, after being bitten – without bleeding – by a sibling living in the same home [567]: to avoid any perplexities, we must note that the history was reconstructed retrospectively and it is not at all certain if the child was HIV-positive before biting his brother.

Several authors have studied IgE concentrations in HIV^+ children, noting a possible protective role [500] or, more frequently, a marker associated with PCP and infections spread by CMV (cytomegalovirus) [165] or with the progression of AIDS revealed by the increase in bacterial infections and the vertical drop in CD4 levels [562]. Instead, atopy, evaluated by family history, PTC or RAST, has no correlation with IgE titers [165, 297, 562].

Clinical Presentation

In vertically infected infants, ID manifests itself very early, and the disease has characteristics which markedly differentiate it from adult AIDS, with severity inversely proportional to the age when symptoms begin and with rapid progression [46, 177, 360, 540], accentuated by high levels of p24 antigen [23, 54, 360]. In addition to what we noted previously, it is thought that *the average age at onset is 5.2 months* [200]; 15%–20% contracted a

[a] Meta-analysis of previous data.

severe form of AIDS in the first 12 months of life [49], and 32.4% of these infants died at an average age of 4.9 months [177], 9%–17% at an average of 12 months [177, 499, 544] and 29.5% at 13 months [200]. The course of disease in infected children enrolled in two European prospective studies of infants born to HIV-infected women has been studied: 20% of these children progress rapidly to AIDS and die between the ages of 2 and 4 years, whereas the majority progress more slowly, with a median survival time of 8 years. Progression to CDC group C disease or HIV-related death is an estimated 20% during the 1st year of life, and 4.7% per year thereafter, giving a cumulative incidence of 36% by 6 years [50]. In 11 European centers >15% of infected children will progress to category C or death by age 1 year and nearly 50% by 10 years, and <20% of children will show severe ID by age 1 and 75% by 10 years. However, the prognosis has improved with more widespread availability and use of combination ART [224].

Pediatric infection has characteristics that clearly distinguish it from the disease in adults (Tables 23.11, 23.12): a more severe progression and a wide variety of significantly different associated pathologies. The frequency of initial symptoms, in infants aged 2.5–12 months, that should arouse the attention of parents and attending physicians is summarized in Table 23.18 [81, 83, 177, 225, 267, 331]. In infants, the pleomorphic clinical manifestations are initially predominated by polyadenopathy and hepatosplenomegaly and by delayed growth. Between 6 and 12 months, infected children grew on average 1.6% less in height and 6.2% in weight than uninfected children, who by 10 years were on average an estimated 7 kg heavier and 7.5 cm taller than infected children, with no difference before and after use of ART prophylaxis [405] (Table 23.18). In 10% of cases, the onset is associated with gastroenteric manifestations such as abdominal distension, diarrhea, malabsorption and malnutrition [81]. This picture evokes a subpopulation of children with an immune phenotype characterized by evident thymic dysfunction (Fig. 23.13) such as what is seen in DiGeorge syndrome [296]. On the one hand, this recalls the thymic lesions observed in the fetus [425]: in infants

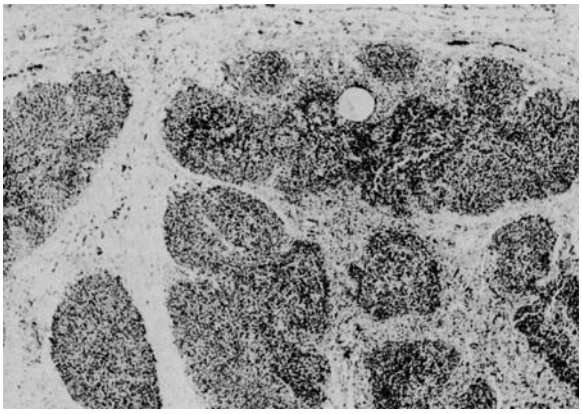

Fig. 23.13. Early involution of thymus. The loss of corticomedullary demarcation should be noted, as should the virtual absence of lymphocytes, particularly in the cortex and marked quantitative reduction in the Hassall's corpuscles: only one dilated is seen (magnification ×100)

infected in the perinatal period, the virus damages the immune cells involved in ontogenesis and the immune mechanisms, which are devoid of previous antigenic experiences and are instead physiologically oriented toward tolerance (Chap. 2). In older children, the common clinical manifestations at presentation included oral candidiasis (43%), pulmonary tuberculosis (35%), recurrent respiratory infections (RRI) (26%), bacterial skin infection (21%), papulopruritic dermatitis (19%), hepatosplenomegaly and lymphadenopathy (14%) each and chronic diarrhea (7%) [349], as well as mucocutaneous findings such as oral candidiasis (33%), *herpes zoster* (6%), chronic *herpes simplex virus* (HSV) (3%) related to a degree of immunosuppression [569]. In a group including children as young as <15 months, the clinical signs were predominantly cutaneous lesions (59%), diarrhea (41%), fever and malnutrition (35%) each, as well as oral moniliasis, sepsis, esophageal candidiasis, otitis, and varicella in different patients [133]. In 187 children, clinical symptoms and signs were not adequately sensitive or specific. HIV was common in children with malnutrition (40%), lower respiratory tract infection (LRTI) (29%) and sepsis (28%) [466].

Respiratory Infections

Recurrent infectious episodes do not differ much from the ones that characterize primary immune deficiencies (PID) (Chap. 22). Typically, the subjects are infants and small children with serious infections borne by agents that are rarely (or never) very pathogenic such as *Candida albicans*, *Pneumocystis carinii*, *Toxoplasma gondii*, CMV, HSV, *varicella zoster virus* (VZV), EBV, atypical mycobacteria [*Mycobacterium avium-intracellulare* (MAIC)], *Streptococcus pneumoniae*, *Streptococcus aureus*, etc. [411]. Respiratory infection is the leading cause of death, accounting for 29 of 35 (83%) deaths among HIV^+ and 8 of 12 (67%) deaths among HIV^- children [21]. Over half of cases start with respiratory manifestations, in 53% of cases with PCP [464], among the leading causes of morbidity and mortality in infants and young children with AIDS [21, 46, 81, 83, 182, 225, 411, 464, 477, 540, 545]. Children with PCP died 1 month after diagnosis [499] or at the age of 3–4 months [177], and in 59% of them HIV was identified about 30 days prior to PCP diagnosis [505] (Fig. 23.14). PCP is the most severe pulmonary manifestation (Fig. 23.15), observed earliest and most frequently, is marked by an acute onset, thus responsible for 48% of deaths in infants ≤1 year [21]. It is characterized by fever, cough, tachypnea, dyspnea, hypoxia, blood gas analysis indicative of alveolocapillary block, subcrepitant rales and prolonged exhaling [91]. Thirty children with a median age of 10.4 months experienced respiratory insufficiency, in 13 (43.3%) due to PCP, in six (20%) to CMV and in five (16.6%) to *Pseudomonas aeruginosa* [559].

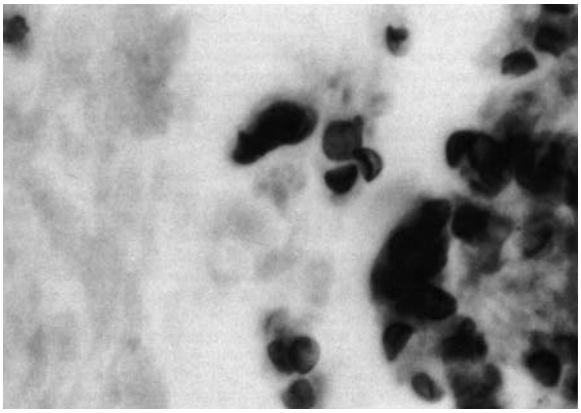

Fig. 23.14. *Pneumocystis carinii* pneumonia characterized by the organism in the alveolar lumen (magnification ×400)

Fig. 23.15. Chest radiograph of HIV-infected infant with *Pneumocystis carinii* pneumonia

The frequency of infections from capsulated bacteria may depend on the scarce repertory of specific antibodies established by young children to these organisms present in most adults when they become HIV-infected [496]. CMV infection is often the first manifestation, because virus exposure can occur during delivery, with disseminated forms in 18%–28% of cases (Table 23.18), substantially shortening the survival in these infants, who can even be 2–5 months old [174]. In addition, it can lead to interstitial pneumopathies of unknown origin, lymphocyte interstitial pneumonia (LIP), enteritis and, more rarely, hepatitis, chorioretinitis and encephalitis [56]. MAIC infections, more common among children with a CD4 count <50/mm^3, initially begin with gastroenteric or pulmonary locations, which precede the septic and disseminated forms, with a clinical picture of weight loss, anorexia, lymphadenopathies and splenomegaly [333].

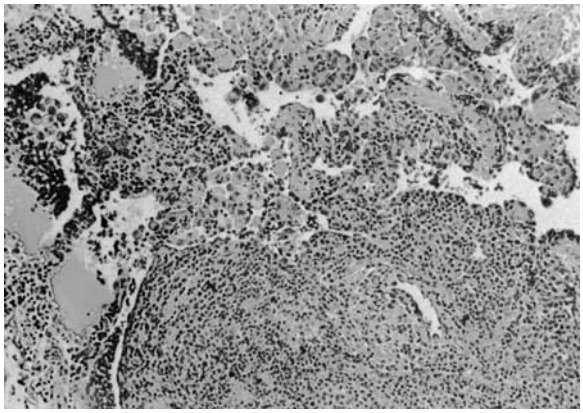

Fig. 23.16. Lung biopsy specimen showing pulmonary lymphoid hyperplasia (PLH)/LIP, with a lymphoid nodule and lymphoid infiltrate extending into alveolar septa. Alveolar PBMCs represent a desquamative interstitial pneumonia-like reaction (magnification ×200)

Among mycotic infections, the earliest one in the child is recurrent oral candidiasis in 34%–76% of cases (Table 23.18), while the invasive forms, also from catheters, are more rare. Other mycoses such as cryptococcosis, cryptosporidiosis and strongyloidiosis are observed more and more often in these young AIDS patients, with proteiform pictures in which meningitis stands out [566]. Cryptococcal meningoencephalitis in African children presents acutely or subacutely, can have a fulminant picture and is consistent with progressive meningoencephalitis. Affected children presented with headache (85%), nuchal rigidity (69%), vomiting (46%), impaired mental status (38%), convulsions (38%) and focal neurological signs (23%) and were significantly more likely than adults to have seizures (38% vs 11%) and normal cerebrospinal fluid protein (67% vs 10%). Convulsions and impaired mental status were associated with increased mortality The in-hospital mortality was 43% [233]. A number of authors have pointed out the incidence of interstitial lung diseases caused by unknown germs, including LIP, as observed in certain PIDs. LIP, which strikes 30%–70% of infants (Table 23.18) and is probably associated with EBV infection [279], is defined as a reticular-nodular pulmonary infiltrate that persists ≥2 months with or without hilar adenopathy, and it does not respond to the usual antibacterial treatments [120]. The initial symptoms are tachypnea (88%), exertional dyspnea (88%), persistent cough (86%) and fever (79%) [120]. From a histological standpoint, it is characterized by interstitial infiltrates of PBMCs and plasma cells distributed around the bronchioles and between the interalveolar septa (Fig. 23.16); these nodules, which can vary in size, tend to be located at the hilar site and extend peripherally [587]. According to CDC, this form is not a cause for concern but it is reported nevertheless.

Neurological Manifestations

As occurs during infection by other *lentiviruses* [82], HIV infection is often distinguished in children – as in adults – by numerous neurological findings, which range from peripheral forms to cortical atrophy that occur early and frequently, similar to the respiratory manifestations [35, 113, 300, 342, 359, 379, 403, 446, 451, 455, 502, 503, 535]. HIV-infected children have an increased incidence of cerebrovascular disease that is associated with severe immune suppression and with vertically or perinatally acquired HIV infection [426]. In infants and children with perinatal infections, neurological locations may be frequent and represent another sign of a poor prognosis. In the youngest, in addition to slow postnatal growth and the arrested acquisition of psychomotor skills (followed by regression), hypotonia is also observed, with bilateral pathological reflexes (foot clonus, persistence of Moro reflex and of the neck's tonic reflexes > the 4th month) [403]. In older children, in addition to foot symmetrical clonus the extensor plantar reflex also persists [379], correlated with the results of EEG examination (diffuse background slowing) [291]. Ensuing microcephaly is associated with pyramidal disorders that become increasingly evident [379], while histological tests show a reduced volume in both hemispheres, the cortex, the white and gray matter, and the basal ganglia [300]. Neuroimaging studies showed cortical atrophy, calcification of the basal ganglia, and toxoplasma abscesses [291], aneurysms, infarctions, and fusiform aneurysms of the cerebral arteries [426]. In most cases, progressive encephalopathy (PE) is observed [359, 451], with mononuclear cells and astrocyte infection [502], associated clinically with apathy, lack of acquisition of motor and intellectual skills, which can be followed by spastic diplegia [35].

The great prevalence of severe neurological dysfunctions and the very early onset of symptoms, starting at age 2 months, in children infected during the perinatal period suggest that *HIV-1 is more neurovirulent in the immature host* [35, 535]. As we noted, the brain can be a site of fetal infection, and thus the damaging mechanism involves structures that are in a differentiating and developing process. As a result, this completes and expands the lesions following birth [587]. If these infants have been infected in utero, it is unclear whether HIV-1 invasion occurs throughout the entire pregnancy (and in which trimester) or in the neonatal period or even later. In other words, does the CNS act as another sanctuary for HIV-1? [35]. Since encephalopathy was not prevented by AZT treatment during gestation [535], this indirectly contrasts the fetal origin. The CNS represents a unique reservoir site for HIV-1 [595]. HIV has been cultivated positively in fetal cerebral cells [274, 518], thus confirming that, in addition to lymphocytes, the brain can also be a primary site for HIV infection *and replication* (Fig. 23.17). Astrocytes can be infected by primary

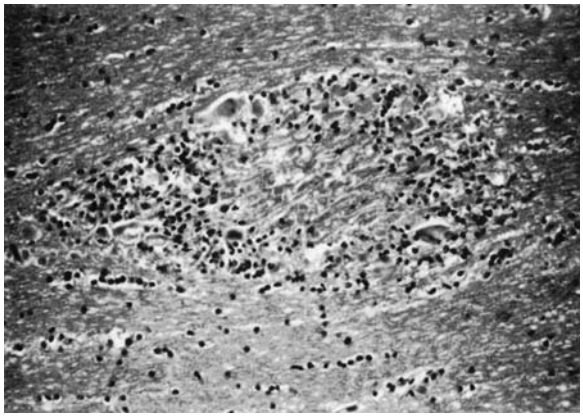

Fig. 23.17. Focus of cerebral necrosis surrounded by inflammatory cell infiltrate (magnification ×100)

HIV-1 isolates and be potential carriers of latent HIV-1: activated cells may spread the infection to other neighboring cells such as microglia or macrophages [479]. HIV or viral DNA and RNA sequences have been observed in the brain of three infants [503] and nine children [249, 446, 535] with PE, who later died of AIDS. The risk of HIV-mediated PE in children infected in the perinatal period is 4% by age 1 year and 13.9% by age 4 [342]. The comparison with adults shows another difference (Tables 23.11, 23.12). The incidence of encephalopathy was higher in children than in adults during the 1st year (9.9% vs 0.3%) and the 2nd year (4.2% vs 0%) after infection but was similar thereafter (<1%/year in each group). However, the resulting cumulative incidence at 7 years postinfection reached 16% in children and 5% in adults [535], a 3.2-fold difference. Mortality of 58 HIV-1-infected children who developed PE was significantly higher than of children who did not develop PE. Blood $CD8^+$ T-lymphocytes <25% in the first months of life suggest a RR of progressing to PE fourfold higher than those with $CD8^+$ >25% [487]. PE is aggravated by its potential association with cardiomyopathy [342]. These data confirm the *HIV neurotropism* [35, 359, 446, 503], although it is still debated how the virus penetrates the CNS (the HIV-infected macrophage is probably the infection vehicle), and which pathogenic mechanism may underlie the neurological symptoms [250]. The genetic and morphological correlation between HIV and the visna virus, a lentivirus that causes chronic degenerative neuropathy in sheep, certainly suggests that the virus is neurotropic [219]. However, proof comes from the observation of apoptotic neurons in the cortex and basal ganglia of children with HIV-induced PE, associated with inflammatory infiltrates containing HIV-infected macrophages and polynuclear giant cells [209]. Recent studies have investigated the interactions between the immune system and the CNS and have identified the potential role of depression, anxiety and stress in modulating immune responses [533]. This might suggest starting HAART regimens for HIV-1 infection of the CNS early and the need for new therapies either to preserve or to augment an adequate $CD8^+$ T-lymphocyte immune response [487].

Gastroenteric Manifestations

In children with HIV infection, gastroenteric symptoms include poor growth, diarrhea, anorexia, abdominal pain, malabsorption, weight loss and, less frequently, vomiting, dysphagia and death [386]. Diarrhea is reported in 13%–53% children <1 year (Table 23.18). As for pathogenesis, the virus's broad range of damaging actions involves the mucosal CD4 and even nonspecific defenses such as the secretion of gastric acid and peristalsis. Many enteric pathogens, which are often opportunistic, have been implicated in the enteric forms of pediatric AIDS (Fig. 23.18), including infections from *Cryptosporidium, Lamblia, Salmonellae, Isospora belli, Candida albicans* [236] and CMV [272]. CMV causes ulceration, hemorrhages, perforations, intestinal blockage and a high rate of morbidity (particularly because of associated arteriopathies) and mortality [272]. The infections occur by fecal-oral transmission, via contaminated water or food or interpersonal contagion, while the amount needed to produce them varies, but is lower in children with ID; the clinical manifestations triggered by different agents are essentially similar [386]. When the reaction late phase occurs, the functional alterations caused by infections on a cellular level lower the immune system response: these functional losses play a role in the appearance of opportunistic infections [586]. In a cohort of infants born to HIV^+ mothers, the infected infants had 3.2 episodes of diarrhea per year, as opposed to only 1.5 for noninfected infants. Moreover, the symptom incidence peaked in the first 5 months of

life and diarrhea often lasted >14 days, while its persistence was *a marker of HIV rapid progression* [294]. In a study conducted in Zaire among HIV^+ infants, the risk of dying following complications from diarrhea was 11-fold higher than in HIV^- babies [537].

Renal Disorders

In five children infected in the perinatal period, progressive nephropathy associated with HIV was observed between the ages of 6 months and 9 years. From a histological standpoint, focal glomerulonephrosis and mesangial proliferative glomerulonephritis were noted [119]. The prevalence of nephropathy diagnosed via biopsy was 10%, but the renal complications of pediatric AIDS are probably far more prevalent than has been thought to date [119, 499, 527]. The mean age at diagnosis was about 3 years [499, 527], but nephropathy can also be the first symptom [499].

Hematological Disorders

Thrombocytopenia ($<10^5$/µl) is an important blood complication and it can be part of a fulminant clinical picture accompanied by opportunistic infections. However, it can also mark HIV infection onset in infants and children [460]; it is observed in 10.7% of children aged 0–12 months [200]. Anemia (Hb <8 g/dl) is seen in up to 94% of children and can be so severe that it becomes an indicator of AIDS progression [166]. Likewise, *neutropenia* (<1,000/µl), reported in 3.7%–5.4% of cases [200, 544], is *a negative prognostic factor* and, like anemia, it arises regardless of the mechanisms responsible for it. It is notable that the high incidence of blood disorders observed in these children is caused not only by HIV-1 infection, which also precedes the impoverishment of the related precursors, although not everyone is in agreement [390], but also by the production of antibodies and the factors suppressing hematopoiesis that specifically accompany cases of immune deficits.

Cancer

In children with HIV infection, >60 cases of cancer have been reported, two-thirds of which are lymphoid in origin, 90% being non-Hodgkin's lymphoma, with an incidence of 7% in one cohort [272]. Age at diagnosis is between 5 months and 6.5 years, with a median of 31 months [163]. The association with KS has been found in 15 children aged 6 days to 11 years (reviewed in [163]) (Fig. 23.19), and with malignant lymphoma, even in the case of two children dying at age 14 months or 2 years [113, 451]: compared to adults, these complications are quite rare in children. Primary cerebral lymphoma should be suspected if there are convulsions, sensory alterations or focal signs [163]. In addition, smooth muscle tumors can also develop (leiomyomas, leiomyosarcomas) [234, 371], as seen in 14 subjects aged 3–17 (reviewed in [163]), and EBV infection of these cells can contribute to the pathogenesis of these tumors [163].

Fig. 23.19. Child with Kaposi's sarcoma

Miscellaneous

We must also mention skin infections caused by *Herpes simplex* (Fig. 23.20) and *zoster* (Fig. 23.21) and *Molluscum contagiosum* (Fig. 23.22). Ocular lesions in pediatric AIDS patients are frequent, including anterior uveitis and CMV retinitis (Fig. 23.23) (33%) followed by retinal detachment (16.7%) and vitreous hemorrhage (16.7%) [43]. Manifestations in children infected by transfusions (Fig. 23.24) or vertical transmission (Figs. 23.20, 23.25) are also characteristic.

As the life expectancy of children with HIV/AIDS increases, *quality-of-life* outcomes are of increasing concern. The use of analgesia in neonates undergoing repeated venipuncture or other medical procedures associated with pain was formally recommended [16]. Increasing age is significantly associated with increased reports of pain. The OR of a report of pain for children aged 5–11 increased 69% compared with those <5 years, that for females was 66% greater than for males, and for adolescents (≥ age 12) was doubled compared with children ≥5 years. Finally, the OR of a report of pain for black, non-Hispanic children was 37% lower than for white, non-Hispanic participants. As the percentage of CD4 T lymphocyte cells decreased, reports of pain increased [207].

Immunological Aspects

Immunological aspects are summarized in Table 23.19 [81, 132, 401, 461]. The typical picture is one of persistent T-lymphocyte reduction (quantitative and qualitative), associated with B-lymphocyte hyperactivity. The outcome is hypergammaglobulinemia, often quite noteworthy, stemming from B-cell hyperactivity. This principally involves IgG and/or IgM (91% of cases) and, due to the selective CD4 reduction (20.4% between 3 months and 18 years) [169], a rightward shift of the CD4/CD8 ratio (between 0.28 and 0.88). In chronic viral infections, such as those caused by CMV or EBV, a reduced CD4/CD8 ratio is also observed, but in this case the decrease is due to a rise in CD8 suppressors.

Table 23.19. AIDS ongoing immune dysfunction in infants and children

Cell-mediated immunity
Absolute lymphopenia
Increased counts of CD8 lymphocytes
Marked depletion of CD4 lymphocytes
Reduction/inversion of CD4/CD8 ratio (unstable)
Decreased proliferative response in vitro to mitogens and antigens
Cutaneous anergy to different antigens
Reduced IL_2 production in vitro
Decreased proportion of naive T cells
Reduced direct cytotoxicity of NK cells
Thymic dysplasia/hypoplasia
Disruption of thymopoiesis
Humoral immunity
Increased counts of B lymphocytes
Lower antibody titers
Hypergammaglobulinemia (IgG and/or IgM) or hypogammaglobulinemia
Defective IgM–IgG switch
Defect of IgG subclasses
Elevated autoantibody levels
Increased circulating immune complexes (CIC), decreased in vitro proliferative response to B mitogens and antigens
Decreased in vitro primary and secondary antibody response

Data from [81, 132, 401, 461].

Diagnosis

Early in life, diagnosing HIV infection can be a difficult problem (Table 23.18), but early diagnosis is important in order to start treatment immediately and offer a reliable prognosis [95]. A New York State program of expedited HIV testing (48-h turnaround results) of pregnant women and newborns (unknown HIV status at the time of delivery) found that 39 (37.5%) of the newborns were unanticipated, and 9 (70%) of HIV-infected babies were also born to mothers whose HIV status was unknown at the time of delivery [373].

For the clinical diagnosis, since 1985 CDCs have regularly updated the diagnostic criteria: the updated pediatric staging of HIV infection can be found in Tables 23.20 and 23.21 [89], the CDC criteria for the diagnosis of HIV infection are in Table 23.22 [89], and the

Table 23.20. Staging of pediatric HIV infection: clinical categories

	HIV infection symptoms			
Evidence of immune suppression[a]	N: none [b]	A: mild	B: moderate	C: severe

3. Severe	<750	<15	<500	<15	<200	<15

Data from [89].

Table 23.22. CDC classification: diagnosis of pediatric HIV infection

Diagnosis: child with HIV-1 infection
Category N: not symptomatic. Children who have no signs or symptoms considered to be the result of HIV infection or who have only one of the conditions listed in category A
1. A child <18 months of age who is known to be HIV seropositive or born to an HIV-infected mother or the source of HIV transmission is unknown:
Has positive results on two separate determinations (excluding cord blood) from one or more of the following HIV detection tests:
a. HIV culture
b. HIV PCR
c. HIV antigen p24
Or
Meets criteria for AIDS diagnosis based on the 1987 AIDS surveillance case definition
2. An infant or child >15 months of age born to an HIV-infected mother or any child infected by blood, blood products, or other known modes of transmission (eg, sexual contact) who:
Is HIV-antibody positive by repeatedly reactive EIA and confirmatory test (eg, WB or IFA)
Or
Meets none of the criteria in 1) above.
Diagnosis: perinatally HIV-1 exposed
Infants and children who meet any of the criteria above:
1. An infant or child who does not meet the criteria above who: is HIV seropositive by EIA and confirmatory test (eg, Western blot or IFA) and is <18 months of age at the time of test
Or
2. Has unknown antibody status, but was born to a mother known to be infected with HIV-1
Diagnosis: seroreverter
Infants born to HIV-1-infected mothers
1. A child who is born to an HIV-infected mother and who has been documented as HIV-antibody negative (ie, two or more negative EIA tests performed at 6–18 months of age or one negative EIA test after 18 months of age)
And
2. Has had no other laboratory evidence of infection (has not had two positive viral detection tests, if performed)
And
3. Has not had an AIDS-defining condition

Modified from [89].
CDC Centers for Disease Control, Atlanta, USA, *EIA* enzyme immunoassay, *IFA* immunofluorescence assay, *WB* Western blot.

Table 23.23. 1994 Revised Human Immunodeficiency Virus Pediatric Classification System: clinical categories

Category N: asymptomatic
Category A: mildly symptomatic, two or more of the conditions listed below but none of the conditions listed in Categories B and C
Lymphadenopathy (≥0.5 cm at more than two sites; bilateral = one site[a])
Hepatomegaly
Splenomegaly
Dermatitis
Parotitis
Recurrent or persistent upper respiratory infection, sinusitis, or otitis media
Category B: moderately symptomatic
Children who have symptomatic conditions other than those listed for Category A or C that are attributed to HIV infection
Examples of conditions in clinical Category B include but are not limited to:
Anemia (<8 g/dl), neutropenia (<1,000/mm^3), or thrombocytopenia (<100,000/mm^3) persisting ≥30 days
Bacterial meningitis, pneumonia, or sepsis (single episode)
Candidiasis, oropharyngeal (thrush), persisting >2 months in children >6 months of age
Cardiomyopathy
Complicated chickenpox
Cytomegalovirus infection (onset <1 month of age)
Diarrhea, recurrent or chronic
Hepatitis
Herpes simplex virus (HSV) stomatitis, recurrent (more than two episodes per year)
HSV bronchitis, pneumonia, or esophagitis with onset <1 month of age
Leiomyosarcoma
Lymphoid interstitial pneumonia (LIP) or pulmonary lymphoid hyperplasia complex
Nephropathy
Nocardiosis
Persistent fever >1 month
Shingles (*Herpes zoster*) involving at least two distinct episodes
Toxoplasmosis of the brain, onset *before* 1 month of age
Category C: severely symptomatic (see Table 23.24)

Modified from [89].
CDC Centers for Disease Control, Atlanta, USA.
[a] Bilateral lymphadenopathy at the same site is considered as belonging to the same site; development of any of the conditions listed in categories B and C excludes the above diagnosis.

CDC criteria for classification into clinical categories are shown in Tables 23.23 and 23.24 [89]. The CDC diagnosis is based on the positivity of one or more parameters. For the most seriously affected children, they involve an ID that cannot be explained otherwise, indicated by the presence of infections caused by opportunistic germs (particularly PC) or, more rarely, the presence of KS, non-Hodgkin's lymphoma or primary cerebral lymphoma. Invasive diagnostic procedures are required to demonstrate infections caused by the opportunistic germs observed most frequently (PC, *Candida*, disseminated CMV), such as the isolation of PC during bronchoscopy, but this exam can be quite invasive and is not very suitable for small children who are seriously ill [436]. Otherwise, in the first episode of PCP a diagnosis can be made using the bronchoalveolar lavage fluid (BALF), showing lymphocytosis [227]. On the other hand, infections such as cryptococcosis, cryptosporidiosis and strongyloidoisis are also observed in young children with AIDS. Since the association with KS or

Table 23.24. CDC classification: clinical categories of pediatric HIV infection. Category C

Category C: severely symptomatic
Children who have any condition listed in the 1987 surveillance case definition for HIV infection, with the exception of LIP
Severe bacterial infections, recurrent or multiple (ie, any combination of at least two culture-confirmed infections within a 2-year period), of the following types: septicemia, pneumonia, meningitis, bone or joint infection, or abscess of an internal organ or body cavity (excluding otitis media, superficial skin or mucosal abscesses, and indwelling catheter-related infections)
Candidiasis, esophageal or pulmonary (bronchi, trachea, lungs)
Coccidioidomycosis, disseminated (at site other than or in addition to lungs or cervical or hilar lymph nodes)
Cryptococcosis, extrapulmonary
Cryptosporidiosis or isosporiasis with diarrhea persisting >1 month
Cytomegalovirus disease with onset of symptoms at age >1 month (at a site other than liver, spleen, or lymph nodes)
Encephalopathy (at least one of the following progressive findings present for at least 2 months in the absence of a concurrent illness other than HIV infection that could explain the findings):
a. Failure to attain or loss of developmental milestones or loss of intellectual ability, verified by standard developmental scale or neuropsychological tests
b. Impaired brain growth or acquired microcephaly demonstrated by HC measurements or brain atrophy demonstrated by CT or MR imaging (serial imaging is required for children <2 years of age)
c. Acquired
Symmetric motor deficit manifested by two or more of the following: paresis, pathological reflexes, ataxia, or gait disturbance
HSV infection causing a mucocutaneous ulcer that persists for >1 month; or bronchitis, pneumonia, or esophagitis for any duration affecting a child >1 month of age
Histoplasmosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes)
Kaposi's sarcoma
Lymphoma, primary, in brain
Lymphoma, small, noncleaved cell (Burkitt's), or immunoblastic or large cell lymphoma of B-cell or unknown immunological phenotype
Mycobacterium tuberculosis, disseminated or extrapulmonary
Mycobacterium, other species or unidentified species, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes)
Mycobacterium avium complex or *Mycobacterium kansasii*, disseminated (at site other than or in addition to lungs, skin, or cervical or hilar lymph nodes)
Pneumocystis carinii pneumonia
Progressive multifocal leukoencephalopathy
Salmonella (nontyphoid) septicemia, recurrent
Toxoplasmosis of the brain with onset at >1 month of age
Wasting syndrome in the absence of a concurrent illness other than HIV infection

Modified from [89].
CDC Centers for Disease Control, Atlanta, USA, *HC* head circumference, *MR* magnetic resonance, *CT* computerized tomography.

cerebral lymphoma is exceptional, if not virtually nonexistent [113, 163, 451], the diagnostic parameters listed in Table 23.24 are applied to older children. These children should be divided into two arbitrarily defined clinical categories: asymptomatic infection or symptomatic infection (wasting, thrush or unexplained fever for >2 weeks). All children in the second category should be offered ART (see "Treatment").

Table 23.25. Characteristics of virological assays for early diagnosis of pediatric HIV infection

Test	Sensitivity	Specificity	Days to results	Cost
HIV culture	Good	Excellent	15–35	High
ELISPOT[a]	Good	Moderate[d]	1–2	Moderate
IgA	Good	Excellent[d]	1–2	Moderate
IVAP[a]	Good	Moderate[d]	7–10	Moderate
p24	Moderate	Excellent	1–2	Low
HIV DNA PCR[b]	Excellent	Excellent	1–2	High
HIV RNA PCR	26.7%	100%	At birth	Unknown
OraQuick[c]	Excellent	99.6%	20 min	Unknown

Data from [162, 313, 452, 473 and FDA press release, March 5, 2003].
[a] According to CDC [60], anti-HIV IgA and ELISPOT/IVAP are less commonly used.
[b] A branched DNA (bDNA) assay yielding an overall specificity of 97.2% (95% CI, 92.0–99.4) (timing unspecified) [473].
[c] Complete name: OraQuick Rapid HIV-1 Antibody Test; can be stored at room temperature, requires no special equipment, and can be performed outside clinical settings.
[d] Only after 2–3 months of life.

Table 23.26. Sensitivity of virological assays for early diagnosis of pediatric HIV infection

	Timing of testing				
Test	1[a] week	2–4 weeks	1–2 months	3–6 months	>6 months
HIV culture	30–50	50	70–90	>95	>95
HIV DNA PCR[a]	30–50	93	96	>96	>96
p24[a]	10–25	20–50	30–60	30–50	20–40
p24 (–IC)	30	NQ	NQ	>90	>90
ELISPOT	Low, NA	Low, NA	Low, NA	>95	>95
IgA	<10	10–30	20–50	50–80	90
IVAP	Low, NA	Low, NA	Low, NA	>95	>95

See Table 23.25.
Data from [162, 303, 452].
– *IC* less immune complexes, *NA* not applicable, *NQ* not quantitated.
[a] A 100% sensitivity was obtained at 4–9 weeks for both PCR and p24 antigen [303].

Laboratory Diagnosis

In a newborn or nursing infant with anomalous results from immunological tests showing CMI or humoral ID (Table 23.19), the diagnosis – though based on the presence of characteristic symptoms – is confirmed by tests for early diagnosis. Table 23.25 [162, 313, 452, 473] indicates the characteristics of these tests and Table 23.26 [162, 303, 452] their sensitivity in the period ranging from 7 days to 6 months. None of these assays can give certain results in the 1st week after birth (for treatment purposes), and above all their positive predictive value is poor. Viral culture is the gold standard test but is costly and takes 2–4 weeks for the result to be available, and sensitivity varies with the time. It has 33% sensitivity in the first 2 weeks, 70% between 1 and 2 months and 100% at 5–7 months. The HIV DNA PCR test is used for the early diagnosis of HIV infection in the newborn with a sensitivity of 30%–35% within the 1st week after birth, which increases to 100% by 1 month of age [452]. In a meta-analysis of published data, the HIV RNA PCR test was positive in 38% of 271 HIV-infected newborns *by age 48 h* [162]. These data suggest that a positive PCR assay within 72 h after birth may reflect *not only intrauterine transmission* but also intrapartum transmission of actively replicating HIV-1 virus. At birth and age 6 weeks, a significantly larger proportion of infected infants were identified by means of the RNA PCR assay than by the other assays. RNA assays require less blood volume and yield rapid results (the sensitivity for the RNA PCR assay was 94.7% at 6 weeks of age and 85.7% at 24 weeks of age); thus RNA PCR assays may be used

Table 23.27. Differential diagnosis between bimodal forms of pediatric HIV infection: with significant differences at birth in infected neonates: mean (+ SD)

Characteristics	PCR or viral culture				*p*
	Positive		Negative		
Head circumference (cm)	33.2	(2.2)	34.0	(1.7)	<0.03

Data from [360].
RR relative risk.
[a] RR=2.5 (CI 95%, 1.4–6.0), PCR or culture; RR=2.8 (CI 95%, 1.3–6.1), p24.
[b] RR=3.5 (CI 95%, 1.9–6.2).

Table 23.28. Differential diagnosis between bimodal forms of pediatric HIV infection: other variables

Clinical features	Early/severe HIV infection	Evolutive HIV infection
Frequency	15%–25%	75%–85%
Asymptomatic period	Short	From 2 to >10 years
Opportunistic infections	Severe <18 months of age	After 2 years
Severe encephalopathy	Yes	No
Other manifestations	Hepatosplenomegaly, adenomegaly	LIP, parotitis, recurrent bacterial infections
High mortality rate	Within 18 months	After 4–5 years and longer
Laboratory data	Early/severe HIV infection	Evolutive HIV infection
Viral charge in the neonatal period	Elevated	Low or undetectable
Lymphopenia CD4	With rapid progression	Stable from 2 to >10 years, then progressive

Data from [45].

for early diagnosis of HIV-1 infection in infants [313]. The OraQuick test gives results *within 20 min with 99.6% specificity (100% for the RNA PCR assay)* [313] and facilitates receipt of test results. HIV-positive test results will require confirmation by Western blot or immunofluorescence assays [95].

In the neonatal period, virus isolation in the circulating blood or *in a culture* by *in situ* hybridization is the test of choice to diagnose an infection that is underway, although a negative result cannot totally exclude possible infection [150]. In this case, a PBMC culture lasting at least 1 month is used, subsequently examining the culture supernatant for antigen p24 or RT, which will reveal the presence of HIV in ≤50% of infected infants [150]. Alternatively, the viral genome can be assayed via PCR, amplifying the provirus DNA >10^6 times: this test is as sensitive as a viral culture and *takes only 1–2 days to complete,* but it requires two successive concordant determinations [145]. The results are contrasting in newborns: PCR may be not positive in the neonatal period [553] or be positive at the age of 2–3 days, as opposed to other tests [322], or in 38% [162] or in 62% of newborns at birth [380], or in 67%–83% between the ages of 1 and 3 months [380]. In conclusion, PCR was positive at birth in 26.4% of newborns at risk and in 9.3% of those with negative tests and a high RR, and a sensitivity of 35% in the 1st week of life (Tables 23.27, 23.28) [45, 360]. In the first few months, *antigen p24* cannot be used for this type of assay, as the child must be 3–6 months old, although as shown in Table 23.26, the immune complexes in serum samples can be dissociated from p24 by acid hydrolysis, improving sensitivity [417]. However, as we can see from Tables 23.27, 23.28, in 1-week-old newborns p24 levels were also significantly higher in the newborns who would later suffer from the most severe form of AIDS: 50% vs 14.4%, with a high

RR. The task of IVAP (in vitro antibody production) is to identify the B lymphocytes that secrete anti-HIV antibodies, whereas ELISPOT targets other cells with similar characteristics [145]: these assays likewise guarantee identification of >95% of cases only after the 3rd month (Table 23.26). False-positive results during the neonatal period are caused by maternal B-cell spread in the fetal circulation, due to the mother-to-fetus transfusion that can be noted occasionally during labor. The false-negatives must instead be attributed to the short duration of infection, since a sufficient number of B lymphocytes is not circulating yet [548]. US guidelines state that since plasma HIV RNA levels are higher in HIV-infected infants than in older infected children and adults, it may be difficult to interpret HIV RNA levels in infants <12 months of age, since the levels are overall high and there may be overlap in HIV RNA levels between infants who have and those who do not have rapid disease progression [240].

Specific IgA will point to infection: this is a very sensitive and specific test, particularly starting 3–6 months after birth (Tables 23.25, 23.26), since their levels are low in the first few months (Table 1.15), thus leading to false-negative results [356]. In an 8-week-old infant who was apparently infected *in utero,* a characteristic pattern was observed in the development of specific anti-HIV IgG subclasses: IgG_1 and IgG_3 were present, and IgG_2 and IgG_4 absent [445], indicating HIV infection and permitting diagnosis when total IgG and anti-HIV subclasses decrease [302].

If the culture or PCR is positive, for a firm diagnosis they must be repeated after the 1st month [68] or at about the 3rd month [15, 150]. Instead, if these tests performed at birth and at 1–2 months are negative and the infant is asymptomatic, they should be repeated at age 4 months [15]. However, the positivity of these tests in the 1st week after birth *is 3-fold more likely to be associated with the severe form of pediatric AIDS* in the child's 1st year. Consequently, despite their low diagnostic value, it is best to perform them routinely at birth in newborns who are at risk [360]. An infant about 4 months old *in whom neither the viral culture nor PCR are positive* (despite assays performed at the age of 1 and 4 months) [68] has a >95% probability of not being infected. Follow-up is indicated for infants of about 12 months exposed to HIV who, if they test negative and have no indicative symptoms, *are considered uninfected,* with the recommendation of repeating serum assays at the age of 2 years [15].

Beyond the neonatal period and the need for early diagnosis, other methods include ELISA (enzyme-linked immunosorbent assay), WB immunoprecipitation on gel, and virus load. ELISA has a sensitivity of 99.5% and a specificity of 99.8%, and can be considered a good screening test, due also to its low cost. In WB, electrophoresis in polyacrylamide gel separates the viral proteins by molecular weight (MW), and they are then transferred to nitrocellulose strips. Incubation with the serum being examined (thus with anti-HIV antibodies) causes the formation of antigen–antibody complexes directed against viral antigens such as p24 and gp120: the minimum criterion for a positive WB requires the presence of at least two bands among those of p24, gp41 and gp120/160 molecules, possibly with the addition of p31 [302]. ELISA is believed to require confirmation by other tests such as WB, to avoid diagnosing false-positive results as positives and vice-versa, although WB effectiveness can also be poor [257]. Measures of viral load, except for values from the 1st week of life were significantly associated with imminent vulnerability to CDC-C or death during the first 18 months of life [4].

In addition, even if many laboratories have requested adequate funding to perfect these techniques, they remain the prerogative of specialized centers and, for the time being, they cannot be used for routine diagnosis without turning to nonoriginal tests because of the high cost of WB [536]. Given what we noted above, any expenditure should be considered appropriate (or even mandatory) if it serves the purpose of an early and certain diagnosis of AIDS in a newborn or nursling. In conclusion, a child who is not HIV-infected could have a negative PCR and WB after 2–3 months and after 9 months, respectively, or an ELISA that is also negative at ±18 months, while in an infected child the results should essentially be the opposite, that is, two positive PCRs at any age, one confirming the other, and a positive WB or ELISA at ±15–18 months.

Diagnosis of HIV-2 is essentially made after 18 months. Viral cultures and DNA PCR are used, or modified versions of ELISA (HIV-1+2 test), which are highly sensitive but not always specific and must thus be confirmed with HIV-2-specific WB. Other tests reveal both HIV-1 infection and HIV-1/HIV-2 coinfection [183].

Differential Diagnosis

- *The French register* has proposed an important differentiation among children from the groups with characteristics that do not differentiate between early and severe phases, based on the positivity of viral culture or PCR [360]. Tables 23.27, 23.28 report the pertinent significant differences and RR. It has thus been confirmed that the incubation period follows a bimodal curve [464].
- The difference between intrauterine and subsequent forms lies on the *positivity of viral culture and PCR* [67], possibly broadened to include the other parameters in Tables 23.27, 23.28.
- The type with different PID (Chap. 22) indicates that there is ID in the parents and a positive anti-HIV serum assay only in pediatric AIDS [83].

For the time being, *prenatal diagnosis* cannot be proposed for a number of reasons: 1. The serum negativity of the fetus does not mean that there will not be infec-

tion later. 2. There is a risk of contaminating an uninfected fetus. 3. The virological diagnosis may not be reliable. 4. There is the possibility of mother-to-fetus transmission at a later stage in the pregnancy [84].

Treatment

Guidelines for ART use in pediatric patients are rapidly evolving [240]. Current US pediatric guidelines thus recommend therapy for all infected infants <12 months of age in clinical stage A, B, or C or with CD4+ T-cell values <25% and recommend consideration of therapy for asymptomatic infected infants <12 months of age who have normal immune status [240]. The European guidelines recommend initiating therapy in infants only if they have any of the following findings: clinical stage C, <20% CD4+ T cells, or HIV-1 RNA levels that persistently exceed 10^6 copies/mm. All infants presenting with clinical stage C disease should start HAART as soon as treatment of their AIDS-defining illness permits [454, 492]. However, HIV infection progresses more rapidly in infants than in older children or adults; therefore some experts would treat all HIV-infected infants <6 or <12 months of age, regardless of clinical, immunological or virological parameters [240]. In general, treatment should be offered to children with <350 CD4+ T cells/mm^3 or plasma HIV RNA levels >55,000 copies/ml (by RT-PCR or bDNA assay). Treatment is divided into various approaches, such as ART, treatment of infective complications including PCP prophylaxis, other forms of treatment, appropriate nutritional support and psychological support. Before starting therapy or prophylaxis, the levels of CD4 with prognostic value must be checked (Table 23.29) [89, 91 240]. From this table, we can see that in infants and children the percentage values (above) or the CD4 count (below) at which ART or PCP prophylaxis should be started vary based on age (Tables 1.34–1.38, for comparison). In infants, the values must be checked at the ages of 1 and 3 months, proceeding at 3-month intervals up to the age of 2 years. Subsequently, controls must be performed every 6 months, unless the percentage or CD4 count reaches threshold values correlated with age: in this case, the assays must be repeated every month. Instead, infants and children *with episodes of PCP must receive prophylaxis regardless of their CD4 values* [89, 91]. The death of some infants at 10 (in 1990–1995) and at 29 months (in 1996–1997) was related to age <12 months, low CD4+ count, severe bacterial infection and PCP, although PCP prophylaxis and combined ART ensured *increased survival and lower mortality rates* [179]. In HIV-infected children, mutations associated with resistance after nucleoside ART and syncytium-inducing phenotype, higher HIV-1 RNA load and lower CD4+ cell count were significantly correlated with increased risk of HIV clinical disease progression [171]. In HIV-1-infected children, mainly African-American or Hispanic, total lymphocyte count and serum albumin independently predicted mortality, an assessment warranted in resource-poor settings [389].

Prevention of HIV-1 Mother-to-Child Transmission

Several articles illustrate this relevant aspect. Researchers are testing to see whether drugs such as NVP could protect babies during breast-feeding [20].

A two-dose intrapartum/newborn NVP regimen reduced perinatal HIV transmission in Ugandan women not receiving antenatal ART. Detection of HIV infection was very low since it occurred in 9/631 (1.4%) NVP group deliveries and 10/617 (1.6%) placebo group deliveries, thus with no difference [154].

A subsequent report demonstrates the astonishing efficacy of dual ARTs in reducing HIV-1 MCTC, which

Table 23.29. CD4 counts suggested to start antiretroviral therapy or PCP prophylaxis in children under 13 years of age

Age at CD4+ measurement	Values suggested for antiretroviral therapy	Age at CD4+ measurement	Values suggested for PCP prophylaxis
CD4 (%)			
<1 year	<25	<1 year	None
1–5 years	<25	1–5 years	<15
6–12 years	<25	6–12 years	<15
CD4 (cells/mm^3)			
<1 year	<1,500	<1 year	None
1–5 years	<1,000	1–5 years	<500
6–12 years	<500	6–12 years	<200

Factors to be considered in decisions about initiation of therapy include the risk of disease progression as determined by CD4+ percentage, the potential benefits and risks of therapy, and the ability of the caregiver to adhere to administration of the therapeutic regimen.
Data from [89, 91, 240].

showed that adding single-dose NVP to an AZT prophylaxis beginning at 28 weeks of pregnancy, in women not breast-feeding, and with viral loads of at least 2,500 HIV-1 RNA copies/ml and CD4 cell counts of ≤200/mm^2 or less, can achieve effective and safe results. The rate was reduced from 6.3% among 348 women who, like their infants, received the placebo to 1.1% among 353 women who received the standard regimen plus a single intrapartum dose of NVP, with a single dose of NVP also given to their infants soon after birth [311].

In a study done in Malawi, breast-feeding mothers received a 200-mg single oral dose of NVP intrapartum (n=448) and infants received either a 2-mg/kg oral dose of NVP or NVP (same dose) plus 4 mg/kg of AZT twice a day for 1 week (n=446). The MCTC of HIV at birth was 8.1% in infants administered NVP only and 10.1% in those administered NVP plus AZT. A life table estimate of transmission at 6–8 weeks was 14.1% in infants who received NVP and 16.3% in those who received NVP plus AZT. For infants not infected at birth and retested at 6–8 weeks, transmission was 6.5% in those who received NVP only and 6.9% in those who received NVP plus AZT [532].

A similar short course of AZT had previously been established as the standard regimen in Thailand, reducing the rate of HIV-1 MCTC from 25% to 6.5%. [275], a 3.8-fold difference.

Of 8,221 deliveries in a routine service setting, 1,234 (15%) occurred in women known to be HIV-infected. HIV transmission rates of 8.7% at 6 weeks and 8.9% at 3 months of age in the study population verify the high rate of NVP administration. The authors underline the ability of women to formula-feed their babies and abstain from breast-feeding [493].

In Cameroon, HIV-1-positive pregnant women were given a single dose of NVP at the onset of labor, and babies were given 2 mg/kg NVP syrup within the first 72 h of life. NVP-treated children were regularly followed up and examined for HIV-1 infection at 6–8 weeks and 5–6 months: out of 123 children, 13 (10.6%) were infected and presented with high viral loads, in general >500,000 copies/ml [27].

A recent Cochrane review concluded that short-course AZT and single-dose NVP are effective therapies for reducing HIV MTCT. The potential value of NVP used for longer durations in breast-fed populations should be considered, as it may further reduce the MTCT risk, particularly if combined with early weaning [62].

Antiretroviral Therapy

The ART effect was demonstrated in the 1996–1999 period, when the transmission rate for mother–infant pairs not breast-feeding was 8.6% with elective cesarean delivery, 4.4% with any ART, and 2.4% with these interventions combined [266]. The drugs that are currently used are analogs of 2'-3'-dideoxynucleosides that can inhibit RT, which, as we noted, enable the transcription of viral RNA into DNA. They include:

- *Nucleoside RT inhibitors* (NRTI): zidovudine (ZDV or AZT), dideoxyinosine (ddI) or didanosine, dideoxycytosine or dideoxycytidine or zalcitabine (ddC), stavudine (d4T), lamivudine (3TC), abacavir (ABC), adefovir
- *Non-nucleoside RT inhibitors* (NNRTIs): delavirdine (DLV), nevirapine (NVP) and efavirenz (EFV)
- *Protease inhibitors* (PI): saquinavir (SQV), ritonavir (RTV), nelfinavir (NFV), indinavir (IDV) and amprenavir (APV)
- *Entry inhibitors:* T-20

Drug dosages are listed in Table 23.30 [19, 106, 121, 143, 254, 288, 345, 398, 418, 450, 481, 482, 560, 580]. Table 23.31 deals with the management of *in utero* exposed babies [15, 418].

The CDC suggests that when initiating therapy in children naive to ART, one should begin with a regimen that is expected to achieve sustained suppression of plasma HIV RNA, a sustained increase in CD4$^+$ T-cell count, and a favorable clinical outcome. Strongly recommended regimens include either IDV, NFV, RTV + SQV, RTV + IDV, RTV + lopinavir or EFV in combination with one of several dual NRTI combinations [88]. WHO/UNAIDS now recommend quality-assured, *fixed-dose combinations of 3TC, d4T and NVP in a single pill* as first-line treatment of MCTC for 3 million mothers, making it happen by 2005 (*the 3-by-5 strategy*) [576]. This seems to be unlikely. However, there is reason to be hopeful that growth rates will continue to increase in the three-year period 2005–2007 [583]. The Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection [240] strongly recommend for children ≤3 years old or who cannot swallow capsules two NRTIs + NVP, and for children >3 years two NRTIs + EFV (with or without NFV), and as an alternative for children >3 years, two NRTIs + NVP. These guidelines recommend therapy for all infected infants aged <12 months who have symptoms or immune suppression and recommend consideration of therapy for asymptomatic infected infants aged <12 months who have normal immune status [240]. However, a study in HIV-1-infected children aged 0.5–3.0 months (median, 2.0) (*early therapy*), or 3.5–24 months (median, 7.6) (*delayed-therapy*) found no significant differences among the treatment regimens in the rate of viral suppression at week 16, but the regimen of d4T, 3TC, NVP and NFV appeared to be superior to the two regimens of RT inhibitors in suppressing viral replication at weeks 48 and 200 (>50 copies/mm in 85% of 26 children). *Early initiation of therapy (at ≤3 months of age) also appeared to be associated with improved long-term suppression of viral replication.* Treatment-related adverse clinical or laboratory events were infrequent, and only one of the 52 children discontinued therapy because of drug-related adverse effects [347] (see the doses in Table 23.30). In four infants with vertically acquired HIV-1 infection, plasma HIV-1 RNA

Table 23.30. Antiretroviral agents in infants/children

Agents	Age	Oral dosage	Reference
Nucleoside reverse transcriptase inhibitors (NRTI)			
Abacavir (ABC)	Infants aged <90 days	50 mg/m^2 q 12 h	[19]
	>1–3 months	8 mg/kg q 6–12 h	[450]
	Adolescents	300 mg q 12 h	[19]
Adefovir	≥3 months	1.5 mg/kg bw per day	
	≥1 year	3.0 mg/kg bw per day	[254]
Didanosine (ddI)	2–16 months	120 mg/m^2 q 12 h	[345]
	4–10 years	180 mg/m^2 q 12 h	[289]
Lamivudine (3TC)	Neonate	2 mg/kg q 12 h	
	Children	4 mg/kg q 12 h	
	Adolescents	150 mg q 12 h	[19]
Stavudine (d4T)	0.8–15 years	2–4 mg/kg/die q 12 h	[288]
	0.4–6 years	1 mg/m^2 q 12 h	[289]
Zalcitabine (ddC)	Children	0.01 mg/kg q 8 h	
	Adolescents	0.75 mg q 8 h	[19]
Zidovudine (AZT)	0–2 weeks	2 mg/kg/dose q 6 h	
	2–4 weeks	3 mg/kg/dose q 6 h	
	4 weeks to 13 years	90–180 mg/m^2 q 6–12 h	[121]
Non-nucleoside reverse transcriptase inhibitors (NNRTI)			
Delavirdine (DLV)	5–18 years	40 mg/kg q 12 h	[579]
	Adolescents	400 mg q 8 h / 600 mg q 12 h	[19]
Efavirenz (EFV)	5–18 years	9–13.5 mg/kg/day	[579]
Nevirapine (NVP)[a]	2–16 months	5 mg/kg or 120 mg/m^2 for 14 or 28 days, then 200 mg/m^2 q 12 h	[345]
	Pediatric	120–200 mg/m^2 q 12 h	[19]
	Adolescents	200 mg q 12 h	[143]
Protease inhibitors (PI)			
Amprenavir	Children 5–18 years	20–40 mg/kg q 12 h	[579]
Indinavir	Children	300–600 mg/m^2 q 8 h	
	Adolescents	800 mg q 8 h	[19]
Nelfinavir (NFV)	Pediatric age	30–50 mg/kg q 8 h	[418]
Ritonavir (RTV)[b]	6 months to 14 years	250–400 mg/m^2 q 12 h	[398]
	6 months to 12 years	230/57.5–300/75 mg/m^2 q 12h	[481]
Saquinavir (SQV)	NS	300 mg/m^2 q 8 h	[143]
	Adolescents	600 mg q 12 h	[143]
Entry inhibitors			
T-20	Children	30 or 60 mg/m^2 q 12 h sc	[106]

Table 23.31. Specific management of babies exposed to HIV in utero

Age	Management
Birth	HIV DNA PCR, start AZT
2 weeks	HIV DNA PCR, CBC (monitor for anemia)
6 weeks	HIV DNA PCR, CBC, discontinue AZT, start PCP prophylaxis
4 months	Continue PCP prophylaxis
6 months	Discontinue PCP prophylaxis if HIV tests remain negative
12–18 months	HIV-1 ELISA

Data from [15, 418].
CBC complete blood count.

levels ranged from 230,000 to 1,000,000 copies/ml before onset of triple therapy (<2 months of age) and fell <50 copies/ml at 12–33 weeks of life in three infants [235]. In a meta-analysis of eight cohort studies and nine clinical trials in the US and Europe that included nearly 4,000 untreated, infected children, the 1-year risk of AIDS or death was substantially higher in younger than older children at any given level of $CD4^+$ percentage, particularly for infants aged <12 months [245]. Therefore, ARTs are safe, effective, and well tolerated during years of administration and should be started in infancy [512], as early as possible [347].

NRTI

- *ZDV* is phosphorylated inside the cells to arrive at the triphosphate form, which is active in inhibiting retroviral RT, as it competes with the normal thymidine triphosphate nucleoside, thereby blocking the synthesis of viral DNA. It is absorbed well when administered orally, with a bioavailability of 60%–65%; following ingestion, it reaches a peak concentration in 30–60 min. Concentrations of >1 µmol are preferable, as they can inhibit viral replication. ZDV serum half-life is 1 h and the intracellular half-life is 3–4 h; as a result, its rapid elimination suggests a dose every 6 h. However, two doses a day seem to be equally sufficient for maintaining satisfactory levels [45]. In children with mild to moderate disease, low-dose (90 mg/m^2 per dose) ZDV will result in substantial cost savings and should be the recommended dose. ZDV's distinctive features are good distribution in the tissues, with a volume equal to 1.4 l/kg, and its ability to cross the blood–brain barrier, reaching the CSF with a CSF/plasma ratio of 0.24 [370]. ZDV is metabolized by the liver and cleared through the kidneys. However, these favorable results are offset by its myelotoxicity, particularly cytopenia [227, 439]. Thus, ZDV toxicity may restrict its extended use in pediatrics [151]. A recent report suggested that mitochondrial dysfunction in eight of 1,754 children (0.46%) and symptomatic hypokinetic hypertrophic cardiomyopathy in one child may have been caused by ZDV alone or in combination with 3TC, but two infants previously exposed to ZDV–3TC contracted severe neurological disease and died [51]. No significant differences in ventricular function were observed between infants born to HIV-infected women and exposed to ZDV in the perinatal period and controls not exposed to ZDV during the first 14 months of life [338]. Studies conducted in France and the USA have indicated that ZDV may also be used in infants and young children at a daily dosage of 90–100 mg/m^2 qid with equivalent results [57, 227], or by continuous IV infusion at a dose of 0.5–1.8 mg/kg/h [439]. These studies noted an increase in weight and cognitive capacity, as well as a drop in p24 levels in the blood and CSF, parallel to an increased CD4 number, but the effect was limited to 3 months [368]. This may be *the*

[a] Nevirapine doses may be greater than 300 mg/m^2/day, which is higher than currently recommended [560].
[b] Pediatric oral solution: 80 mg lopinavir and 20 mg RTV per ml; capsules: 133.3 mg lopinavir/33.3 mg RTV [482].
The drugs and dosages received by 52 children [345] were as follows: *For infants <29 days of age,* Zidovudine (ZDV) was dosed as 4 mg/kg tid; Lamivudine (3TC) as 2 mg/kg bid; Stavudine (d4T) as 0.5 mg/kg bid; Abacavir (ABV) as 8 mg/kg bid; NLF as 30 mg/kg tid; and NVP as 5 mg/kg qd for 14 days, followed by 120 mg/m^2 bid for 14 days, followed by 200 mg/m^2 bid. *For infants 30 days of age,* ZDV was given as 180 mg/m^2 bid; 3TC as 4 mg/kg bid; d4T as 1 mg/kg bid; ABV as 8 mg/kg bid; NLF as 30 mg/kg tid; and NVP as 120 mg/m^2 qd for 14 days, followed by 200 mg/m^2 bid (K. Luzuriaga, pers. comm., 26 July 2004). Except for efavirenz, delavirdine, indinavir, ritonavir, and saquinavir available in tablets or capsules, all other agents are in oral solution formulations [418]. *ddI* is a dry powder that should be reconstituted with water to reach a concentration of 20 mg/ml but requires antiacid formulation to reach a final concentration of 10 mg/ml. The stomach should be empty 1 h before and 1 h after each administration. A combination ZDV (300 mg) and 3TC (150 mg) called *Combivir* is available [418]. d4T should be diluted until 0.2–1 mg/ml, without antiacid coadministration; it is available in gel capsules of 1, 5, 20 and 50 mg [288]. *Indinavir* is administered on an empty stomach and adequate hydration is a must to avoid the risk of nephrolithiasis. *Saquinavir* is instead administered on a full stomach [143]. *Neonatal dose: under evaluation* in Pediatric AIDS Clinical Trial Group protocol 332 [19]. *Nevirapine:* initiate therapy with 120 mg/m^2 (maximum 200 mg) administered once daily for 14 or 28 days. Increase to full dose (120–200 mg/m^2) administered every 12 h (maximum 200 mg every 12 h) if no rash or other untoward effects. A problem not always taken into account is the possible lack of compliance of young children due to the necessary administration of a high number of tablets daily, since better adapted liquid formulations are not available. Some children and adolescents may be unable to adhere to rigid protocols. The *poor knowledge of the minimal effective dose of these agents in the pediatric age is significant.*

reason why ZDV use was limited to initial treatment. In a 26-month-old child with encephalopathy, ZDV was used in association with intravenous Ig (IVIg) [359]. Moreover, it is unclear whether positive results noted following a 9-week cycle are attributable to ZDV, Ig, or both. A targeted study (Pediatric AIDS Clinical Trials Group, PACTG 076) concluded that among mothers who had not been treated previously, administering ZDV before (beginning anytime between the 14th and 34th week of gestation until the end of pregnancy) and after delivery, followed by an IV infusion during labor (2 mg/kg in 1 h), plus administration to the newborns within 8–12 h of birth (Tables 23.30, 23.31) for the first 6 weeks of life, reduced the incidence of HIV infection by 67.5% [121] or, according to a similar study, by 78% [8]. In France, a trial similar to PACTG 076 achieved a 66.6% reduction, uninfluenced by maternal CD4 levels or p24 antigenemia during delivery [361]. An eightfold reduction in maternal viral load was also noted [152], but this has not been confirmed [8]. Subsequently, it was clarified that ZDV must be started during pregnancy or even earlier [361], regardless of virus or CD4 serum levels [516], thus reducing HIV transmission from 20% to 5% [361]. Four additional studies have demonstrated dramatic decreases in perinatal transmission with incorporation of the PACTG 076 ZDV regimen into general clinical practice [124, 187, 188, 238]. In the setting of maternal transmission, ZDV effectively *protects fetal cells from infection* even when maternal viral burden is high [8]. Despite these therapeutic efforts, the protocol of PACTG 076 cannot be applied fully. Several mothers are not informed in time and/or exhaustively of the protocols, they refuse to undergo diagnostic testing for HIV even after being advised to do so, or they refuse ZDV treatment even though they are aware of being HIV^+ [565]. Combination therapy was received by only 323 (8%) women studied [178] vs 1,150 (78%) of 1,472 women (PACTG 367) [551]. A large meta-analysis of seven clinical studies that included 2,123 HIV-infected pregnant women who delivered infants during 1990–1998 and had received prenatal ART and 1,143 women who did not receive prenatal ART demonstrated that the use of multiple ART as compared with no therapy or treatment with one medication was not associated with increased rates of preterm labor, low birth weight, low Apgar scores, or stillbirth [547]. A significant contribution to overcoming this difficulty is the demonstration that ZDV is effective even if *first administered to the mother intrapartum* and *to newborns during their first 48 h of life* [565]. A randomized, DB equivalence trial comprised four regimens of ZDV: started in the mother at 28 weeks' gestation, with 6 weeks of treatment in the infant (the longer regimen), which is longer than protocol 076 [516]; ZDV starting at 35 weeks' gestation, with 3 days of treatment in the infant (the shorter regimen); and two intermediate regimens. The rate of *in utero* transmission was significantly higher with the two regimens with shorter maternal treatment (5.1%) than with the two with *longer maternal treatment* (1.6%) [310]. Infants who became HIV-infected despite maternal ZDV monotherapy were observed to *experience more rapid disease progression,* more severe immune suppression, and a lower survival rate than infants born to mothers not receiving treatment [267].

- *Dideoxyinosine or ddI,* converted inside the cell into dideoxyadenine, is phosphorylated to ddATP, the active substrate that inhibits RT. It is given to children suffering from intolerance or with virus strains that are resistant to ZDV. Pharmacokinetic studies have shown that in children, there is a marked inter-individual variability in the absorption of ddI, so it is wise to monitor its plasma levels to arrive at the optimum dosage [151]. The safety and tolerability of ddI given once daily are substantially similar to those of the traditionally recommended schedule of two divided doses [354]. Given its acid lability, when administered orally it must be taken on an empty stomach, together with an antacid. It has a plasma peak of approximately 0.5 h and its intracellular half-life is >12 h; 33% of the drug reaches the renal emunctory unchanged [151]. In children, it has shown *clinical improvement* and, less constantly, an improvement in the neuropsychological picture, with a reduction of adenomegaly and splenomegaly, an increase in body weight, and a parallel *positive progression of the immunological parameters,* with a significant increase in CD4 lymphocytes and a decrease in p24 antigenemia, both of which are correlated with *the dosage of ddI that is absorbed* and not how it is administered. In terms of *side effects,* pancreatitis is reported in children in up to 7% of cases, more frequently in those who received the highest dosage, with prompt regression when treatment is discontinued. Other side effects include diarrhea, increased transaminase, uricemia and triglyceridemia, which are generally reversible following reduction or discontinued treatment. It is not myelotoxic [151].
- A 70%–90% bioavailability has been attributed to *ddC,* but its half-life in children is 1.4 h, as opposed to 1.9 h in adults, leading to the presumption of a lower level of bioavailability or faster clearance. It is not present extensively in the CSF (20% of plasma concentrations) and is cleared through the kidneys. If ddC is administered at mealtimes, its plasma level drops by 39%, also prolonging the time required to reach maximum concentration in the plasma. There is little myelosuppressive effect in ddC, but it can cause dose-dependent *peripheral neuropathy* that regresses when the treatment is discontinued. However, the incidence of this disorder is low in the pediatric field [151]. Administration may be followed by skin rash, aphthous stomatitis, headache, hyperglycemia and, rarely, pancreatitis [585]. The ddC anti-HIV activity has been reported in treated children, demonstrated by *p24 antigen reduction and CD4 lymphocyte numerical increase,* along with a better appetite and growth increase, as well as a reduced adenopathy and hepatosplenomegaly [440].

• *Stavudine or d4T* has the same characteristics and mechanism of action as ZDV; its bioavailability following oral administration is 90%, while peak levels are reached rapidly, in 0.5–1.5 h, dropping off just as fast, as its mean half-life is 1.2 h [151]. In CSF, it reaches 46.5% compared to serum levels and is cleared through the urine. On a clinical level, it shows *lower cytotoxicity than ZDV* [288]. Twenty percent of children experienced nonrelevant side effects such as rhinitis, cough, diarrhea, vomiting, nausea and skin rash in 51%–76% of cases, peripheral neuropathy in 22% and a decline in neurological tests in 11% of cases [288]. Neutropenia occurs less commonly among children receiving d4T than ZDV [288], and doses of dT4 can be halved [57]. From an immunological standpoint, a *significant increase in CD4* is observed starting in the 12th week, remaining constant for at least 24 weeks in 44.4% of children, with a parallel *drop in p24 antigenemia* below basal values [288].

• *Lamivudine or 3TC* is a ddC analog and it is less toxic in vitro than other NRTIs; bioavailability is 62% following oral administration, and it goes into the CSF. Preliminary results show that the drug is safe and well-tolerated, and an increase in appetite and weight gain have been observed [151]. A phase I/II study of 3TC showed that 3TC could decrease viral burden by 0.77 logs when used as monotherapy; 3TC has activity against HIV-1, HIV-2 as well as hepatitis B virus. The CSF/plasma ratio in children is relatively low (0.11) compared with that of ZDV (0.25), but higher than that of ddI (0.05) [334]. In PACTG 300, *children receiving ZDV and 3TC had a lower risk of HIV disease progression* or death than those receiving ddI alone [369]. In a trial of q12h- vs q24h 3TC and ABC, 80% of children had a viral load <100 copies/ml at baseline compared with 89.5% at week 24. There was no marked difference in antiviral activity between q12h and q24h regimens [36].

• *Abacavir (ABC)* can induce a 1.5–2 $\log_{10}$ decrease in plasma RNA, but in a randomized study comparing ABC/ZDV/3TC with ZDV/3TC alone, four of 146 (2.7%) children receiving ABC and two of 44 (4.5%) children in the ZDV/3TC group who switched to open-label ABC therapy developed a *hypersensitivity reaction,* which resolved upon discontinuation of therapy [480]. Common toxicities are rash, nausea, vomiting and fever, which are difficult to diagnose and can even culminate in shock, in which case ABC treatment must be stopped definitively [19].

• *Adefovir,* unlike some antiviral nucleosides, does not require the initial phosphorylation step for its activity [254]. It can induce a 0.5–0.7 $\log_{10}$ decrease in plasma RNA and be administered in a single dose together with L-carnitine [450].

• *Tenofovir is not recommended by the CDC* [88], although serious adverse events leading to discontinuation of tenofovir DF were infrequent (5%), occurring with an incidence similar to that with placebo (8%) [198]. Patients receiving tenofovir must be monitored closely for early signs of tubulopathy since renal failure, proximal tubular dysfunction and nephrogenic diabetes insipidus have been reported in such patients [278]. Elevated *hepatic transaminase levels* during tenofovir monotherapy developed in 2/18 HIV-infected children aged 8.3–16.2 years who had progressive disease with ≥2 prior ART regimes. The monotherapy for 6 days was followed by the addition of individualized ART regimens. Children were monitored through 48 weeks. The remaining 16 children had a median of *4 ART agents* added to tenofovir. HIV plasma RNA levels decreased from a median pretreatment level of 5.4 $\log_{10}$ copies/ml to 4.21 $\log_{10}$ copies/ml at week 48, with 6 children having <400 copies/ml, including 4 with <50 copies/ml. $CD4^+$ cell responses among the responders were high and sustained. An additional toxicity attributed to tenofovir was a >6% *decrease in bone mineral density* for 5/15 children evaluated at week 48, necessitating the therapy discontinuation for 2; all 5 children had >2 $\log_{10}$ copies/ml decreases in HIV plasma RNA levels [239].

NNRTI

• *Delavirdine (DLV)* is metabolized in part by the hepatic cytochrome P450 3A (CYP3A) enzyme system, and in contrast to EBV inhibits P450 isoenzymes and may decrease the metabolism of certain drugs resulting in increased APV levels. Alternatively, DLV may be administered with APV in children [580].

• *Efavirenz (EFV)*, switching from PI to an EFV-containing regimen in 17 HIV-infected children, 24–160 months of age, elicited a significant improvement in fasting total cholesterol, low-density lipoprotein cholesterol, triglycerides, and the cholesterol:HDL ratio. The EFV-containing regimen was well tolerated and successfully maintained virological suppression in all children [365].

• *Nevirapine (NVP)* (dipyridodiazepinone) is used in association with ZDV and/or ddI, and has proven to be safe and effective. NVP is metabolized by the liver and the hepatic enzymes induce a twofold increase in its clearance, so that the dose must be reduced in the first 2 weeks [345]. NVP has various properties that make it an ideal candidate *for interrupting the HIV-1 transmission during childbirth and in the early postpartum phases,* given that it is absorbed rapidly and transferred to the newborn through the placenta if given to the mother during labor or delivery. In PACTG 316, a single-dose NVP administered during labor and to the newborn was added to the woman's existing ART regimen, but newly detectable NVP-resistance mutations were detected at 6 weeks postpartum in 14 (15%) of 95 women who received single-dose intrapartum NVP and had detectable HIV-1 RNA at delivery: the *overall transmission rate was 1.4* [134]. Resistance mutations to NRTIs (which include ZDV) were detected 10 days after delivery in 5% of mothers and in blood samples obtained 10 days postpartum from 32% of the women who

had received intrapartum NVP and who had at least one mutation that conferred resistance to NNRTIs [273]. In an open-label short course ART regimen of either NVP or multiple-dose ZDV/3TC, the overall estimated HIV-1 infection rates in 1,307 infants by 8 weeks were *12.3% for NVP and 9.3% for ZDV/3TC.* There were no drug-related serious maternal or pediatric adverse events [392]. However, children in the NVP-containing arms experienced moderate or worse skin rash more frequently than those not receiving NVP [581].

PI

- *Amprenavir (APV)* is a substrate for and inhibitor of the cytochrome P450 isoenzyme CYP3A4. Like other agents in this class, there could potentially be multiple drug interactions [19]. So far it has not been used *widely for children* (>4 years), and its dosage is limited to bid [580]. Children receiving APV should be advised not to take supplemental vitamin E [19].
- *Indinavir (IDV)* tends to precipitate in the renal tubules, causing hematuria and nephrolithiasis, thus requiring adequate hydration. Headache, nausea and abdominal pain were reported by 10% of patients [418]. In 33 infected children who had received >96 weeks of IDV/ZDV/3TC treatment (with an initial 16 weeks of IDV monotherapy), a median *increase in CD4$^+$ cell* count of 199/mm^3 and a median *decrease in HIV RNA* of 0.74 log was observed at 96 weeks [269].
- *Nelfinavir (NFV)* can cause headache, nausea, diarrhea and vomiting, and must be administered with food [450]. PACTG 382 studied 57 ART-experienced, PI and NNRTI-naive children given a combination of NFV, EFV and at least one NRTI. The combination was well tolerated by most children in the study. Viral suppression to <50 copies/ml was seen in 53% of the children studied at 48 weeks of treatment [520]. In a cohort of 22 HIV-infected infants aged 15 days–2 years in PACTG 356 given the recommended NFV dose of 20–30 mg/kg tid, clearance was significantly higher than in older children (2.7 l/h/kg vs 1.2 l/h/kg in older children), and the peak NFV levels were less than half those reported in older children [86]. As a consequence, doses of 55–65 mg/kg bid are currently under study in the young children in this protocol. Since NFV shows high interindividual variability in children, children <2 years tend to be at increased risk for low NFV levels. These data show that the NFV suggested dose is inadequate in most children. Also, these data suggest that pediatric dosing of NFV based on body surface area should be considered [38]. NFV in the absence of NVP resulted in less than half the drug exposure in children who weighed <25 kg compared with children who weighed >25 kg. An NFV dose of 50–55 mg/kg bid, to a maximum of 1,500 mg per dose, in children who weighed >30 kg resulted in equivalent or superior drug exposure [189]. NFV, 45 mg/kg was given bid to 25/39 children [33].
- *Ritonavir (RTV)* is a coformulation with lopinavir and has a notable antiretroviral activity; peak concentrations are reached in 2–4 h. In PACTG 338, children receiving RTV and one or two NRTIs had a mean decrease of >1.5 log in viral RNA levels after 12 weeks of therapy. After 48 weeks of RTV plus two NRTIs, 42% of children had an undetectable viral load (<400 CD4$^+$ cells/mm^3) compared with 27% of children receiving RTV plus one NRTI [401]. After 12 months of therapy, PI-naive children receiving RTV with two NRTIs *had <400 CD4$^+$ cells/mm^3* [542]. The increase in CD4 cell numbers is independent of dose level and is also observed even in children with low counts at study entry [398]. Early increases in lymphocytes after RTV therapy are a result of recirculation, as shown by increases in B cells and CD4$^+$ CD45RO and CD8$^+$ T cells [508]. PACTG 377 randomized ART-experienced, PI- and NNRTI-naive children into four different treatment regimens including RTV/d4T/NVP. They had a median *increase in CD4$^+$ cell count* of 254 cells/mm^3 and 41% of children had *HIV RNA <400 copies/ml* at 24 weeks of treatment [580]. In 31 children with advanced HIV infection who were receiving a triple therapy with RTV as PI, no correlation could be demonstrated between elevated plasma drug concentrations and abnormal cholesterol or triglycerides values [160].
- *Saquinavir (SQV)*, used in adults, is a highly specific inhibitor of HIV proteases, which are essential for final assembly of the viral particles for HIV replication. In combination with NRTIs, it further reduces viral load with respect to other monotherapies [151]. SQV can cause headache, nausea, diarrhea and abdominal pain, and must be administered within 2 h after a large meal [450]. In *a trial of 13 children,* adding NFV to a regimen of SQV with one or two NRTIs significantly increased SQV concentrations, and median change in HIV RNA levels was 2.58 log, with 62% of children having HIV RNA levels <50 copies/ml at 48 weeks [290]. In another cohort of *11 HIV-infected children* with intensive prior therapy, salvage therapy with combination SQV/RTV and SQV/NFV with at least one NRTI was well tolerated; reduction in viral load and increase in CD4$^+$ cell count were more pronounced in the group receiving SQV/RTV combination [251]. An advantage of PI-based combination therapy was *the largest CD4% increase among the youngest participants* (9.2% and 8.0%, for ages <5 years, and 5–9 years). Moreover, 16% of significantly immunocompromised entrants achieved CD4% values >25%, whereas children with pre-PI values >25% maintained such values. Although PI-based therapy was associated with substantial improvements in CD4%, initiation before severe immunosuppression and *at younger ages* may be more effective for recovery or maintenance of normal CD4% [512].

All PIs interact with the hepatic cytochrome P450, giving rise to potential interactions with other antiretrovirals and commonly used drugs, some of which are frequent and sometimes dangerous. Doctors and

family members should be given lists of these interactions in order to prevent them [418]. The use of combination therapy including PIs has markedly reduced mortality from 5.3% in 1996 to 0.7% in 1999 (<4.6%) among HIV-1-infected children and adolescents [221]. Their use was not associated with retardation of growth in height or weight, but with small annual increments in height and weight growth in HIV-infected children [70].

Recent studies have shown that long-term HAART therapy induces in HIV-infected patients an increased cell count of CD4 lymphocytes from year 3 to 6, whereas 55% of subjects may demonstrate decreases in CD4 cells counts from year 5 to year 6. A significant difference was noted when comparing naive CD4 cell increases from baseline to year 6 with year 1 *thymus thickness* [510]. Also in vertically HIV-infected children treated with potent ART regimens the rise in CD4 cells and in $CD4^+$ $CD45RA^+$ $62L^+$ T cells was statistically associated with *changes in thymus size* observed over time [563].

Entry Inhibitors

Entry inhibitors, a new class of antiretroviral agents, interfere with the attachment, coreceptor interaction or fusion of HIV-1 with host target cells. The fusion inhibitor *T-20 (enfuvirtide),* the first in this new class, is associated with suppression of HIV-1 replication during 24 weeks of administration. T-20 has been studied *in 14 children,* 4–12 years of age, with incompletely suppressed HIV-1. In ten subjects (71%) virologic suppression of ≥1.0 $\log_{10}$ was achieved at 24 weeks; six subjects (43%) had viral loads >400 copies/ml and three (21%) had <50 copies/ml at 24 weeks. No child discontinued because of adverse events [106]. In 491 patients at 24 weeks, there was a decrease of 1.696 $\log_{10}$ copies/ml in the T-20 group, and a decrease of 0.764 $\log_{10}$ copies/ml in the control group, but more cases of pneumonia (5.6%) were seen in the T-20 group than in the control group (0.3%). The addition of *enfuvirtide* to an optimized ART provided significant immunological benefit through 24 weeks in patients who had previously received multiple ART drugs and had multidrug-resistant HIV-1 infection [323]. In addition to T-20, investigational entry inhibitors include *PRO 542* (a CD4 attachment inhibitor) and *T-1249,* 5 Helv and IQN-17, other inhibitors of membrane fusion [232].

Anti-HIV Drug Updates

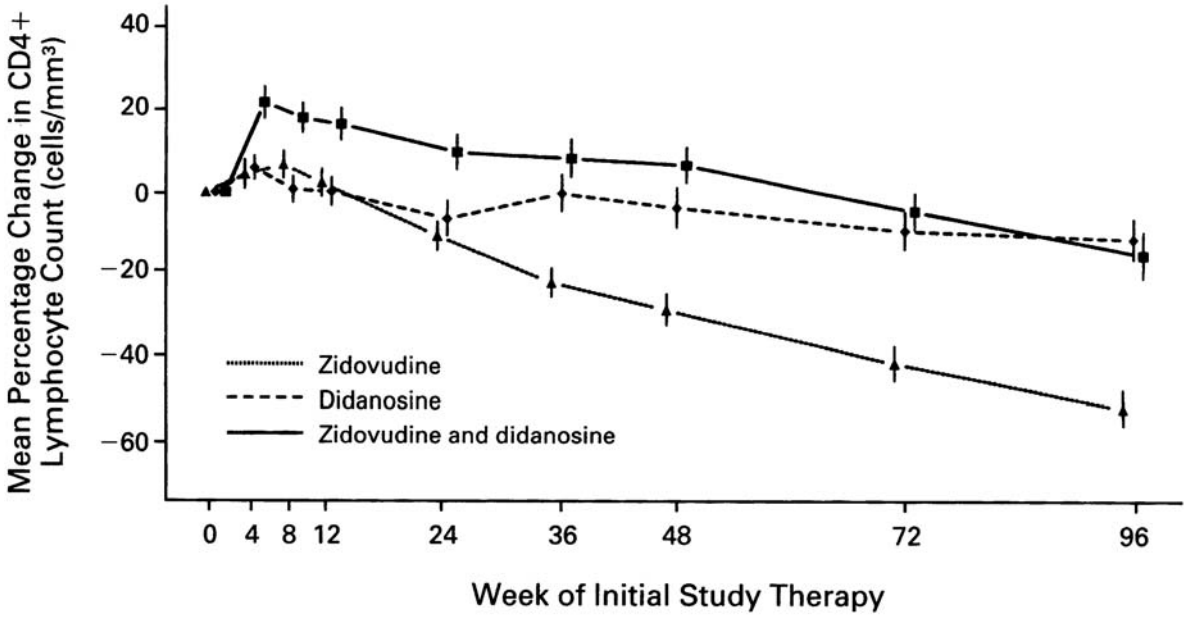
Despite the availability of 17 ART drugs approved for the treatment of HIV infection, nine candidate drugs with novel properties are in development. Investigational NRTIs include *emtricitabine* (FTC) and *amdoxovir* (DAPD). FTC, a potent deoxycytidine NRTI recently approved by the USFDA for the treatment of HIV infection proved to be effective and safe in *25 children* 22 months to 17 years of age receiving two single oral doses of FTC (60 and 120 mg/m^2, up to a maximum of 200 mg, in solutions) [570].

Investigational NNRTIs include DPC 083 and TMC 125. Investigational PIs include *atazanavir*, *tipranavir* (TPV), *rever set* (RVT) [259] and *TMC 114* [232].

Studies with Associated Therapies

So far, we have examined the properties of different drugs. However, anti-HIV-1 monotherapy has now been replaced by multitherapy associations, which have proven to be more effective. Two studies have reported results: one treated eight 2- to 16-month-old children with a combination of *ZDV, ddI and NVP,* which was very effective and well tolerated [345], while in PACTG 152, a multicenter study, 831 children aged >30 months were given ZDV or ddI or both drugs [170]. It was clear that ddI as well as the ddI-ZDV combination were more effective than ZDV alone (Fig. 23.26) [170]. It was found that *ddI alone had an efficacy* similar to that of ZDV plus ddI (RR of disease progression or death, 0.98), and a significantly lower risk of anemia or neutropenia was seen in children receiving ddI alone [170]. In a further pediatric study comparing therapy with ZDV alone or associated with ddC, the combination was well tolerated, apart from an increase in neutropenia (14%) compared to children treated with monotherapy (5%). However, the decreased number of CD4 was greater with monotherapy (25% per year) vs 13% per year [29]. In turn, d4T was well tolerated, without showing symptoms of myelosuppression and alterations of the blood parameters, probably due to the incremental dosage that was used [288]. These objectives were extended to PACTG 327, a randomized trial to evaluate the safety, tolerance and antiviral activity of ddI and d4T in combination or d4T alone, which found the combination to be superior to d4T monotherapy in 108 ART-experienced children previously enrolled in PACTG 240 (d4T monotherapy vs ZDV monotherapy) or who had received ZDV monotherapy for at least 6 months, with a greater safety from a clinical standpoint and a favorable effect on viral load [288].

Triple therapies, as we have prviously seen, are effective in view of the increasingly frequent isolation in HIV^+ subjects of HIV strains that are resistant not only to ARTs but also to PIs [241]. For example, the therapy referred to as *HAART relies on two NNRTIs and a viral-PI.* Administered twice a day, it also permits better compliance. Long-term (>96 weeks) immunological improvement and reconstitution with a naive T-cell phenotype ($CD4^+$ $CD45RA^+$) have been seen in some children receiving the combination ZDV, 3TC and the PI indinavir [269]. ZDV has been studied as part of a PI-sparing, three-drug nucleoside analog regimen (ZDV, 3TC and ABC) in ART-experienced children. Increased viro-



number of patients

Zidovudine	273	235	232	241	237	225	210	165	107

Fig. 23.26. Mean (±SE) percent change from baseline in $CD4^+$ lymphocyte counts at interim analysis

logical benefit was found in those children who had two new NRTIs added to their regimen [481]. Combination triple therapy with NVP, ZDV and ddI in eight infected infants 2–16 months of age with HIV-1 MCTC has been associated with sustained viral suppression [345]. PACTG 377 randomized 181 mild to moderately suppressed children to one of four combination treatment regimens. Interestingly, those children receiving a *quadruple regimen* containing both NVP and a PI had a significantly greater increase in $CD4^+$ cell count from baseline to week 24 than those receiving other regimens [581]. In two pediatric open-label studies, 70% of children receiving IDV/ZDV/3TC had HIV RNA levels of <500 copies/ml after 6 months of therapy [554], or HIV RNA levels were maintained at <400 copies/ml after 18 months of IDV/d4T/3TC therapy in 87% of children who entered the study with $CD4^+$ cell counts in CDC immune class 2 and 72% of those who entered with CDC immune class 3 [561]. Early treatment with d4T, ddI and NFV was well tolerated and associated with good clinical and immunological outcomes at week 72. However, a high rate of virological failure with emergence of genotypic resistance is of great concern. More palatable drug combinations for infants are required [1]. In a phase II, randomized, multicenter study, 41 children aged 5 months–21 years with prior NRTI and no prior NNRTI or PI experience received either NFV 30 mg/kg bid, RTV 400 mg/m bid and ddI 240 mg/m/day (arm A) or NFV 50–55 mg/kg bid, NVP 120 mg/m bid and d4T 1 mg/kg bid (arm B). The proportion of children with HIV-1 RNA ≤400 copies/ml at 48 weeks was 65% among children in arm A vs 28 in arm B ($p = 0.039$). No significant difference in median CD4% change from baseline to week 48 was found (3% vs 1%) although a trend toward a higher rate of permanent discontinuation of study treatment was noted among children in arm A compared with those in arm B (35% vs 10%), $p = 0.12$ [285]. NRTI-sparing regimens have not yet been systematically evaluated in children. To take advantage of NVP and EFV lowering PI plasma levels, coadministration of *lopinavir*/RTV with NVP and EFV necessitates an increased dose of 300/75 mg/m^2 tid lopinavir/RTV to compensate for the EFV-induced drug–drug interaction in HIV-infected children [37].

The PACTG studies also examined *quadruple therapies:* PACTG 152 demonstrated that ddI or ZDV + ddI treatments were superior to ZDV alone [170]; PACTG 356 in children aged 2 weeks to 2 years includes a triple regimen with ZDV, 3TC and NVP, and two quadruple ones, one with ZDV, 3TC, NVP and ABC and the other with the three previous ones + NFV, while PACTG 345 involving children aged 4 weeks to 2 years includes another triple therapy with ZDV, 3TC and RTV. The US-based Pediatric AIDS Foundation has instead promoted a trial with ZDV, 3TC and ABC, and combinations with adefovir and APV are also being studied [344, 345]. The

RH (relative hazard) of death in children receiving monotherapy or double or triple combination therapy was 0.77, 0.70, and 0.29, respectively, vs no ART [144].

Results of epidemiological and clinical trials suggest that women receiving HAART regimens that effectively reduce HIV-1 RNA to <1,000 copies/ml or undetectable levels *have very low rates of perinatal transmission* [125, 154]. Children receiving HAART achieved a plasma HIV-1 RNA level <400 copies/ml by a median of 4 weeks after initiation of therapy and a decline to <50 copies/ml by 20 weeks. Children whose CD4 lymphocyte counts increased >70 cells/μl by 20 weeks on therapy were more likely to achieve durable virological and immunological benefit [515]. Among 57 children treated with EFV, NVP, and NRTI, 76% had plasma HIV-1 RNA levels >400 copies/ml at 48 weeks of therapy and 63% had levels <50 copies/ml. A high plasma HIV-1 RNA level at baseline significantly decreased the likelihood that plasma HIV-1 RNA levels would become undetectable during treatment [520]. Because transmission can occur even at low or undetectable HIV-1 RNA copy numbers, RNA levels should not be a determining factor when deciding whether or not to use ZDV for chemoprophylaxis [388]. Use of combinations of RT drugs should not overlook the fact that these can act together to further increase HIV-1 mutant frequencies, which could have important implications for virus population dynamics and could compromise drug therapy regimens [353].

To conclude, the virological effectiveness of multidrug ART in previously drug-naive individuals appears to be such that viral suppression, once achieved, can be maintained for several years in patients not interrupting therapy. Clearly, it is necessary to develop regimens that can be followed consistently and safely for such long periods of time [434].

There are data on the decline of CD4 cells or percentage during *structured* [99] (STI) *or unplanned* [213] *treatment interruptions* in HIV-infected children. It is suggested that when designing pediatric trials of planned treatment interruptions, although the average CD4 decline after stopping HAART appears similar to that in adults, the length of interruption should be determined by the time taken for CD4 to decline below a threshold, rather than by imposing interruptions of fixed duration [213]. An STI HAART regimen that consisted of dosing every other week AZT, 3TC, and NFV was started in three chronically HIV-1-infected, ART-naive African children with advanced disease. After 14 months, *a sustained increase of CD4$^+$ T lymphocytes was observed.* At 26 months after the initiation of the STI regimen of HAART, the three children *attended school regularly* and rarely missed days because of AIDS [99]. This approach may increase HIV-1-specific cellular immunity by intermittently exposing the patient to autologous virus, which results in the control of HIV-1 replication [391], particularly during acute primary HIV-1 infection, since treatment interruption has been shown to boost HIV-1-specific immunity in some cases. [381]. Although virus recrudescence was noted during the treatment interruptions, and the off-treatment viral rebound rate [415], *failure to reach full viral suppression rarely occurs,* and the development of resistance after reinitiation of treatment has been infrequently described [381].

Drug Resistance

The issue of drug resistance is not new, the evolution of ART phenotypic and genotypic drug resistance to ZDV, 3TC, ABC and NFV was studied in 113 prior untreated children in the PENTA 5 trial, which showed that selection of 3TC-resistant virus was most frequent, followed by NFV and/or ABC; selection of ZDV-resistant virus was rare. The most sustained HIV-1 RNA response was in the 3TC+ABC arm, but mutations conferring reduced susceptibility to 3TC and/or ABC evolved more frequently if virological failure occurred with 3TC+ABC than with ZDV+ABC [211]. *Genotypic resistance was common in children* treated with 3TC (91%), NVP (75%), and ZDV (64%). The prevalence of mutations was lower among those receiving other NRTIs and PIs. It is noteworthy that ART resistance was common among children failing treatment: as adherence to treatment was low in 50%, this was likely to be an important contributory factor [399]. Following the progress of children who had HIV genotyping performed after HAART failure, resistance mutations to antiretrovirals was detected in two-thirds of children without prior exposure to that drug [116]. *HIV-1 resistance to T-20 emerged in 2/16 HIV-1 infected adults* enrolled in the phase I T-20 clinical trial during 14 days of treatment [573]. There is increasing evidence that resistant strains of HIV are being transmitted in North America with an estimated prevalence of 1%–11% [336], in Europe [60], Ivory Coast [5], Gabon [558], and in infants [184] as a result of the difficulty of completely suppressing viral replication [457]. Resistance to one drug often confers some level of reduced sensitivity to other drugs of the same class, which dictates that genotypic resistance be evaluated before switching therapies [501].

In conclusion, we should disclaim early expectations that combination ART would eradicate infection, since virus can persist in latent reservoirs for many years despite effective ART [186, 431]

Immunological Rationale

We must consider that newborns physiologically have a relative lymphocytosis, with a characteristic profile of lymphocyte subpopulations (Tables 2.5, 2.6). The relative increase in CD4 lymphocytes depends, in normal T cell ontogenesis, on a stage where CD4 and CD8 membrane proteins are coexpressed by the same cell, so that these lymphocytes are present in the newborn's circula-

Table 23.32. Recommendations for PCP prophylaxis and CD4+ monitoring for HIV-exposed infants and HIV-infected children, by age and HIV infection status[a]

Age/HIV infection status	PCP prophylaxis	CD4+ monitoring
Birth to 4–6 weeks, HIV exposed	Prophylaxis	1 month
4–6 weeks to 4 months, HIV exposed	Prophylaxis	3 months
4–12 months HIV infected or indeterminate	Prophylaxis	6, 9, and 12 months
HIV infection reasonably excluded	No prophylaxis	None
1–2 years, HIV-infected	CD4+ counts <750 cells/μl in first 12 months	
	Or <500 cells/μl at 12 or 24 months, or CD4<15%	Every 3–4 months
2–5 years, HIV-infected	CD4+ counts <500 cells/μl or percentage <15%	Every 3–4 months
6–12 years, HIV-infected	CD4+ counts <200 cells/μl or percentage <15%	Every 3–4 months
All ages, HIV-infected, at risk of PCP		Every 3–4 months

See text related to children with negative tests.
Data from [15, 60].
[a] If CD4 counts or percentages (Table 23.29) are approaching the age-adjusted threshold level for initiation of prophylaxis, the CD4+ lymphocyte count should be assessed more frequently (at 1-month intervals) to evaluate the rate of decline and the need to initiate prophylaxis. PCP prophylaxis may be considered independently of T-cell count, as follows: (a) All children previously suffering from PCP reasonably ascertained; (b) All HIV-infected children in the first 2 years of life; (c) All children aged >2 years with severe clinical manifestations or severe immunodeficiency. Prophylaxis should be considered on a case-by-case basis for children who might otherwise be at risk for PCP, such as children with rapidly declining CD4+ counts or percentages or children with Category C conditions (severely symptomatic). Children who have had PCP should receive lifelong PCP prophylaxis.

tion, thus inducing a relative increase in CD4 lymphocytes. As compared to adults, children have a much higher proportion of virgin T cells that are initially undifferentiated and pluripotent, differentiating into CD45RO only after their encounter with the antigen. As long as the thymus continues to function, children may greatly recover T lymphocyte number and function via their reserve of virgin cells. This also explains why, in *HIV-positive newborns and infants, the lymphocyte percentage and absolute decrease is more difficult to detect* and, in any event this is a more laborious parameter to identify than in adults [46, 83, 169, 174, 182, 225, 416, 464]. Since it is impossible to preserve the immune infrastructures, this prevents the renewal of impaired T lymphocytes and complete immune reconstruction [242]. However, adequate suppression of viral replication by combination ART results in the rapid correction of TcR diversity within CD8 subsets because of the emergence of new T cells from the thymus [295]. Moreover, an increase in naive CD4 T cells in treated patients was shown to occur more precociously and at a higher rate in young children than in adults [117, 193]. Resting or naive cells contributed significantly to the rise in CD4 T cells in infants and young children [52]. Additionally, in children with CD4 rates <20%, usually associated with higher viral load, the decreased viral load after ART *allows the generation of new CD4 T cells by the thymus,* thus recovering their normal number [128]. Suppression of viral replication in HIV-infected children particularly occasions a recovery of thymic function that should help to reestablish diversity within the T-cell repertoire and correct T-cell function [156]. Significantly, at 96 weeks, CD4+ cell counts were 85% higher in the children receiving ddI and 76% higher in the children receiving combination therapy than in the children receiving ZDV alone [345].

Treatment of Infective Complications

PCP Prophylaxis

PCP was reported as a disease marker in 33% of affected children in 1991 [174] and in 39% in 1994 [177], and only in 2.4% in 1996 [169], showing that many children are identified earlier as being at risk for HIV infection and thus receive PCP prophylaxis [15]. For this purpose, the infants who were not given prophylaxis prior to PCP diagnosis have also been screened, thus allowing their identification at the time of diagnosis [506]: prophylaxis must therefore be initiated in more children than recommended by guidelines [505], expanding this prophylaxis to all newborns of HIV+ mothers. Since PC can also be transmitted to the fetus [395], this prophylaxis should also be necessary for pregnant mothers.

Therapy and prophylaxis for PCP, the most common and highly lethal opportunistic infection, is based on CD4 values according to age, as noted (Table 23.29). Data on PCP prophylaxis and CD4 monitoring are listed in Table 23.32 [15, 60].

Table 23.33. CDC recommended drug regimens to prevent first PCP episode in children ≥4 weeks of age

Drug	Preventive regimen		
Trimethoprim	150 mg/m^2/day		
+ Sulfamethoxazole	750 mg/m^2/day administered orally in two divided doses three times a week on consecutive days		
	Or		
Trimethoprim	5 mg/kg/day		
+ Sulfamethoxazole	25 mg/kg/day administered orally in two divided doses three times a week on consecutive days		
Alternative regimens	As above, administered orally as a single dose three times a week on consecutive days, or in two doses administered orally on three alternate days, or bid/day		
Alternative regimens if trimethoprim + sulfamethoxazole is not tolerated			
Dapsone	Children aged ≥1 month, 2 mg/kg, max 100 mg, orally q day, or 4 mg (max 200 mg) q week		
Pentamidine	Aerosolized in children aged ≥5 years, 300 mg administered q month or pentamidine IV, 4 mg/kg, every 2–4 weeks[a]		
Or			
Atovaquone	Weight (kg)	Daily dose	Dosage regimen
/proguanil HCl	11–20	62.5 mg/25 mg	1 pediatric tablet daily
(Malarone)[b]	21–30	125 mg/50 mg	2 pediatric tablets daily
	31–40	187.5 mg/75 mg	3 pediatric tablets daily

Data from [1, 90, 96].

[a] see Chap. 19 for details.

[b] At the time of writing no data are available on safety and efficacy of Malarone for PCP prophylaxis in children weighing <11 kg, although studies are in progress.

Start of PCP Prophylaxis

In all infants born to HIV-infected mothers, PCP prophylaxis must be started at the age of 4–6 weeks, regardless of CD4 values indicated in the table. If PCP is identified after the 6th week, prophylaxis must begin at the time of diagnosis. Prophylaxis must not be moved up, due to the immaturity of bilirubin metabolism, which can lead to side effects. Especially among children being treated with ZDV, it can potentially exacerbate ZDV-induced anemia: in this case, prophylaxis should be started at the 6th month, when ZDV is discontinued [15, 91].

Prophylaxis in 4- to 12-Month-Old Infants

PCP prophylaxis must be continued until the child is at least 1 year old, unless the two subsequent tests (culture, PCR) are negative at the ages of 1 and 4 months, or at 6 months if these tests are not available. The drugs and their dosages are listed in Table 23.33 [1, 90, 96], and it must be remembered that co-trimoxazole triggers several reactions, which are documented in Chap. 19. Nevertheless, this therapy substantially lowers the risk of PCP in HIV-infected infants <18 months old [538], although certain children may experience PCP despite regular prophylaxis [397]. *Atovaquone* is a medication employed for malaria treatment that can be employed in children who cannot tolerate the other medications [1].

Prophylaxis in Children 12 Months and Older

All children of ≥12 months with HIV infection must have CD4 monitored based on the indications in Table 23.32; those who have not undergone prophylaxis due to the lack of an initial diagnosis or because the prophylaxis has been interrupted must start it based on the data listed in Table 23.29. On the other hand, children who have received prophylaxis regularly between the ages of 12 and 24 months must be retested [91]. A hospital-based study in Malawi described the clinical presentation and outcome of PCP in young children. Among 150 children with Rx-confirmed severe pneumonia, 16 cases of PCP were identified and 10 of these children died. All cases of PCP were <6 months of age [223].

Other Infections Caused by Opportunistic Agents

There are several active infections in pediatric AIDS, each of which must be treated aggressively and in a targeted manner, according to specific protocols. Again, the main viral infections are caused by CMV, EBV, HSV, and

Table 23.34. Antiviral agents and related dosages for treating opportunistic infections in HIV-infected infants and children

Virus	Agent	Dose/day	Route
CMV			
Severe, life-threatening disease	Ganciclovir		
	Induction	5 mg/kg × 3	IV
	Maintenance	6 mg/kg	IV
	Or		
	Foscarnet		
	Induction	60 mg/kg × 3	IV
	Maintenance	120–150 mg/kg	IV
HSV			
Mucocutaneous			
Mild	Acyclovir	10–20 mg/kg × 4	PO
Generalized	Acyclovir	500 mg/m^2	IV
Encephalitis	Acyclovir	10–15 mg/kg × 3	IV
Acyclovir-resistant	Foscarnet	40 mg/kg	IV
Measles			
Severe disease	Ribavirin	5 mg/kg× 3	IV
Pneumonia	Ribavirin	6 g	Aerosol
VZV			
Chickenpox	Acyclovir	500 mg/m^2	IV
	Or		
	Acyclovir	20 mg/kg	IV
Zoster	Acyclovir	20 mg/kg	IV
		Or	
	Acyclovir	500 mg/m^2	IV
Acyclovir-resistant	Foscarnet	40 mg/kg	IV

From [56, 566].

VZV. Table 23.34 [56, 566] summarizes the main drugs that can be used to treat these infections. For CMV, initial therapy with ganciclovir or foscarnet must continue for 14–21 days and be followed by IV maintenance therapy indefinitely, with the likely association of anti-CMV hyperimmune Ig [56]. It should be noted that, in children, *ganciclovir* provokes reversible neutropenia, thrombocytopenia and exanthema, while *foscarnet* triggers tubulopathy, hypocalcemia and alteration of liver function tests [566]. Treatment with acyclovir must be continued for at least 10–14 days. For *ribavirin,* we refer to the comments concerning the treatment of bronchiolitis. Among infections caused by atypical mycobacteria, MAIC ranks first. The spread of these infections has also fostered a new propagation of *M. tuberculosis*. Pediatric therapy relies on drug combinations: Tables 23.35, 23.36 [1, 14, 56, 252] indicate the most effective ones also for infections caused by *M. tuberculosis*. Other opportunistic infections include candidiasis, which is responsible for systemic forms, and *cryptococcosis, cryptosporidiosis and strongyloidiosis,* which are increasingly prevalent in the pediatric age range (Table 23.37) [56, 448, 566]. By incorporating amphotericin B in liposomes, higher dosages of the drug can be administered without increasing the side effects [352]. For infections caused by parasites, the therapy for toxoplasmosis is summarized in Table 23.38 [1, 56, 552, 566]. Given the surge in tuberculosis (TB) infections, a frequent and important coinfection of HIV, it has quite recently been observed that the risk in children of HIV-infected mothers can increase, regardless of the child's specific status. Therefore, before the child is allowed to leave the maternity ward or, better yet, during pregnancy, it is advisable to ascertain the mother's TB status, giving due consideration to the anergy that frequently accompanies HIV infection and can yield a negative Mantoux test (MT),

Table 23.35. Treatment of tubercular infection in HIV-infected infants and children[a]

Treatment	Dosage/day (per os)
Isoniazid	10–20 mg/kg/day, max 300 mg/day
	Or 20–30 mg/kg (max 900 mg) bis in week
Isoniazid-resistant	
Rifampin	10–20 mg/kg/day, max 600 mg/day
Multidrug-resistant	
Ethambutol	15 or 25 mg/kg day, max 2.5 g/day
Pyrazinamide	20–40 mg/kg/day, max 2 g/day

[a] Usually a two- to three-drug regimen is recommended, and a four-drug regimen for disseminated infections: in this case isoniazid and rifampin are coadministered as a single medication, which is coadministered with pyrazinamide as a second medication.
Data from [1, 14, 56, 252].

Table 23.36. Treatment of intracellular *Mycobacterium avium* infection in HIV-infected infants and children

Treatment	Dosage/day (per os)
Amikacin	15–22.5 mg/kg in 2–3 doses
Azithromycin	5–10 mg/kg once a day
Ciprofloxacin	10–15 mg/kg × 2
Clarithromycin	7.5 mg/kg × 2
Ethambutol	15–25 mg/kg/day
Rifabutin	<6 years 5 mg/kg once a day
	>6 years 300 mg once a day

Amikacin and ciprofloxacin have been used above all in adults.
Data from [1, 14, 56, 252].

making a chest X-ray necessary [14, 56]. We recommend obtaining information about the TB status of other persons living in the same household and keeping the child away from anyone who is contagious. Every child exposed to these people, even if the MT and X-ray are negative, must follow *preventive treatment with isoniazid* (Tables 23.35, 23.36) in a single dose for 3 months, then repeating the MT: if it is positive, specific therapy must be started [14].

Other Forms of Treatment

Immune-modulating therapies with IL_2 have been partially ineffective in adults [298], as well as with IL_{15} [259]. In the presence of antibody defects, IVIg is used, and this has yielded encouraging results so far: both the clinical progression and several immunological parameters have shown improvement in children aged <2 years, with significant differences with regard to the rate of infections in those not being treated with TMP-SMZ (trimethoprim-sulfamethoxazole) [514]. The administration of Ig at high doses is thus justified in pediatric AIDS based on the following considerations:

- Replacement of the insufficient formation of antibodies against new antigens, which is extremely important in pediatric AIDS
- Prevention of infections caused by concomitant viruses (particularly EBV)
- Favorable effect of Ig on autoimmune phenomena, which indubitably participate in the pathogenesis of AIDS [83]

However, in 30 HIV-infected children aged 2–11 years who received 6 monthly IVIg infusions, plasma p24 levels decreased, but CD4 cell levels, plasma RNA copy number, cellular virus, Ig levels, and neutralizing antibody titers were minimally affected by the infusions [526].

Future Perspectives

Mother-to-fetus transfer can be used to prevent the vertical transmission of AIDS, if the possibility to compensate for the deficient anti-gp120 antibody transmission is confirmed [316]. Following this line of research, HIVIg (anti-HIV Ig) for the prevention of viral transmission was transfused to pregnant mothers and their babies, and this led to a reduction in p24 levels, an effect that was not achieved with standard IVIg [314]. Data regarding currently or imminently available immunoprophylaxis to prevent MTCT of HIV-1 indicate a potential use in neonatal trials within the coming 1–2 years [484].

Perhaps, as previously mentioned, the *defensins* inhibited the replication of HIV-1 isolates in vitro (Tables 23.9, 23.10). *Soluble CD4* (a known ligand for HIV gp120) completely reverses HIV gp120-mediated immunosuppression and may be a potential immune adjuvant in HIV-infected individuals [280]. Another option is the non-expression of CCR5, which translates into a reduced disease progression; thus subjects HZ for a mutant allele of CCR5 (*CCR5D32*) are safe from sexually transmitted infection [341]. The genetic variants that cause *coreceptor deletion cause AIDS resistance in HIV-exposed* high-risk individuals, or they can delay its progression [146, 341, 486]. Therefore, taking a cue from CCR5, *CCR5D32* mutant alleles valid for HZs [341] and CCR2, CCR2-641 that can delay AIDS onset in HZs and heterozygous (HET) by 2–4 years, exogenous or mutated chemokines could be administered, stimulating the host to produce them in greater quantities, or their actions could be mimicked with different substances [407, 444].

Caucasians in North America or Europe who are HZ for a 32-bp (base pair) deletion in the coding region of the *CCR5* gene, which results in a truncated, nonfunc-

Table 23.37. Antifungal agents and related dosages for treating mycotic infections in HIV-infected infants and children

Infection	Agent	Dose/day	Route

Treatment	Dose/die	Route
Clindamycin	20–30 mg/kg in four doses	PO
	Plus	
Folinic acid	5–10 mg every 3 days	PO
Leukovorin	5 mg every 3 days	PO
Pyrimethamine	1 mg/kg/day[a]	PO
	Plus	
Sulfadiazine maintenance or (for nonresponders)	50 mg/kg q 6 h 80–120 mg/kg q 6–12 h	PO

Data from [1, 56, 552, 566].
The daily dose of TMP-SMZ recommended as the preferred regimen for PCP prophylaxis appears to be effective against toxoplasmosis encephalitis. If children cannot tolerate TMP-SMZ, the recommended alternative is dapsone-pyrimethamine, which is also effective against PCP. Atovaquone might also provide protection [552] (Table 23.33).
[a] Maximum, 25 mg/daily.

tional receptor in CCR5, lack expression of this receptor and thereby resist infection [18, 283, 341]. HET mutations are associated with lower pre-AIDS viral loads and delayed progression to AIDS [203], but at least four HIV-1-infected individuals HZ for the 32 allele deletion in the *CCR5* gene have been described [44]. This hypothesis is not supported in patients of other races or continents [374, 408, 589]. The participation of other receptors, such as CCR2b and CCR3, has also been suggested [105, 148]. An association between CCR5 promoter polymorphisms and long-term asymptomatic HIV-1 infection with individuals lacking the *CCR5 59029A/CCR5 59353C* HZ genotype is likely to progress more slowly towards AIDS [109]. *Two pediatric studies* have observed a benefit of the *CCR5D32* deletion on disease progression [32, 385]. *CCR5D32* HET exerted a protective effect against perinatal transmission in 181 infants exposed to a low maternal viral burden [412]. However, there is discrepancy as to the impact of the *CCR532* allele on pediatric HIV-1-related disease progression. A meta-analysis *on 1,317 HIV-1-infected children* showed that no deaths occurred among *CCR5D32* carriers in the first 3 years of life, and for *CCR2-64I*, the HR for death was 0.69 (OR) in the first 6 years of life and 2.56 (OR) in subsequent years. *CCR5532* and *CCR2-64I* offered *no clear protection after clinical AIDS had developed* [261].

Another option of CCR5 deletion is the anti-CCR5 which blocks the coreceptor binding to HIV env. Blocking the HIV-CD4 fusion means blocking the virus entering the cell, and thus HIV replication [259].

Another option could be to block the interaction between IP-10 and CXCR3: this may represent a possible new target for ART [317].

Gene therapy instead entails a head-on fight against HIV. Modification of vesicular stomatitis virus (VSV) genome, by replacing the genes coding its env proteins with those of human CD4 and fusin proteins, leads to HIV fusion with VSV, as HIV thinks it is binding to lymphocytes. Instead, once inside, VSV will ultimately destroy it. Moreover HIV loses its ability to infect the host, but continues to replicate indefinitely. This allows VSV to enter HIV-infected cells, multiplying inside the cells and making them unable to spread AIDS, almost as if it were a targeted drug released on a cell level. In fact, a few days after VSV was added in vitro to a mixture of lymphocytes and HIV, levels decreased by 300–10,000-fold [495]. Another study reached similar results using the rabies virus that was unable to replicate [375].

As regards *the vaccines,* studies gave rise to the hope that, once they leave the limbo of research in vitro and on animals, vaccines can be applied to numerous other human disorders. Vaccines in monkeys with *inactivated viruses* or with *live attenuated viruses* have not yielded positive results in humans so far, but current promising study results need a period of 5 years in order to be turned into an effective vaccine for humans. Currently, several proteins from the HIV env are being used, such as gp120, or structural ones from the env, such as inactivated tat protein, or the natural and active type. The inactivated (or dead) HIV virus or gene therapy could also be used. One of the challenges faced by an HIV vaccine is the different HIV clades and recombinants of these clades. Therefore, an HIV-1 vaccine will need to be made for each cluster or cross-clade protection will be sufficient [461]. An infection can escape a T-cell vaccine by a single nucleotide mutation within its epitopes [30], or exhaust its T-cell response by the persistence of activated virus-specific T cells without effector function [590], or by suboptimal T-cell help due to progressively impaired function of HIV-specific $CD8^+$ T cells [293]. A recently tested HIV vaccine is composed of recombinant forms of gp120 that resemble two gp120 proteins found on the HIV strain subtype B. This vaccine was shown to be protective only in non-white people. Considering the high prevalence of AIDS in children outside Europe (Fig. 23.10), this vaccine could be a notable advancement in the anti-HIV fight [364]. A series of therapeutic RNA-based inhibitors of HIV-1 infection may suppress HIV infection by targeting a different gene product including a U6 Pol III promoter-driven short hairpin RNA targeting the *rev* and *tat* mRNAs of HIV-1, a U6 transcribed nucleolar-localizing TAR RNA decoy, and a VA1-derived Pol III cassette that expresses an anti-CCR5 ribozyme [335]. The HIV infection could be blocked by the gene encoding CCL3L1 (MIP-1αP), a potent HIV-1-suppressive chemokine and ligand for the HIV coreceptor CCR5. Protection from HIV infection could depend on a high CCL3L1 copy number. These findings could provide key insights into the immune correlates of an effective vaccine [220].

Outcome

A number of children have presented transitory forms of AIDS [33, 54, 69, 145, 175, 210, 544], which in some large studies reached a figure of 2.5%–4.7% [175, 544]. These were children diagnosed at birth by isolating the virus from PBMCs [69, 210], and they subsequently proved to be HIV-negative in all specific analyses after 5 [69] and 9 years [210]. To avoid any uncertainty, guidelines have been proposed for diagnosis [372]. An extensive European study has verified that the incidence drops with cesarean delivery [430]: if it is *associated with ZDV therapy, the rate drops to 1%* [42].

Ever since it became clear that HIV infection is not an illness circumscribed to small groups but that it strikes growing numbers of patients around the world, in many countries AIDS has become public enemy number one. Critically important is the fact that >90% of the estimated 2,000 new pediatric infections that occur each day around the world occur in developing countries [528] and hundreds of thousands continue to become infected annually [3], even in those settings where concerted efforts are being made to prevent HIV MCTC with proven interventions that reduce, but do not completely eliminate, new infections [268]. It is even more important that during an overwhelming epidemic among adults, many countries may opt to neglect the specific needs of infected children and treatment programs sometimes appear to *include children only as an afterthought* [3]. Systematic sidetracking of mothers at risk could ensure the most appropriate and timely treatment of their infected children (Table 23.39) [84, 565]. In a trial including 826 *pregnant women interviewed, 8% (n=65) refused HIV testing*. Independent predictors of HIV testing refusal were being foreign-born, not receiving general information about HIV, and not receiving specific information about HIV and pregnancy (OR between 2.11 and 7.48 with related CI). The most common reasons for testing refusal were being in a monogamous relationship for foreign-born women (41%) and already being tested for US-born women (65%) [26]. The prognosis for infants with early forms is very reserved, survival is low and the mortality rate is high in 50% of cases at 3–4 months after the onset of PCP [161]. *The analogy with the Slaughter of Innocents by a new Herod* is bewildering but by no means unjustified: however, those little, blameless victims died at the age of 2 and in a matter of minutes, not after months or years of unspeakable and inhuman suffering [79, 83].

Confronted with the unprecedented development of effective prophylactic and therapeutic strategies, everyday complications are extensive. Children with neurological and psychological disorders may suffer from problems and difficulties of socialization since their families' lives were damaged by isolation and rejection from the community [291]. The psychiatric manifestations in the general pediatric population <15 years of age in 2002 had an incidence of 6.17 cases per 1,000 person-years, significantly higher than the incidence of 1.70 cases per 1,000 person-years, as reported in the 2000 National Hospital Discharge Survey, yielding a 3.62-fold increase [206].

Table 23.39. Prenatal care in HIV-infected women encouraging positive thinking

1.	Identification of HIV infection should start early in pregnant women, especially in those with unknown serology: awareness of HIV status of pregnant women identifies HIV-exposed infants.
2.	Recommend to HIV+ women of child-bearing age, whether symptomatic or not, to voluntarily accept HIV counseling and specific prenatal HIV testing.
3.	If HIV+ mothers prefer not to get pregnant, inform them about the pharmacological and therapeutical progresses, both in HIV infection prevention and management.
4.	Expectant mothers who decide to give birth should be assisted with particular care, allowing mothers to become informed about the effectiveness of a treatment that can also be delayed.
5.	Advise against prenatal diagnosis.
6.	Weigh the prospect of anticipating the start of treatment in pregnant women as well as of multiple chemotherapy and prophylaxis.
7.	Reduce to a minimum the risk of intrapartum HIV transmission by programmed cesarean sections.
8.	Select an economic, rapid and reliable HIV testing to ensure an early diagnosis of neonatal HIV infection, thus differentiating the infant carrier of maternal antibodies from the truly infected ones.
9.	Consider unborn babies at risk and initiate without delay a preventative/therapeutic program starting zidovudine at birth.
10.	Educate and motivate prospective mothers to take care of their general health, avoid infecting others by abstinence or engaging in safer sex (must use condom for every sexual act).

Data from [84, 565].
OraQuick test facilitates routine HIV testing of all pregnant women, and, as a safety net, the routine screening of any infant whose mother was not screened.

Current Implications

Prevention

The primary prevention is that of MTCT. The first step is the primary prevention of HIV among parents to be, then the prevention of unwanted pregnancy among HIV-positive females, and, moreover, prevention of HIV transmission from HIV-infected females to their in-

Table 23.40. HIV infection prevention in healthy children

What is not infectious
Indoor contacts with HIV+ children
Haphazard use of toys, combs, coffee cups, dishes, flatware, glasses, bed and bath linen, toiletries
Sleeping and bathing together
Hugging and kissing on the lips
Outdoor contacts with potentially HIV+ children
Saliva (do not indulge in prolonged kissing)[a]
Tears
Droplets (cough, sneeze)
Direct contact, sweating (contact with body parts, handshake, caressing, gymnastics, etc.)
Use of sanitary facilities (check that no blood is on the toilet bowl)
Promiscuous use of bar and restaurant coffee cups, serving in general, glasses, flatware, napkins and the like
Bathing with a lot of water (shower, swimming-pool)
Domestic pets, mosquitos and other stinging insects
The above suggestions are no longer valid with bleeding lesions
Particular issues
Vaccinations, blood sampling, injections:
Always use only disposable syringes or droppers
Medical consultations:
Use only disposable tongue depressor, other instruments (gynecological speculum, hammer for reflexes, etc.) should be disinfected after a single use
Dental visits and cures:
All metallic instruments should be disinfected after their use
Nonmedical use of metallic instruments and utensils or of sharp and/or cutting materials capable of initiating bleeding:
Razors, combs, scissors, other instruments used by barbers, beauticians, manicurists and chiropodists, needles or sharp or cutting instruments for whatever use (acupuncturists, tattooing, including ear/nose piercing, re-use of depilatory wax, etc. should be disinfected after their use with common disinfectants) (1:10 or 1:100 Na hypochloride, chlorhexidine, etc.)
Toiletries
Avoid sharing personal objects outdoors, of whatever type, including toothbrushes and other items that may be contaminated by blood

Data from [80, 123, 196, 465].

[a] Saliva could contain HIV-inhibitors such as lysozyme and ribonuclease.

fants, through ART to pregnant females and infants, and where applicable, replacement feeding for the infant. Primary prevention of HIV infection in prospective parents is the only 100% effective method in preventing HIV transmission to infants [277]. It includes HIV education, safe sex practices, avoidance of infected syringes and introduction of infected blood into the body by any route [80]. Subsequently, three main mechanisms are essential for achieving maximum effective reduction of MTCT: 1. Reduce maternal viral load with ART drugs. 2. Prevent avoidable exposure to maternal virus at birth through improved obstetric practices. 3. Reduce exposure to HIV through "3 by 5" [259].

Those most at risk are teenagers who are unwilling to use condoms (in 27%–56% of cases) [110]. Unprotected sexual intercourse between men and women is the predominant mode of transmission of the virus. In addition, it must be pointed out that even if the sexual act is interrupted, it is nevertheless possible to become infected, because the initial secretions contain the virus thus endangering drug addicts who postpone ART [241]. However, many studies have reported positive results with the measures taken among teenagers.

HIV infection is a disease that can be prevented very effectively. The virus is not transmitted by air, water or food, nor by 99% of human relations. As we can see from Table 23.40 [80, 123, 196, 465], all commonplace items can be used without any danger and all normal situations can be faced unreservedly. These data come from specific studies [465] and have been checked with observations that have cumulatively lasted several decades [196]. The preventive measures listed in Table 23.41 [80, 505] are not associated with any type of risk, in the sense that in school workers the possibility of contracting AIDS by assisting an HIV+ student is no different than the risk of health workers in the broadest sense. The risk is virtually wiped out by applying minor precautions that are universal and are simply common sense, to be adopted in all cases in which assistance implicates potential contact with contaminated blood. Breast milk is expressed manually or by a breast-pump and subjected to pasteurization by boiling and inactivating by heat (over 60 °C) for 30 min, which kills the virus. This cannot be used at the individual level, but it is important for breast milk banks to avoid HIV infection [80, 277].

Nutritional Support

A priority aspect we previously mentioned is *malnutrition*: the digestive symptoms aggravate the nutritional disorders, which reflect negatively on HIV infection [84]. This can be prevented with complex intervention using food supplements, to be established in the hospital and continued at home.

PI-treated children should be given supplemental vitamin D preparations because PI medications may markedly suppress the activities of 25- and 1α-hydroxy-

Table 23.41. Seropositive children: possible HIV infection transmission to schoolmates

Schools, daycare centers etc.
There is no risk for teachers, school staff and other children. Several studies have demonstrated that no community runs risks by adopting the well-known preventive hygienic measures.
In particular, children may touch their schoolmates, exchange effusions, and play with them, but if children play with bodily fluids, they should wash the hands immediately with soap and warm water for 10 s (same principles universally valid).
During campaign of dental prevention, each child should use an individual toothbrush.
Precautionary measures to be adopted in daycare centers and/or school
Open cuts and sores of whatever type should be completely covered with waterproof medications.
The school should be given vinyl/silicon gloves and disinfectants (1:10 or 1:100 NaCl, chlorhexidine, etc.).
School personnel caring for children should wash thoroughly after having changed or washed the child with gloves and should be preventively trained in proper disinfecting techniques to be utilized in case of wounds and/or spontaneous hemorrhages.
Avoid the promiscuous use of blood-contaminated objects of whatever type.
Thorough prevention against exposure to blood should be followed.
Specific attention should be paid to protect young children, who may be unable to prevent such exposures on their own.
Areas in the daycare center should be selected for the temporary or ongoing care of young victims of injury or illness.
When a seropositive child requires emergency medical care, personnel should know to which hospital he could be admitted.
General hygienic measures
Dishes and flatware can by cleaned with warm water or dishwasher by using a common detergent.
Laundry can usually be washed with warm water (60 °C) or in a washing machine.
Daily cleaning of the rooms does not require special precautions: walls, floors and other surfaces alike are not associated with HIV infection transmission; if surfaces appear to be contaminated by blood or other biological fluids, diluted NaCl is sufficient, as above.

Immunosuppressed children may be at increased risk of having serious complications of infectious diseases, even trivial. Data from [80, 505].

lase, which are critical in 1,25(OH) D synthesis, while exerting mild inhibition of 24-hydroxylase, responsible for 1,25(OH) D catabolism. Defective 1,25(OH) D production could contribute to the bone demineralization in HIV children [131].

Social Considerations

In disseminating information, the preferable course of action is one that is widespread at various levels, to be handled by qualified experts. This should involve the establishment of centers to provide information and advice to users from different extractions (but organized with a DB method to guarantee maximum privacy), as well as equally anonymous centers that test the samples of anyone who contacts them. In these cases, *discretion is a top priority* and it has been observed that patients prefer to receive delicate information in neutral places like the office or private places like their own home, rather than at the doctor's office [571]. In 73.5% of cases, young people aged 14–20 have obtained helpful information from television and/or radio, and in 73.3% of cases they feel no doubts and/or fears of becoming infected after sex. The majority of female college students (71.5%) have *discussed AIDS with their friends,* while discussion with siblings, parents and teachers was not common [181]. Adolescent females were found less knowledgeable about HIV [449] (Tables 23.42, 23.43). In 67.5% of cases, they are faithful to their partner (Tables 23.44, 23.45). However, Table 23.45 highlights a serious aspect of the falseness factor: a study conducted on 665 subjects of both genders revealed that 34% of men and 10% of women lie to ensure sexual relations [115].

Management of the HIV^+ child is important, and as always, the pediatrician plays a leading role. We have demonstrated that these children, for whom survival studies suggest that a large percentage also reach the age of socialization and schooling, are youngsters who are the same as others on the outside and are not a danger for anyone. Instead, there is a higher risk of exposing the immunodepressed child to infectious diseases, even commonplace ones (Table 23.41). Among persons living with HIV/AIDS individuals, the impact is particularly hard on girls and young women: the burden of care usually falls on them. *Girls drop out of school to care for sick parents or for younger siblings.* Young women often take on the burden of caring for ailing parents and later, when they die, adopt the parental role for the orphaned children. They are often also responsible for producing an income or food crops. In addition, young women caring for orphans and sick children may be isolated socially because of AIDS-related stigma and discrimination [259].

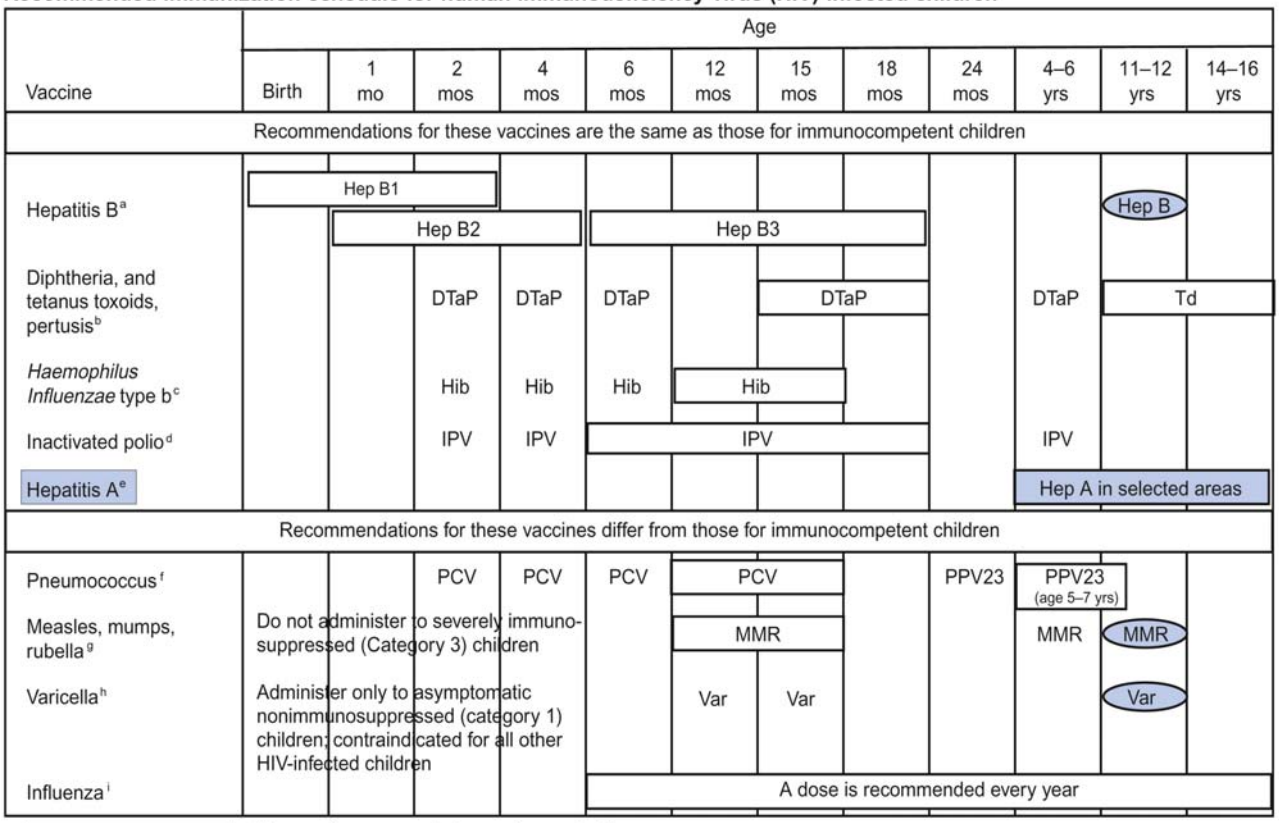
Data from [115].

Recommended immunization schedule for human immunodeficiency virus (HIV)-infected children*



Range of recommended ages for vaccination

Vaccines to be administered if previously recommended doses were missed or were administered at other than the recommended minimum age

Recommended in selected states or regions

* This schedule indicates the recommended ages for routine administration of licensed childhood vaccines as of November 1, 2000, for children aged birth–18 years. Additional vaccines might be licensed and recommended during the year. Licensed combination vaccines might be used whenever any components of the combination are indicated and the vaccine's other components are not contraindicated. Providers should consult the manufacturer's package inserts for detailed recommendations.

[a] Infants born to hepatitis B surface antigen (HBsAg)-negative mothers should receive the first dose of hepatitis B vaccine (Hep B) at birth and no later than age 2 months. The second dose should be administered ≥1 months after the first dose. The third dose should be administered ≥4 months after the first dose and ≥2 months after the second dose, but not before age 6 months. Infants born to HBsAg-positive mothers should receive Hep B and 0.5 mL hepatitis B immune globulin (HBIG) ≤12 hours after birth at separate sites. The second dose is recommended at age 1–2 months and the third dose at age 6 months. Infants born to mothers whose HBsAg status is unknown should receive Hep B ≤12 hours after birth. Maternal blood should be drawn at delivery to determine the mother's HBsAg status; if the HBsAg test is positive, the infant should receive HBIG as soon as possible (no later than age 1 week). All children and adolescents (through age 18 years) who have not been immunized against hepatitis B should begin the series during any visit. Providers should make special efforts to immunize children who were born in, or whose parents were born in, areas of the world where hepatitis B virus infection is moderately or highly endemic.

[b] The fourth dose of diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) can be administered as early as age 12 months, provided 6 months have elapsed since the third dose and the child is unlikely to return at age 15–18 months. Vaccination with tetanus and diphtheria toxoids (Td) is recommended at age 11–12 years if ≥5 years have elapsed since the last dose of diphtheria and tetanus toxoids and pertussis vaccine (DTP), DTaP, or diphtheria and tetanus toxoids (DT). Subsequent routine Td boosters are recommended every 10 years.

[c] Three *Haemophilus influenzae* type b (Hib) conjugate vaccines are licensed for infant use. If Hib conjugate vaccine (polyribosylribitol phosphate-meningococcal outer membrane protein [PRP-OMP]) (PedvaxHIB® or ComVax™ [Merck and Company, Inc., Whitehouse Station, New Jersey]) is administered at ages 2 and 4 months, a dose at age 6 months is not required. Because clinical studies among infants have demonstrated that using certain combination products might induce a lower immune response to the Hib vaccine component, DTaP/Hib combination products should not be used for primary immunization among infants at ages 2, 4, or 6 months, unless approved by the Food and Drug Administration for these ages.

[d] An all-inactivated poliovirus vaccine (IPV) schedule is recommended for routine childhood polio vaccination in the United States. All children should receive four doses of IPV at age 2 months, age 4 months, ages 6–18 months, and ages 4–6 years. Oral poliovirus vaccine should not be administered to HIV-infected persons or their household contacts.

[e] Hepatitis A vaccine (Hep A) is recommended for use in selected states or regions and for certain persons at high risk (e.g., those with Hepatitis B or C infection). Information is available from local public health authorities.

[f] Heptavalent pneumococcal conjugate vaccine (PCV) is recommended for all HIV-infected children aged 2–59 months. Children aged ≥2 years should also receive the 23-valent pneumococcal polysaccharide vaccine; a single revaccination with the 23-valent vaccine should be offered to children after 3–5 years. Refer to the Advisory Committee on Immunization Practices recommendations (see CDC. Preventing pneumococcal disease among infants and young children: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 2000;49[No. RR-9]:1–38) for dosing intervals for children starting the vaccination schedule after age 2 months.

[g] Measles, mumps, and rubella (MMR) should not be administered to severely immunocompromised (category 3) children. HIV-infected children without severe immunosuppression would routinely receive their first dose of MMR as soon as possible after reaching their first birthdays. Consideration should be given to administering the second dose of MMR at age 1 month (i.e., a minimum of 28 days) after the first dose rather then waiting until school entry.

[h] Varicella-zoster virus vaccine should be administered only to asymptomatic, nonimmunosuppressed children. Eligible children should receive two doses of vaccine with a ≥3-month interval between doses. The first dose can be administered at age 12 months.

[i] Inactivated split influenza virus vaccine should be administered to all HIV-infected children aged ≥6 months each year. For children aged 6 months–<9 years who are receiving influenza vaccine for the first time, two doses administered 1 month apart are recommended. For specific recommendations, see CDC. Prevention and control of influenza: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR 2002;51(No. RR-4):1–32.

Fig. 23.27. Recommended immunization schedule for human immunodeficiency virus (HIV)-infected children

Vaccinations

The opinion on whether or not it is appropriate to vaccinate children with AIDS does not diverge from the criteria commonly applied in the active immunoprophylaxis for the pediatric population at large [13] (Fig. 23.27). Children in whom the infection is asymptomatic must be vaccinated according to the usual calendar. For the others, including symptomatic ones, as a rule the recommendation is to *avoid using vaccines composed of viruses or attenuated live bacteria* (antipolio, BCG) and to prefer the inactivated antipolio vaccine, such as the Salk vaccine [321]. Triple vaccines against diphtheria-pertussis-tetanus and measles-mumps-rubella (MMR) can be administered according to the usual schedule (12–15 months) to HIV-infected children without any risk of complications, with a booster dose at 4–6 years [321]. MMR can be anticipated (before 15 months) in the event of exposure to the measles virus: in this case, the vaccine must be repeated at 15 months. The measles vaccination is recommended in HIV-infected children despite the concern about administering a vaccine with live viruses to an immunocompromised host [56]. In children with a symptomatic HIV infection, the antibody titer to the above vaccines generally tends to drop as the infection continues, until it no longer reaches protective levels. In the severely immunocompromised child (based on CD4 percentage counts) and also in HIV-exposed or HIV-infected children, in case of contact immediate prophylaxis is advised with hyperimmune γ-globulins, unless IVIg was administered in the previous 3 months. In the case of measles, if exposed the HIV^+ child may benefit from immunization if administered within 72 h of exposure, or from γ-globulins even within 6 days following exposure [56]. In the event of contact with subjects affected with other infective diseases, the child with symptomatic HIV infection, even if vaccinated, can be given immediate prophylaxis for whooping cough, diphtheria and *Haemophilus influenzae* with macrolides, penicillin and rifampicin, respectively [56]. The influenza vaccine must be administered regularly to HIV-infected children who are at least 6 months old or who live with infected people; the antipneumococcal vaccination must be given at the age of 2, while the *chicken pox vaccine is not recommended for these children*. Notably, HIV-infected children undergoing stable HAART with $CD4^+$ cell counts of 25% or higher and lower viral loads at the time of vaccination developed a higher additional clinical protection gain from 23PSV vaccination than did children with a lower percentage of $CD4^+$ cells [534]. If one person in the household has been vaccinated and develops a rash, contact must be avoided until the rash disappears. In a study to determine the safety and immunogenicity of varicella vaccine in 41 children with HIV infection who were mildly affected by HIV (CDC stage N1 or A1) and had no history of prior varicella infection and had negative titers, they were immunized with two doses of live attenuated varicella vaccine separated by 3 months [329]. Only a minority of the vaccine recipients had mild local or systemic reactions. In HIV-exposed or HIV-infected children, or in not definitively diagnosed children, it is advisable to utilize anti-varicella hyperimmune γ-globulins within 72 h of exposure, unless IVIg has been administered in the previous 3 months [13].

Medical and Legal Aspects

Table 23.46 [80] summarizes the child's position, a lawful subject/object with regard to AIDS. We must recall that the law bans any type of third-party ascertainment without the child's knowledge and, therefore, many medical actions can be performed with informed consent, as we clarified in Chap. 6. As with all other cases, information about case history must be requested from the parents or legal guardians, who should be informed of diagnoses and/or the need to proceed with additional testing. Naturally, what we have pointed out in the preceding section indicates that there is no risk to health personnel and nurses as a result of tests performed on an HIV-positive child and these checks do not differ from normal medical services. If necessary, all health personnel should wear vinyl gloves or masks and so on for normal procedures. Likewise, they should disinfect surfaces contaminated with blood and/or body fluids. Only two activities are prohibited by law: refusal to assist the patient and the disclosure of patient information to third parties.

Table 23.46. The child subject/object of rights and HIV infection

The child, at birth, is a citizen (with full rights) and a minor (object of protection)
The neonate-citizen benefits from the right to live
The HIV-infected neonate/child-citizen benefits from a limited right to live
The neonate/child-citizen cannot come to conscious anti-AIDS decisions
HIV exposure is damage from a third party:
In utero transmission
Perinatal transmission
Postnatal transmission
Others
Specific juvenile legislation regarding infantile HIV infection is lacking
The HIV-infected/seropositive minor may be the innocent recipient of prejudice deriving from the disease

Data from [80].

Pediatricians and HIV-Positive Children

Pediatricians who must face emerging clinical problems and everything they entail such as the need to establish specific ART and promptly prevent complications using the appropriate instruments, or who must urgently step in to handle current complications, must cope with the need to ensure a satisfactory *quality of life* as long as possible. We are the advocates of simple and basic measures, and we believe that the best actions for prevention and information begin at the base, for example, at home, at day-care centers, at school, at work, etc. History has taught us that important battles are won not so much for the general ability, soldiers' bravery, or effective weapons, as for the importance given to preparation, equipment, and field knowledge. In this sense, everything possible must be tried for these toddlers, children and adolescents, *whose label as pariahs is palpable*. At the same time, we should reflect on the outstanding results that have been achieved in Ireland, where for 4 years, not one HIV-infected child has been born to an HIV^+ mother treated during pregnancy and childbirth, to the point that a number of HIV^+ women want to have more children. And yet recent data [565] offer the option of stepping in even at the last minute, a first task reinforcing the pediatrician's functions. AIDS has also taught us that fixed concepts can be subjected to a 360° revolution. During the early 1980s, when the first perinatally acquired AIDS cases were documented, HIV infection in the greater part of children progressed rapidly to death. Now, the number of HIV-infected females who are becoming both sexually active and pregnant is increasing [181]. This underscores the need for early disclosure of HIV status to infected adolescents of both sexes and for increased discussions about sexual risk reduction among all perinatally infected adolescents [598], especially adolescent females [449], a second task reinforcing the pediatrician's functions.

Primary Immunodeficiencies

A World in Motion

Primary immunodeficiencies (PIDs), once considered to be very rare, are now increasingly recognized because of growing knowledge in the immunological field and the availability of more sophisticated diagnostic techniques and therapeutic modalities [161]. However in a database of >120,000 inpatients of a general hospital for conditions suggestive of ID 59 patients were tested, and an undiagnosed PID was found in 17 (29%) of the subjects tested [107]. The publication of the first case of agammaglobulinemia by Bruton in 1952 [60] demonstrated that the PID diagnosis is first done *in the laboratory*. However, PIDs require specialized immunological centers for diagnosis and management [33]. A large body of epidemiological evidence supports the hypothesis of the existence of a close etiopathogenetic relation between PID and atopy [73]. In particular, an elevated frequency of asthma, food allergy (FA), atopic dermatitis and enteric pathologies can be found in various PIDs. In addition we will discuss another subject that is certainly of interest: the pseudo-immunodepressed child with recurrent respiratory infections (RRIs), an event that often requires medical intervention and that very often leads to the suspicion that it involves antibody deficiencies [149].

Immunodeficiency and Atopy

In several PIDs (Table 22.1) [61, 65, 76, 101, 162, 351, 414, 480, 514, 543], atopic symptoms are present: gastroenteric and rhinitis in selective IgA deficiency (SIgAD), severe AD in Wiskott-Aldrich syndrome (WAS) and hyper-IgE syndrome (HIgES), in which it spreads over the entire body, and to which other allergic manifestations can also be associated such as asthma, rhinitis and angioedema. Various acquisitions indicate that PID is also an *opsonization deficiency*, observed in 5% of the normal population [469]. In this disease, microorganism phagocytosis by polymorphonuclear (PMN) leukocytes appears annulled, and the patient is subject to severe infections supported by capsular bacteria: the deficiency, described in association with severe and recurrent infantile infections [175, 485, 487], depends on the lack of mannose-binding lectin (MBL) [487], its structural genes, and also perhaps on the lack of 2/4 C4 genes [506]. MBL deficiency is due to one of three point mutations in the gene for MBL, each of which reduces levels of the lectin by interfering with the protein oligomerization [351]. In children with this kind of deficiency, the level of MBL is 4.9 µg/l compared to the 143 µg/l in controls [487]. Regardless of whether the children are homozygote (HZ) or heterozygote (HET) in relation to a given mutation, the defect appears to be more consistent in small babies aged 6–18 months [487], who show an immaturity in providing immune response to capsular bacteria and in whom low levels of opsonin are incapable of compensating for this [506]. The risk of contracting infections is similar in HZs [175] and HETs [486], though it persists throughout life in HZs because of an abnormal allele, while it exhausts itself in the HETs, where the frequency of abnormality is similar to that of the general population [175]. Anomalies in immunoglobulins (Ig) and in opsonization have been observed, respectively in 13%–20% of children suffering from frequent asthma and IgG subclass deficiencies. Children suffering from *cystic fibrosis* also present an elevated prevalence of immediate cutaneous reactions to aeroallergens, and although without primary defects of adoptive immunity, they are susceptible to severe RRIs; therefore it may be possible that they suffer from the mucosal antigenic exclusion [61]. Unlike asthmatic children, in whom a relatively high concentration of IgE for respiratory viruses was observed [172, 173, 457], positive skin prick tests (SPTs) are more common for *Aspergillus fumigatus* [61].

The hypothesis suggested by these observations is that atopy derives from an unbalanced immune response to foreign antigens, with a consequent lack of their early identification or the capacity to neutralize or eliminate them. This hypothesis is based on the evidence that ID precedes the development of atopy: in the Taylor et al studies, 22 newborn babies, the children and/or siblings of atopic patients, presented a significant reduction in serum concentrations of IgA when aged 3 months: this was *transient hypogammaglobulinemia (hgG) of infancy* (THI). The association of very low IgA levels with atopy has been proposed again in the classic prospective study on the association of viral respiratory infections (VRI) and the onset of allergic manifestations, which proved serum IgA levels at the lowest normal levels in the children studied [173]. This data has been confirmed within

a possible atopy dependence on IgA underproduction rather than on IgE hyperproduction (Fig. 4.1): in children with levels of IgA at the minimum normal level, and followed from birth until the age of 18–23 months, a greater severity of atopic manifestations and an increased cumulative incidence of asthma, AD and otitis media with effusion (OME) were observed compared to controls.

The close links between ID and atopy are confirmed by *symptoms similar to AD* present in some forms of WAS (70%), HIgES (85%), XLA (X-linked agammaglobulinemia) or autosomal recessive (AR), ataxia-telang-

Table 22.2. Serum IgE concentrations (U/ml) in patients with PID

PID	No.	Age	Range (U/ml)	GM
Ataxia-telangiectasia	7	5–14 y	<1–54	7

iectasia (ATA), thymic alymphoplasia, SCID (severe combined ID) (48%) [44] and, occasionally, by DiGeorge syndrome (DGS), ID with hyper-IgM (HIgMS) now CD154/CD40L deficiency, selective IgM deficiency, biotin-dependent carboxylase deficiency, CGD (chronic granulomatous disease), primary neutropenia, and in Netherton, Nezelof, Omenn and Shwachman syndromes [434]. Other forms, in addition to those discussed, are associated with *gastrointestinal symptoms*: diarrhea and malabsorption of XLA and THI, diarrhea in WAS and DGS, food-related allergies (43%) in SIgAD and also an elevated frequency of asthma [36]. Among *secondary ID*, only AIDS is associated with AD (Chap. 23).

Immunodeficiencies Associated with Hyper-IgE

The association between a deficiency of T cells and high levels of IgE, observed in patients with HIgES, Nezelof syndrome, ATA, WAS and other diseases, has been known for some time (Table 22.2) [62]. Experimental studies on animals indicate that there may be an inverse correlation between serum IgE levels and T-cell functions: this could be attributed to a T-lymphocyte deficiency in atopics, genetically determined, which makes them more vulnerable to the cAMP inhibiting activity, and consequently causing an imbalance between the two subclasses of T cells, which could lead *to IgE hyperproduction and atopy development;* however, in no case is there evidence of a relationship between CD8 deficiency, IgE levels and allergic symptoms. It has been proposed that in these patients CD4-Th2 levels are sufficient for modulating IgE synthesis, but CD8 T-cell levels are inadequate for inhibiting IgE synthesis, which results in increased IgE synthesis. This hypothesis is supported by the observation that Omenn syndrome, WAS and especially HIgES, with an immunological phenotype characterized by a quantitative and qualitative reduction of CD8 T cells, are accompanied by extremely high levels of serum IgE [61, 162, 196]. Lymphocytes in subjects with normal levels of IgE are incapable of producing them, not even after stimulation with polyclonal activators such as PWM (pokeweed mitogen) or EBV (Epstein-Barr virus), while patients with high antibody levels spontaneously synthesize in culture sIgE (specific) levels between 200 and 2,000 pg/ml, also releasing factors capable of increasing IgE secretion (IgE-PF) [287]. Supernatant derivatives from the T cells of patients with HIgES are in fact capable of inducing in vitro the pre-B cells to increase IgE production; furthermore, when the T lymphocytes in these patients are isolated on the basis of receptors for the IgE Fc fragment, the remaining cells release IgE-PF [287]. Considering the suppressive activity of human lymphocytes with CD8 phenotype on sIgE, it has been observed that these lymphocytes are able to suppress sIgE synthesis in patients with high antibody levels; similarly $CD8^+$ cells from a bone marrow transplant (BMT) can suppress IgE production in the HLA-compatible recipient [478]. The study of patients with ID associated with hyper-IgE has supplied useful information concerning IgE system biology, although the immune defect essentially responsible for IgE increased production and for severe atopic

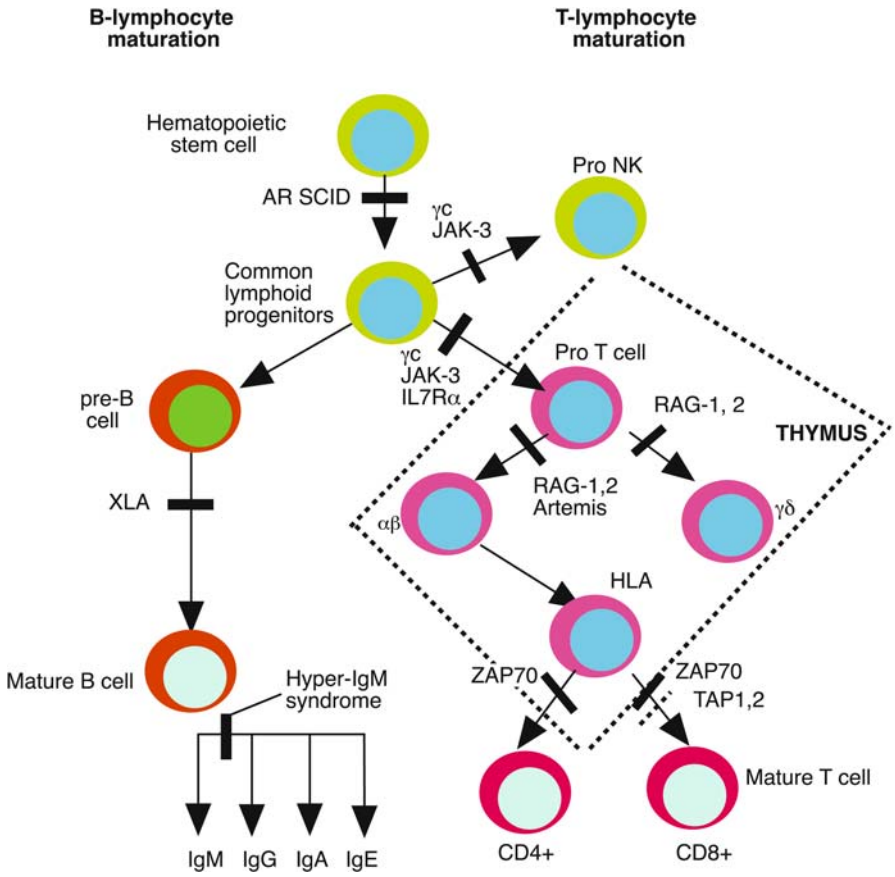

Fig. 22.1. Pathogenesis of some PIDs based on B and T lymphocyte maturation (fully analyzed in Chap. 2).The *bars* indicate where maturation is blocked, thus evidencing the main molecular defects of the related PID. (Modified from [413])

manifestations has not yet been identified. The most interesting syndromes from this point of view are the three syndromes analyzed above, characterized by common clinical indications such as early AD onset, increased susceptibility to all varieties of pathogens, as well as an exceptionally high IgE serum level [162, 394] (Table 22.2).

Immunodeficiency with Autoimmunity

Several PIDs have autoimmune features, including Chédiak-Higashi syndrome, CGD, complement deficiencies C1q, C1r, C1s, C2, C4, Griscelli syndrome, HIgMS (CD154 deficiency), LAD (leukocyte adhesion deficiency), HLA class I deficiency, HLA class II deficiency, Omenn syndrome, WAS, and XLP (17), which will be dealt with subsequently. In 25 children with a mean age of 44 months, autoimmunity was chronic and severe requiring prolonged immunosuppression, however with no spontaneous remission of such manifestations [44].

Primary Immunodeficiencies

Definition

PIDs (Fig. 22.1) [413] consist of a heterogeneous spectrum of congenital, individual and combined anomalies of the immune system (humoral deficiencies, combined deficiency of B and T cells, the complement, phagocytes, neutrophils, etc.), as well as syndromes and diseases associated with ID that are traditionally classified as PIDs. The updated classification (Table 22.1) has divided ≈100 PIDs into six main groups, also including secondary ID with infections (first among them all AIDS) that cause deficiency and immunosuppression [414]. The classifications of PIDs is based on characteristic clinical features and specific alterations in immune status. Advances in molecular genetics now make it possible to complete the table according to the types of genetically altered molecules involved [63]. To complete this data, see Table 22.1 and Table 22.3 [236, 246, 407, 453] showing the behavior of antibodies and circulating B and T cells.

Table 22.3. Characteristics of B and T lymphocytes and serum Ig in PID

Disorder	Antibody	B lymphocytes	T lymphocytes
A. Primary antibody deficiencies			
1. X-linked agammaglobulinemia	All isotypes ↓	–	
2. Hypogammaglobulinemia with hyper-IgM	N ↑ IgM, other isotypes ↓	+ (B_{IgM} and B_{IgD})	
3. Gene deletion for H chains	Various subclasses ↓	N	
4. κ/λ chain deficiency			
5. Selective IgG subclass deficiency	Various subclasses ↓	N or immature	
6. Antibody deficiency with normal Ig levels	N	N	
7. Common variable ID	Various or all isotypes ↓	N/↓	
8. Selective IgA deficiency	IgA ↓	+ or immature	
9. Transient hypogammaglobulinemia of infancy	IgG, IgA ↓	+ or immature	
B. Combined T-cell and B-cell deficiency			
10. Severe combined ID (SCID)

C. Other well-defined immunodeficiency syndromes			
17. Wiskott-Aldrich syndrome	IgM↓ IgE↑	N	↓
18. Ataxia telangiectasia	↓/variable	N	↓
19. DiGeorge syndrome	N/↓	N	N/↓

Some PIDs in the literature are indicated without number.
Data from [236, 453]; other data from [246] (Omenn syndrome) and [408] (JAK3).
ADA adenosine deaminase, *ID* immunodeficiencies, *JAK* Janus-family kinase, *PNP* purine nucleoside phosphorylase, ↓ decreased, ↓↓ markedly decreased, ↑ increased, – absent, + present, *N* normal.
[a] Progressive.
[b] Not functional.

Epidemiology

Data concerning incidence has increased considerably thanks to a greater availability of specific tests and more widespread knowledge in the medical profession related to these PIDs, including ATA [94]. However, because PIDs occur infrequently and are highly heterogeneous in nature, relatively few centers gain extensive experience in the diagnosis, so it is difficult to estimate the prevalence of these disorders from routinely collected health statistics [33]. Studies in 13 countries on all continents have included 10,895 patients: Tables 22.4 and

Latin America includes eight countries.
XLA X-linked agammaglobulinemia, *CVID* common variable immune deficiency, *THI* transient hypogammaglobulinemia of infancy, *SCID* severe combined ID, *WAS* Wiskott-Aldrich syndrome, *ATA* ataxia-telangiectasia, *CGD* chronic granulomatous disease.

22.5 report the incidence of the main PIDs in 13 countries (the US and Japan twice) and all continents [33, 35, 41, 141, 151, 200, 214, 236, 297, 299, 321, 425, 472, 525, 550]. High incidences were also found in Colombia [352] and Singapore [292], especially of antibody (IgA) deficiency. Among 172 infants with SCID, consecutively seen, 45.9% had X-linked SCID with mutations of γc receptor, 16.3% ADA deficiency, 9.9% AR, 9.9% IL_7R deficiency, 6.4% Jak3 (Janus kinase 3) deficiency 0.6% reticular dysgenesis, 0.6% cartilage hair hypoplasia,

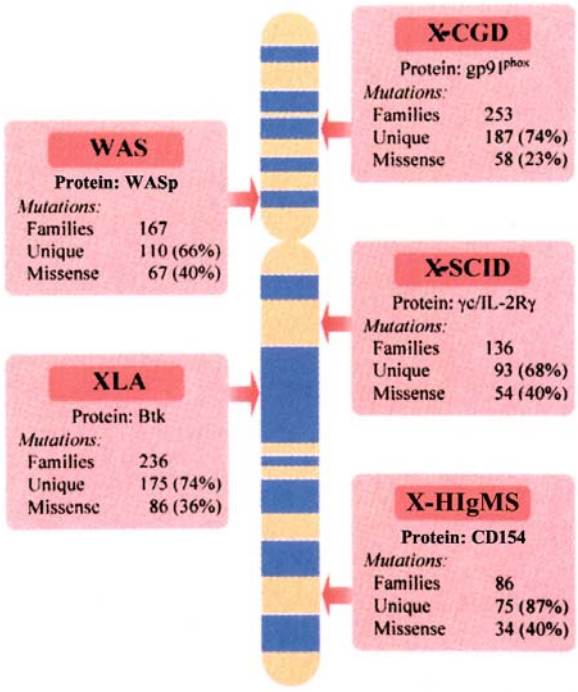

Fig. 22.2. Schematic representation of chromosome X with five X-linked PIDs. *phox* Phagocyte oxidase, *Btk* Bruton's tyrosine kinase, *SCID* severe combined immunodeficiency, *WAS* Wiskott-Aldrich syndrome, *WASp* Wiskott-Aldrich syndrome protein, *X-CGD* X-linked chronic granulomatous disease, *X-HIgMS* X-linked hyper-IgM syndrome, *XLA* X-linked agammaglobulinemia

11% unknown mutations, 2.9% RAG deficiency, 1.2% Artemis [67], 11.1% SCID of undetermined type [68] and 2.2% IL_7R deficiency [69]. Over 20 years, 400 cases were found in Iran, a country with 62.3 million inhabitants, with an incidence of 3.3×10^5 [1]. Predominantly antibody deficiency were found in 45.9% of patients, phagocytic disorders in 29.09%, T-cell disorders in 24.31%, and complement deficiencies in 0.68% [1]. The comparison with Norway data is interesting: antibody deficiencies total 50.8%, combined deficiencies including other ID syndromes 12.4%, complement deficiencies 21.0%, phagocyte disorders 6.7%, and ID associated with other congenital diseases 9.1%. With a population of 4.45 million people, the total prevalence of 302 PID-affected in Norway in 1999 is 6.7×10^5 inhabitants [482]. Not all studies report the range of years during which the patients were found. However, an average incidence of 1×10^5 is seen as acceptable [101], with the exception of SIgAD, in which it varies between 1×300 and $1 \times 20{,}000$ [367]. SCID has an incidence of 1×10^6 [462] or 1.5×10^6 [514]. *The age of onset at diagnosis* is classified as follows: 40% during the 1st year, 40% by the 5th year, 15% by the age of 16 and 5% in adults [101]. In a retrospective study during a 20-year period, antibody deficiencies were found in 52.6%, T-cell disorders in 24.69%, phagocytic disorders in 22.2% and complement deficiencies in 0.4% of 130 children. Common variable immunodeficiency (CVID) was found in 50%, ATA in 30%, XLA in 25.3%, CGD in 22.3% and SIgAD in 15.4% of children [149].

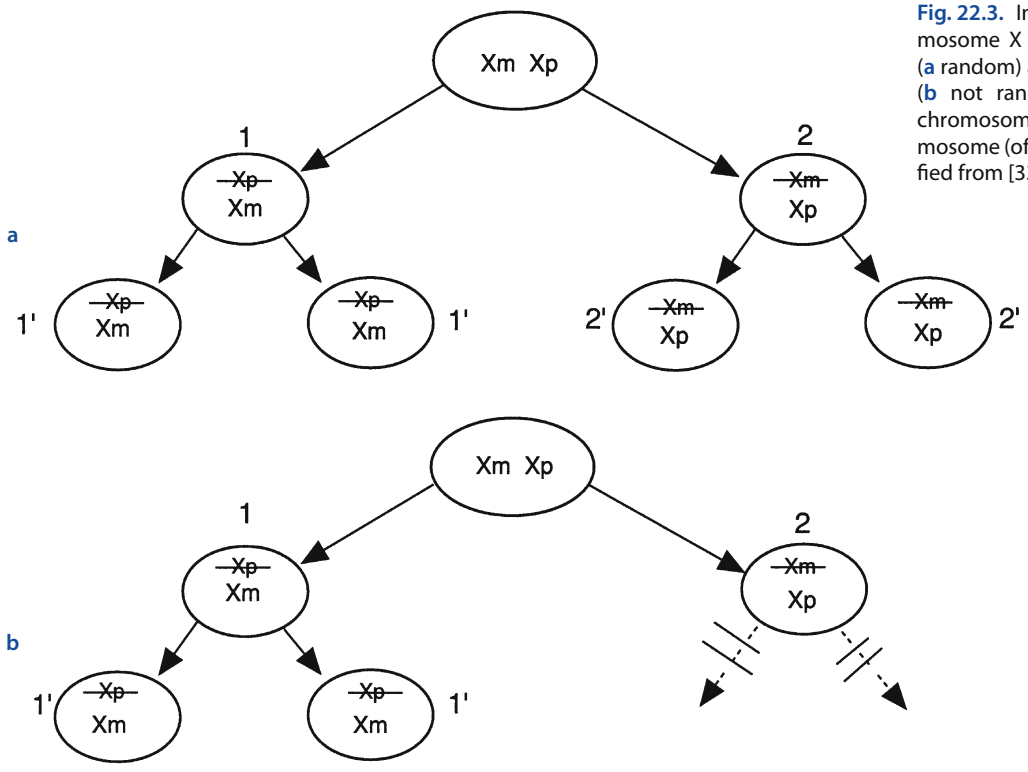

Fig. 22.3. Inactivation of chromosome X in normal women (**a** random) and carrier women (**b** not random). *Xm* normal chromosome, *Xp* carrier chromosome (of mutations). (Modified from [335])

General Characteristics

The genes responsible for ID linked to chromosome X have been recently mapped on the respective chromosome bands (Fig. 22.2): the bands on the short limb are designated "p" and those on the long limb "q" (Table 22.1). This was possible thanks to the refinement of DNA recombinant technology (rDNA), including DNA probes (sequences of radio-marked DNA) and restriction fragment length polymorphism (RFLP). The closer the gene segregates to RFLP, the lower the chance that they might be separated by recombination phenomena when meiosis occurs: the identification of deficient genes allows early diagnosis, even prenatal, and if necessary gene therapy or BMTs [76]. Furthermore, the observation that numerous PIDs are transmitted with an X-linked modality allows a relatively simple diagnosis of males with a positive family history (FH); if FH is negative (40%–50% of XLA cases) or there are females presenting a clinical pattern of PID, or when sporadic cases are caused by a new mutation, carrier identification is based on the study of immunologically normal female carriers, with two populations of B precursors, using X-chromosome inactivation analysis. This test does not take into account the existence of possible gene mutations and the availability of already affected relatives, and it is also relatively simple and fast [537]. Molecular studies follow the hypothesis that, at an early stage during embryogenesis, one of the two X chromosomes is randomly inactivated in the cells of all tissues of female embryos (persisting as Barr's chromatin) [300]. Therefore in normal conditions, one has a cell mosaic that actively expresses for 50% the paternal X chromosome and for the remaining 50% the maternal X chromosome (lionization) [300] (Fig. 22.3a) [355]. In female carriers of XLA, the cell mosaic expresses 50% for an X chromosome with Btk in an active form and the remaining 50% for an X with a mutated Btk (Bruton tyrosine kinase). This means that in the carrier mother it is inactivated in preference to the X chromosome carrier of the defective gene in B, which matures therefore in an unbalanced manner (not randomly), while in all other cells activation occurs randomly. It follows that in fixed carriers only the B lymphocytes that have the X carrier of a normal gene complete the differentiating route, while the precursors that express the X chromosome with a mutated Btk do not mature into B cells, but remain blocked [100, 413] (Fig. 22.3b). In X-SCID, the study of fixed carriers follows the corrected Lyon hypothesis, because the cells with a normal active X develop into normal T lymphocytes; however, when T precursors with a mutant X reach the stage where the X is needed, they do not find it and consequently do not develop: thus female carriers have only one normal and active X, instead of the random mixture of cells with one of the two active X [389]. The inactivation test appears to be reliable and can also be used for other recessive X-linked PIDs to identify cell lines with genetic defects, as is the case of WAS [537]. One must, however, properly consider the phenomenon of mutations, that can render useless the inactivation method, as has been proved in WAS, in XLA and also in SCID, in which the mutation is not in the maternal T cells but in the germlines [389]. The main clinical aspects of humoral and cellular PID are schematized in Table 22.6 [80]; further in numerous PIDs there is a deficiency of chemotaxis (Table 1.65) as in CGD [416]. In antibody deficiencies, current treatment, while waiting for genetic treatment to become available, complicated in XLA by several Btk mutations, is based on the prophylactic administration of IVIg, combined with quick antibiotic treatment during infectious episodes.

Table 22.6. Clinical data of humoral and cellular ID

Clinical data of humoral ID
Chronic sinusitis, otitis, enteritis
Chronic sinopulmonary infection leading to bronchiectasis and respiratory insufficiency
Recurrent infection with high-grade extracellular encapsulated pathogens
Growth retardation not evident
Palpable lymphoid and nasopharyngeal tissue is scarce in X-linked agammaglobulinemia
Increased incidence of autoimmune disorders and malignancies
Survival to adulthood or for several years after onset of the condition may occur[a]
Clinical data of cellular ID
Intractable diarrhea, pneumonia, thrush, growth retardation, failure to thrive
Severe, recurrent infections with low-grade or opportunistic infectious agents such as fungi, viruses, or *Pneumocystis carinii*
Sepsis, meningitis, mastoiditis, otitis, and abscesses
Absence of lymph nodes and tonsil tissue
High incidence of malignancies
Short life span[a]
Susceptibility to GvH disease caused by maternofetal transfusion or if given fresh blood or plasma, or from allogeneic cell transfusion
Fatal reaction following live virus or bacteria (BCG) vaccination

Modified from [79].
BCG Bacillus Calmette-Guérin.
[a] Dependent on treatment (for details see text).

Predominantly B-Cell Immunodeficiency

X-Linked Agammaglobulinemia or Bruton Tyrosine Kinase Deficiency

Inherited in an X-linked trait, only 50% of males have a FH positive for PID; female cases are also known, supporting an AR trait [100]. Classically affected subjects present levels of IgG at <100 mg/dl, with very low circulating IgA, IgM and B cells (Table 22.3), in which are found, in addition to BM, pre-B lymphocytes in an almost normal quantity [100]. XLA is characterized by a *blocking of B-cell differentiation* that results in an arrest of the evolution of *pre-B1a cells*: low levels of cytoplasmic IgM and high levels of *surrogate light (L) chains* (CD179b) into later-stage B cells [348].The B-cell differentiation arrest in the majority of XLA patients appears to be homogeneous, with approximately 80% of the pro B-cell compartment being negative for cytoplasmic Igμ expression [349]. The size and nature of the residual more mature B-cell population (leakiness) varied among patients, independent of the type of Btk mutation. Further, it appears that the pro B-cell compartment composition in bone marrow (BM) of some XLA patients can be influenced by low levels of wild-type Btk mRNA [349]. On the contrary, T cells are normal both in function and in number, as is thymus architecture, including Hassall's corpuscles and thymus-dependent areas of spleen and lymph nodes. B lymphocyte zones are typically depleted, with an absence of GCs, plasma cells, and cortical and medullar differentiation compared to normal (Figs. 22.4 and 22.5) and an absence of adenoidal tissue (Fig. 22.6). The intestinal lamina shows a similar deficiency [227], even if both B and T cells use the same recombination (Chap. 1). In the BM, increased pre-B lymphocytes without CD19 and CD21 can be observed. The pre-B cells are capable of transcribing and translating microgram intracytoplasmic (IC) H chains, but not the L chains [453], thus pre-B only form microgram chains not associated with V_H, while only 5% of normal cells produce incomplete chains [278]. Experimental data currently indicate that the defect lies in the XLA gene mutations that codify for btk [505, 513]. The *XLA* gene is expressed by B cells during differentiation, but is not transcribed in the T cells, thereby explaining the B lymphocyte maturative block at the pre-B level [61] (Fig. 2.6), immediately after their appearance in the BM [302]. XLA, however, presents a genetic heterogeneity, explained by mutations in the 5 btk domain (PH, TH, SH3, SH2, kinase), with a frequency proportional to the pertinent domain dimensions [514]. The mutation size was ascertained by finding 175 mutations in 236 patients (Fig. 22.7). Equally, genes codifying for marker proteins and receptors that are essential for B-cell maturation and development are also involved: in fact many of these proteins, including btk, Hμ chains and surface proteins are crucial for B-cell differentiation [395]. Studying children of both sexes with XLA, various mutations of Hμ germline have been identified, in addition to deletions affecting the D, J_H and Cμ genes and other gene alterations capable of blocking H chain synthesis on B lymphocytes [548]. An equivalent molecular defect was observed in an infant girl with XLA, with differentiation block preceding the Ig gene rearrangements by early pre-B cells [316].

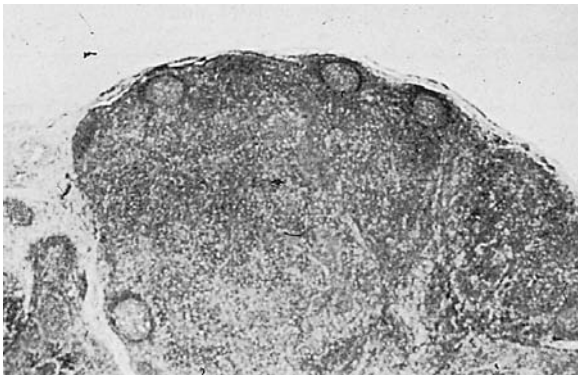

Fig. 22.4. Normal lymph node from a healthy 4-month-old boy, showing differentiation into cortex and medulla, with well-formed germinal centers (*GC*) and groups of lymphocytes

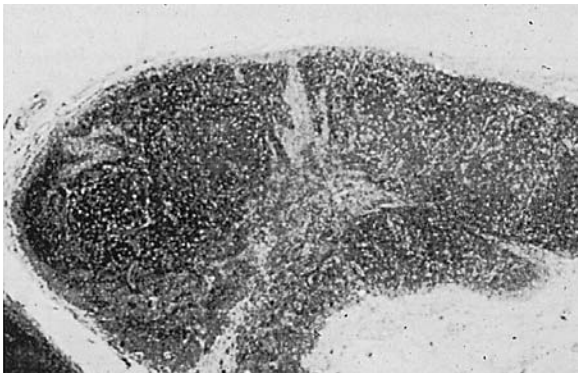

Fig. 22.5. Lymph node from a 10-year-old boy with XLA showing absence of differentiation into cortex and medulla, no GCs or lymphoid follicles and no plasma cells

There are also the so-called leaky forms, with absent or few B cells and various antibody deficiencies [240], which can be attributed to individual mutations of btk [267], for example in the non-kinase domain, which permits the expression of normal btk levels [427]. However, btk mutations can be even more detrimental for B lymphocyte proliferation compared to the total kinase absence [370]. XLA is *clinically characterized* from its onset in male babies, at 5–6 months of life (but also at the end of the 1st year), when the maternal IgG passive protection ceases. It usually attracts attention due to delayed growth and mostly recurrent and severe bacterial infections dominate (sinusitis, otitis, bronchitis,

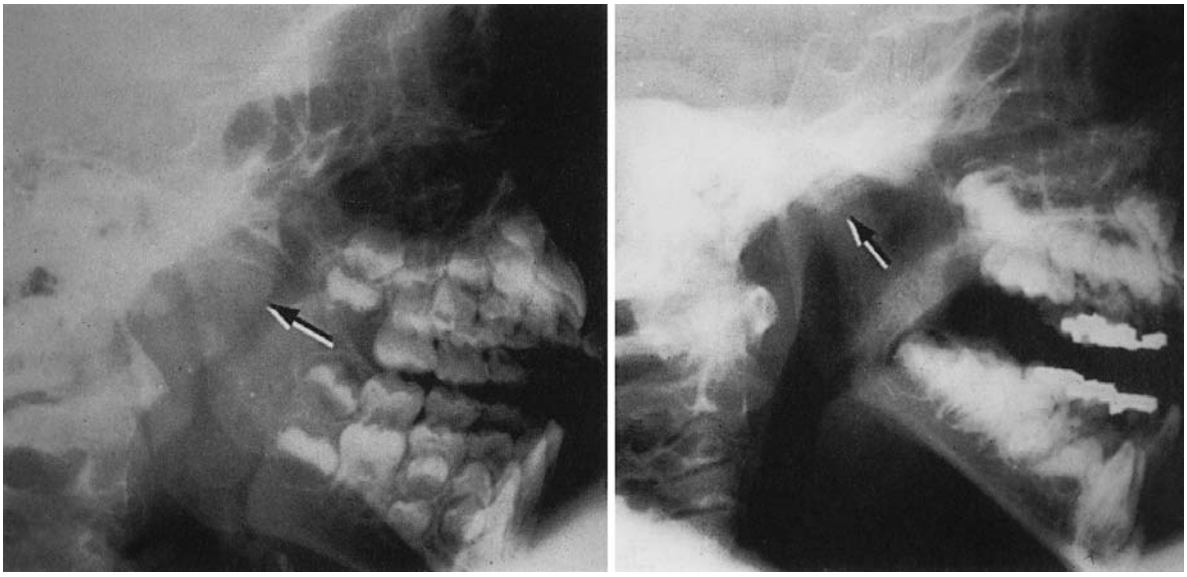

Fig. 22.6. Lateral roentgenograms of the nasopharynx: Adenoidal tissue is present in a normal 10-year-old boy (*left, arrow*), but is absent in a 10-year-old boy with XLA (*right, arrow*)

pneumonia), caused by pyogen bacteria such as streptococci, pneumococci, staphylococci and *Haemophilus influenzae*, typically capsulated and Gram+ (not by fungi, which are a T-cell competence), chronic diarrhea with malabsorption caused by *Giardia lamblia* and *Campylobacter jejuni* [61, 79, 302]. *Rotavirus* and *ECHO viruses* also cause severe meningoencephalitis in 5%–15% of patients [100]. Phenotypic variability may occasionally be present, as in a family spanning three generations [332]. In 33 patients with a median age of 9.4 years the median age at the XLA onset was 8 months and the median age of diagnosis was 4 years, with a median diagnosis delay of 33 months. The common infectious diseases were pneumonia, otitis, diarrhea, sinusitis, and arthritis. The most common chronic infections were seen in 75.8% of the patients: in the respiratory tract in 93.9%, in the gastrointestinal tract in 75.8%, in the central nervous system (CNS) in 33.3%, and in the musculoskeletal system in 21.2% of patients [324]. Bronchiectasis, malabsorption, arthritis, autoimmune and tumor-related diseases are the most common complications, as well as edema, contractures, etc. (Fig. 22.8). One must predict the onset of bronchiectasis and intervene quickly with specific physiotherapy, because forms that are initially localized later spread, causing respiratory failure in older children and adolescents. One-third of all cases start with mono- or rheumatoid arthritis (RA) caused by *Ureaplasma urealyticum* with a sterile exudate, which usually regresses following treatment with IVIg [355]. Anti-polio vaccinations with live attenuated viruses should be forbidden, because they can cause very severe pneumonia [278].

About ten cases of XLA associated with GHD are known. In addition to reduced growth, clinical symptoms are typical of XLA, though it is not a variant, because a molecular study reveals the absence of detectable mutations [476]. Although representing the phenotypic picture of humoral ID, confirmed as a separate deficiency [459], XLA associated with GHD is mapped in the same region as the X chromosome of the isolated XLA.

Gene Deletion for H Chains

The observation of HZ deletion of one or more C_H genes for the H chains of Ig in 5%–10% of normal patients has led to the identification of various polygenic deletions concerning the genes of one or more isotypes and subclasses [282, 414]. Some subjects are lacking in genes of all or some IgG subclasses, associated with IgA_1 and IgE deficiency, with no clinical symptoms in 94% of cases [282, 414]. In Italy these deletions have a frequency of 2.7% and the expected frequency in HZs is of 1:1,400 [385].

κ and λ Chain Deficiency

Only some of the families that produce λ chains and not the κ chains are known. In one family the molecular bases of the deficiency were ascribable to two different punctiform mutations, one in each *Cκ* allele that prevented the formation of -S-S bridges between the κ and H chains. The κ:λ ratio in human Ig is 2:1, and the relative alterations can be observed in numerous primary or secondary IDs [414]. Only one patient is known with an λ chain deficiency, hgG and RRI (upper and lower respiratory tract) [508]. Table 22.1 indicates the pertinent loci.

Selective Ig Deficiency

IgG Subclass Deficiency with or Without SIgAD

Sporadic cases have been described, occasionally associated with SIgAD (10%–20%) and more often with ATA (80%) and susceptibility to infections [227] or without RRIs [385], differentiating patients with probable PID from those with low levels of IgG_2 (Table 22.7) [387], in whom it may represent delayed maturation [450]. Selective deficiency of IgG subclasses presents three different aspects:

- *Total lack* of a subclass
- *Two SD levels* below average
- *Inability to produce antibodies* relative to the subclass in question, even when hematic concentrations are normal [465]

The following selective deficiencies are present [283, 465]:

- *Isolated IgG_1:* deficiency in only a few cases has been described, also because this subclass represents 60%–70% of all IgGs (the others account for 25% [IgG_2], 6% [IgG_3] and 3% [IgG_4]), its absence is very probably an indication of an evident HgG; these patients usually have a reduced level of total IgGs and react normally to antigens with a polysaccharide capsule.

Table 22.7. Age-related reference values of IgG subclasses (M + 2 SD) mg/ml in normal subjects

Age (years)	IgG_1	IgG_2	IgG_3	IgG_4
<1	2.7 (1.6–5.4)	0.83 (0.2–1.8)	0.25 (0.11–0.37)	0.05 (0.01–0.45)
1–2	3.3 (1.8–5.1)	1.12 (0.4–2.2)	0.3 (0.24–0.64)	0.12 (0.04–0.70)
3–5	4.4 (1.5–13.6)	1.5 (0.7–4.1)	0.28 (0.19–0.75)	0.28 (0.06–1.24)
6–9	4.0 (2.4–9.6)	1.8 (0.6–4.5)	0.38 (0.20–0.60)	0.35 (0.05–0.87)
10–14	5.3 (2.1–12.6)	2.8 (1.0–7.2)	0.50 (0.15–1.06)	0.51 (0.11–1.43)

Fig. 22.7 a,b. Domain organization of Btk. **a** From the N-terminus the protein contains pleckstrin homology (*PH*), tec-homology (*TH*), src-homology 3 (*SH3*), SH2 and kinase domains. The exon boundaries are shown by vertical lines. The *green numbers* specify the number of families having mutations in the exons that are numbered in *red*. The number of families having intron mutations is shown in *black* below the exon-intron boundaries. **b** Mutations causing XLA. The sequences are arranged according to domains. The mutations shown *above* the sequence cause either severe (classic) or moderate XLA, whereas those *denoted* below the sequence cause clinically mild disease. The number of affected families is color coded: from *black* (one family), *blue*, *green*, *magenta*, to *red* (five or more families). Insertions are shown with @, deletions with #, and stop codons with ∗

- *Isolated IgG_2* deficiency: often associated with an IgG_4, IgA and IgE deficiency.
- *Isolated IgG_3* deficiency: often occurs with a selective IgG_1 deficiency.
- *Isolated IgG_4* deficiency: often linked to an IgG_2 deficiency.
- *Other combined ID* (CID): for example IgG_2+IgG_4, IgG_2+IgG_3, IgG_1+IgG_2+IgG_4, IgG_1+IgG_2, IgG_2+IgG_3+IgG_4, some of which are associated with a deficiency of IgA or its subclasses [153, 465].

The association of SIgAD and defects of IgG subclasses is explainable in view of Ig production ontogenesis by B cells: one starts with IgM, moving on to IgD, and then to IgG ending up with IgA passing by IgE [296]; therefore the deficiency could originate with an immunological defect involving the T lymphocyte regulating work or B cells secreting Ig, with an effect on the final stages of their production. In rare cases, more or less extended deletions in chromosome 14 have been observed, in the region that codifies the H chains; in most cases the genome is instead intact, confirming a possible defect in B lymphocyte switching [367]. Very rarely this deficiency depends on gene HZ deletions [227].

Selective IgA Deficiency

This PID is probably the most common of all (Tables 22.4, 22.5), especially in nonselected populations of Caucasian origin [367]. It is defined by the presence of a serum level of IgA <5 mg/dl and the absence of sIgA in the total deficiency; in the partial SIgAD levels are <5 mg/dl but <2 SD compared to normal levels for age, with measurable sIgA [367]. In total deficiencies, IgM and IgG levels can be normal [414] (Table 1.15), but IgG_2 and IgG_4 levels are low [153]. In several cases, the partial deficiency is transient [383], returning to normal levels of IgA in 50% of cases by the age of 14 and in 80% by 18 (Fig. 22.9) [383]. The SIgAD is transmitted sporadically; however, cases of multifactorial and dominant AR, with a variable or incomplete expression [105, 536] transmitted within the same family have been reported. Functional alterations reflect on the final maturing process of B lymphocytes, given that about 80% of B_{IgA}+ lymphocytes show an IgM+IgD+IgA+ membrane phenotype, a normal aspect only in newborn babies [103].

Studies on chromosome 18 have not led to conclusive results, because deletions in children with SIgAD are associated with mental retardation, facial dysmorphisms, failure to thrive, etc. An association with HLA haplotypes situated on chromosome 6 is instead more consistent, and common in patients with CVID. Interesting indications for understanding the pathogenesis come from molecular genetic studies that have allowed the formulation of a hypothesis of multifactorial origin, given that the combinations of more widely involved HLA haplotypes and extended haplotypes involve the class I–III genes, to the extent that they are more often

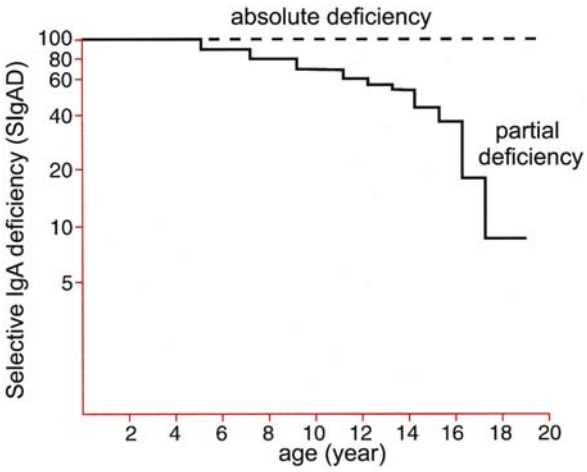

Fig. 22.9. Selective IgA deficiency (SIgAD). SIgAD natural history, its persistence in 40 SIgAD-affected children (*dashed line*) and 40 affected with partial IgA deficiency (*solid line*), the complete deficiency is irreversible. Serum IgA levels normalized in 40% of children with partial deficiency at about 14 years. (Modified from [383])

encountered in the general population [105]. Among the class III alleles the most studied is the gene that dictates the C4A, among class I and II the most common are *A1*, *A28*, *B8*, *B13*, *B40*, *CW6*, *DR1*, *DR3*, *DR7*, *DQW1*, associated with haplotypes such as *A1*, *B8*, *DR3*; *B13*, *DR7*; *A1*, *B14* or *A28*, *B14*. Other haplotypes are extended, such as *B8/SCO1/DR3*, *Bw65/SC2[1,2]/DR1*, *Bw57/SC61/DR7* and *B44F/FC31/DR7*, the first of which is increased in patients with a combined IgA, IgG_2 and IgE deficiency [170, 313, 536]. The association with *DR3* gives SIgAD a risk factor of 13 (Table 18.3). One HLA supertype is also found in deficiencies of 21-hydroxylase with a late onset, suggesting an important locus for IgA differentiation close to class III HLA genes [99]. It has been thought that to induce SIgAD a non-HLA gene or an environmental penetration factor might be necessary, due to the possible SIgAD discordant expression in HLA-identical twins [536]. However, the analyzed sequence of involved alleles showed a significant SIgAD correlation with some alleles belonging to HLA-DQ locus, composed of a protective allele with aspartic acid and a susceptible one with valine or alanine in the β chain in position 57 [358]. We have observed that the presence of aspartic acid ensures protection in DM.

Furthermore, the immunological deregulation extends to the typical formation of auto-antibodies and characterized by the presence of IgG anti-IgA [61, 196]. In these subjects, there is a wide symptom range, mostly represented by RRIs, allergic and autoimmune diseases (AIDs), among which is diabetes. Allergic diseases are twice as common in partial deficiencies, unlike AIDs [507]. From a clinical point of view, the frequency of chronic diarrhea and malabsorption, associated with celiac disorders and *Giardia lamblia* infestation are not surprising, considering sIgA's prominent

role in the formation of a barrier against the penetration of polypeptidic macromolecules through the intestinal mucosa. SIgAD therefore facilitates the penetration of food antigens through the mucosa followed by the formation of specific antibodies. For example, 50% of patients present CICs and precipitins to CM, 23% to bovine anti-serum and 13% to anti-serum of calf fetus [106]. Symptoms affecting the respiratory tract are also caused by the absence of sIgA, as in 30/36 children aged 1–15 with increased susceptibility to RRIs [327]. Patients balance the sIgA deficiency with the sIgM, but in some cases the compensation is insufficient for exempting them from RRIs and asthma [227]. SIgAD should be diagnosed on the basis of both serum and secretory IgA, because normal levels in adults are achieved at different times (Table 1.15). Some drugs such as phenytoin (an anticonvulsant) can determine SIgAD, sometimes persisting in time after the drug has been discontinued. The clinical symptoms in these cases are not different from those of patients with SIgAD [507]. There is no random treatment; these patients do not benefit from therapy with IVIg, even when enriched in IgA. There are no counter-indications for obligatory and optional vaccinations [507]. Whole blood or plasma transfusions containing IgA can sensitize patients or cause anaphylactic shock in those already sensitized [105]. *Life expectancy is excellent;* however, the random discovery of SIgAD in asymptomatic children should not be underestimated. They should in fact undergo periodic clinical and laboratory controls so as to identify as early as possible any possible pertinent symptoms. At the same time, there is the need to ensure a *good life quality* with adequate prevention of RRIs in those patients whose respiratory tract is affected [383].

Selective Antibody Deficiency with Normal Ig Isotypes

SADNI translates into the inability to respond to certain antigens, especially if polysaccharide. While some individuals are normal, others contract sinopulmonary infections. The reduction of IgG_2 levels is more of an associative relationship than a random one; IgG_2 levels, on the other hand, do not predict antibody responses. Subjects who do not respond to anti-hepatitis vaccination may fall into this category [414]. In one retrospective survey at a pediatric tertiary care center, SADNI was the most frequent diagnosis, accounting for 23% of ID diagnoses [236].

Selective Deficiency of Other Igs

Selective IgE Deficiency

There are cases of patients in good health, without IgE due to gene deletion [62]. In two siblings, deficiency of IgA_1, IgG_2, IgG_4 and IgE due to deletion of Ig H chain constant region genes were associated with undue susceptibility to infection [384] (see "RRI").

Selective IgM Deficiency

A few cases of selective IgM deficiency are known, associated with RRIs and various other symptoms [414]. IgM deficiency was detected in four children with RRIs. Isolated IgM defect was present in two children, and two more children had an associated IgG_3 subclass deficiency [160].

Common Variable ID

CVID includes a heterogeneous group of unhealthy conditions that have in common hgG and RRIs; it has an incidence of between 1:50,000 and 1:200,000 [414]. The inheritance of two susceptibility genes within the HLA on the short arm of chromosome 6: one located near the class II region and the other near the junction between the class III and class I regions is a serious risk for the development of CVID [441]. There are autosomal dominant or AR forms also linked to sex; sporadic cases are the most common [413]. The molecular bases are not totally clarified as yet: the pathogenetic mechanisms may depend on B lymphocyte (80% of patients) and T lymphocyte (20%) defects [227]. The B-cell intrinsic defect is attributable to an alteration of the differentiating line at different stages of maturation, resulting in a poor formation of antibodies, with hgG of variable degrees, while in patients with XLA the circulating B lymphocytes are virtually absent. The IgGs are <500 mg/dl (with a reduction in all the subclasses: a normal phenotype is observed in only 14% of patients) [367]. More often there is a hierarchical order in the shortage: $IgG_3 < IgG_1 < IgG_2 < IgG_4$ [528]. IgA and IgM antibodies are <5–50 mg/dl [102], reflecting the potential CD154 underexpression, implying an activation deficiency [150] or a T–B cooperation defect [232].

A study of T lymphocyte subpopulations indicates various subgroups of patients: 60% have T cells with scarce IL_2, IL_4 and IL_5 levels, while 30% have a reduced CD4:CD8 ratio, with an increase in CD8 bearing the CD57 marker, which suppresses IgG production, elaborates normal IL_2 levels and increases IFN-γ production [232]. It can also accompany a deficiency of interleukins (ILs: IL_{10}, IFN-γ), suggesting a defect in the signaling mechanisms based on the TcR/CD3 [191]. A T-lymphocyte deficiency is therefore difficult to evaluate [527], also because this could be a VRI effect [232]. CVID can also be observed following congenital rubella or EBV infections; it can also be induced by some drugs such as phenytoin [355]. In 2/9 CVID families, 5 subjects were identified with identical large mutations in the ICOS (inducible costimulator) gene, expressed on the surface

of activated T cells, which interacts with the ICOS ligand gene expressed on B cells. An additional 181 patients with sporadic CVID were examined, and no mutations were found. Only 9 in 226 patients with CVID screened thus far (<4%) have been found to have ICOS mutations. One unexplained feature of CVID is that the onset of clinical symptoms does not occur until late childhood or adulthood [429].

PID is variable either in the clinical and immunological pattern, or in the onset period, more common during the school years or in adults, but also between the ages of 1 and 3 [102]. The acute bacterial recurrent and/or severe *lower respiratory tract infections* (LRTI) are characteristic: sinusitis (60% of pediatric cases), otitis media (47%), bronchitis, pneumonia (87%) and/or digestive tract infections (diarrhea 57%) [213]. The prevalence of infections caused by mycetes has increased as well as cases of pneumonia caused by *Pneumocystis carinii*, a signal for cell-mediated immunity (CMI) [152]. The *gastroenteric tract* is dominated by symptoms similar to those seen in celiac disease, with generalized malabsorption, steatorrhea, lactose intolerance, protein-losing enteropathy, inflammatory bowel disease (IBD), saccharidase deficiency and malabsorption of vitamin B_{12} and folic acid, supported also in this case by intestinal infestation caused by *Giardia lamblia* [527]. The tumor necrosis factor receptor family (TNFR) member TACI (transmembrane activator and calcium-modulator and cyclophilin ligand interactor) mediates isotype switching in B cells. In 4/19 unrelated subjects with CVID and 1/16 subjects with SIgAD there was a missense mutation in one allele of TNFRSF13B (encoding TACI). None of these mutations were present in 50 healthy subjects. TNFRSF13B mutations cosegregated with the phenotype of CVID or SIgAD in family members of the 4 index subjects. B cells from subjects with TACI mutations expressed TACI but did not produce IgG and IgA in response to the TACI ligand APRIL (a proliferation-inducing ligand), probably reflecting impaired isotype switching [87]. Other characteristics are hemopathies, hepatosplenomegaly, autoimmune hemolytic anemia (AIHA) and X-linked lymphoproliferative disease (XLP), and cutaneous and internal organ granulomas (which differentiate it from XLA), in particular RA, thrombocytopenia, and neutropenia [102]. Offspring of CVID patients are at risk throughout their lives for CVID development and should be monitored with a high index of suspicion [441].

IgA- and CVID-Associated Deficiency

Based on experimental evidence, it has been hypothesized that IgA- and CVID-associated deficiencies may be the extreme opposites of one clinical spectrum: there is a block of B-cell differentiation, different only in the isotype involved. Both defects often appear in different members of the same family groups and more or less the same alleles are present [313]. The most accredited hypothesis is that a number of extended haplotypes of the HLA system are shared, to which gene duplications, deletions and polymorphisms codifying for some class II and III alleles correspond [22]. In fact, a number of common HLA haplotypes, especially belonging to class III, are observed in patients, and at least two haplotypes in 77% of cases [518], such as *HLA-DQB1*0201*, *HLA-DR3*, *C4B-Sf*, *C4A*, *G11–15*, *Bf-0.4*, *C2a*, *HSP-70–7.5*, *TNFa-5*, *HLA-B8* and *HLA-A1*, postulating therefore the existence of a common genetic basis [22], with a susceptible gene (*6p21.3*) possibly the association marker [61]. For example in five members of a large family with one of the two PIDs, duplications of the *C4* genes were associated with a selected group of HLA class II and III genes [22]. The fact that four members without PID also had these haplotypes indicates that their presence alone is not sufficient for expressing PID, leaving room therefore for other factors [22] such as overlapping relations with celiac disease. The analysis of linked genes has confirmed a strong association with locus 4A, suggesting that an important role in both PID is played by the gene codifying C4A or an adjacent one [162].

Not-X-Linked Hyper-IgM

See "X-linked Hyper-IgM (or Hyper-IgD) or CD154 Deficiency (XHIgMS)" for further discussion.

Transient Hypogammaglobulinemia of Infancy

Unlike transient hgG that occurs when the maternal IgGs gradually disappear from circulation (Table 1.15), in the original study by Taylor et al IgA levels had fallen, becoming regular in newborn babies with THI after 1 year, corresponding to the nonatopic levels [493]. It consists therefore of a pathological delay in the normal antibody production maturing process. Walker et al have calculated that the prevalence of *THI* is 23×10^6 in children, equal to the prevalence of symptomatic SIgAD (24×10^6) [525]. In all 15 children the IgG and in 12/15 (80%) the IgA were <5th percentile, 9/15 (60%) had IgM levels <20th percentile resolved around the 22nd month; further confirmation consisted in the fact that the 12 children had symptoms either of AD or of FA or food intolerance [525]. From Table 22.4 the mean incidence is from 1 to 61×10^6. During 7 years 30 children aged 6–46 months were diagnosed with THI and an incidence of 4.3/year [124]. In other studies the main defect was in the IgG: in one it had normalized between 18 and 40 months [129], in another trial 13/247 babies (5.3%) exhibited at the age of 10 months an absence of serum IgG levels and of specific antibodies to viral agents, which in eight children were detected before the serum IgG levels returned to normal, whereas in

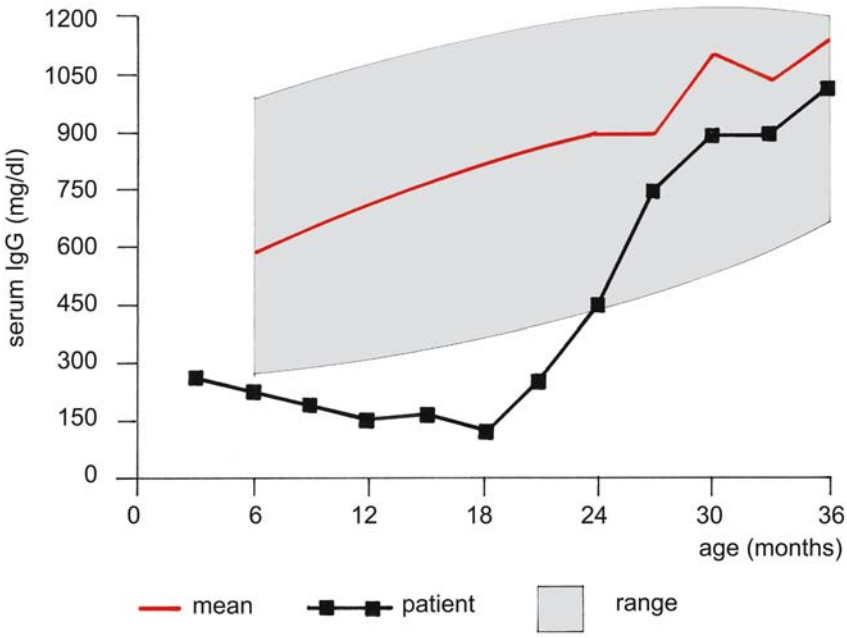

Fig. 22.10. IgG levels in transient hypogammaglobulinemia of infancy (THI). IgG levels normalized at age 2 years

two children normal IgG levels were detected even before the appearance of specific viral antibodies. IgG levels usually normalize at between 15 and 36 months [78], at the age of 2 years (Fig. 22.10) or before 36 months of age in 33/40 children; however, 7/40 still had low Ig levels at 40–57 months of age [253]. At 27 was in 9/30 children Ig levels were still <2 SD for age and in 5/9 various IgG subclass deficiencies were detected [124].

A prospective study with an 8-year follow-up found that IgG and IgA deficiency is normalized by the age of 6, but in a minority of cases this may be a prodrome of SIgAD or another humoral deficiency [315]. A study with a 10-year follow-up of 35 children with IgG deficiency as well as IgA deficiency in 34% of the cases, observed multiform clinical symptoms. Since THI can gradually normalize, some children have low antibody titers, and others low IgG levels. However, both groups experienced significant infections [110]. In some cases, THI is asymptomatic; in others infections, especially of the respiratory tract, are present. The designation of THI may be a misnomer, and an alternative designation could be added to THI such as "with recovery" or "with development of other dysgammaglobulinemia" [315].

Combined T-Cell and B-Cell Deficiency

General characteristics of combined T-cell/B-cell immunodeficiency are summarized in Table 22.8 [453].

T^-B^+ SCID

T^-B^+ SCID is a heterogeneous group with an incidence of between 1:50,000 and 1:75,000 livebirths [509]. *X-linked* FH is positive in 53% of cases [68]. The genetic basis is an IL_2R deficiency [529], more precisely of the γ receptor mapped on chromosome *Xq13* [347]. The sole deficiency of IL_2R is not sufficient for producing an immunological phenotype as devastating as SCID [529]. Because the γ chain of IL_2R ($IL_2Rγ$), a shared component of IL_4R, IL_7R, IL_9R, $IL_{13}R$, $IL_{15}R$, $IL_{21}R$ and $IL_{23}R$ [351], γc mutations interfering with its link to the ILs deprive the lymphoid progenitor cells of the crucial signals for normal lymphocyte intrathymic development [424]. Mutations in any of the genes: *$IL_2Rγ$*, *$IL_7Rα$*, *JAK3*, *ARTEMIS*, *RAG1*, *RAG2*, *CD38*, *ADA*, *CD45* cause SCID [68, 69, 211, 247, 272, 347, 350, 365, 391, 424, 443].

A total of *264 $IL_2Rγ$ gene mutations* have been sequenced, of which 169 are unique [341]. Each of these mutations has resulted in *γc deficiency* with varying degrees of ID. The mutations are distributed throughout the eight exons of the gene, as well as in the regions necessary for proper transcription and translation. The penetrance of each of the above $IL_2Rγ$ mutations is unknown. Exons 5 and 7 have mutation hot spots. The types of mutations identified include missense, nonsense, insertions, deletions, splice mutations, and mutations that affect RNA processing and translation [341]. Among 93 mutations in 136 patients, the most numerous (67%) are punctiform mutations (Fig. 22.11) plus one missense related to amino acid residues [390], with a lack of JAK3 and γc interactions [424].

In an atypical form, the substitution with residual cysteine of the arginine at position 115 appears to be decisive for γc chain expression, probably a mutation reversion at the basis of the molecular defect, with a numeric and functional T-cell normalization [475]. The mutations, by inactivating the common γ chain, render the T cells of boys with SCID-X1 unresponsive to several ILs. The result is a block in T-cell development and a severe deficiency of mature T cells. B cells, although pre-

sent in normal or even increased numbers than in other forms of SCID, are dysfunctional [347]. B cells do not mature or produce antibodies due to a complete B-cell differentiation arrest at the pre-BcR checkpoint, showing the absence of complete *VDJ* recombination [350]. Other forms are also known with an attenuated phenotype and a partial T-cell function [162]. Typical SCID-X1 represents the most common form, with 45.5% of cases [68] (5.5% in Tables 22.4, 22.5).

In the thymus, there is a severe hypocellularity, without lymphocytes and Hassall's bodies where thymic epithelial cells predominate without grossly evident corticomedullary differentiation (Fig. 22.12). Severe lymphopenia is often associated with eosinophilia; NK cells are within the norm or rare. The majority of infants with SCID-X1 lack both T and NK cells (T^- B^+ NK^- phenotype) [68, 391]. CD3 T cells, if present, are of maternal origin, because the block, as also in SCID AR, occurs at the level of $CD4^-$, $CD8^-$, $CD44^-$, $CD3^+$ and $CD1a^+$; developing T cells and $CD83^+$ thymic DC are reduced >50-fold when compared to age- and gender-matched control thymus [209] (Fig. 2.2, pre-T, TN), thus SCID T^- B^+.

The study of other subpopulations distinguishes the SCID subtypes: T cells are reduced in all variants, the absolute cord blood (CB) number is 158–2,400 lymphocytes/mm^3 (Tables 1.34, 1.35, so that any count below 4,000/mm^3 is lymphopenic). Moreover, in ADA deficiency (adenosine-deaminase) there is a maximum reduction in total lymphocytes, in SCID-X1 and in JAK3 defi-

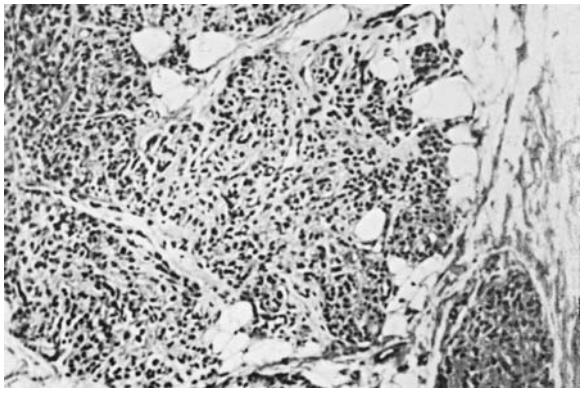

Fig. 22.12. Histological section of the thymus

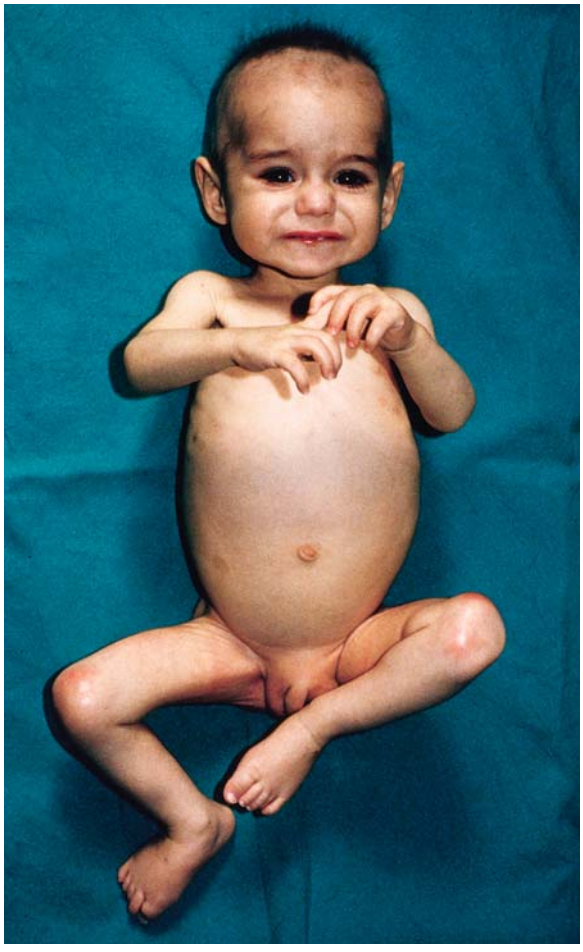

Fig. 22.13. Infant with SCID

ciency, the number of B cells is the highest and that of NK cells is the lowest ($B^+ > T^- > NK^-$); NK cells on the contrary reach their highest levels in the AR form [68]. In SCID there can also be B alymphocytosis [474]. This divergent data is, however, characteristic of $T^- B^+ NK^-$ molecular defects (γc, JAK3 defects), $B^+ T^- NK^-$ (ADA deficiency), or T and B (possible recombination anomalies) and against a common T and NK cell drop [68]. Furthermore, in two cohorts [68, 474] the affected females had the same phenotype, indicating a possible complex molecular defect [68]. There is no response to delayed SPTs, and there is an absence of lymphocyte proliferative responses to mitogens and to a specific antigen such as tetanic toxoid [61, 189, 474].

The *average age at diagnosis* was 4.4 months in 31 children [21], similar to the ages reported in >200 children with SCID from all causes [68, 474]. The male:female ratio is 3:1 and diagnosis is often missed or occurs too late to save the lives of those infected infants who may manifest GvHD early on with morbilliform eruption in the first few days of life due to the transplacentally acquired maternal T cells, *intractable diarrhea* resulting in a *severe malabsorption* (Fig. 22.13), *severe interstitial pneumonia* (Fig. 22.14), or giant cells caused by anti-measles vaccination or BCG (Bacillus Calmette Guérin), with death caused by chickenpox or infections caused by *Pneumocystis carinii*, herpes, adenovirus, CMV (cytomegalovirus), etc. [63]. The absence of tonsils is observed and also lymphoid tissue [508] and thymus [453] hypoplasia. These children must be transferred urgently to a specialized center and be placed in a sterile room to receive a BMT [474].

γc Gene Mutations

On rare occasions, *$IL_2R\gamma$ mutations* have caused an atypical mild SCID that presented beyond infancy [390]. Up-regulation of bcl-2 by an IL_2R lacking $IL_2R\beta$ tyrosine residues leads to increased cell survival after IL deprivation; astonishingly, this survival signal does not occur when γc tyrosine residues are absent. Thus, if

γc-dependent signals are revealed only in the absence of $IL_2Rβ$ tyrosine, IL_2R engages at least two distinct signaling pathways to regulate apoptosis and ccl-2 expression [293]. In two clinical series, patients with mutations in $IL_2Rγ$ represent 28%–45% of all SCID cases [68, 474]. Children with $IL_2Rγ$ mutations have lymphopenia in 95% of cases, with total lymphocyte counts <2,000/mm^3 (normal levels, 4,000–13,500/mm^3), based on clinical case series [68, 474]. All patients have *very low or absent T cells,* and approximately 88% have *low or absent NK cells* [390].

AR SCID

AR mutated genes on autosomal chromosomes have been identified in ADA deficiency, Jak3 deficiency, and RAG1 or RAG 2 deficiency [65]. The existence of B- and T-lymphocyte lymphoid precursor differentiated defect is particular, in some cases a *RAG1* and *RAG2* mutation, the two genes that activate VDJ recombination [443] was observed; however, this *RAG2* gene function has been questioned [411] since a RAG defect is more present in T^-B^- SCID and the Omenn syndrome [491]. In babies suffering from SCID, there is a marked reduction of T and B lymphocytes (Table 22.3) and all in vivo and in vitro responses are absent. Onset and clinical and histological pattern is similar to that of X-SCID.

JAK3 ID

The *JAK3 gene mutation* (Tables 1.31–1.33) variant has a frequency of 5.9%–7.4% [68, 408] among babies affected by SCID and in the absence of T (3±2%) and NK cells (1±1%) [407]. The molecular base is the mutation affecting the JAK3, which prevents it from associating with the γc chain and from sending signals to the above-mentioned ILs [354] and to other marker proteins belonging to the JAK–Stat complex [301]. At the origin is a lack of T lymphocytes that transform into the SCID phenotype [424]. These patients present B^+ T^- NK^-: the B (70±12%) with IgA equal to 2±2% [407], and those with X-SCID present a defective differentiation, but are capable of producing elevated levels of IgE in the absence of other isotypes [354]. This data indicates that γc and JAK3 are essential for T- and NK-cell development [407]. The clinical characteristics are identical to those in X-SCID, with the difference that the SCID-JAK3 phenotype is also observed in females (50%) [408]. Furthermore, a JAK3 deficiency could be an important cause of SCID AR and should be considered in all patients with the B^+ T^- NK^- phenotype, without an X-recessive heritage [68]. In a 6-month SCID-X1 infant presenting with a history of recurrent infection and failure to thrive, a novel splice mutation, γc-dependent, was described, characterized by near-normal count of functionally deficient NK cells (B^+ T^- NK^- cell phenotype). Cell surface γc expression was undetectable on NK cells and in trace amounts in the minority of B cells. T cells were absent, IgG and IgA undetectable, and IgM were within the normal range [183]. BMT is not a perfect therapy, because B-cell function developed in 3/9 children, and NK functions normalized in 2/9 children after BMT [408].

IL_7R Deficiency

The family pedigree shows an inbred family with consanguinity across five generations. Two brothers were diagnosed with SCID. One, at the age of 4 months, presented with persistent oral thrush, oral ulcers, and failure to thrive. He had no palpable lymph nodes and no thymus shadow on a chest X-ray film. The second was diagnosed soon after birth and the third brother has always been healthy. Three other male cousins died in infancy from severe infections consistent with SCID; a 4th cousin presented with oral candidiasis at the age of 2 weeks and failure to thrive. No thymic shadow was detected on chest X-ray film and peripheral blood lymphocytes showed persistent lymphopenia. He had no lymph nodes, failed to reject a skin allograft and did not show an increase in the blood IgG and IgM antibodies for DTP after three vaccinations. The three affected patients were HZ for a C→T transition at nucleotide 394 in exon 4, leading to a proline to serine substitution (P132S) in the extracellular domain of IL_7R. The cousins and their parents harbored both wild and mutant alleles. This partial deficiency is sufficient to block T-cell development and lead to a SCID phenotype. The FH of severe PID with multiple affected male infants strongly suggested an X-linked inheritance. Nevertheless, this family consanguinity is in favor of an AR inheritance [410]. Defective IL_7R expression caused in three patients a T^- B^+ NK^+ SCID, indicating that the T-cell defect in SCID-X1 resulted from inactivation of $IL_7Rα$ signaling. Thus IL_7R-mediated signaling is required for T cells but not for NK ontogenes. Mutations in the gene for the IL_7R chain on chromosome *5p13* were found in all three patients [391].

T^-B^- SCID

RAG1/RAG2 Deficiency

These infants resemble those with other types of SCID with respect to their susceptibility to infection and the absence of functional T cells and B cells. However, they differ in that their circulating lymphocytes *are primarily NK cells.* RAG1 and RAG2 are required for the rearrangement of *TcR* and *BcR* genes [343]. Half of the patients with T^-B^- SCID had mutations in their RAG1 or RAG2 genes, thus highlighting the crucial role of these genes in normal V(D)J recombination machinery [443]. RAG-thymocytes lack a functional pre-TcR and hence arrest at the CD44-/CD 25+ stage of differentation [491]: without RAG1 and RAG2, mature *Ig* and *TcR* genes cannot be assembled, and lymphocyte development is arrested at very early stages [53].

Table 22.9. Biochemical features associated with ADA deficiency

1. ADA undetectable in red cells, lymphocytes and in all tissues
2. Marked elevation in red cell deoxyadenosine triphosphate (ATP) (>200- to 1000-fold increase)
3. Total deoxyadenosine nucleotides (AXT) also very high
4. Increased plasma concentrations of adenosine and deoxyadenosine (adenosine >deoxyadenosine)
5. Excretion of adenosine, deoxyadenosine and methylated compounds (deoxyadenosine >>adenosine)
5. Secondary inhibition of SAH hydrolase

Modified from [219].

ADA Deficiency

The lack of ADA is observed in 14.8% of patients with SCID [68]. The ADA enzyme catalyzes the conversion of adenosine and deoxyadenosine into inosine and deoxynosine; although ADA is found in all cells (CD26 anchors ADA to the lymphocyte cell surface (Table 1.2), the deficiency damages above all the immune system [219]. Table 22.9 [219] summarizes the biochemical foundations of this PID.

More than 50 ADA mutations are known, including >30 amino acid substitutions, deletions and punctiform mutations or anomalies of the gene itself, such as exon 1 deletion and exons 4, 5, 7 and 9–11 mutations with a total of 15, nine of these in patients with ADA-SCID and six in those with a partial deficiency [219]. An additional 29 mutant alleles have been found (28 missense and 1 single-codon deletion) [21].

Adenosine and deoxyadenosine are also apparent suicide inactivators of the enzyme S-adenosylhomocysteine (SAH) hydrolase, with consequent accumulation of SAH, a powerful inhibitor of virtually all cellular methylation reactions [61]. The accumulation of metabolites, including cAMP, deoxy-ATP and 2'-*O*-methyladenosine, has a toxic effect on the cells by blocking DNA synthesis and dividing and resting T lymphocyte proliferation [61] (Fig. 22.15).

Four different clinical phenotypes have been described for ADA-deficient subjects (Table 22.10) [219], which cover a broad spectrum of immunological aberrations, from the complete absence of B and T immunity, indicating SCID (85%–90% of patients) (the thymus in Fig. 22.16) to forms with a delayed onset or partial deficiency (10%–15%) [219]. In children, the delay between onset of symptoms and diagnosis has been estimated to average 2 months [474]. If clinical symptoms indicate an *early onset,* in addition to typical SCID symptoms, there are also X-ray pathognomonic skeletal abnormalities of the chondrodysplasia type, especially

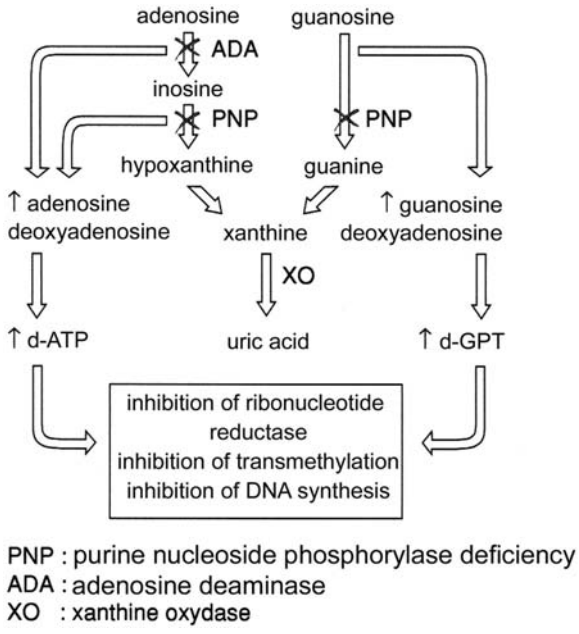

Fig. 22.15. Abnormalities of purine metabolism associated with ADA and PNP deficiencies. *XO* xanthine oxydase

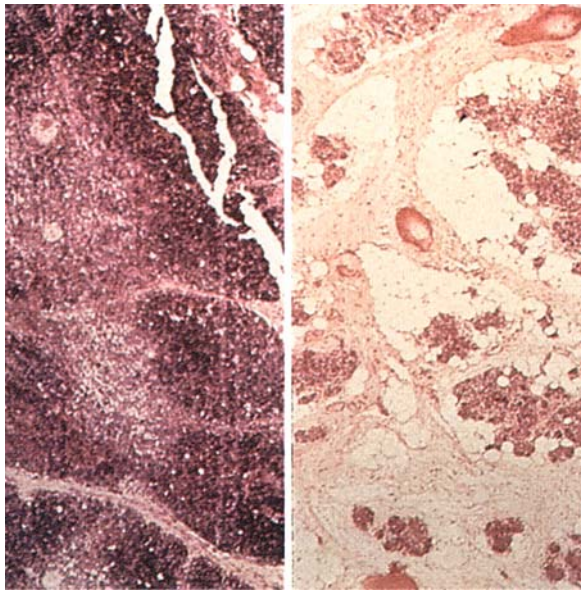

Fig. 22.16. Thymus in SCID. *Left*: normal pattern; *right*: thymic dysplasia

abnormalities of the chest, scapula and iliac bones and short and stumpy limbs [219, 224]. X-ray abnormalities are documented in Fig. 22.17: the absent thymic shadow and a notable cupping and flaring of the ribs' ends (arrows) can be observed, while histological studies of the chondrocostal junctions document their *total cellular disorganization* (Fig. 22.18). This deficiency is the object of a great deal of attention because it was the first to be treated using gene therapy [313].

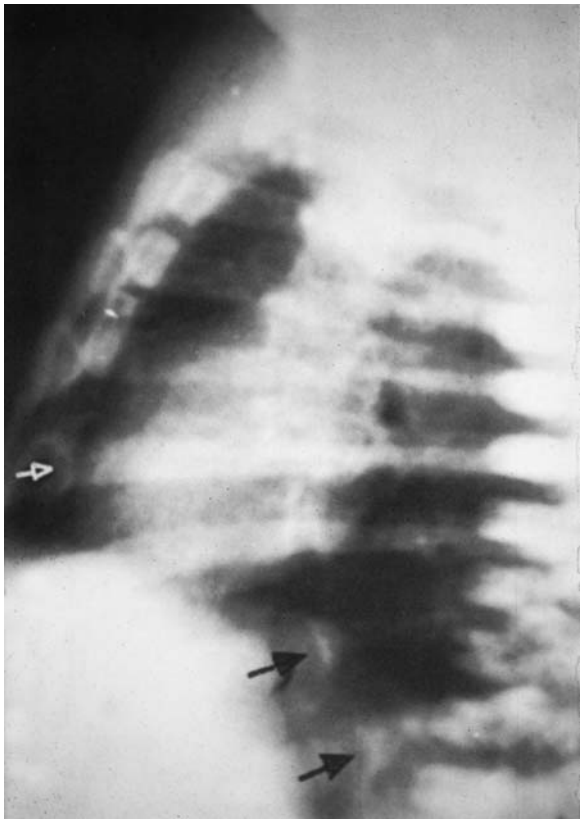

Fig. 22.17. Lateral view in ADA deficiency (for details see text)

Table 22.10. Phenotypes of ADA deficiency

1.	SCID (85%–90%). Closely resembling SCID without ADA deficiency, except for bony lesions
2.	Delayed-onset (10%–15%). Predominant cellular ID with markedly decreased antibodies and absent over time
3.	Late-onset. Diagnosis not before 5–8 years of age with predominant cellular ID and antibody assays reveal no clear-cut deterioration
4.	Partial deficiency. Immunologically normal? Found as a result of normal infant screening

Modified from [219].

Reticular Dysgenesis

This very rare AR type of SCID was observed for the first time in 1959 in identical twin male infants who exhibited a total lack of both lymphocytes and granulocytes in their peripheral blood and bone marrow. It has a frequency of 1% in cases of SCID [68]. The children are symptomatic in 90% of cases within the first days after birth [46] and is usually fatal within the 3rd month of life without a BMT [224]. Due to the common stem cell (SC) non-maturation [224], it is characterized by total block in lymphoid and myeloid precursor differentiation, therefore not only by an extraordinary lymphopenia, but also by a *marked cytopenia in all sections* (Table 22.11) [474], in the spleen, in the lymph nodes and in the gastroenteric tract, and a high frequency of severe successive infections [474]. The thymus is always much reduced in volume, no Hassall's bodies are seen [224]. Seven of the eight infants reported by WHO with this defect died between 3 and 119 days of age from overwhelming infections; the eighth underwent complete immunological reconstitution from a BMT [543]. An additional three of five children who required two HSCTs (hematopoietic SCT stem-cell transplantation) and received intensive conditioning therapy before haploidentical HSCT (matched for 3 of the 6 HLA loci) are alive and well

Fig. 22.18 a,b. Photomicrographs of costochondral junctions. **a** Normal child. Note the normal linear columns of proliferating cells and hypertrophic cells in the growth plate. **b** Child with ADA deficiency: in comparison to **a** there is no cell organization, no transition of proliferating to hypertrophic cells, only scattered hypertrophic cells, with uninterrupted calcified cartilage formation

Table 22.11. Immunological characteristics of a child with reticular dysgenesis

Immune cells	Child's values	Laboratory ranges
Leukocytes (cells/µl)	300	5,000–19,600
Lymphocytes (cells/µl)	100	4,000–13,500
CD3 (cells/µl)	75	1,800–3,000
CD4 (cells/µl)	60	1,000–18,500
CD8 (cells/µl)	15	800–1,600
B lymphocytes (cells/µl)	10	700–1,300
IgG (g/l)	7	2.28–6.16
IgA (g/l)	0	0.27–0.63
IgM (g/l)	0	
Neutrophils (cells/µl)	200	1,000–8,500

Data from [474].

with myeloid and T- and B-cell lymphoid reconstitution [46]; another child is alive and well after 32 months [13].

Radiation-sensitive SCID

B-SCID, characterized by increased cell sensitivity to radiation secondary to mutations of the *ARTEMIS* gene, could carry a poorer prognosis because of defective repair of DNA breaks [406], occurring around the time of BMT, from the effects of chemotherapy, infections, and GvHD [206, 247, 332]. One group of patients with SCID with an additional sensitivity to radiation was found to harbor large deletions or truncation mutations in the *ARTEMIS* gene mapped on *chromosome 10p* [65], implying a role for Artemis in DNA double-strand break repair, which is mutated in human SCID [350].

T^+B^- SCID

Omenn Syndrome

Omenn syndrome is classified as a SCID because newborn babies exhibit symptoms similar to a GvHD, due to 1a antigen expression and CD1a absence [241], and because it can coexist in families with alymphocytosis [117]. This is an AR syndrome with an unknown pathogenesis, sharing characteristic clinical and immunological abnormalities with T^+B^- SCID [515]. Severe cutaneous lesions with hyperkeratosis, apoptotic Malpighian necrosis and basal membrane destruction can be associated [241]. *No lymphoid cells or Hassall bodies are found in the thymus* [241]. The immunological structure reveals histiocyte infiltration of the skin, BM and lymph nodes, with proliferation of T infiltrating the epidermis and the enteric mucosa, increased T cells with an activated phenotype and poor functional capacity [117]. Studies involving HLA typification and DNA polymorphism show that T cells belong to the host, ruling out, therefore, the etiology of maternal cell engraftment [117], unlike other types of SCID [474]. The *absence of circulating B* is also characteristic [117], equal to 3.8%–7.1% of normal levels [474], reaching 0% [520], *high IgE levels* (526 UI/l), hypereosinophilia reaching $3{,}000\times10^9$ cells/l (normal, 0–0.5 cells/l), and low Ig levels at the beginning [246] then declining to the point of agammaglobulinemia [520], comparable to that in reticular digenesis (Table 22.11) [474]. The marked B-cell depletion can also bear *RAG1* and *RAG2* gene missense mutations that decrease the efficiency of VDJ recombination, which results in impaired but not absent rearrangement of both BcR and TcR. Four missense mutations were detected in the RAG-2 in 6/8 patients [491]. In 13/16 patients (81%) the mutations affected the RAG1 gene, and in 3/16 (19%) the RAG2 gene [515]. Increased IgE is linked to Th2 primary infiltration, with spontaneous production of IL_2 IFN-γ, IL_4, IL_5 and IL_{10}, which is down-regulated by IFN-γ therapy [437]. Clonal expansion of $V\beta14^+$ $CD3^+$, $CD4^-$ $CD8^-$ secreting high IL_5 levels and low IL_4 and IFN-γ levels [318] could indicate an analogy with the Fas (CD95) defect. T lymphocytes show an activated phenotype and a spontaneous apoptosis associated with reduced expression of bcl-2 gene product, and a higher cell death of $CD4^+$ $CD45R0^+$ cells [59]. Given that high CD30 levels in the lymph nodes, skin and serum of three children generated Th2 lymphocytes [95], a Th2-mediated pathogenesis is possible: the CD30 are Th2 markers (Chap. 1). As in human SCID, B and T cells are found in mice with SCID, but with a final repertoire that is decidedly oligoclonal and lacks the heterogeneity characteristic of a normal immune system, so lymphopenic SCID and Omenn syndrome could be two aspects of the same disease with different clinical expressions, especially of time [224]. Clinically, young babies *soon after birth* show a generalized exudative erythroderma and desquamation, often mistaken as AD, alopecia, widespread lymphadenopathy, hepatosplenomegaly, persistent and profuse diarrhea, failure to thrive with malnutrition (Fig. 22.19), AIHA, recurrent infections caused by common and opportunistic germs (Fig. 22.20), and markedly elevated serum IgE levels [136, 241, 474, 520]. This outline included four babies from the same family with the same symptoms until death occurred at 10–19 months, but who did not present hypereosinophilia and were diagnosed as DM [375]. *Differential diagnosis* may be challenging since Omenn syndrome and GvHD show dyskeratosis and basal vacuolation, but the first always shows acanthosis and usually parakeratosis. GvHD shows a flat epidermis and rarely parakeratosis. Both can be distinguished after immunohistochemical staining for CD45 and CD68, which shows predominantly lymphocytes in the dermal infiltrate in Omenn syndrome, and relatively more macrophages in GvHD [438].

Fig. 22.19. Infant with Omenn's syndrome. The infant shows erythroderma, alopecia and edema

Fig. 22.20. Infant with Omenn's syndrome and *Pneumocystis carinii* pneumonia

IL_2 Deficiency ($IL_2R\alpha$-Chain Gene Mutations)

In a child with SCID and circulating T cells within the norm, a gene transcription deficiency was ascertained [414]. A male infant of first cousin parentage presented at the age of 6 months with CMV pneumonia, persistent oral and esophageal candidiasis, adenovirus gastroenteritis, and failure to thrive. He developed lymphadenopathy, hepatosplenomegaly, iron deficiency anemia with no evidence of hemolytic anemia, and chronic inflammation of his lungs and mandible. Biopsies showed extensive lymphocytic infiltration of his lung, liver, gut, and bone. Serum IgG and IgM were elevated, but IgA was low. He had T-cell lymphocytopenia, with an abnormal CD4:CD8 ratio of 1:1. The T cells responded poorly to anti-CD3, phytohemagglutinin and other mitogens, and to IL_2. He was found to have a truncated mutation of the $IL_2R\alpha$ chain (CD25). He was given a successful allogeneic BMT after cytoreduction [452].

X-Linked Hyper-IgM (or Hyper-IgD) or CD154 Deficiency Syndrome (XHIgMS)

About 225 cases have been reported, [75, 290, 539], 78% [75] or 100% [539] of which have the X-linked form of CD154 deficiency [75]. Patients are generally male, but there can be a non-X-linked form [224], in which 22% of patients are females [75]. An estimated minimal incidence was calculated of 1 in 1,030,000 live births. Over half of 79 patients developed ID symptoms and were diagnosed by 1 year of age, and over 90% by 4 years of age [539]. Although carriers of XHIgMS are considered to be asymptomatic, an extreme lyonization of the normal X can lead to a mild expression of the XHIgMS which is similar to CVID [118]. It can be secondarily caused by environmental factors and also stem from congenital rubella [278]: this indicates its heterogeneity.

Mutations in the *TNFRSF5* encoding CD154 in XHIgM patients result in a lack of B-cell signaling by activated T cells [53]. However, 21 boys out of 56 failed to express CD154, and *TNFRSF5* mutations were found in 20 of these boys, whereas no *TNFRSF5* mutations were found in 16 boys with weak expression of CD154 [184]. As a result, XMIgM B cells fail to undergo isotype switching and produce only IgM due to a defect in the RNA editing enzyme, activation-induced cytidine deaminase (AICDA), an enzyme expressed only in B cells and required for the processes of class-switching and somatic hypermutation of Ig genes [357]. The marked reduction of IgG (<150 mg/dl), IgE and IgA is accompanied by a sharp increase in mature IgM and circulating IgD, but B cells do not express other Ig [227]. Interestingly, 25% of patients with confirmed XHIgMS who had *TNFRSF5* mutations had low concentrations of IgG, IgA, and IgM. Most of the remaining patients with XHIgMS had the classic pattern of normal or raised IgM with low concentrations of IgA and IgG [184]. The *CD154* gene defect is usually expressed on the membrane by activated T lymphocytes, which therefore cannot bind B-cell CD40 [266, 346]. Figure 22.21 shows *75 CD154 localizations and mutation frequencies,* in 39.5% of cases mistakenly. For example, a sense codon substitutes for a missense one, creates a premature stop signal: therefore specific pertinent mutations, such as *G144E*,

The *blue numbers* represent the number of families with mutations in the respective red-numbered exons. The sum of families with splice-site mutation is shown in *black below the vertical bars*. **b** Distribution of the type of mutations in CD40L gene identified in families with X-HIgM. *ECU* extracellular unique, *IC* intracytoplasmic, *TM* transmembrane. *TNFH* Tumor necrosis factor homology

can interfere directly with the link site for CD40 (Fig. 22.22). Consequently the signal which indicates that B cells should begin isotype switching, limited to the production of low-affinity IgM, is missing [346]. Without isotype switching, GC formation is minimal [508] (Fig. 22.23) and follicular dendritic cells (FDCs) are reduced in number, also having an abnormal phenotype [147]. As shown by Figs. 1.31–1.33, the lack of cross-linking of CD40 by CD154 results in B-cell failure to up-regulate CD80 and CD86, important costimulatory molecules that interact with immunoregulatory molecules on T cells such as CD28 and CTLA-4.

Two patients with normal levels of CD154 have also been described [359]. As in males with XLA, infections start during the 12th month, those most often observed are otitis, pneumonia or sepsis cased by pyogenic bacteria, opportunistic infections, in particular caused by *Pneumocystis carinii* [290], and also ulcerative stomatitis, RA, neutropenia, AIHA, lymphoproliferating complications and type B gastroenteric lymphomas with IgM [224, 413]. The most prominent clinical infections were pneumonia (81% of patients), upper respiratory infections (URTI) (49%–87%) including sinusitis (43%) and recurrent otitis (43%), LRTI (82.1%) recurrent/protracted diarrhea (34%–55.3%), CNS infections (12.5%–14%), sepsis (13%–14.3%), cellulitis (13%), hepatitis (9%–16.3%), and osteomyelitis (1%) [290, 539]. Lymphoid tissues are normal or hyperplastic [75].

Recently, a rare form of HIgMS associated with hypohydrotic ectodermal dysplasia (EDA) characterized by the absence or hypoplasia of hair, teeth, and sweat glands has been described. Unlike patients with HIgMS, these patients failed to have a history of opportunistic infections. This disorder is related to mutations in the gene that encodes the nuclear factor κB (NF-κB), which is required for activation of the transcription factor NF-κB, or NEMO (NF-κB essential modifier), also known as IKK (inhibitor of B kinase). The phenotype observed in X-HIgMS-EDA patients shows that the putative zinc-finger domain of NEMO has a regulatory function and demonstrates the definite requirement of CD40-mediated NF-κB activation for B cell Ig class-switching [233]. Three other genes, expressed by B cells, have been associated with the HIGM phenotype giving place to HIGM 2–4. Mutations of activation-induced cytidine deaminase (AICDA) (HIGM2) and uracil glycosylase (UNG) (HIGM4), both expressed by follicular B lymphocytes, lead to defective class switch recombination and somatic hypermutation. Mutations of CD40, the CD154 receptor, cause a rare autosomal form with a clinical phenotype similar to CD154 deficiency (HIGM3). These rare PIDs may shed light on the complex events leading to the production of high-affinity, antigen-specific antibodies of different isotypes [146, 355].

Early treatment with IVIg associated with antibiotic prophylaxis have reduced the incidence of life-threatening infections and improved the growth of children with HIgMS [290]. Cycles of G-CSF (granulocytecolony stimulating factor) in the presence of severe neutropenia are advised [290]. Substitute therapies with soluble forms of recombinant or gene type CD154 [76] are being studied. A recent review of CD154-deficient patients showed that 75% develop liver disease and only 20% survive into the third decade of life [290]. BMT has a *successful outcome in young children* (65%); older patients with more ad-

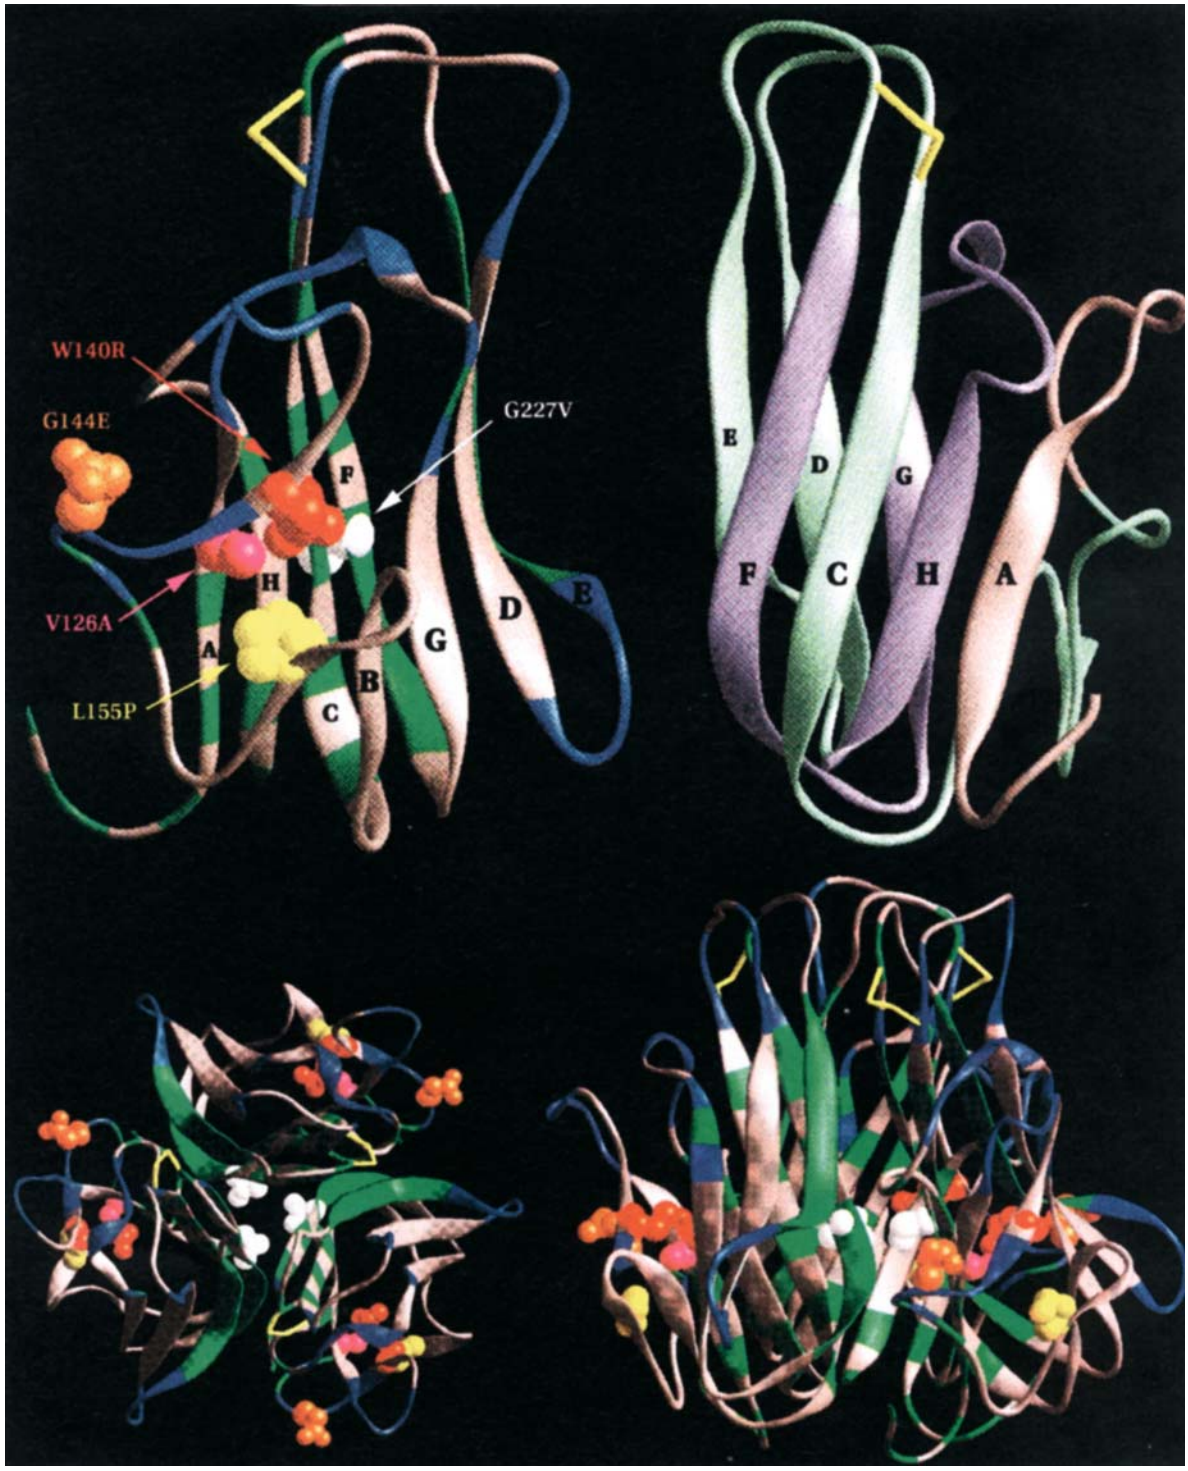

Fig. 22.22 a–d. Ribbon representation of the human CD40L (CD154) models. In **a** and **b** there is a monomer structure and in **c** and **d** a trimer structure. The *ribbon color code* in **a**, **c** and **d** indicates loops potentially interacting with the receptor (*blue*) and residues involved in subunit contacts leading to trimer formation (*green*). In **b** the *ribbon color* indicates the remainder of CD40L structure in two identified truncated mutations in the TNFH domain. The five point-mutations of TNFH domain are shown in **a**, **c** and **d**, regarding mutants affecting either monomer folding, trimer formation, or the CD154 contact sites with CD40. The β-strands forming the CD140 monomer are indicated by *black letters* on the monomer structures in **a** and **b**. The disulfide bond linking the C-strand end with the loop connecting E- and F-strands is depicted by *yellow bars*

vanced liver disease may die because cryptosporidia infection that has progressed rapidly following pretransplantation cytotoxic conditioning therapy [252]. Therefore, a patient with end-stage liver disease related to CD154 deficiency first received a liver graft, and as soon as liver-graft function was satisfactory, BMT was performed with a nonmyeloablative conditioning protocol of fludarabine and melphalan [208].

The screening for CD154 deficiency should include children with severe RRI, and with dysgammaglobulinemia with a normal or increased IgM level [197]. Conventional allogeneic HSCT from an HLA-matched or a matched unrelated donor (MUD) is curative and feasible, if performed before significant infections and organ damage occur [503]. An approach for high-risk patients including nonmyeloablative HSCT was workable in a retrospective analysis of 38 European patients undergoing HSCT for CD154 deficiency in eight European countries between 1993 and 2002. The donor SC source included 14 HLA-identical siblings, 22 MUDs, and two phenotypically matched parental stem cells (SCs) (12 TCD [T-cell depleted]). Of these patients, 12 (32%) died from infection-related complications, with a positive result in 68.4% of patients [180]. Carriers can be detected, and this is useful for making *a prenatal diagnosis* [407].

Purine-Nucleoside Phosphorylase Deficiency

Purine-nucleoside phosphorylase (PNP) deficiency, AR, for which 35 patients have been reported [53], is characterized by the absence of an enzyme necessary for the catabolism of purines, which converts inosine, deoxynosine, guanosine and deoxyguanosine into hypoxanthine and guanine (Fig. 22.15); the responsible gene has been mapped to chromosome *14q* at position 13.1 [414]. This has also been observed in 33 patients with Nezelof syndrome [304]. A variety of mutations have been found in the PNP gene in patients with PNP deficiency [432]. Although ADA and PNP are both purine salvage pathway enzymes, PNP deficiency does not lead to as severe an ID as ADA deficiency. Patients have considerably reduced concentrations of serum and urinary uric acid. Numbers of T cells fall progressively, more than that of B cells (Table 22.3), just like the proliferating responses to mitogens and antigens, especially because PNP deficiency causes an intracellular accumulation of deoxy-GTP (guanosine triphosphate) inhibiting ribonucleotide-reductase and T- and B-lymphocyte proliferation, so combined T and B defects are critical. PNP-deficient patients are as profoundly lymphopenic as those with ADA deficiency, with absolute lymphocyte counts usually <500/mm^3. Ig levels and production of specific antibodies are all normal [19]. *Onset may be early,* as for SCID, but also delayed until the age of 3–5 years. The clinical pattern is dominated by recurrent bacterial, viral and fungal infections, with an abnormal susceptibility to opportunisic germs. Two-thirds

of patients suffer from neurological alterations, ranging from spastic symptoms and alterations, etc., to mental retardation and one-third from AIDs, the most common of which is AIHA. The consequence of severe infections, generalized vaccination, severe chickenpox, lymphosarcoma and GvHD caused by blood transfusions in the first decade of life is death [304, 397] unless BMT is successful [25, 58, 67, 83, 98]. However, poor neurodevelopmental progression may result [25] or may not [98]. Since the biochemical bases of PNP and ADA deficiencies are similar, it is hoped that genetic treatment will also be effective in children with this PID [76].

HLA Deficiency

HLA Class II Deficiency

This deficiency of HLA molecule expression occurs in the more severe forms of PID if they are class II: about 80 cases [140, 428] are known of this AR syndrome [140], heterogeneous for the numerous complementation groups the patients are divided into [76]. *HLA class II molecules are absent in all tissues* [400], to the extent that the cells of patients maintained in cultures for years preserve the negative phenotype [400]. There is a deficiency of class II gene transactivator (CIITA) codified by chromosome *15,* the expression of which plays an important role in T-cell activation: its absence makes class II gene expression impossible [473]. This function is shared with another protein mapped on chromosome *2,* RFX5, with a binding site in the promoter region of genes codifying class II chains [401]. Two additional class II-specific transcription factors are RFXAP and RFXANK [314]. These act on the class II promoter region and are essential and also nonreplaceable, to the extent that alternative routes cannot compensate for their absence [311]. Furthermore inactivation, or the deficiency of these factors, has a specific effect on the genes dictating HLA class II, the li chain and HLA-DM, because there is no indication that other regulating systems may be involved [401]. The absence of HLA class II is associated with a CD4 lymphopenia. HLA class I expression is normal in the patients tested and CD8 lymphocyte numbers are not reduced [428]. Interestingly, in a twin study, despite the deficiency, there were antibody responses and class II-dependent T cells; hence the authors envisage that this represented a HLA class II residual expression below the test sensitivity [540]. The clinical outline is dominated very early on, *before the age of 6 months* (range, 2 weeks to 12 months) [428], by severe and recurrent gastroenteric and pulmonary infections, with a severe and prolonged course, associated with malabsorption and failure to thrive [77]. Bacterial and viral infections, bronchopneumonia, hepatitis, cholangitis, viral meningoencephalitis and various autoimmune manifestations are common complications [140]. Even though an HLA class II deficiency is clinically less severe than SCID, the result is uniformly fatal during the first or second decade of life [162].

The most evident immune defect consists in the complete lack of reactivity to exogenous antigens, which in vivo reflects an anergy to SPTs, as well as the complete lack of HLA class II expression and absence of cellular and antibody responses to antigen stimulation [140], which are instead positive to mitogens (Table 22.8; Fig. 22.24) [508]. Laboratory investigations show a normal B lymphocyte number, but children may be agammaglobulinemic [140]. The thymus and other lymphoid organs are remarkably hypoplastic, with a severe CD4 lymphocyte depletion, while CD8 and B-cell levels are normal. The syndrome involving a deficiency of HLA antigens confirms an important HLA biological role in the complex system of T–B cooperation [77, 140]. Some studies suggest that there are more types of deficiency. When placed together in a culture, the B lymphocytes of these patients, previously transformed by EBV, the lymphocytes correct each other so as to allow HLA class II molecule expression. This has led to the identification of so-called complementary groups [251]. The specification that the gene is mapped on chromosome *19p13.3* can lead to an *earlier prenatal diagnosis* [166]. Long-term survival seems to depend primarily on HLA-identical and HLA-haploidentical BMT performed in the first 2 years of life, before the acquisition of chronic virus carriage and sequelae of infections [257, 140]. A child recently received a transplant [428] with a novel protocol [208]: the CD4 count increased up to 300 cells/μl [428]. A direct correction of the genetic defect is based on the transduction of cells from patients with lentiviral vectors encoding CIITA, RFXANK, RFX5, or RFXAP. The RFXANK vector restored class II expression in a T-cell line from one patient. The RFXAP vector corrected primary cells from a second patient [314].

HLA Class I Deficiency

The study of the common association of HLA class I molecule deficiency, already known as bare lymphocyte syndrome, has led to the identification of various patients with an isolated deficiency and of one patient with a deficiency associated with class II, the most severe [85]. The deficiency is caused by *TAP-1–TAP-2* mutation, accompanied by severe and chronic bacterial RRIs [115]. In two brothers with the AR HLA class I defect, the onset of RRIs took place between the ages of 4 and 7; the poor expression of NK cells was so severe that it led to the development of bronchiectasis [125]. The immunological structure is characterized by few CD8: the deficient expression of HLA class I molecules is diagnostic [115] (Tables 22.1, 22.3).

CD3γ, CD3δ, CD3ε, CD3ζ Deficiency

The CD3γ chain deficiency due to γ or ε gene mutations [19] determines a lack of CD8 and the absence of CD45RA [249]. In the first two cases described, one brother died at 31 months because of viral pneumonia after a clinical history indicating SCID with severe AIHA, while the other was asymptomatic at the age of 10 years, although with the same molecular defect [18]. The study of these brothers proved that, in spite of the absence of functioning γ chains and 50% of the expressive levels of the CD3/TcR complex, the lymphocytes were normal. According to the authors, other chains may act in the place of missing ones; however, the correlated scarcity of CD8 may have negatively interfered with the mechanisms discriminating between self and non-self, while γ chain deficiency could have modulated the onset of the deceased brother's severe autoimmune disease (AID) [18].

A CD3ε deficiency was found in a 4-year-old child with mild RRI symptoms and otitis media; the expression of the CD3/TcR complex was only 10%, but the stimulation with anti-CD3 induced a normal proliferating response. In fact, despite the ongoing mutation, a Northern blot analysis showed production of a low amount of transcribed RNA, corresponding to a small quantity of ε normal chains, even though their dimensions were smaller than normal ones [471, 496].

The ζ chain deficiency found in the two brothers is similar to the deficient expression of CD3/TcR [5]. In the younger brother, the thymus, markedly reduced, showed no Hassall bodies; the elder brother had similar chain mutations with no symptoms referable to an ID, therefore integrating a genetic heterogeneity. Two other brothers and both parents were healthy [5]. While *the ε chain deficiency produces modest clinical symptoms,* the other two are severe also from an immunological point of view: *in the γ chain deficiency resulting from the profound CD8 and CD45RA decrease* caused by altered thymic activity that leaves the CD45RO unaffected [249], and in those of *the ζ chains due to the severe thymic atrophy* [5] and thymocytes falling to 15% of normal levels, with limits at between 1% and 50% [249].

The CD3δ deficiency due to a heritable mutation of the CD3 gene that prevents the synthesis of the CD3 protein has been reported in 3 cases HZ for the CD3 mutation. Two cousins died at 2–3 months of age because of overwhelming infection. The thymus shadow is clearly visible on chest x-rays. The thymus becomes populated with developing thymocytes, with an arrest of differentiation *at the $CD4^-CD8^-$ stage of T-cell development*. A girl (3rd patient) survives after a BMT [111].

ZAP-70 Deficiency or Selective CD8 Deficiency

This rare deficiency transmitted as an AR trait is caused by mutations of the ZAP-70 gene, a non-src family protein tyrosine kinase (PTC) important in T-cell signaling (Tables 1.31–1.33). ZAP-70, known to be crucial for T cell activation, is a key player in TcR down-modulation and ζ degradation [136]. ZAP-70 has an essential role in

the positive and negative selection of maturing T cells in the thymus [342]. In several babies (most of Mennonite origin) with SCID [20, 92, 139, 179], the nonfunctional CD4 T cells (Table 22.3) were either normal or increased ($CD3^+$ $CD4^+$, 75%). CD8 absence in the thymus and in circulation ($CD3^+$ $CD8^+$, 0%–2%) [139, 179] suggests that the selective process is arrested during the transition from double-positive (DP) to mono-positive (MP) T cells [20, 140, 179]. Arrested thymocytes had terminated *RAG* gene expression and up-regulated TcR and bcl-2 expression, but failed to differentiate into mature CD4 or CD8 MP thymocytes, to be rescued from death by neglect or to sustain $IL_7R\alpha$ expression [294]. ZAP-70 deficiency results in an impairment of transendothelial migration that can be rescued by the transfection of ZAP-70 because cross-talk between the ZAP-70 signaling pathway and the chemokine receptor CXCR4 is required for T-cell migration [502]. Although the thymic architecture is normal with presence of Hassall bodies [179] and CD8 seem normal in the cortex, very few migrate to the medulla [20]. The near absence of $CD8^+$ cells and an increased CD4:CD8 ratio dominate [27]. The few CD8 coexpress $CD56^+$, the NK-cell marker; B cells appear normal and functional, $CD3^-$ $CD19^+$ is at a level of 20%–40% [139, 179], and serum Ig values are normal [27]. The same phenotype was found in the brothers [92]; other relatives were HET [20, 139]. *The absence of CD8 expression* was shown to correlate with a missense mutation in both Ig alleles of the CD8 α gene domain in a 25-year-old man and his sister, whereas high percentages of $CD4^-$ $CD8^-$ $TcR\alpha\beta^+$ T cells were found in the three siblings [114]. The proliferative responses in vitro to phorbol myristate acetate (PMA) and ionomycin, PKC activators (protein kinase C), were normal, unlike PHA (phytohemagglutinin), PWM, tetanic toxoid, anti-CD3, etc. [20, 139]. The positives operate below the TcR, while the negatives react directly with the CD3/TcR complex [92, 140, 179], confirming the ZAP-70 deficiency [20]. The CD4 are present despite the deficiency because Syk, the other member of the family, ensures a compensatory role in the infrathymic CD4 selection, although with a limited efficacy [179]. Seven months after BMT, a child was clinically well and immunologically recovered [27].

TAP-2 Deficiency

Studies in two siblings HZ for a stop mutation in the TAP-2 gene suggest that NK cells express still unknown inhibitory receptor(s) (the missing receptor, discussed in Chap. 1) capable of down-regulating the NK cell cytotoxicity on binding to surface ligand(s) expressed by T cell blasts. Functional analyses were consistent with the concept that this putative inhibitory receptor is expressed by virtually all TAP-2/NK cells, whereas it is present only in rare NK cells from healthy persons. Another prospect would be that TAP-2/NK cells are actually missing this still unidentified triggering receptor involved in NK cell-mediated killing of PHA blasts. Since cells derived from patients displaying defective expression of either of the TAP subunits are characterized by a strong reduction of mature HLA class I molecules at the cell surface, a *TAP deficiency is connected with HLA class I deficiency* [517].

NFAT Deficiency

As discussed in Chap. 1, NFAT (nuclear factor of the activated T cells) is a transcription factor that forms a powerful transcriptional activating complex and, by linking with specific DNA-regulating sites, plays a critical role in the synthesis of various T-cell ILs which, due to the deficiency or excessive migratory mobility of NFAT, although normal in number and in distribution, are incapable of activating and/or secreting the genes of IL_2, IL_4 and IFN-γ [86]. A 4-year-old girl with SCID presented during infancy with severe recurrent infections and failure to thrive; her mRNA was not produced for IL_{2-5} and IFN-γ due to poor T-cell proliferation, although these were normal in number and in distribution, to initiate the transcription of the relative genes, regulated by NFAT, with a binding site in the proximity in the 5′ region. This severe clinical picture is accompanied by evident hgG [19, 86].

NK-Cell Deficiency

NK-cell deficiency is found in SCID, CVID, reticular dysgenesis, Chédiak-Higashi syndrome, XLP, LAD in TAP-2 deficiency and in CFS (chronic fatigue syndrome), in particular CID such as SCID, suggesting an association between NK- and T-cell deficiencies [478]. There is one known case of an adolescent with an isolated numerical and functional deficiency of NK cells and of precursors, recurrent neutropenia, severe and recurrent EBV, CMV, *Herpes simplex* virus (HSV) infections and life-threatening chickenpox. Another child, diagnosed at the age of 2.5 years with a CD8 deficiency, suffers from severe viral and bacterial infections although he has antibodies to various viruses [49]. The growing list of human genetic defects that impair NK-cell function has been recently joined by NEMO-ID [356] which occurs in a group of patients with antibody deficiency combined with exquisite susceptibility to infection with nontuberculous mycobacteria. Infectious susceptibilities common to these disorders stress the important role for NK cells in host defense [59]. The *natural history of three boys with NEMO mutations* outside of the 10th exon has been described. Including these boys, there have been 22 families described as having NEMO-ID. The resulting estimated incidence of NEMO-ID is 1:250,000 live male births, making this disorder significantly less common [356].

Undifferentiated SCID

Human p56lck deficiency

p56lck deficiency is an AR SCID due to a defect of an src kinase critical for the generation of mature thymocytes in adult mice. p56lck is important in TcR signaling and phosphorylation of the ITAMs of the CD3/TcR complex proteins. Mutant mice lacking p56lck have pronounced thymic atrophy, a critical reduction in DP ($CD4^+CD8^+$) thymocytes, no detectable MP thymocytes, and only a few peripheral T cells. Both proliferation and development of a given defined cell subpopulation depend on meuse age. The absolute numbers and proliferation of DN and ISP (immature single positive) thymocytes only proliferate during fetal and early postnatal life up to 14 days after birth, whereas the proliferation is significantly decreased beyond that age, thus lck may have differential roles in the proliferation and maintenance of DN, ISP, and MP/DP thymocyte populations [151]. The first demonstration of a human SCID patient with an abnormal expression of p56lck is an SCID infant hospitalized at 2 months for dehydration, failure to thrive, and sepsis. The immune phenotype included hgG, selective CD4 lymphopenia, lack of CD28 expression on $CD8^+$ T cells and poor T cell blastogenic responses to various mitogens and IL_2. p56lck protein expression was only minimal with an unusual mRNA splicing pattern of the lck gene. The levels of p59fyn were normal and it is therefore possible that p59fyn played a role, albeit incomplete, in the development of his mature T cells. The child has since undergone an allogeneic BMT (at 32 months) from a matched unrelated donor (MUD) [185]. Unfortunately the boy died 2 months later due to CMV infection and GvHD (FD Goldman, pers. comm., 8 Nov. 2005).

Human whn deficiency

whn (winged-helix-nude) encodes for a transcription factor that is crucial for maturation of the thymus microenvironment [185]. nu/nu mice fail to develop a thymus and mature T cells due to a defect in the whn gene encoding a transcription factor necessary for terminal epithelial cell differentiation. A defective whn gene could lead to the disrupted early T cell development in the BM. T cell progenitors were associated with a lack of pTα gene expression and a failure to give rise to mature T cells in adoptive euthymic hosts. Wild-type HSCs rapidly matured into functional T cell progenitors in the marrow of euthymic or thymectomized but not nu/nu hosts. Therefore defects in BM prethymic T cell development can contribute to T cell deficiency in nu/nu mice [90]. In two sisters a severe SCID caused by mutation of the whn gene was associated with complete alopecia. HLA-identical BMT in one of the two girls resulted in a clear reconstitution of $CD4^+$ and $CD8^+$ CD45RA cells and a marked clinical improvement. These data indicate that the thymus is differentially required in the maintenance of the TcR repertoire complexity [380].

Predominantly T-Cell Defects

Primary CD4 T-Cell Deficiency

Known also as idiopathic lymphocytopenia, primary CD4 T-cell deficiency is revealed by a profound and persistent reduction in circulating CD4 and with a CMI deficiency. It is documented in patients suffering from infections caused by opportunistic germs such as cryptococcus-induced meningitis and oral candidosis, also including ten children and a number of adolescents, for whom the following minimum levels of CD4 per age have been established: <1,000 cells/mm^3 from 0 to 23 months and <300/mm^3 from 2 to 12 years, or a total lymphocyte count of <20% on two separate occasions without being HIV-infected [463]. A family has been reported involving two brothers aged 13 and 18 with T counts between 150 and 200/mm^3, recurrent respiratory, intestinal and cutaneous infections, and failure to thrive. The mother showed a low CD4:CD8 ratio [122], while the entire family showed normal levels of Ig and subclasses and HLA molecules [128]. Other symptoms included mental retardation, pansinusitis, bronchiectasis [168], but no infections caused by opportunistic germs such as those reported by the WHO Scientific Group [414].

Primary CD7 Deficiency

One case of primary CD7 deficiency is known of a child with SCID without genetic transmission of the deficiency. T-cell proliferative responses to mitogens were defective and IL_2R expression was deficient on his T lymphocytes, and B cells did not differentiate into antibody-secreting cells when provided with the help of normal T cells [245].

Primary CD45 Deficiency

The index patient for primary CD45 deficiency was the first child of consanguineous Kurdish parents. She presented aged 2 months with a rash, pyrexia, hepatosplenomegaly, lymphadenopathy, pneumonitis, pancytopenia, and disseminated CMV infection. Laboratory analysis showed absolute lymphopenia, low T cell numbers, with markedly low $CD4^+$ and low $CD8^+$ and normal B cell numbers. She responded well to anti-CMV treatment and at 8 months underwent a MUD BMT. T-cell engraftment was demonstrated 3 weeks after BMT. Despite continuous anti-CMV treatment, her

CMV reactivated, and she died 55 days after BMT [74]. A 6-bp deletion in the gene encoding CD45 resulted in the loss of glutamic acid 339 and tyrosine 340 in the first fibronectin type III module of the extracellular domain of CD45, identifying a region important for CD45 structural integrity and lack of surface CD45 expression. This was almost certainly responsible for the ID in this girl [494]. A second child presented at 2 months of age with severe CID, showing similar T-cell defects. Despite normal B-lymphocyte numbers, serum Ig levels decreased with age [272]. Introduction of a *functional CD45 minigene* was sufficient to overcome the main SCID-associated defects and represents a potential route to a gene therapy for human CD45-deficient SCID [516].

Multiple IL Defects

Two male infants born to consanguineous parents had SCID despite phenotypically normal blood lymphocytes. Their T cells were unable to produce IL_2, IFN-γ, IL_4 and TNF-α [154]. Another child with SCID had defective transcription of IL genes encoding IL_2–IL_5 [86]. DNA binding of activation protein 1 (AP-1), Oct, CREB, SP1, and NF-κ B was normal, but the binding of NFAT to its IL_2 promoter response element [154], or the ability of nuclear factors from the child's T lymphocytes to bind response elements present in the IL_2 regulatory region [86] was barely detectable [86, 154] both before and after T-cell stimulation [154]. These results indicate that the NFAT abnormality may underlie the multiple IL deficiency in these boys.

Nezelof Syndrome

Nezelof syndrome, also known as cellular ID with Ig, or combined with a predominant T-cell defect, or as a SCID variant, clinically *less severe compared to the previous ones,* is characterized by a form of AD, concentrations of IgE that may also be extremely elevated (Table 22.2), and normal or increased serum levels of other Ig classes [62]. The CMI study emphasized the mature T-cell reduction or absence, various expressions of immature cells, with cutaneous anergy to SPTs and a reduced or absent in vitro lymphocyte response to mitogens. From infancy, patients present recurrent or chronic pulmonary infections, pondostatural retardation, oral and/or cutaneous candidosis, chronic diarrhea, recurrent cutaneous and urinary tract infections, Gram-negative bacterial sepsis and a particularly severe form of chickenpox [394]. Differential diagnosis must include pediatric AIDS, also marked by proportionably increased Ig and a lack of antibody and T-cell function [79].

Fas (CD95) Deficiency

Inherited through AR modalities, CD95 deficiency has been observed in 8 children, two of whom were brothers, with mutations of the Fas gene, one HZ and 7 HET [166, 281], as well as in 9 unrelated children [468]. These mutations most often arise as a result of mutations in the gene encoding the lymphocyte apoptosis receptor Fas/APO-l/CD95. A novel mutation has been identified in the intracellular apoptosis signaling domain of Fas in 11 members of a family, with several members monitored for up to 25 years [228]. Thus, the deficiency is inherited in an autosomal dominant fashion but with a high degree of variability in clinical expression [228], but also in an AR fashion [510]. The clinical picture is dominated by imposing hepatosplenomegaly with an early onset, even neonatal, accompanied by T-cell hyperproliferation, chronic and persistent lymphadenopathy, and failure to thrive [468]. An extensive lymphocyte infiltration of lymph nodes, spleen and liver is observed, with T cells reaching 35,000/μl [$CD3^+$, $CD4^-$ $CD8^-$ (DN) equal to 35–60 cells/μl compared to 0–3 in controls], as in Omenn syndrome, also in the bloodstream, with possible oligoclonality of T cellularity. DN T cells expressed the α/β TcR [468]. Immune dysregulation is associated with G and A HgG (hypergammaglobulinemia, auto-antibodies and AIDs, especially of the hematological type, such as AIHA, and with a severe and recurrent thrombocytopenia [166, 281]. Autoimmune features are discussed in Chap. 18. An overlapping mechanism could belong to the etiopathogenesis of XLP and Omenn syndrome.

Other Well-Defined ID Syndromes

Wiskott-Aldrich Syndrome

WAS has a prevalence of approximately 4×10^6 live births [402]. It is transmitted as a recessive hereditary trait linked to the chromosome X, localized in a pericentrometric position on the short limb of chromosome X (*Xp11.22–p11.3*) [274]. It is therefore possible to identify the female carriers and to provide *prenatal diagnosis* [61].

The gene that codifies the WAS defective protein (WASp) has been isolated [458] and has 167 mutations distributed among all 12 exons of the entire gene, 110 of which are unique and 38 familiar, with two large deletions, one embracing exons 1–7 and one intron 8 [275, 444] (Fig. 22.25). Six novel mutations have been identified that involve nonsense mutations, or small deletions, all of which result in predicted truncation of WASp synthesis [57]. A new, recurrent mutation is V75M, due to a CpG island was found in a HZ girl, who showed microthrombocytopenia and infections to the same degree as her hemizygous father and brother. The amount of WAS protein was about 10% in platelets and 15% in mononucleated white cells [388].

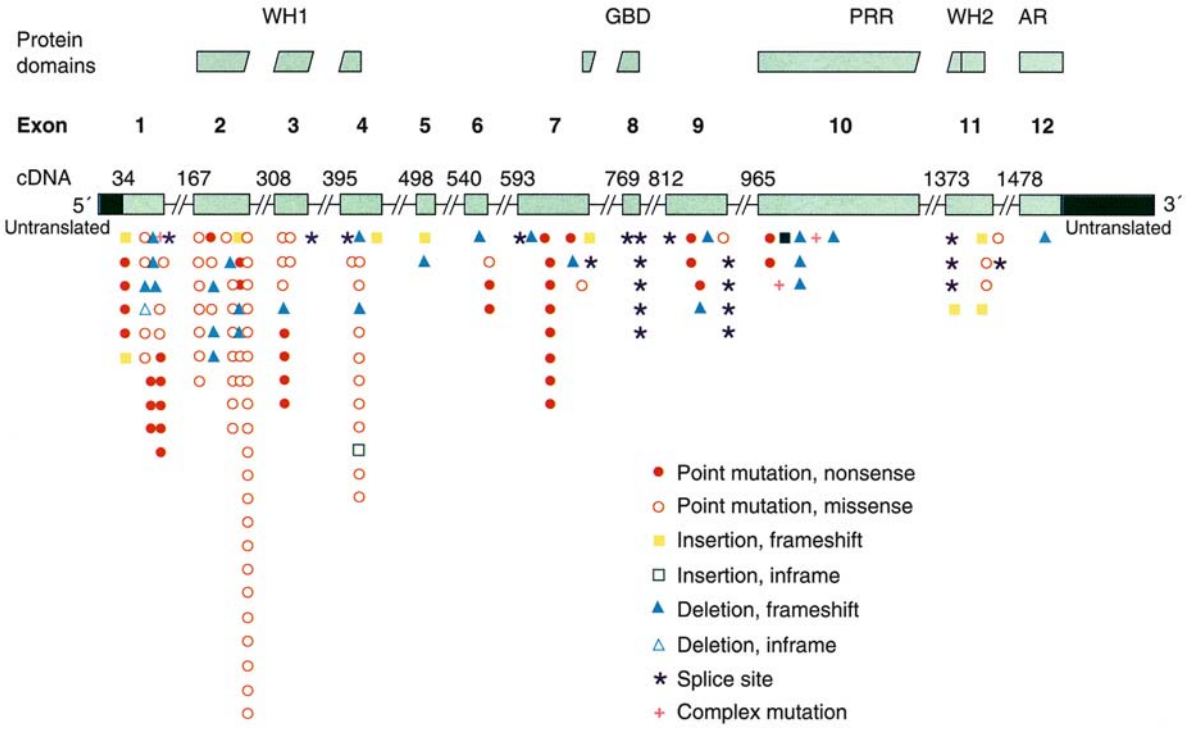

Fig. 22.25. Distribution of mutations across WAS exons and domains

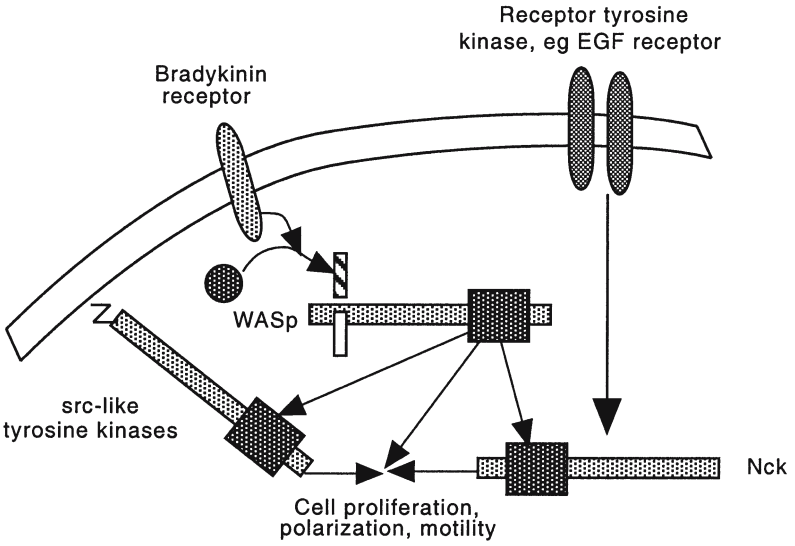

Fig. 22.26. WASp involved in cell signaling. Receptor signals (such as bradykinin receptor) cause exchange of GDP bound to Cdc42 (*dark shaded areas*) to GTP. Cdc42-GTP (*light shaded areas*) binds to WASp in a specific site (*white areas*), thus inducing cell-shape changes. WASp also binds its proline-rich region to SH3 domains in other signaling proteins such as Nck and Src-like tyrosine kinases. (Modified from [152])

Molecular biology has proven that WASp found only in blood cells binds the small GTPase CDC42H2 in the GTP but not in the GDP [23, 265, 490]. CDC42H2 plays a critical role in the assembly of actin filaments [490] and in T-cell polarization when they encounter a B-lymphocyte APC [481]. WASp activity is regulated by several proteins acting in concert to control WASp configuration. The WASp-interacting protein, when phosphorylated, releases WASp from its grip, allowing WASp to be activated by Rho-family GTPases [433]. Experimental data also indicate that Cdc42, WASp and actin might be involved in ensuring the T lymphocyte functional polyvalence, also explaining why microvilli and platelet defects are absent [152]. WASp and several related proteins (the WASp family) are all involved in the organization of the actin cytoskeleton. To carry out vital functions, cells have to rearrange their actin cytoskeletons [467].

The characteristics peculiar to WASp as a meeting point for the marking pathways is illustrated in Fig. 22.26 [152]. The WASp function is absent in 135 cases of WAS, in ten with attenuated WAS and in 23 with XLT [372]. In normal subjects, it is found in the cyto-

Table 22.12. Immune characteristics of WAS

1. Very elevated IgA and IgE concentrations
2. Decreased IgM concentrations
3. Normal total IgG concentrations
4. Quantitatively normal B lymphocyte, in progressive expansion
5. Progressively decreased T lymphocyte number and function (generally with preserved reciprocal rate) so that lymphopenia is almost never marked before age 6
6. No response to polysaccharide antigens, so patient serum is deprived of isohemagglutinins
7. Poor lymphocyte response to mixed lymphocyte culture and to mitogenic effects of antibodies to CD3

Data from [287, 413].

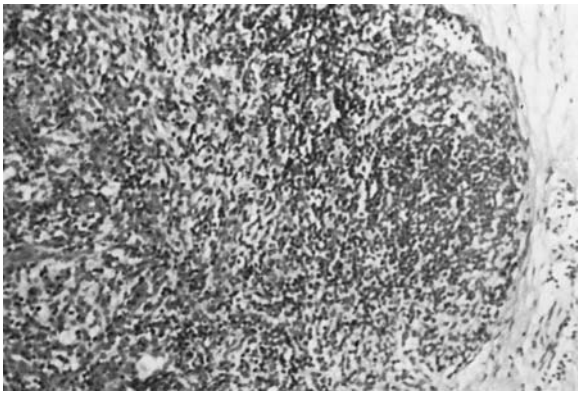

Fig. 22.27. A lymph node biopsy specimen from a 4-year-old boy with WAS. There is a moderate degree of depletion of lymphoid cells in both thymus-dependent and thymus-independent areas, with lack of follicular formation

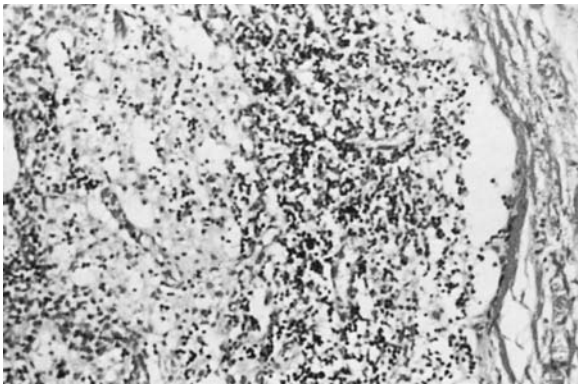

Fig. 22.28. A lymph node biopsy specimen from an 8-year-old boy with WAS, the older brother of the patient shown in Fig. 22.27. There is a greater degree of depletion of lymphoid cells in both thymus-dependent and thymus-independent areas, and no follicular formation

plasm but not in the nucleus of various cells such as platelets, T and B lymphocytes and monocytes [477]. The XLT gene is located on the same *locus* as the WAS and could therefore be a variant [444]; the main immunological anomalies are summarized in Table 22.12 [287, 413]. Children with WAS have *significantly elevated levels of IL_4 and IgE* (Table 22.2) and *decreased levels of IFN-γ* [217]. The pathogenetic mechanism unifying the symptom triad is not clear; the glycosylation defect has been proved, primarily concerning sialidation, therefore resulting in an instability on the membranes of platelets, neutrophils and lymphocytes expressing a glycoprotein sialopherin (CD43) [402], localized on chromosome 16, which makes it an improbable candidate, even though CD54 is indeed the binding agent of CD43 and could therefore play a role in T-cell maturation, differentiation and activation, thereby acquiring marking capacities that are independent of TcR/CD3 [19]. However, the TcR-mediated signaling defect is characteristic of WAS [259], in addition to the reduced expression of CD23 [458], which can explain immune and hematological defects.

In the lymph nodes, there is a shortage of lymphatic follicles and the thymus-dependent and -independent areas are depleted, moderately at the age of 4 years (Fig. 22.27) and to a greater extent at 8 years (Fig. 22.28). The predominant immunological outline is constituted by elevated IgA and IgE levels, low IgM and all IgG levels, as well as the absence of a response to polysaccharide antigens, which is why the children's serum lacks isohemagglutinin [278, 528]. In unweaned babies, the most striking finding is the CD4:CD8 ratio =5 [549], compared to 2.65 in normal children aged 0.63–3.06 (Tables 1.36–1.39).

WAS usually *starts at 13.7 months* (range, 1–58) [132] with hemorrhagic manifestations, petechiae and prolonged bleeding from the umbilical scar or the circumcision site, observed in newborn babies [402]. The clinical triad is characterized by cutaneous lesions that are practically *indistinguishable from rather severe AD* (70%), congenital thrombocytopenia (100%), a marked susceptibility to RRIs (91%) [132] (Figs. 22.29, 22.30) and gastroenteric symptoms such as hematemesis, melena and chronic diarrhea [132]. Other complications may include neutropenia (25%), arthritis (29%), skin vasculitis (22%), cerebral vasculitis (7%), inflammatory bowel disease (9%), and renal disease (3%) [132]. A reduced thrombopoiesis (level <50,000/ml), with microthrombocytes and an accelerated turnover in boys must allow for a suspected diagnosis [413]. It has recently been proven that the classic presentation is more common in children aged 6.8 months than in those aged 7.2 months (60% compared to 25%), unlike platelet counts [549]. However, only 27% of 154 unselected children with persistent thrombocytopenia, positive FH, small platelets and defects associated with T and/or B lines had the classic triad and 20% only thrombocytopenia before diagnosis [484].

Fig. 22.29. Child with WAS (for details see text)

Fig. 22.30. Child with WAS, particularly of the face with eczematous dermatitis and some petechiae

Infections, appearing during the first months of life, are often marked by otitis media, pneumonia, meningitis and sepsis, caused by viruses (CMV and *Herpesvirus*) and by bacteria (*pneumococci* or other capsular polysaccharide). These are followed by more common infections caused by opportunistic germs, *Pneumocystis carinii* and mycetes such as *Candida albicans*. Differential diagnosis should also include a rare AR syndrome similar to WAS, also reported in female patients, characterized by AD, RRIs and thrombocytopenia with microthrombocytes [62]. When caring for these children one must monitor the platelet count, the immunological structure (Ig, lymphocyte and subpopulation counts) and the potential onset of autoimmunity and tumors [224]. AIHA may be found in 36% of children [132]. Prophylactic treatment for infections is done with IVIg; 500 mg/kg every 3 weeks) and sulfamethoxazole (25 mg/kg/2 days) after diagnosis [132]. Splenectomy may decrease the bleeding tendency [224], but early relapse of thrombocytopenia after splenectomy is predictive of a poor prognosis [132]. On average death occurs around the age of 11 (8 in untreated children), but can occur between 0.5 and 4.5 [549], with survival also >18. Death is caused by massive hemorrhages (23%), tumors (26%) and severe infections (44%) [484].

The second largest group of patients with ID given BMTs since 1968 are those with WAS, with *78.8% of children aged <5 years* [158]. Fourteen out of 18 patients underwent phenoidentical (n=1) or haploidentical (n=13) HSCTs; the other four died before HSCT could be undertaken [132]. Boys who had received a MUD HSCT transplant <5 years *had survival rates similar to those receiving HLA-identical sibling transplants,* but the success rate decreases dramatically at the age of 5–6 [158]. WAS-associated T-cell signaling defects can be improved upon retrovirally transduced HSCTs [258].

Recently, correcting the T-cell defects has been proposed. The potential for correction of the T-cell defects has recently been demonstrated by transduction with *an oncoretroviral vector encoding the WASp,* which resulted in correction of the deficient proliferative response to TcR stimulation characteristic of WAS [483].

Ataxia-Telangiectasia

ATA is a complex AR inherited syndrome, associated with neurological, immunological, endocrinological, hepatic and cutaneous abnormalities, characterized by progressive cerebellar ataxia, oculocutaneous telangiectasia, and increased susceptibility to RRIs [379] with an incidence estimated at 1:100,000–1,300,000 live births [61]. In Italy the frequency on the general population, is of 1.3×10^6, with an increase in HETs from 1.7% to 3.43% [94]. It is characterized by a genetic heterogeneity, which is reflected in the division into four main groups of complementation, to which one must add the Nijmegen and AT-Fresno variants, perhaps caused by

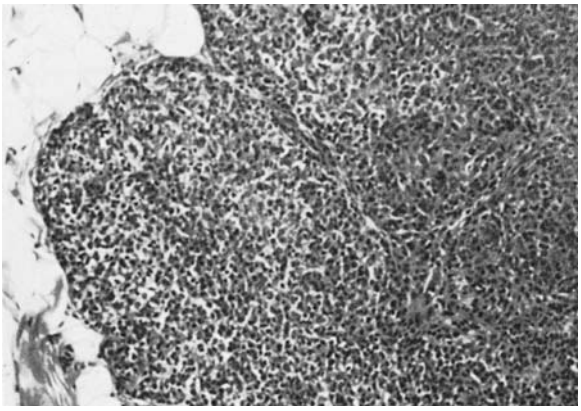

Fig. 22.31. Biopsy specimen of a thymus from a patient with ATA. Although some degree of cellularity is seen, there is no corticomedullary differentiation, and no Hassall corpuscles

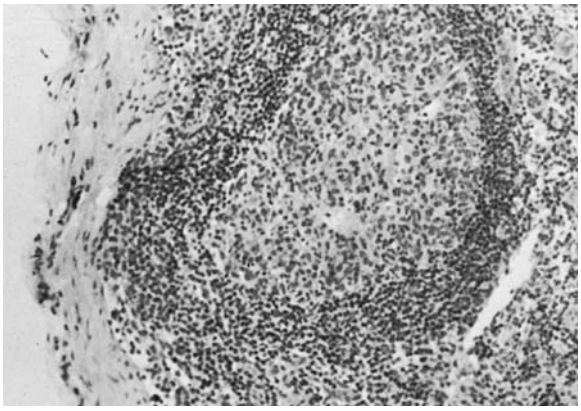

Fig. 22.32. A lymph node biopsy specimen from a 2-year-old child with ATA (for details see text)

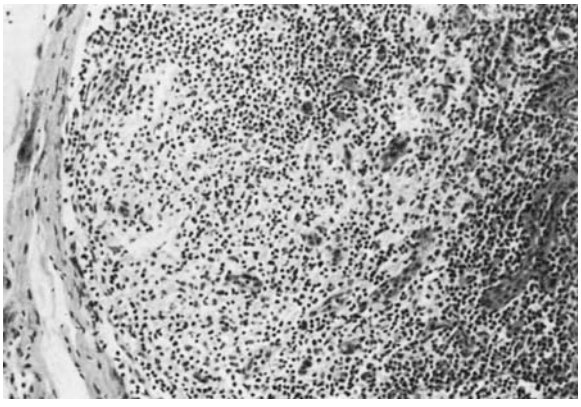

Fig. 22.33. A lymph node biopsy specimen from an 8-year-old child with ATA. In comparison with Fig. 22.32, the degree of depletion of lymphocytes is extensive in both thymus-dependent and thymus-independent areas

the same gene, also localized on the long arm of chromosome *11q22.23* [176].

The 12-kb gene, called ATM (AT mutated) because of its mutations by defective splicing in all patients with ATA, permits HET identification [435]. A DNA clone complementary to ATM shows considerable affinity to factors responsible for signals involved in regulating the cell cycle and codifying a protein similar to phosphatidylinositol-3-kinase (PI 3K) [435], involved in mitotic signal transduction, meiotic recombination, and cell cycle control. A result could be a recombination defect which interferes with B and T lymphocyte gene rearrangement, involving TcR and isotype switching, consequent to a damaged DNA triplication and therefore accounting for Ig deficiencies [176]. Cells from these patients progress too rapidly from the G_1 phase, in which they receive ionizing radiations, to the S phase, then continuing irradiation, to the G_2/M phase with further delay, evolving in apoptosis [279]. This hypothesis has received further credit after observing that the *p53* gene expression does not increase in human cells exposed to radiations [250]. The *p53* gene is part of the normal cell cycle and during the S phase provides time for the DNA physiological repair after exposure to radiation that may also be cosmic [279].

The thymic tissue is either absent or degenerated with a fetal appearance (Fig. 22.31): some follicles, also with B cells, are visible at the age of 2 (Fig. 22.32), at 8 there is complete cellular depletion (Fig. 22.33). Immune deficiencies are humoral and cellular (cutaneous anergy and depressed proliferative responses) [70]. The karyogram shows that the lymphocytes have common rupture points at the chromosomal level with *inversions and translocations involving precisely the TcR and Ig genes* [320]. Most chromosomal translocations involve the genes encoding TcR on chromosome 7 and the Ig H chains on chromosome 14: most breakpoints occur at the *loci* that encode Ig and TcR for antigen (regions *7q35*, *7p12*, *14q32*, *14q12*) [264], in areas typical for codification of molecules of immunological importance (Chap. 1). An important role is played by genes belonging to Ig gene superfamily (IgSF) (Table 1.4). Possibly the progressive ID of ATA, like its apparently unlinked manifestations, is at least in part linked to the accumulation of clonal anomalies affecting the TcR and the IgSF: this suggests the intervention of "illegitimate" recombinations damaging above all the T cells [162]. T-cell immunological deficiency is completed with lymphopenia, a decreased CD4:CD8 ratio due to the drop in cytotoxic CD8, and a rise of immature forms with TcRγδ [80].

Another consequence is the isotype deficiency: about 70% of patients present SIgAD; >50% are also affected by an IgG_2–IgG_4 deficiency with IgM becoming monoclonal, and 30% by serum IgG deficiency [364, 379, 528]. Anatomopathological studies explain the reason for the widespread and progressive cerebellar cortex degeneration, showing in the intermediate and deep layers rare

Fig. 22.34. Conjunctival telangiectasia in a girl with ATA

Purkinje cells (PCs) and degenerated granular cells. That the number of basket cells, so called because they form with the axons bunches of fibrils distributed so as to form a nest in which the nucleus of each PC settles, is almost normal, proving that PCs are probably normal at birth and degenerate only later [176].

Typical clinical manifestations are ataxia, telangiectasia of both auricular lobes and sclera, RRIs and an elevated incidence of neoplasia [489]. From a review of 331 patients [70], the percentages of symptoms are as follows: progressive ataxia (100%), typically cerebellar, becomes evident *when children start walking* or a little later, affecting intentional movement and becoming complicated by dysarthria (100%) and involuntary choreic movements (92%), causing the majority to be unable to walk by about the age of 10–12 [276]. At a later stage it is possible to observe nystagmus (67%), strabismus, oculomotor apraxia (88%), reduction or absence of reflexes (77%), and dyslalia, increasingly amplified and, in some patients, also mental retardation [176]. Telangiectasias develop between the ages of 1 and 6 on the bulbar conjunctiva (97%) (Fig. 22.34), on the flexor surfaces of the limbs and areas exposed to sun rays (17%). Height and weight are <10th percentile (64%) and the appearance is progeric (63%). Severe RRIs are common (70%), encouraged by antibody deficiencies. The pathogens involved can be bacterial or viral, often resulting in lung bronchiectasis, all starting after the onset of neurological manifestations [276, 489]. Associated neoplasia (6%) is usually lymphoreticular, less common than adenocarcinoma, with an eightfold increased trend for all kinds of tumors [224]. In cultures the fibroblasts of these patients are three times as sensitive, compared to controls, to ionizing radiations and to radiomimetic chemical substances, but not to UV rays, unlike what is observed in the cells of subjects affected by xeroderma pigmentosum [70]. In addition, the persistence of elevated serum α-1-fetoprotein (AFP) levels was observed in all patients. An interesting in vitro study has reported that by introducing a normal human chromosome 11 into cells, the chromosomal aberrations induced by X-rays were suppressed [261].

The rare AR *Nijmegen breakage syndrome*, so called because it was initially seen in two brothers of second-cousin parents living in that city, and at the moment observed in approximately 80 patients, has various characteristics of ATA but without ataxia, telangiectasia, or high concentrations of AFP. Clinical characteristics are singular: short stature and microcephaly with prenatal onset, bird-like profile, prominent midface, a long nose, low-set ears, cutaneous depigmentation with café-au-lait spots, an almost normal intelligence, and also RRIs and bronchiectasis. Humoral and cellular ID includes reduction of antibodies and lymphoproliferative responses [70, 224]. During an 8-year period of observation, the ID was found to be profound, highly variable, and with a tendency to progress over time in 40/50 children [193]. There is a high proclivity to expressing rearrangements of chromosomes 7 and 14 as in ATA [70, 224].

DiGeorge Syndrome

DGS is usually sporadic, with known cases of positive FH [224]. It is caused by a defective development of the 3rd and 4th branchial pouches which takes place before the 12th week of gestation, with consequent thymic hypoplasia or aplasia and parathyroid hypoplasia; the 5th and 6th pouches and branchial arches can also be affected [497]. The cause can be found in the neural crest cell incapacity to migrate and interact appropriately with endothermic cells of the brachial pouches and arches [295].

Deletions (often microdeletions) at the pericentrometric region of chromosome *22q11-pter* have been described in 80%–90% of cases [130]. A microdeletion *22q11.2* was recorded in 112 children aged 4–70 months, 54% of whom had developmental delays, mild hypotonia, as well as language and speech delays [181]. Another 80 children had deficits in the areas of attention, story and visuospatial memory, arithmetic performance relative to other areas of achievement, psychosocial functioning [541], and mental retardation in 73% of 44 children [11], thus indicating the need for early intervention beginning in infancy [181].

Overlapping alterations are present in the syndrome complex known as CATCH 22, which in turn includes the CHARGE association. Other cases of DGS can derive from microdeleted chromosome *10p* (fetal-alcoholic syndrome, retinoic embryopathy, maternal diabetes) [414]. This variable phenotype is reliably referred to microdeletion *22q11.2*; the greater it is the more complex is the associated phenotype [508]. Another difference depends on the variable spectrum of T-cell abnormalities in individuals with DGS who might have normal T-cell numbers and function, low T-cell numbers but fairly normal T-cell proliferative function [32] or no T cells

Table 22.13. Clinical manifestations of DiGeorge syndrome

External features	Malformations
Thymus	Aplasia
Parathyroids	Aplasia
Eyes	Hypertelorism, antimongoloid slant
Ears	Low-set, prominent with notched pinnae
Mouth	Micrognathia, absent/short labial philtrum, high arched palate
Heart	Interrupted aortic arch type B, common truncus arteriosus

Modified from [79].

Fig. 22.35. Infant with DGA (DiGeorge anomaly) with eye antimongoloid slant, micrognathia and low-set prominent ears

[305]. A second group is referred to as having partial DGS (DGSP) or transient forms (DGST), with mild symptoms. The designation "complete DiGeorge syndrome" (DGSC) is reserved for the third group of infants who have absence of thymic function in addition to other defects of the 3rd and 4th pharyngeal pouches, <1% of patients with DGS, although they can have high T-cell numbers that respond to mitogens [32, 305]. These patients have profound ID, with its associated clinical findings [308]. DGST includes cases with a spontaneous quantitative and qualitative T lymphocyte recovery [162]. The thymus can also be ectopic: in DGSC the T zones are depleted, the CD4/CD8 markedly reduced both in number and in function with SPT anergy, and B cells appear unaffected or increased [162]. In DGSP, the most common type, T-cell number and function are instead usually normal, as are the CD56/CD16 cells with a NK phenotype, or they may be moderately reduced [162]. The proliferative response to mitogens can be pathologically reduced [224] and the response to polysaccharide antigens may be absent [442]. From neonatal age, there are malformations of other structures that form during the first weeks of embryogenesis, presenting a *suggestive but not pathognomonic picture* (Table 22.13) [79].

Diagnosis is usually suspected within the first 2 days after birth, due to the presence of hypocalcemic tetany caused by hypoparathyroidism and cardiac malformation. The facial dysmorphism is also characterized by a small mouth with thin lips described as fish-like [79, 192] (Fig. 22.35). The two rare cardiopathies indicated in Table 22.13 depend on neural crest nonintegration, as mentioned, which accounts for >50% of the alterations alone [295]. Others can be observed affecting the right heart, such as Fallot tetralogy, pulmonary athresia with an interventricular septum defect, and pulmonary infundibular stenosis [508].

Babies surviving the neonatal period manifest from the very first months an increased susceptibility to infections, particularly those of the respiratory and digestive tract, viral and/or fungal, but also caused by *Pneumocystis carinii*, which can be fatal in DGSC [162]. Other findings include gastroesophageal reflux, speech delay, laryngomalacia, absent kidney, conductive or sensorineural deafness, 6th cranial nerve palsy, and hypothyroidism [535]. Treatment with high doses of vitamin D and diets enriched with Ca gluconate are needed immediately, also ensuring that calcemia remains at the lower limit of normal values so as to avoid SNC and renal damage. Subsequently the possible correction of cardiac malformations should be evaluated. ID may be severe, but can regress spontaneously with reconstitution of CMI and T functions; compensating hyperplasia of the residual parathyroid tissue can make it possible to discontinue Ca and vitamin D treatment [192]. *DGS natural history* is, however, complicated by mental retardation and the difficulties encountered in correcting cardiac malformations and in controlling hypoparathyroidism [224]. Because of variability in the ID severity, it is difficult to evaluate claimed benefits of BMT: in two cohorts of 8 [305] and 5 transplanted infants [306], the survivors were 3 out of 13 (23.1%). Recently, 5/6 and 7/12 infants underwent postnatal transplantation with cultured unrelated thymic tissue, with immunosuppression, with positive results [307].

Del22q11.2 syndrome, characterized by a 3-Mb deletion on chromosome *22q11.2* is the most frequent known chromosomal microdeletion syndrome, with an incidence of 1 in 4,000–5,000 livebirths. Patients show

cardiac abnormalities, T-cell deficits, cleft palate facial anomalies, and hypocalcaemia. At least 30 genes have been mapped to the deleted region. Recently, in 5/13 patients with del22q11.2 syndrome without *22q11* deletion mutations were found in T-box 1 that is a major genetic determinant of the del22q11.2 syndrome [545].

X-Linked Lymphoproliferative Syndrome

XLP is caused by a defect in the *SH2D1A* gene (Table 22.1), which binds to the cytoplasmic domains of CD150 SLAM (signaling lymphocyte activation molecule) and 2B4, and may regulate signals transmitted by these receptors in T and NK cells, respectively [345]. XLP has been reported in >270 males from >80 families [446, 460], and in an other 27 males [381], it is inherited with the X-linked model. It is set off in males aged 5–6 by an EBV infection that became manifest with a very polymorphous pattern, often with unusually severe or fatal infections mononucleosis caused by the immune system incapacity to respond to EBV, or evolving into a hgG with IgA and IgG deficiency and HIgMS, or medullar aplasia and/or a Burkitt type lymphoma [446]. The disease has been reported in 15 female subjects [381].

XLP polymorphism could be explained by the fact that the EBV receptor is expressed on differentiating B lymphocytes starting with the preceding isotypic conversion stage [500]. It has recently been verified that before EBV infection, males already suffer from dys- or pan-hgG, incapable of regulating the expression of Ig and/or containing B or T lymphoproliferation. Even after EBV infection, the immune system is unable to provide adequate Th2 responses, and therefore releases cytotoxic alloreactive CD8 and Th1-like T cell ILs, causing extensive damage to the entire parenchyma, exemplified by *fulminating hepatitis, cellular infiltrations and tissular necrosis.* The lymphoid tissues with an altered structure are also affected by necrosis, with a high incidence of mostly nonlocalized lymphomas [381]. The thymus is also affected by thymocyte rarification, with clinical outlines not unlike GvHD [446] (Fig. 22.36) [508], suggesting a possible connection to a Fas deficiency (CD95) or apoptosis syndrome. The SH2D1A gene was found altered in two families, thus indicating that XLP must be considered when more than one male patient with CVID is encountered in the same family, and SH2D1A must be analyzed *in all male patients with CVID* [330].

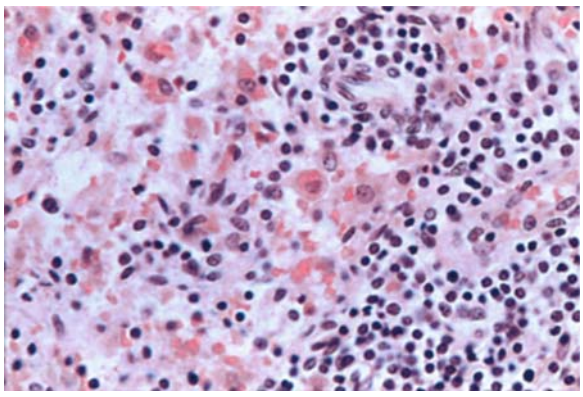

Fig. 22.36. Bone marrow biopsy specimen in a 3-year-old boy: numerous histiocytes in erythrophagocytosis

Hyper-IgE Syndrome

Recently a critical revisitation of this experiment in nature has allowed the identification of links between ID and allergy [62, 178, 196, 287]. The rare HIgES is associated with bacterial RRIs, chronic AD, coarse facial features and very elevated IgE levels [60, 250] (Table 22.2), up to 40,000 IU/ml [549]. Linkage to a region on chromosome *4q* has been demonstrated in several affected families; however, neither the fundamental host defect nor the defective gene has yet been identified [195]. FH is frequently positive for atopic disease, at times HIgES is combined with an unusual predisposition to *Staphylococcus aureus* infections [62, 178, 196, 287]. In Buckley's study, it was present in 36.4% of cases, of both sexes, indicating an autosomal dominant transmission with incomplete penetrance [62]. Onset occurs in the pediatric age in 90% of cases [64]. Clinical presentation is unusual: there are no complaints during the first months of life, toward the 3rd–4th month a *severe form of chronic AD* appears all over the body, which can be associated with other allergic manifestations, including asthma in 13.6% of cases [62]. Skin biopsy specimens reveal spongiosis and perivascular dermatitis and/or folliculitis with a predominance of eosinophils [91]. There is an excessive predisposition to cutaneous and respiratory tract infections (deep and superficial abscesses, otitis, pneumonia, sepsis) (Fig. 22.37), also encouraged by *neutrophil chemotactic deficiency* caused by defective cellular functions (Table 1.65), which, if present, is so pronounced that it becomes a characteristic, unlike AD where it is secondary [226]. The subcutaneous abscesses, described as cold, not covered by warm and reddened skin, are pathognomonic to HIgES but not essential to the diagnosis [144]. The abscess is filled with pus that always grows *Staphylococcus aureus*; in some cases mucocutaneous candidosis and chronic herpetic keratitis are associated [178].

Infections appear within the first 18 months [62]. The face shows coarse and dysmorphic features, midline facial defects such as a prominent nose and a high, arched palate, and disproportionate cheekbones and mandible; pondostatural growth notably retarded [64], pneumatocele (Fig. 22.38) and osteoporosis caused by reduced bone density with a tendency to fracture [287] complete the picture. Six consanguineous families have been reported with an AR form of HIgES, including 13

Fig. 22.37. Hyper-IgE syndrome (for details see text)

Fig. 22.38. Chest roentgenogram of a 12-year-old boy with hyper-IgE syndrome: evidence of giant pneumatoceles

affected children aged 15 months to 12.5 years, with AR-HIgES presenting with the classic immunological findings, including RRI, eczema, elevated serum IgE, hypereosinophilia, and severe recurrent fungal and viral infections [64]. Notably, patients with AR-HIgES did not have skeletal or dental abnormalities and did not develop pneumatoceles, as seen in autosomal dominant-HIgES [404].

Among the immunological characteristics (Table 22.14) [93, 287], cutaneous anergy to several antigens such as *Candida* and tetanic toxoid is characteristic, which is associated with the anomaly of proliferative responses by the T cells to antigens and mitogens, in contrast with the integrity of other functions tested in vitro [196]. T subpopulations appear to be normal [64]. However, the lymphocyte proliferation to anti-CD3/CD28 monoclonal antibodies can be impaired [226].

As noted, *IFN-γ deficiency* associated with a pathological Th2 prevalence has a fundamental impact on IgE

Table 22.14. Immunological abnormalities of HIgES

1.	Markedly elevated IgE levels (up to 40,000 IU/ml)
2.	Specific IgE directed against *Staphylococcus aureus*, *Candida albicans* and *Herpes simplex* antigens
3.	IgG-anti-IgE antibodies
4.	IgE-containing immune complexes
5.	Normal lymphocyte proliferation responses to PHA and PWM, but reduced to con-A
6.	DHST negativity
7.	Markedly variable chemotactic abnormalities of neutrophils
8.	Normal phagocytic and bactericidal activity
9.	Marked peripheral and local eosinophilia
10.	Reduced IFN-γ synthesis
11.	Selective CD8 deficiency
12.	Underexpression of chemokines ENA-78, MCP-3, and eotaxin

Data from [93, 287].
Con-A concanavalin A, *DHST* delayed hypersensitivity skin test, *PHA* phytohemagglutinin, *PWM* pokeweed mitogen.

hyper-production [178, 287]. In HIgES, some studies have confirmed IFN-γ deficiency compared to controls [120, 368], also due to an impaired response to IL_{12} [56], while others have not [62, 512]; however, compared to AD, normal levels of T producers of IL_4 are characteristic [120]. Considering the IFN-γ/IL_4+ correlation of AD, in HIgES no specific T-cell anomalies are noted, nor does the hyper-IgE explain this pediatric abnormal susceptibility to infections: high IgE levels are also seen in children with AD, who do not, however, have an unusual predisposition to abscess formation [226]. One typical characteristic is sIgE directed against microbial antigens: the anti-staphylococcal sIgE rise to 8.9% compared to normal levels of 0.2%–0.6%. Another constant finding is the increase in 100% of cases of eosinophil concentrations, which make up 6%–12% of leukocytes [64], reaching 30%–50% [178]. By expressing the CD40–CD154 duo, they stimulate the isotype B-cell switching to IgE. We studied children affected by severe AD, chronic FA-induced diarrhea and asthma. The allergens responsible were CM and Der p [73]. In case of HIgES caused by FA, atopic manifestations can clearly improve following an exclusion diet, reducing the frequency of infections and partially correcting the immune defect [420], revealing how FA can induce several immunological anomalies. *Diagnosis* is made on the basis of the data in Table 22.14; *differential diagnosis* with AD is schematized in Table 22.15 [287]. Treatment with cromolyn is extremely effective, anti-staphylococcal antibiotic treatment [64, 226] and if necessary antifungal therapy provide good results [144].

Table 22.15. Differential diagnosis between HIgES and AD

Features	HIgES	Atopic dermatitis
Age of onset	1–8 weeks	>2 months
Frequency	Very rare	Common
Coarse facies	Common	Rare
Dermatitis	Atypical eczema	Typical eczema
Growth	Often delayed	Normal
Osteoporosis	Present	Absent
Erythemas	Absent	Present
Abscesses	Typical	Absent
S. aureus infection	Deep-seated sepsis type	Superficial skin-limited
Other infections	Frequent	Rare
Respiratory allergy	Uncommon	Common
Kerato-conjunctivitis	Rare	Infrequent
IgE level	Extremely high	Normal to very high
Eosinophilia	Frequent	Frequent
Defect of chemotaxis	Frequent	Absent

Data from [61, 287].

Chédiak-Higashi Syndrome

The clinical features of this rare AR disease include oculocutaneous albinism and susceptibility to especially *S. aureus* and β-hemolytic *streptococcus* [549]. Approximately 85% of patients develop an accelerated phase of the disease, with deposition of lymphohistiocytes in the liver, spleen, lymph nodes and BM, resulting in hepatosplenomegaly, lymphadenopathy, BM infiltration hemophagocytosis, pancytopenia as well as fever, jaundice, prolonged bleeding, easy bruisability, neurological changes (nystagmus and neuropathy), mild mental retardation, and partial ocular and *cutaneous albinism* [285, 334, 526]. The cellular hallmarks of the disease include large lysosomal granules in leukocytes, giant melanosomes in melanocytes and affecting other cells of the body such as neural Schwann cells, renal tubular cells, gastric mucosa, pneumocytes, hepatocytes, Langerhans cells of the skin, and adrenal cells [229, 157]. The fundamental defect in this disorder was found to be caused by mutations in a gene mapped to chromosome *1q42–q43* [31] encoding a cytosolic protein on chromosome 1 named *lysosomal-trafficking* (LYST) *regulator*, encoding a 425-kD protein whose function remains unknown [285]. BMT is resolutive in these children [205].

Griscelli Disease

Griscelli disease, mapping to chromosome *15q21* [372], is an AR syndrome caused by mutations in the *MYO5A* (GS1), *RAB27A* (GS2), or *MLPH* (GS3) genes, all of which lead to a similar pigmentary dilution [50, 312]. The disease is also characterized by partial oculocutaneous albinism, predisposition to pyogenic infections and in most patients by abnormal regulation of the immune system, which results in a syndrome of macrophage hyperactivation, known as hemophagocytic lymphohistiocytosis [15]. Mutations in the GTP-binding protein RAB27A (GS2), which appears to be involved in an uncontrolled T lymphocyte and macrophage activation syndrome, leading to death in absence of BMT, occur in this syndrome [319]. A mutation was found in the *MYO5A* gene (GS1) associated primarily with neurological impairment [319]. Two identical twin boys aged 3 months were reported with persisting fever, mouth ulcers, hepatosplenomegaly, pancytopenia and failure to thrive [431], as was an 8-month-old infant [397]. Both infants had silvery-gray hair and pigment clumps on the hair shafts, and skin biopsy showed accumulation of melanocytes on melanosomes. Their parents were first cousins and a sibling with similar manifestations had already died, as did the twins. A genetic study revealed a 5-bp deletion in the *RAB27A* gene (510 del AAGCC in exon 5) [431]. In a 4-year-old child with hemophagocytic syndrome, ID, and secondary neurological disorders, typical melanosome accumulation was found in skin melanocytes and pigment clumps were observed in hair shafts. Two heterozygous mutant alleles of the *RAB27A* gene, a C-T transition (C352T) leading to Q118stop and a G-C transversion on the exon 5 splicing donor site (G467+1C) were found [50]. The finding of *gray strands of hair, gray eyebrows, and eyelids in childhood* should alert pediatricians to considering Griscelli syndrome since an early diagnosis is life- and health-saving [203].

Phagocyte Deficiency

The phagocyte system with the biochemical basis of CGD is analyzed within the framework of innate immunity.

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) has an overall prevalence of 1:500,000 to 1:10^6, although this could be underrated (Table 22.4), considering that some subjects may have a very mild clinical phenotype that escapes diagnosis [501]. A US registry of birth rates found a prevalence of 1:200,000 to 1:250,000 live births for the period 1980–1989 [538]. The youngest patient was *27 days old* [337] and in 12 children with CGD the mean age at the onset of infections was *5 months,* with a median delay in diagnosis of 2.5 years [371]. Otherwise the

median age at onset was 1.12 months, and the median age at diagnosis was 1.1 years [81].

The deficiency appears in two forms (Table 22.1): *X-linked (X-CGD)* is caused by a mutation in the gene encoding the 91-kD (gp91^{phox}) [538], termed CYBB, a subunit of the cytochrome b558 component of the oxidase for which a database includes 304 patients from 261 families and 192 individual mutations [345, 412] (Figs. 22.39, 22.40). *The X-CGD* (56.3%–70.4% of cases) [335, 538], with an H-chain deficiency, is divided into four X91 subtypes (Table 22.16 [84, 97, 109, 112, 185, 501]), also identified on the basis of NBT results, depending on whether the X91 is absent (the most common form), reduced or present but inactive; subtype X91$^-$ is divided into two variants: in one of them the NBT is slightly positive in 80%–100% of cells (6% of patients), in the other in 5%–10% (3% of patients) [84, 109, 412, 501]. More precisely, the four subtypes are caused by mutations in the four gp91^{phox} regions, many of which depend on CYBB gene mutations, causing the X91^0 form, while 17 mutations depend on the NADPH-oxidase activity (X91$^-$ form) and eight others lead to a normal protein expression (X91$^+$ form), but with a total absence of oxidase due to incorrect binding [412].

AR-CGD is caused by a mutation in the genes encoding the remaining oxidases of 47 kD (p47^{phox}) (phox, phagocytic oxidase) [538] (NCF-1), p22^{phox} of 22 kD (CYBA), and p67^{phox} of 67 kD (NCF-2) [109, 501]. The AR-CGD forms (18.5%–22% of cases) [285, 458] are identified using the immunoblotting technique, depending on whether they affect the p22^{phox}, the p47^{phox} or the p67^{phox} [84, 97, 109, 501], with greater prevalence in an American study [97]. Patients with the X-CGD appear to have a more serious clinical phenotype than patients with the AR-CGD, based on the fact that they are diagnosed significantly earlier (mean, 3.01 years of age vs 7.81 years of age, respectively), have a significantly higher prevalence of infections and a higher mortality (21.2% vs 8.6%) [537]. Mutations in any of the 6 structural molecules (Table 22.16) lead to CGD. Mutation of Rac2 (see LAD), the predominant G protein in neutrophils, leads to defects in SO production, as well as in chemotaxis [416]. Activation of the NADPH oxidase requires complex rearrangements between the protein

←

Fig. 22.39. a Domain organization of gp91^{phox}. The *green numbers* indicate the number of families having mutations in the exons that are numbered in *red*. The number of families having intron mutations is shown in *black* below the exon-intron boundaries. Two families having mutations in the promoter (*P*) region are also indicated. **b** Mutations causing X-CGD. The sequences are arranged according to domains. The *underlining* in the N-terminal domain and the beginning of the FAD-binding domain indicates the hydrophobic residues that may be membrane spanning. Further *underlining* in the FAD-binding domain indicates residues that are supposed to be involved in FAD binding, and in the NADPH-binding domain for supposed NADPH-binding. The α-helices and β strands are indicated by *red* and *blue* sequences, respectively. The mutations given *below* the sequence lead to diminished protein expression and oxidase activity (X91 ~ CGD) (*indicated in italics*), normal protein expression and total lack of oxidase activity (X91 + CGD) (*indicated in bold*), or to unknown phenotypical expression (*indicated in normal print*)

subunits, which are in part mediated by noncovalent binding between src-homology 3 domains (SH3 domains) and proline-rich motifs [447].

CGD is a hereditary disease (Table 22.16) characterized by severe recurrent pyogenic infections. This marked susceptibility is caused by the phagocytes' incapacity to kill in particular the catalase-positive bacteria, because of a genetic defect of the NADPH-oxidase enzymatic system situated in the wall of the phagocytic vacuole. In CGD, phagocytosis occurs normally, but the NADPH-oxidase is unable to markedly produce anion superoxide ($O_2^{\bullet-}$), H_2O_2 and other O_2 free radicals, thereby permitting the survival of microorganisms within the cells, where they are protected from the antibodies and from most antibiotics [501]. Another consequence of the lack of O_2 radicals is the development with countless inflammatory episodes, which then result in typical granulomas [109]. The nitroblue tetrazolium (NBT) reduction test is based on the chemical characteristics: in fact, the phagocytes without $O_2^{\bullet-}$ are unable to reduce the yellow NBT of products activated by PHA aspecifically stimulated phagocyte O_2, or specifically with corpuscle particles such as preopsonized yeasts (Fig. 22.41). The result was 0% in 14 children [81]. At a molecular level, the genes that codify the two subunits of flavocytochrome b588, gp91^{phox} and p47^{phox} have been cloned: respectively the cytochrome, H (β) and L (α) chains situated on the phagosome vacuole membrane, and also the cytosolic factors p40^{phox}, p22^{phox} and p67^{phox}, deriving from the NADPH-oxidase activation, all proteins placed inside the cytoplasm and that belong to innate immunity. It has therefore been possible to identify molecular lesions at the CGD origin, with the exception of the p21^{rac1} [16, 412, 533].

The clinical pattern is severe in the X91^0 form and variable in the other two X91 forms; *onset occurs within the 1st year of life in 2/3 of cases, and in others within the 2nd year* [159], although it can appear also at the age of 16 [335]. Purulent recurrent infections, with a granulomatous evolution, predominantly affect the epithelial surfaces normally colonized by bacteria, such as cutaneous, subcutaneous, mucous membranes, the respiratory tract and the intestine: cutaneous and mucosal infections, and lymphadenitis lead to suppuration and fistulation (Fig. 22.42), pneumonia or lung abscesses (Fig. 22.43) are more frequently characterized by persistent fever and diarrhea [159] (Table 22.17) [109, 538]. Pneumonia was the most prevalent infection in 369 patients (79%) (mostly by *Aspergillus*), followed by suppurative adenitis (53%), subcutaneous abscess (42%) and liver abscess (27%); mostly by *Staphylococcus*, osteomyelitis (25%) mostly by *Serratia*, and sepsis (18%), and by *Salmonella* [538]. In a long-term trial, pneumonitis was the most prevalent infection (91%) followed by lymphadenitis (83%), aphthous stomatitis (58%), liver abscesses (25%) and chronic lung disease

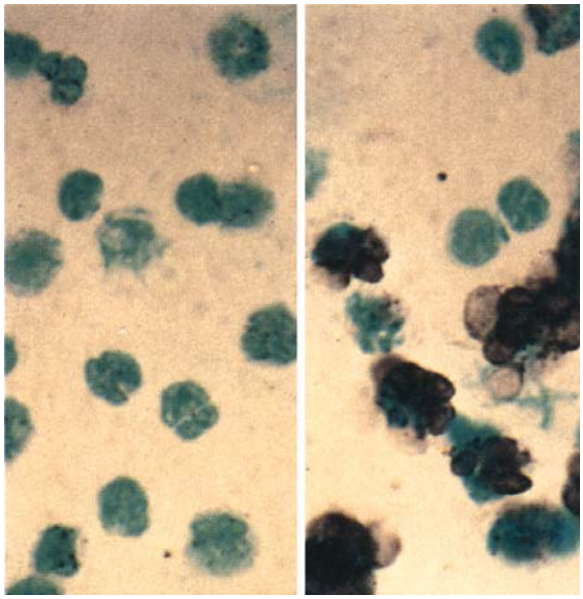

Fig. 22.41. NBT test. *Right*: in normal PMN and PBMC reactive superoxide generated by the respiratory burst reduces the soluble yellow NBT dye to the deep blue of formazan. *Left*: CDG patients cannot form superoxide, so the dye stays yellow

(58%) [371]. Lymphadenitis, lung infections, enteral infections, and hepatic abscesses were the most frequent infections in a cohort of 48 children [335]. Staphylococcal liver abscesses are almost pathognomonic of CGD [447, 538].

Because the infections develop in areas drained by lymphatics, they tend to diffuse via the lymphohematogen route, thus causing *arthritis and osteomyelitis* and *abscess formation,* especially affecting *the bones, which are the most severe manifestation,* and *hepatitis with common upsurge of hepatosplenomegaly.* Lung infections are almost the rule: those initially segmented and parallel tend to gradually spread over the entire lobe [109, 538]. Histological examination shows widespread *granulomas in the entire lung parenchyma,* which are formed by mononucleates (Fig. 22.44a) with giant cells (Fig. 22.44b). The chronology of infection onset is summarized in Table 22.18 [335]: lymphadenitis is the earliest. Osteomyelitis is usually a worrying complication:

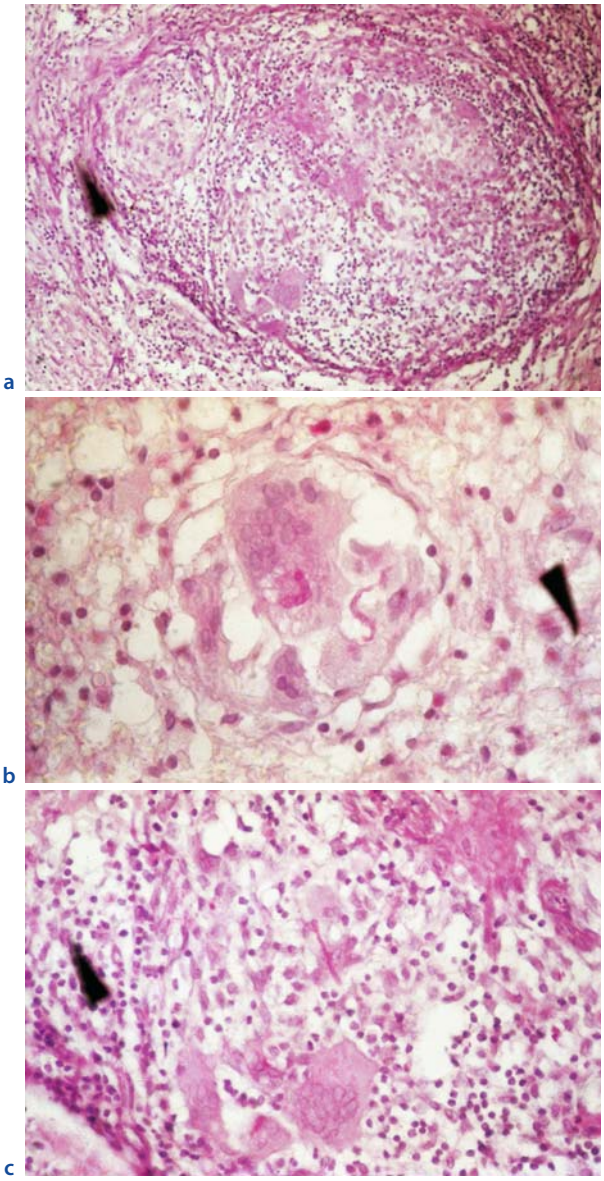

Fig. 22.44 a–c. Child with X-CGD. **a** Granuloma. **b** Giant cells. **c** Pulmonary aspergillosis

extensive bone destruction involves various segments, for example the vertebra, the metacarpus and the metatarsus, causing widespread damage, which is difficult to treat and is also irreversible [109, 501]. *Aspergillus*, pulmonary, bone (Fig. 22.44c) or encephalic infections constitute a severe therapeutic problem and are threatening events, with a mortality rate of 26%, but with specific treatment the prognosis is good as far as recovery is concerned [335]. The treatment includes prophylaxis with trimethoprim-sulfamethoxazole (TMP/SMX) (5 mg/day given in two divided doses), and IFN-γ (50 mg/m^2 subcutaneously thrice weekly) in all patients with CGD, regardless of genotype [81, 416]. Itraconazole therapy (5 and then 10 mg/kg/day)

Table 22.18. Onset age (mean + range) of infections in children with CGD

Infections	Mean (months)	Range (years)
Airway infection	55	0.1–14
Liver abscess	83	0.1–18
Gastroenteric infection	38	0.3–14
Lymphadenitis	16	ND

Data from [335].
ND not done.

has an excellent tolerance in all cases and was effective in 29 of 32 children (90.6%) [336].

Survival until the age of 21 and beyond is achieved by 20% of patients with CGD XL and 37% of those with CGD AR [339]. Because the prognosis is uncertain, as observed, the *only possibility for a definite resolution is with a BMT,* from family donors who are X-CGD or X-CGD-identical [393]. BMT was successful in 27 children out of 31 (87.1%) (see Table 22.30), including a 4-year-old boy with X-CGD who underwent successful HLA-identical peripheral blood SC transplantation during invasive pulmonary aspergillosis and osteomyelitis, which was unresponsive to antifungal treatment [48].

Leukocyte Adhesion Deficiency

LAD is due to mutations in the gene on chromosome 21 at position *q22.3* encoding CD18 (Table 22.1). It is divided into five types: *LAD type I to LAD type V* [24, 71, 138, 367]. The three subunits of the CD11/CD18 complex are involved in PID (LAD type I syndrome), AR, linked to the lack of $\alpha_M\beta_2$ equal to CD11b/CD18 (Table 1.46) surface expression on all leukocyte populations caused by 20 different mutations in the CD18 encoding gene, often severe in infancy [145, 202]. Children with a deficiency of these integrins have a defect above all in phagocyte action, suffer from severe infections from the neonatal period [202] due to absent β2-integrin activity, which impairs neutrophil ability to exit the circulation and travel to sites of infection. On the contrary, leukocyte movements are not prevented, indicating the normal involvement of CD54 and CD102 (Table 1.4). The clinical basis for defining this disease, described in over 200 cases [145], dates back to a study at the Soothill school in 1979 [215].

There are two forms of *LAD type I* [71]: if the deficiency is full blown (no detectable CD18), the clinical symptoms (Table 22.19) [71, 138] are dominated by severe and recurrent infections with a negative prognosis in the first years of life unless corrected by an allogenic BMT, the only resolutive treatment [492]. If instead it is a partial deficiency with residual CD18 expression, the

Modified from [71, 138].
[a] >2 weeks.

clinical outline is less severe and some patients, with appropriate treatment, can live to adult age [24].

LAD type II, AR (CD18 levels are 1%–10% of the normal levels), with a molecular base represented by an sLeX ligand (CD15s) is a defect common to CD62 E and P, which mediate neutrophil rolling. In the absence of a GDP-fucose transporter, the sLeX is not made. LAD type 2 results from mutations in this transporter that takes fucose into the Golgi apparatus for posttranslational fucosylation of newly synthesized proteins. This is the ligand for CD62E; without it, leukocytes cannot make initial attachment to vascular endothelium [7]. LAD has been described in two children aged 3 and 5 with mental retardation, from different families, but both with parents who were blood relatives [145]. It has a lower mortality rate [138]. Mice with a deficiency of both selectins show a LAD-like syndrome, providing a useful model for studying these syndromes [171].

LAD type III shows defective tethering and adhesion and bleeding diathesis. This is a new syndrome where in vitro leukocytes showed normal rolling along endothelial cell cultures but defective tethering and tight adhesion. Thus this is a defect in the capability of vascular integrins on circulating leukocytes to rearrange with their endothelial ligands at adhesive contacts and rapidly arrest on target vascular endothelium in response to endothelial-displayed chemoattractants. However, the expression levels of the major integrins on lymphocytes and neutrophils were largely conserved in the patient cells, ruling out a LAD-I syndrome. Patient leukocytes showed no LAD-II like fucosylation defect, since they expressed normal levels of the fucosylated marker CD15s, comprising the sLex carbohydrate selectin ligand [7].

Defects in both leukocyte and platelet functions that are biochemically and molecularly distinct from the adhesion disorders previously described suggest a mutation in an early myeloid pathway. The defect is associated with regulation of the GTPase activating protein Rap1, as demonstrated by the intact Rap1 expression and activation by phorbol esters, thus ruling out an LAD defect in Rap1 GTP loading [255].

LAD type IV manifests defective CD62E expression or tethering. A girl developed *Pseudomonas* omphalitis at *5 weeks of age,* recurrent ear and urinary tract infections, and had clinical evidence of impaired pus formation reminiscent of a LAD syndrome, but her neutrophils were functionally normal and expressed normal levels of CD18, CD62E, and sLex. However, the patient showed an absence of CD62E from the endothelium, although E-selectin mRNA was present. In contrast to patients with LAD 1, she had mild chronic neutropenia but appropriate leukocyte increases in response to infections or GM-CSF. A BM biopsy performed during a period of health showed normal cellularity for her age. Her FH is remarkable only for a previous sibling who had died at 32 weeks of gestation of a staphylococcal infection of the fetus, amniotic fluid, and

placenta. She also has two half-sisters who are completely well. The FH is negative for recurrent infections in either parent or more distant relatives [121].

LAD type V caused by Rac2 deficiency. *A 5-week-old* boy born to unrelated parents had delayed UC separation, perirectal abscesses, poor wound healing, and absent pus at sites of infection in the setting of neutrophilia, suggesting a neutrophil defect. His neutrophils exhibited decreased chemotaxis, polarization, azurophilic granule secretion, as well as significantly reduced stimulated superoxide production but had normal expression and up-regulation of CD11b. Rac2 constitutes more than 96% of the Rac in neutrophils [9]. A 1-year-old boy who had multiple recurrent, life-threatening infections characterized by leukocytosis and notable for the absence of pus in the inflamed tissues was reported. The presence and density of CD11b, CD11c, and CD18 were normal. The expression of CD62P and CD62L were also normal. A BMT was curative. The boy shared a phenotype that closely mimicked that of a mouse mutant deficient in the Rho GTPase, Rac2 [534]. The disease was shown to be attributable to an AD mutation in the Rho GTPase Rac2 at an amino acid needed for proper interaction with other intracellular proteins. Rac2 comprises >96% of the critically important G protein Rac in neutrophils. Each member of the family appears to control a distinct function of the actin cytoskeleton (chemotaxis and degranulation) and NADPH oxidase (superoxide production) function [9].

Deficiency of Multiple Leukocyte Integrins

A male child from the mother's first pregnancy was born at term from parents of Arab ethnic origin who were first cousins. He had a severe genetic disorder associated with functional defects in multiple leukocyte integrins, reflected in recurrent infections, profound leukocytosis and a bleeding diathesis. Platelet transfusions and antibiotic courses reduced the symptoms, which remained a significant clinical problem. At age 6 years, he died from disseminated fungal infection after a mismatched BMT. A younger brother presented with the same clinical and hematological phenotypes at birth and died at age 1 week from sepsis.

Glucose-6-Phosphate-Dehydrogenase Deficiency

G6PD converts G6P to 6-phosphogluconolactone, generating NADPH and a H^+ ion from $NADP^+$. NADPH oxidase catalyzes the monovalent reduction of O_2 to $O_2^{\bullet -}$, with the subsequent conversion to H_2O_2 by superoxide dismutase [285]. In the form of a partial deficiency, known as the cause of hemolytic anemia or favism, the enzyme's residual activity (20%–25%) permits normal bactericidal activity. The 400 G6PD variants have been classified by the level of residual enzyme activity and propensity for hemolysis and grouped into five classes: *class I,* severely deficient with chronic hemolytic anemia; *class II,* severely deficient with occasional hemolytic anemia (<10% residual activity); *class III,* moderately deficient (10%–60% residual activity); *class IV,* normal activity (60%–150%); *class V,* increased activity [310]. In a trial on 161 G6PD-deficient subjects originating from different parts of Italy, a greater molecular heterogeneity than described by others was observed, especially in Sardinia [310]. In a complete deficiency, sexually transmitted, whose gene is localized on the chromosome X at position *p28* and characterized by several mutations and their variants, with a consequent *deficiency of bactericidal activity,* the neutrophils are unable to kill *S. aureus*, *E. coli* and *Serratia*, and therefore there is an increased susceptibility to infections, rather like CGD [109]. The diagnostic work-up of children may reveal a child with recurrent infections who initially received the diagnosis of G6PD deficiency, subsequently shown to have the phenotype of X-linked CGD [3]. The disorder has a *higher incidence* in Mediterranean countries and Asia, in Japan (10.6%) than in Indonesia (4.3%), as ascertained with a novel screening kit [234], and is low in newborns in Tehran, Iran (2.1%) [1].

Myeloperoxidase Deficiency

Within the framework of oxygen-dependent killing defects, hereditary myeloperoxidase deficiency (MPO) is the most common neutrophil biochemical defect and plays an important role in the host defense mechanism against microbial diseases. The neutrophil disorder characterized by the lack of MPO activity is speculated to be associated with a decreased level of immunity. MPO is unusually accompanied by a specific pathology. AR transmitted, it appears far more common than previously suspected (1:2,000 for the partial deficiency to 1:4,000 for the total deficiency). It is a disorder that is prevalently recorded in entirely healthy patients and therefore, in most cases, a *random laboratory finding*. In addition to three already-known mutations, the genetic characterization of an Italian population showed the presence of six novel mutations: four missense mutations, a deletion of an adenine within exon 3 (*c.325delA*) and a mutation within the 3′ splice site of intron 11 (*c.2031-2A>C*). The *c.325delA* deletion causes a shift in the reading frame with the occurrence of a premature stop codon within the pro-peptide. The activation of a cryptic 3′ splice site located 109nt upstream of the authentic 3′ splice site causes a shift in the reading frame that may lead to the generation of an abnormal MPO precursor lacking the enzymatic activity [303]. In a Japanese patient with complete MPO deficiency, neutrophil function analysis revealed that MPO activity was

significantly diminished with slightly elevated superoxide production. Mutational analysis of the patient revealed a glycine to serine substitution (G501S) in the exon 9 region [356]. Because the granulocytes without MPO cannot kill *Candida*, some subjects, presumably carriers of a more extensive mutation and in association with other diseases, *present severe and recurrent Candida infections.* The MPO defect can be diagnosed via a cytochemical investigation or a quantitative count of enzyme levels [303].

Specific Granule Deficiency

Neutrophil-specific granule deficiency is a rare autosomal dominant disorder characterized by recurrent pyogenic infections, defective neutrophil chemotaxis and bactericidal activity, and lack of neutrophil secondary granule proteins [284]. The markedly decreased level of mRNA expression for the bactericidal/permeability-increasing (BPI) protein, the activation factor PU-1 and defensins in these patients suggests a role for CCAAT/enhancer binding protein (*C/EBPη*) gene in earlier phases of the myeloid differentiation program [187]. *C/EBPη* is a member of the leucine zipper family of transcription factors, expressed primarily in myeloid cells [284]. Recessive mutations in the *C/EBPη* gene were described in one patient; analyses of the *C/EBPη locus* indicated that the disorder could have resulted from HZ recessive inheritance of the mutant allele from an ancestor shared by both parents [187]. Loss of C/EBPη function is the primary genetic defect in this disease [455]. In a second individual lacking functional C/EBPη, analysis of peripheral blood leukocytes revealed aberrant expression of CD45, CD11b, CD14, CD15, and CD16 on the proband cells [455]. A male patient lacking neutrophil-specific granules died from complications of pneumonia at age 20 [284]. Neutrophil-specific granules contain important microbicidal components (Table 1.23). Among other deficiencies of oxygen-independent killing, this AR defect is characterized by severe recurrent bacterial deep-tissue skin infections without patients showing an increased susceptibility to a particular pathogen. They have defects in chemotaxis, disaggregation, and receptor up-regulation. Deficiencies of the oxidoreduction and microorganism-killing mechanisms have also been described. The markedly decreased level of mRNA expression for the bactericidal/permeability-increasing (BPI) protein, the activation factor PU-1 and defensins in these patients suggests a role for C/EBPη in earlier phases of the myeloid differentiation program[187]. The defect is identified through a blood test colored with a Wright reactive in which polymorphonucleates do not present the specific granules that normally contain lactoferrin. From a morphological point of view, the nuclei appear bilobated and the nuclear membrane may show intro- and extroversions. It is also possible to identify the membrane's lack of alkaline phosphatase [414]. Monocyte functional alterations in the second individual suggest that C/EBPη plays a critical role in monocyte/macrophage development of humans and implicates abnormalities in monocytes/macrophages and neutrophils in the onset and development of the disorder [455].

Neutropenia

Severe congenital neutropenia (SCN) and cyclic neutropenia are disorders of neutrophil production predisposing patients to recurrent bacterial infections. Recently, mutations of the gene encoding neutrophil elastase 2 (ELA2) have been indicated as the most common cause for SCN as well as the cause for autosomal dominant cyclic neutropenia [225]. Deficiency of ELA2 leads to regularly fluctuating levels of neutrophils [112]. Linkage analysis on 13 affected pedigrees have shown that cyclic neutropenia and sporadic cases of this disease are due to a mutation in the gene for ELA2, located at *19p13.3* [112]. This enzyme is synthesized in neutrophil precursors early in the process of primary granule formation [225]. A mutation in the *ELA2* gene was detected in one of three apparently autosomal dominant kindreds with familial SCN. No mutations were identified in the apparently AR families [12]. These results fit those showing that mutations were found in all five SCN families [112], but they suggest that not all cases of autosomal dominant SCN caused by mutations in *ELA2* [12]. However, the high frequency of HET mutations in the neutrophil elastase gene in sporadic SCN confirms a previous report [112]. Considering that four novel mutations and a low-frequency polymorphism were detected, nearly all cases of sporadic SCN may result from *de novo* HET mutations in *ELA2* [12]. In recurrent SCN, an absolute neutrophil count of <200 cells/mm^3 (or $<0.1\times10^9$/l) [12] oscillates with an approximate 21-day periodicity. Circulating neutrophils vary between almost normal numbers and zero [225]. In about 30% of patients with cyclic neutropenia, however, the cycles range from 14 to 36 days [42]. In 26 children referred during a 22-year period PIDs were as follows: cyclic neutropenia (30.7%), Shwachman-Diamond syndrome (26.9%), Kostmann syndrome (23%), and Chédiak-Higashi syndrome (19.2%). The mean absolute neutrophil count of children was 398.2±259.3 cells/mm (range, 74–1,152/mm) at the first visit. The children first experienced symptoms of infection suggesting neutropenia at a median age of 7.5 months (range 1 month to 10 years), also suffering from oral ulcer, otitis, pneumonia, diarrhea, cutaneous abscess, and oral candidiasis [398]. Fever, stomatitis, and periodontitis and skin infections occur during periods when the neutrophil count is low.

Cyclic Neutropenia

Cyclic neutropenia is an autosomal dominant disorder in which cyclic hematopoiesis causes intervals of neutropenia and susceptibility to opportunistic infection. In nine families whose children displayed typical blood patterns, pedigrees confirmed dominant inheritance without evidence of heterogeneity or decreased penetrance; three pedigrees suggested new mutations [369]. A wide spectrum of symptom severity, ranging from asymptomatic to life-threatening illness, was observed within the nine families. The phenotype changed with age. Children displayed typical neutrophil cycles with symptoms of mucosal ulceration, lymphadenopathy, and infections [369]. Patients are usually asymptomatic, but during the period of severe neutropenia, recurrent overwhelming infections, inflammation, and ulcers occur in about 10% of patients and can lead to significant chronic morbidity [298]. Severe neutropenia was shown by 21 children, moderate by 4, and mild by 1: 16 of these children had leukopenia, 7 anemia, 2 thrombocytopenia, and 1 monocytosis. During follow-up, respiratory infections developed in 24, oral manifestations in 20 children. The most common infections, in descending order of frequency, were otitis media, abscesses, pneumonia, oral ulcers, acute diarrhea, cutaneous infections, oral candidiasis, and periodontits. Sinusitis, cystitis, conjunctivitis, meningitis, and osteomyelitis were less frequently observed. Hepatomegaly was also detected in 10 children and splenomegaly in one; 3 children died of recurrent infections. Therefore, recurrent infections always deserve further evaluation for detecting such disorders [398]. Abdominal pain must be assessed aggressively because of the high frequency of *Clostridium* infections during the period of severe neutropenia [369]. During the course of SCN, BM shows lack of maturation of granulocyte precursors beyond myelocytes, and there is myeloid hyperplasia during the remainder of the cycle. Occasionally, there is a reduction in the severity of neutropenia and the accompanying infections over time [369]. *A complete clearing of symptoms and a significant increase in quality of life is* noteworthy in children [298]. However, while the disease is commonly described as benign, four children in three of the nine families died of *Clostridium* or *E. coli* colitis, documenting the need for urgent evaluation of abdominal pain [369]. Pediatric cyclic neutropenia is effectively treated with *rHuG-CSF* (recombinant human G-CSF), usually at doses of 1–5 µg/kg/day (median dose, 2.5 µg/kg/day) [449] or twice weekly, or once a month.

Severe Congenital Neutropenia (Kostmann Syndrome)

Typically, children are noted in early infancy to have persistent SCN with absolute neutrophil counts $<0.2\times10^9$/l lasting for months or years [12]. In children aged 4 days to 19 months, the initial and lowest median absolute neutrophil counts were 0.29×10^9/l and 0.06×10^9/l, respectively [289]. Usually, children suffer from long-term recurrent bacterial infections, and maturation arrest of myelopoiesis at the promyelocyte-myelocyte stage of BM development [12]. The disease begins during the 1st year of life, and its infectious complications include cellulitis, perirectal abscess, peritonitis, stomatitis, and meningitis, commonly as a result of infections with *S. aureus, E. coli* and *Pseudomonas aeruginosa* [42]. The numbers of circulating monocytes and eosinophils are often increased [42]. Missing the most important cells in the defense against bacterial infections, the neutrophil granulocytes, children suffer from episodes of severe, often *life-threatening bacterial infections* [42]. They spend many days in hospital, requiring IV antibiotic treatment. Recurrence of bacterial infections leads to irreversible tissue damage, for example in the lungs, requiring often disabling surgical interventions. A high incidence of significant bone mineral loss was seen in children with SCN [545]. The presence of qualitative and quantitative abnormalities of primitive myeloid progenitor cells expressing G-CSFR may play an important role in the impairment of granulopoiesis in these patients, thus nearly all patients have a response to pharmacological doses of rHuG-CSF: neutrophil counts rise, infection rates fall, and mortality is reduced [343]. Since the introduction of rHuG-CSF, most children enjoy a *normal life span and a greatly improved quality of life,* although they still have problems with infections, especially chronic gingivitis and periodontitis [82]. It is more likely that the bone loss was caused by the pathophysiological features of the underlying disease, but it is possible that *rHuG-CSF* accelerates bone mineral loss [545]. Prolonged administration of rHuG-CSF at a dose of 3 U/kg bw twice daily may be associated with increased bone resorption, mediated by osteoclast activation and leading to bone loss. In children, the resulting osteopenia can be successfully managed with antiresorptive bisphosphonate therapy with significant improvement in bone density [449]. A child maintained on long-term rHuG-CSF therapy developed acute myelogenous leukemia associated with a G-CSFR mutation. After having undergone successful allogeneic BMT, both *ELA-2* mutation and *G-CSFR* mutation became undetectable by PCR [237].

Shwachman Syndrome

Shwachman syndrome, a rare AR condition, characterized by pancreatic insufficiency, reduced mobility and neutrophil chemotaxis, cyclic neutropenia, thrombocytopenia, metaphyseal dysostosis, delayed growth and recurrent pyogenic infections, in two cases was associated with isolated GH deficiency [96, 268]. In addition to metaphyseal chondrodysplasia, neutropenia, and pan-

creatic exocrine insufficiency, the findings in children are noted as variable extremity shortening, cup deformation of the ribs, metaphyseal widening and hypoplasia of the iliac bones, and increased echogenicity of the pancreas with no change in size [43]. Recurrent infections begin during the 1st year of life and commonly involve the sinuses, lungs, bones, skin, and urinary tract [42]. Neutropenia, either cyclic or intermittent, occurs in all patients, and 10%–25% of patients also have pancytopenia [464]. Immune functions may be involved in this syndrome, including marked pan-hgG, especially of the IgA, normal/increased cellular immunity, but depressed humoral and NK cell immunity [268]. In 13 patients diagnosed in infancy, a significant growth improvement and a decreasing frequency of infections were observed over time, in addition to improvement or normalization of exocrine pancreatic function [96].

Leukocyte Mycobactericidal Defect

A continuous spectrum from systemic BCG infection to local recurrent nontuberculous mycobacterial infection covered by the clinical features of affected children has recently helped to identify several genetic defects in the monocyte-macrophage-Th1 T-cell pathway [509]. Different types of *mutations in four genes* (IFN-γR1, IFN-γR2, IL_{12}p40, IL_{12}Rβ1) *forming the IFN-γ/IL_{12} axis* [123] have revealed both allelic and nonallelic heterogeneity and result in different disorders whose common pathogenic pathway is impaired IFN-γ-mediated immunity [123, 403]. Several children have been reported who presented a new kind of hereditary ID with severe and/or recurrent infections caused by only one microorganism family, in opposition to other patients with classic PID. Five new syndromes may encompass these children with a genetic predisposition to infectious diseases. If the IFN-γ/IL_{12} axis is impaired, the host becomes highly susceptible to infection with organisms that replicate intracellularly (susceptibility to mycobacterial disease). STAT-1 (signal transducer and activator of transcription-1) deficiency predisposes to viral disease, NEMO and IRAK-4 (IL_1R-activating kinase-4) deficiencies predispose to infections caused by pyogenic bacteria [376].

IFN-γ Deficiency

This PID encompasses several defects: complete, partial, and *AR IFN-γR1 deficiency,* and complete, partial, and *AD IFN-γR2 deficiency* [122]. IFN-γ and the cellular responses induced by it are essential for controlling mycobacterial infections. Patients with AR mutations leading to complete loss of IFN-γR1 or IFN-γR2 expression have the most severe phenotypes, and they present *early in life* with disseminated severe infections, especially if they have received BCG vaccination, and have poor to absent granuloma formation [242]. *Salmonella* and certain viral infections [HSV, CMV, *parainfluenza,* and respiratory syncytial virus (RSV)] are also seen [126]. Most patients bearing an IFN-γR1 deficiency present gross mutations that truncate the protein and prevent its expression, giving rise to severe mycobacterial infections and, frequently, a fatal outcome [6]. Mortality in these children is high, and infections are severe and recurrent [242], as in an 8-year-old girl before receiving a BMT [405]. A point mutation may be fatal: an individual, probably HZ for the mutation, died from meningitis due to *Mycobacterium bovis* [6]. A HZ missense IFN-γR1 mutation was identified in two siblings who did not respond to low or intermediate concentrations, yet responded to high IFN-γ concentrations, probably for a reduced affinity of IFN-γR1 for its ligand [243]. Otherwise the mutation results in normal surface expression of IFN-γR1 that do not bind IFN-γ [244]. A dominant deletion in the *IFN-γR1* gene has been reported in a female patient HZ for a 4-bp deletion in exon 5 of *IFN-γR1* who developed postvaccinal disseminated BCG infection [417]. The AR form of partial IFN-γR1 deficiency was reported in 18 patients of 12 unrelated kindred with susceptibility to mycobacterial infection [403]. An 8-year-old girl with IFN-γR1 deficiency, also with recurrent mycobacterial infections and liver cirrhosis with portal hypertension, received *red cell-depleted BMT from her HLA-identical sister.* The transplantation course was uneventful and 4 years later the child remains in excellent clinical condition and free of mycobacterial infections [405].

A complete IFN-γR2 deficiency was found in a child due to a HZ dinucleotide deletion resulting in a premature stop codon in the protein extracellular domain. This gene defect emphasizes the critical role that IFN-γ plays in *host defense against mycobacteria* [126].

IL_{12} Deficiency

A girl with BCG and *Salmonella enteritidis* infection and a HZ recessive deletion in the p40 subunit of IL_{12} leading to a *complete IL_{12}p40 deficiency* has been reported. A large HZ deletion within the *IL_{12}p40* subunit gene was found, precluding *IL_{12}p70* (composed of p40 and p35 subunits) functional expression by activated DCs and phagocytes. The net result was a markedly impaired IFN-γ production by lymphocytes. However, addition of recombinant exogenous IL_{12}p70 in the assay was able to restore normal IFN-γ production in vitro [8]. The girl suffered from well-organized granulomas, possibly due to residual IL_{12}-independent IFN-γ production [8]. Another kindred [377] and two siblings and one unrelated patient [142] carried the same large deletion, also accompanied by disseminated infections. A 3-year-old female was repeatedly hospitalized since the age of 5 weeks for recurrent episodes of pneumococcal pneumonia with sepsis and other infections in the absence of

fever. She exhibited IL_{12} deficiency that was associated with an abnormality of the *$IL_{12}p40$* gene. Although present, IFN-γ was reduced [211].

A genetic lack of $IL_{12}R\beta1$ surface expression predisposes to severe infections by pathogenic mycobacteria or *Salmonella* and causes strongly decreased, but not completely abrogated IFN-γ production [408]. The deficiency may be complete as well as partial [291]. Several patients with these features have been reported [291]. Three unrelated individuals with severe, idiopathic mycobacterial and *Salmonella* infections were found to lack *$IL_{12}R\beta1$* chain expression. *$IL_{12}R\beta1$* sequence analysis revealed genetic mutations that resulted in premature stop codons in the extracellular domain [116]. A patient with severe infections as above and multiple adverse drug reactions had T cells unable to produce IFN-γ or proliferate in response to IL_{12}, despite the expression of wild-type *$IL_{12}R\beta1$* and *$IL_{12}R\beta2$* [186]. Defective $IL_{12}R$ signaling leads to low T-cell and NK-cell IFN-γ production [509]. $IL_{12}R\beta1$ and $IL_{23}R\beta1$ chains are associated in an AR deficiency with susceptibility to *Mycobacteria* and *Salmonella* infections [351].

The *STAT4* (2 forms, AD and AR [351]) *S721* mutant failed to restore IFN-γ production in STAT4-deficient $IL_{12}R\beta2$ transgenic cells [329]. STAT1, -3, and -5 activation by IL_{12} was lost, an impairment specific for IL_{12}; nor is activation of STAT4 alone sufficient for IL_{12}-induced IFN-γ production and proliferation [186]. Two unrelated infants HZ with respect to mutated STAT1 suffered from mycobacterial disease, but unlike patients with IFN-γR deficiency both died of viral disease [133]

Complement Deficiency

The complement is an integral part of the humoral defense system against infections and also for promoting inflammatory process (Figs. 1.63, 1.65). Complement deficiency was found in 6/176 Dutch patients (3.4%) over a 33-year period (0.1% × year) [156]. From the study of blood donors the prevalence may be of 0.03% in the general population [531]. Congenital deficiencies have been described for most of the proteins it is composed of (Tables 22.20 and 22.1F [167, 169, 453, 531], usually following the AR model. Properdin deficiency is the only complement deficiency that is X-linked [531]. HETs can be easily identified because their relevant component is present in the serum with a 50% concentration. The lack of one component at the HZ level serologically involves the blockage of enzyme release below and the absence of hemolytic activity, while that of controlling proteins causes its uncontrolled activation, consuming the factor that is the object of control and, in various ways, also of successive components [137]. Nonfunctional C1q variants have been observed, C1r and C1s deficiencies are often associated, probably because they are mapped on contiguous genes of chromosome 12 (C1q on 1) [167]. The B, C2 and C4 genes, situated on the short limb of chromosome 6, constitute along with others the HLA class III (Chap. 1). C6 and C7 are codified on chromosome *5p* and have a similar structure; C8 shows a different structure, because the molecule consists in three α, β and γ chains, united to form two subunits, α-γ and β dictated by different genes [495]. Alternative pathway deficiencies are extremely rare [328].

Complement deficiencies are accompanied by an *increased frequency of infectious pathologies* [155], although it is not rare to come across them in individuals who are apparently in good health, as in the case of C2 hereditary deficiency [422]. Also frequent are teens and young adults with autoimmune manifestations (Chap. 18). Classic pathway deficiencies are often associated with SLE-like diseases (systemic lupus erythematosus), ID of the early components of complement (C1-C3) are associated with risks of infections caused by encapsulated bacteria such as *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, as well as by *meningococci* [363]. The incidence of SLE in patients with C1q, C4, or C2 deficiency is 90%, 75%, and 15%, respectively [378]. Partial C4 deficiency is also associated with SLE; 15% of patients with SLE exhibit C4A deficiency [531]. Several components are associated with development of membranoproliferative glomerulonephritis (Table 22.20 [167, 169, 453, 531]). In alternative pathway ID, the infections recognize pyogens as the most common etiological agents, while final common pathway ID (C5-C9) or properdin (P) have been associated with recurrent or invasive infections by *Neisseria (N) gonorrhoeae* or *N. meningitidis*, Gram-negative bacteria, and asplenia, agammaglobulinemia [167, 169, 363, 531]. It is estimated that the frequency of meningitis in subjects with HZ deficiency of the final C5-C9 pathway is 10%, 6,000-fold higher than in non-ID individuals [363, 488]. Some characteristics appear to associate the patients with complement deficiency and meningococcal disease: frequent recurrent episodes, an older age at the first onset, lower mortality compared to patients with a normal complement, and a prevalence of males [167].

C1 Deficiency

Over 50 patients with C1q, C1r and C1s deficiencies have been described, C1s deficiency only in two cases [239]. A selective and complete C1s deficiency in a 2-year-old girl with complex AIDs including SLE-like syndrome, Hashimoto's thyroiditis, and autoimmune hepatitis has been reported. Exon-specific amplification of genomic DNA by PCR followed by direct sequence analysis revealed a MZ nonsense mutation in the C1s gene exon XII at codon 534. Both parents were HET for this mutation [127]. A deficiency in one of these proteins is sufficient to block the classic pathway activation; deficiency results as a consequence of non-synthesis, which in the

Table 22.20. Inherited complement and complement-related protein deficiency

Deficient protein	Incidence		Reported prevalent clinical correlates	
	(%)	MW (K)	Infection	Other manifestations
Classic pathway				
C1q	1.5	450	Pyogenic	SLE-like; GN
C1r	0.5	85	Pyogenic	SLE-like
C1s	0.1	85	Pyogenic	SLE
C1r-C1s	0.5		Pyogenic	SLE-like
C1-Inh	56.7	105		Angioedema
C4	1.5	206	Pyogenic	SLE, GN, vasculitis
C2	8.7	102	Pyogenic	SLE, GN, JRA
Alternative pathway				
C3	1.8	190	Pyogenic	SLE, GN
Factor D	0.2	25	*Neisseria*	Recurrent infections
Factor H	0.8	150	Pyogenic	GN
Factor I	0.9	88	Pyogenic	Recurrent infections
Factor P	2.4	25	*Neisseria*	Fulminant infections
Common pathway				
C5	1.5	190	*Neisseria*	Meningococcemia
C6	5	128	*Neisseria*	Meningococcemia
C7	2.8	120	*Neisseria*	Meningococcemia
C8	3.7		*Neisseria*	Meningococcemia
C9	11.3	71	*Neisseria*	Meningococcemia

The incidence is based on the data from [167]; the inheritance is always AR, with the exception of C1-Inh deficiency (autosomal dominant) and Factor P deficiency (autosomal recessive or X-linked).
Data from [167, 169, 453, 531].
GN glomerulonephritis, *JRA* juvenile rheumatoid arthritis.

case of C1q amounts to 60% of cases, while in the remaining 40% the molecules are malfunctioning but cross-reacting with the native molecule [328]. C1r and C1s deficiencies are usually combined, due to the contiguity of the two genes; typically in these patients C1r is absent and C1s levels are reduced (20%–40%) [422]. Affected patients suffered from a SLE-like syndrome and sporadically from an extended predisposition to infections [155].

C1q Deficiency

Associated symptoms in C1q deficiency are SLE-like syndrome, rheumatic disease, and infection. Several children suffered from meningitis, recurrent septicemia, recurrent otitis media, pneumonia, and stomatitis; two died from meningitis septicemia [241].

C4 Deficiency

Unlike C2, HZ C4 deficiency is very rare and is caused by the non-expression of all 4 alleles (2 of C4A and 2 of C4B, 2 maternal and 2 paternal alleles), which can occur due to punctiform mutations, gene deletions, or other gene alterations that prevent gene transcription [28]. The two *4A* and *4B* genes are polymorphous, just like *C2*, *C3*, *C6*, *C4A* and *C4B* and the B factor (Bf); polymorphic variants of the other proteins are rare, with 12 different alleles for C4A and 23 for C4B identified at the moment. Moreover, two *loci* C4A and C4B null alleles *Q0* (quantity 0), do not codify for any phenotype, although often present in the general population [167]. In a 4-year-old Caucasian child who suffered from several bouts of pneumonia caused by respiratory viruses, eight episodes of acute otitis media, prolonged respiratory and urinary tract infections, molecular studies of the *C4* gene region revealed HZ deletion of HLA class III *CYP21A-TNXA-RP2-C4B*, generating total deficiency of

C4B and the flanking 5′ region up to C4A [230]. Moreover, in 7/13 cases the *C4A*Q0* alleles were related to a *C4A/CYP21P* gene deletion within the *HLA-B8 C2C BfS C4AQ0B1 DR3* haplotype. In 3/13 cases, the *C4B*Q0* allele was related to a *C4B/CYP21P* gene deletion within the *HLA-B18 C2C BfF1 C4A3BQ0 DR3* haplotype [212]. The *C4* null allele incidence is so elevated that 60% of the population expresses all *C4* genes, while 30% lacks 1–3 alleles [328]. The elevated number of *Q0* probably derives from the marked similitude of the two genes, which facilitates the unequal crossover, but this crossover in the HLA can modulate the expression of three *C4A* alleles and one *C4B* or vice versa; the *C4AQ0* allele spreading amplifies the risk of contracting SLE and juvenile RA (JRA).

C2 Deficiency

HZ C2 deficiency, *the most common in the Caucasian population,* has an incidence that varies between 1:10,000 and 1:28,000, whereas the HET carrier rate is 1.2% [456]. It is usually found in the *A25*, *B18*, *DR2*, *BFS*, *C2Q0*, *C4A*, *C4B2* haplotype context which, due to its considerable rarity, could assume a predictive value [238]. Two different types of C2 deficiency are known: in type I the synthesis is deficient due to the protein nontranslation, in type II there is a selective absence of secretion but not of synthesis, therefore C2 levels are 0.5%–2% of normal values [238]. HETs have a nonfunctioning gene, the complement profile is characterized by serum C2 concentrations equal to 50% of normal values; about 50% are asymptomatic, while the other half exhibit frequent infections and quite a few suffer from SLE and correlated syndromes [155]. HET C2 deficiency was associated with a 28-bp deletion in the *C2* gene (type I), mainly within the *HLA-A25 B18 C2Q0 BfS C4A4B2 DR2* haplotype [212]. In a certain number of cases, a C2 deficiency is accompanied by a partial Bf malfunctioning, genetically close to it. HZs can also have a deficient function of the alternative pathway [445]. Possibly this deficiency, like other quite common ones, may not always be reported in the literature: the total number of cases therefore underestimates the real prevalence, as is also found in children with *C7* deficiency [167]. *C2* deficiency must be suspected in all patients presenting pneumococcal infections after the age of 2 years [239].

Both *C2* and *C4* predispose to SLE, but this is not the expression of a particular genetic association caused by the same gene localization, because C1q, r, s, deficiencies, which also cause SLE, are situated as mentioned outside the HLA system [422].

C3 Deficiency

The molecular bases of this PID appear heterogeneous. The *C3* gene exists in different allelic forms, some of which have reduced functionality. One must remember the C3 important role in immune responses, also as far as APC and B cells are concerned, as well as the defensive role played in innate immunity along with C4. Since both pathways converge in the cleavage and activation of C3, there is no way that this defect can be corrected, and furthermore the opsonic power is greatly deficient, as is the C5 chemotaxis; therefore patients affected by HZ deficiency mostly present clinical symptoms totally similar to a congenital hgG with severe recurrent infections and at times the symptoms of CIC disease [239]. Although ID is severe, some patients apparently remain in good health and the syndrome may also in time become less severe, probably due to the higher number of immune experiences that allow a better effector function to antibody reactions mediated by the Fc receptor [167]. C3 protein was defective in noninfected Nigerian children with protein-energy malnutrition (PEM), but rose significantly in the presence of bacterial infection, thus sharing the values found in healthy controls [137].

C5 Deficiency

In its clinical expressions, C5 deficiency does not differ from the other deficiencies discussed here; the clinical consequences of absent C5a anaphylotoxin are unclear [328].

C6 Deficiency

One-fourth of all patients are asymptomatic. In Caucasians incidence is 1:60,000 [495]. Deficiencies associated with C6-C7 are rare but reflect the close genetic proximity of their pertinent genes; in C6-C8 deficiencies, 63% of patients lacking one component experience at least one severe episode of *Neisseria* infection and 5.5% one AID [239].

C7 Deficiency

Rare in Europe, C7 deficiency is the second most common complement deficiency in the Japanese (0.005%) [339]. In Italian children it has a prevalence of 10% and has been identified also in healthy siblings [531]. In Japan C7 deficiency is more associated with meningococcal meningitis than with *Neisseria* infections [339]. In a highly inbred Arab population, a C7 deficiency was associated with a mutation (*G1135C*) that is also prevalent among Israeli Jews of Moroccan ancestry [34].

C8 Deficiency

In the two forms of C8 deficiency (C8α + C8γ and C8β mapped on chromosome 1), the subunit not involved is present in the serum, also with reduced levels, and accompanied by altered functionality of the one involved. C8 deficiency has different characteristics due to the diverse associations of the β and α-γ chains; therefore Caucasians with this deficiency lack the β chain (10%), while colored patients lack the α and γ chains (90%) [495].

C9 Deficiencies

C9 deficiencies are poorly considered because they are often asymptomatic [339]; however, in Japan there is an incidence of 0.1% [339] and between 33% [155] and 25% of cases [339] present meningococcal meningitis. Congenital C9 deficiencies are very common among the Japanese (0.036%–0.1%) and represent 11.3% of all deficiencies (Table 22.20).

There have been >150 cases of congenital C5–C9 deficiencies reported, distributed unevenly between the various ethnic groups: C5 and C6 deficiencies are prevalent in colored patients and the C7 deficiencies appear to be more common in Caucasians [422]. An analysis of published studies shows that 14% of patients with sporadic meningococcal infections may have a C5–C9 deficiency [495]. Clinical patterns are overlapping.

C1 Inhibitor Deficiency

The most common complement deficiency is C1-INH deficiency (C1 inhibitor), responsible for hereditary angioedema that causes symptoms in HETs (Chap. 8).

Factor I Deficiency

At least 15 cases of factor I deficiency are known [328], with autosomal co-dominant transmission because parents show normal complement levels at 50% of factor I [239]. As in an H deficiency, serologically one has the alternative pathway activation, due to C3b non-catabolization that continuously forms C3 conversion with severe C3 deficiency, the levels of which do not exceed 15% of normal values [155]. In HZs, in addition to subsequent pyogenic infections, as in C3 deficiency [422], cutaneous rashes and urticaria caused by massive release of histamine and pro-inflammatory cellular products by anaphylotoxic fragments are reported [167].

Factor H Deficiency

A total deficiency of this 150-kD protein, inherited as an AR trait, has been described in a young patient with a hemolytic-uremic syndrome and in one case in Italy whose parents were first cousins [531]. Among 21 relatives of the proband studied, encompassing 3 generations, ten had low factor H levels, including her two children, indicating a HET factor H deficiency [157]. H deficiency results in uncontrolled breakdown of C3, and in depletion of Bf, P and C5 [157]. C3 and C9 components are decreased in varying degrees, while C3 and C5 are found in plasma in traces and only as activated molecules [167].

Factor D Deficiency

Inheritance of factor D deficiency is for the moment uncertain [488] (Table 22.20): a partial deficiency (6%–12% of normal concentrations) has been described in two MZ twins, and a total deficiency in one male. This deficiency, serologically characterized by the non-functionality of the alternative pathway, is clinically accompanied by an increased susceptibility to *Neisseria* infections [239], leading us once more to emphasize the alternative pathway significance as a substantial means of defense for a broad spectrum of damaging actions caused by bacterial infections.

Properdin Deficiency

Properdin deficiency is the only one inherited as a characteristic linked to the chromosome X and only affects males [190]. At the moment, >50 cases have been described. The deficiency can be materialized by a total P absence, with levels reduced to 10%, with normal levels, however, showing an altered functional activity [239]. Specific research has shown a remarkable reduction of C3A and B titers, which represent the C3-convertase proteins, with a consequent heightened consumption due to the alternative pathway spontaneous activation. Males are affected by septic episodes caused by *Neisseria*, sometime fulminating, with onset even occurring during the 1st year of life [488]. There is no evidence of increased susceptibility to CIC diseases or infections caused by other organisms [155], thus implying that a functioning alternative pathway is particularly important for a defense against infections [328].

Correctly identifying children with complement abnormalities is important and worthwhile if any of the following factors are present: ID (such as repeated or unusual infections with other organisms, FH, unusual course of the illness, etc.), repeated Neisserial infections, infection with an unusual serogroup, fulminant disease in males (P deficiency), coexisting angioedema, autoimmune, or connective tissue disorders [220].

Children with RRIs

The fact that a child during the initial period of life should experience a certain number of URTIs or LRTIs is within the norm: RRIs are mainly caused by immunological immaturity or inexperience, both transient. A typical symptom outline is difficult to define, and prevalence is also little known. In ID children, a basic pathology is present instead, which encourages the recurrence of infections.

Definition and Prevalence

Although a distinction between infection and associated disease is important, childhood infections might have a key role in stimulating the maturation of the immune system, and the microbial burden in early life has been invoked as a protective factor against wheezing and asthma (Chap. 4). Preschool-age children have an especially high frequency of VRIs, with most having three to eight infections per year and 10%–15% have ≥12 VRIs per year. The rate in children aged 0–4 has been about 1 in 200 children compared with about 1 in 500 for children aged 5–10, and about 1 in 1,000 for those aged 11–17 [413]. RRIs may be defined as >six episodes of URTI and/or >3 LRTIs in the previous year, or based on age and ≥8 episodes per year if aged <3 or ≥6 episodes per year if aged ≥3.

Predisposing Factors

Several risk factors can influence the onset and recurrence of infections [217]. It is clear that the younger the child is, the more he/she may fall ill: this is also related to serum Ig levels (Table 1.15). The dogma of primary and secondary responses also may not apply to infections, at least those caused by *Rotavirus,* which confers considerable protection only after various infectious events and in children aged 1 [511].

Environmental factors in the absence of a basic pathology are important. It is also obvious that the more crowded the environment the child lives in, the more probable that infection becomes. In addition to the number of siblings, other factors such as socioeconomic status, age (preschool children), contact with outside persons, especially babysitter, early social contacts, exposure to passive smoke, indoor and outdoor pollution may be found to be related to the hygiene hypothesis (Chap. 4). However, daycare attendance, which was considered to be an indicator of exposure to respiratory pathogens, and the presence of siblings, increased the risk of URTI in preschool children aged 4–5 [273], and in the 1st year of life for children with FHA [88]. Among children with FHA, the protective effect of day care attendance in early life against the development of atopy only begins by 2 years, and against wheezing this may not be observed until after 4 years [89]. The particular ease of smoking parents and/or relatives who fall ill with influenza has been known for some time, to the same extent that the children who live with them are affected by RRIs (Table 4.24). The impact on RRI incidence as it is related to children in kindergartens, has been reflected by a significantly increased morbidity observed in babies aged 3 months to 3 years who go to daycare, who show a number of more severe and longer lasting infections per year [523], with an incidence of 6.5% in children who stay at home compared to 13.1% of those in kindergartens [524] and an increase of 49% of OME persistence (Chap. 15). In children exposed to cigarette smoke, the risk increased 3-fold for LRTI [221] or by 3.5-fold, equal to ≤3 episodes of respiratory infections each year [26].

Studies on *environmental pollution* have identified the most damaging agents: conclusive data on fine particles in suspension and polluting derivatives is available, proving a significantly increased risk of infantile RRIs: Table 4.20 indicates that NO_2 reduces immune defenses against RTIs, provoking alterations of the epithelium and of the lymph node cells, with negative effects on mucociliary clearance and macrophages.

The *biological role played by* NO_2 in the *domestic pollution* derived from the home has been ascertained to be related to cooking and the smoke released by combustion [26]. Using wood for heating leads to SO_2 development, while radiators cause the air to dry, which in turn causes potentially infected particles to remain in suspension. Pollutants are increasingly responsible for indoor pollution (Chap. 4).

Although levels of *micro-pollution* are not easily ascertained, significant associations with acute RRIs and conditions such as polypnea and dyspnea have been reported, especially in <2 year-old children [507]. These children's capacity to evoke adequate responses is genetically controlled; however, it is commonly known that their parents or siblings have suffered similar illness as children. In subjects with physiological immaturity of the immune system, VRIs more easily cause infectious episodes, which are important factors to be considered only in the presence of recurrent or incompletely cleared conditions [165].

Predisposing factors related to a basic pathology derive from perinatal factors, more common in premature babies, which can lead to respiratory tract alterations and consequently to bronchopulmonary dysplasia; anatomical anomalies; cystic fibrosis, which can become recurrent pneumonia; adenoiditis causing otitis and OME; congenital ciliary dyskinesia; humoral deficiency and PID characterized by recurrent sinopulmonary infections [101] (Table 22.21) [79].

Viruses are the principal etiological agents, and over 159 different kinds have been isolated (see Chap. 15):

- *Pharynx: Rhinovirus, Coronavirus, Herpesvirus, Adenovirus, Coxsackie-virus, Influenza and Parainfluenza virus, EBV, CMV*

Table 22.21. Infections most frequently seen in patients with primary immunodeficiency

Data from [79].

- *Middle ear: RSV, Adenovirus, Influenza virus*
- *Larynx: RSV, Adenovirus, Influenza and Parainfluenza virus, Rhinovirus*

A novel member of the coronavirus family has been characterized, which is associated with cases of SARS (severe acute respiratory syndrome). Phylogenetic analyses and sequence comparisons showed that SARS-coronavirus is not closely related to any of the previously characterized coronaviruses [421].

As investigated by a 15-year study the overall prevalence is age-related, and different between children aged 0–4 (Fig. 22.46) [326] and those aged 5–19 (Fig. 22.47) [326]: *RSV and rhinovirus have a different impact on the first group* (58% vs 28%) *and the influenza viruses on the second group* (9%–48%). Incidence in young children was 1.75-fold higher than in those aged 5–19 [326]. RSV causes bronchiolitis in breast-fed babies, with a higher frequency the younger the child is (Tables 11.24, 11.25), and rhinitis in older siblings. Even an infectious agent neglected for some time, such as *Ureaplasma urealyticum*, causes a lung pathology in younger children while sparing those >3 years old [271].

The *bacteria* most commonly involved are: *Streptococcus pyogenes* (pharynx and larynx); *Haemophilus in-*

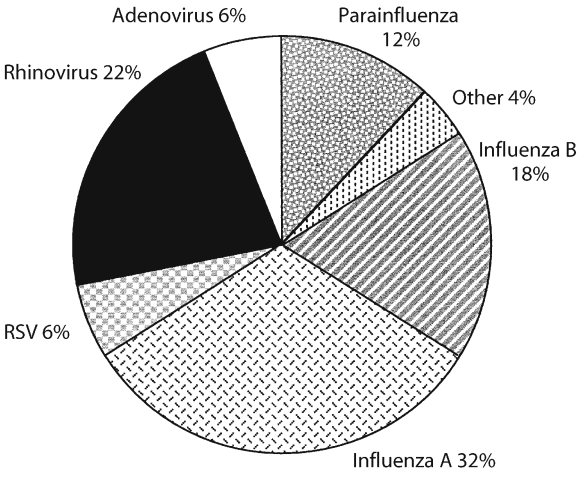

Fig. 22.47. Prevalence of respiratory viruses in children aged 5–19 years. Annual isolation and percentages. (Data from [326])

fluenzae (middle ear and larynx reaching the epiglottis); and *Streptococcus pneumoniae* (middle ear). There are often secondary bacterial infections such as complications caused by VRIs, which certainly contribute to recurrent infections and/or the onset of chronicity [508]. In Chap. 4 we reported several studies which concluded that early infections may protect from atopy development (hygiene hypothesis).

Immunodeficiency

We must distinguish PID outlines and pseudo-ID in children with RRIs.

Children with PID

Summarizing the aforementioned, severe and recurrent LRTI and sinusitis are the principal clinical manifestations in children affected by deficiencies prevalently involving *humoral immunity* (Table 22.1). These children fall ill *during the first weeks of their lives* and often contract infections caused by opportunistic agents, fungi, protozoa and viruses, and as months go by are also affected by malnutrition and failure to thrive. Episodes affecting the airways, particularly common in cellular and combined ID, tend to become longer or severe, especially if complicated by pneumonia [44]. Chronic disorders such as sinusitis and bronchiectasis (sinobronchial syndrome) are not rare; interstitial pneumonia is in most cases caused by *Pneumocystis carinii* and results in tachypnea and lung hyperinflation [409]. Infections supported by the *Herpes simplex*, EBV and CMV are also common: males with XLP exhibit a deficient response to EBV [446]. Severe and recurrent sinopulmonary, WAS, HIgES and ATA infections as well as severe RRIs in CGD, complement deficiencies and LAD 1 to V must also be borne in mind. Cases of recurrent pneumonia should be warning signals to rule in 4.8% pediatric cases of PIDs [392]. The second most important manifestation is *chronic diarrhea:* in some cases the infections are caused by rotavirus and enterovirus among which the ECHO: *Giardia lamblia, Salmonella* and *Campylobacter* can also cause chronic enteric infection; malabsorption resistant to treatment can be ascribed to *Cryptosporidium* [80].

Children with RRIs

RRIs are common in children. They reflect the immaturity of the immune system in its encounter with environmental antigens; this developmental delay during the first years of life fosters the development of RRIs. Thus, *RRIs are part of the growing-up process of any child* [47]. The consequences of RRIs can be of a profound and sometimes protracted alteration of the different immune defense mechanisms, which place the child in an undefended position, similar to the condition observed in children with PIDs, compromising the phagocytes, lymphocytes, NK cells, antibody production, and ILs at every occasion [419]. The responsible viruses for these infections have a development limited to surface mucous cells, spreading from cell to cell due to contiguity, while the viremic stage is absent or remains marginal. The incubation period is therefore brief, normally <3 days; consequently the immune response may not be capable of ensuring a protective function, or it only intervenes partially, clarifying the potentially unlimited number of infectious episodes [392]. From a pathogenetic point of view, the virus works by triggering the development of IgE and allergic sensitization and/or damaging the immune structures [322, 519]. In the first case, it is known that experimental infection in mice with RSV is capable of significantly increasing the absorption of ovalbumin (OVA) administered by aerosol, of IgG, IgE and anti-OVA sIgA (Fig. 4.26) and of increasing the synthesis of IgE and specific IgG to ragweed also administered by aerosol. The result is that the majority of infants become infected with RSV, although LRTIs develop in only about 20% [382]. Approximately 25%–50% of those subsequently experience recurrent acute asthma from VRI [530].

The mechanism by which VRIs induce atopic sensitization in experimental models is identified with antigen penetration and sIgE synthesis [322]. Studies show that viruses increase mucosal permeability, by modulating antigen uptake and altering antigen processing by the mucosa, which results in the IgE-suppressor T-cell depression, while IFN-ɣ-modulated histamine release further increases mucosal permeability [162]. It is probable that the immune deficiency is secondary to VRIs, because many viruses are capable of inducing transient

modifications of both humoral and CMI, therefore not only of antibody synthesis or phagocyte and neutrophil functions, but also of T lymphocytes and related ILs [457]. It is also possible to hypothesize that *persistent VRIs are capable of inducing Th2 activation* by antigens or super-antigens: Th2 T cells with IL_4 help induce virus-specific $CD8^+$ to produce IL_5, which recruits eosinophils in the respiratory tract, thus reducing IFN-ɣ secretion. Thus there may be an increased interaction of IgE mast cells in these subjects with immunoregulatory alterations, due to a marked lymphoproliferative response and the elaboration of other ILs, which consequently amplifies IgE production in the respiratory tract. The IgE response is thought to lead to a greater production of bronchoconstrictor mediators by effector cells; viral infections themselves may induce these cells to release histamine. It is also known that humoral deficiency, especially of IgA, very often opens the way to Gram-positive germs causing viral and bacterial infections, thereby completing the circle [409]. Interestingly, only 2/13 children have at least a significant production of antigen-specific salivary IgA against *Klebsiella pneumoniae* [418]. Even if the alterations are transient and aspecific in children with RRIs, their occurrence and persistence for a number of months, for a year and even longer, leads to believe that the immunosuppressive mechanisms set off by the first episode occasion more severe, profound and lasting consequences for the immune functions than those occurring in their normal peers [36, 273]. Having at least one physician-diagnosed LRTI in the 1st year of life was significantly associated with recurrent wheezing (OR, 2.0) and asthma (OR, 2.5) [89]. At the base of this exclusive predisposition in children for contracting RRIs, there is a NK cell reduction [419] and immune deficiencies related to the global lymphocyte population, the CD4 and the CD4:CD8 ratio, unbalanced toward CD4 T cells, prevalent in children expressing coughing compared to those with bronchial hyperreactivity (BHR) [374]. Other T-cell deficiencies in children with humoral anomalies include a considerable spontaneous production of IL_2 and IL_4, both generated by Th phenotypes, or alternatively by the Th0, which express both ILs [216]. It is similarly feasible that virus-specific CD8 deprived of cytolytic activity are converted into Th2-like T cells when IL_4 is present [216].

CMI in these children consists above all in the transient T-cell numeric and functional depression, coinciding with a deficiency of ILs necessary for their activation, proliferation and differentiation. The virus toxic effect also acts directly on the T cells, inciting rough structural modifications including giant polynucleate cells, which jeopardize homing and recirculation capacities, to the point of immunosuppression, affecting the specific lymphocytes for that particular virus, thus favoring the attacking organism [552]. A condition of immunosuppression occurs also as a result of superantigen (SA) orchestration, which, stimulating a large number of lymphocytes to release ILs, deter the specific response addressed at them. Some SAs, especially the staphylococcal enterotoxins and the *Pseudomonas* endotoxins A (Table 1.29), seem to activate the cytolytic effector cells capable of destroying the host cells [323]. Viruses, on the other hand, can both induce and inhibit apoptosis (Table 1.19). The host is, however, ready to fight them and *can rely on well-organized defensive bases:* if the viruses recombine the DNA, the host T and B cells recombine the genes codifying the antigen receptors; if they mutate, and they can do so at each generation, B cells hypermutate their V exons by at least four times; if they invade different sites, B cells respond with their isotype machinery directing the more appropriate antibodies wherever requested [521]. The lack of NK cells, which are in the front line of defense against viral infections, and with which the altered production of IL_2 and factors activating the phagocytes are associated, appears significant, but it is unclear whether the deficiency is primary or secondary to viral infections [419]. The basic question with potential therapeutic consequences therefore remains unanswered, and is probably destined to remain so until more sophisticated tests are available to clarify this issue, although the NK-cell reduction in these children corroborates the first hypothesis.

Recent data emphasizes the important defensive activity of cytotoxic CD8 T cells and by different ILs, including IL_{10}, IL_{28} and IL_{29} active in antiviral defense: if the infected cells express on the surface the viral antigen processed in association with HLA class I molecules, cytotoxic CD8 take care of killing the cell. Normally the CD8 are activated by the virus itself or by soluble factors released by the infected cells and mediate the cellular lyses after recognizing HLA class I antigens on the same cell. However, if the APC is a macrophage, it can be parasitized by the virus, with consequently reduced chemotaxis and microbicidal activity and in particular the capacity to cooperate with T cells [322]. Considering that macrophages may have evolved specific mechanisms for directing T-cell development toward the Th1, since CMI can solve some infections, it is clear that their dysfunctions appear in the insufficient NK cell activation and inadequate Th1 development in response to infections. IFN-ɣ, produced not as a direct consequence of infection, but probably by IL_{12} and/or IL_{15}, stimulates the nearby cells to block the nucleic acid transcription and therefore the viral replication, preventing the infection of those cells to which virus spreads due to contiguity. Therefore the IFN-ɣ species-specific antiviral activity takes place at the very first stages of the infection, preceding the antibodies [322].

The response to germs' capsular polysaccharides, particularly deficient until the age of 2, although encounters with these germs are abundant during this period of time, still remains to be evaluated [508]. However, selected children, although normal from an immunological point of view, *may have a deficient antibody response* even aged 4–8 [195] with a percentage of

nonreactive children of 4%–19% [143, 430], rising to 13%–42% if with an IgA and/or IgG subclass deficiency [198, 216, 430]. While 50% of children have low anti-pneumococcus IgG_2, antibody responses are totally absent in 40% of dysimmunoglobulinemics with a virtual absence of IgA and IgG_2 [430], confirming previous data [198]. IgA and IgG_2-deficient children show a clinical pattern with elevated susceptibility to *S. pneumoniae* infections [430].

Von Waldeyer ring (NALT) is a significant constituent of immune response, and of resistance to NALT-dependent infections. Among the consequences of chronic adenotonsillitis (Table 15.2) the *statistically significant decrease in Ig levels, including sIgA*, must be evaluated eventually in relation to RRI complications (Chap. 15).

IgG Subclass Deficiencies and RRIs

IgG subclass deficiencies can be present in children with chronic and/or severe asthma, associated or not with SIgAD, in children affected or not by asthma with severe RRIs or with chronic nonallergic respiratory clinical symptoms, in children with SIgAD, ATA, WAS, CVID, SCID and in healthy subjects [80]. The anti-virus antibodies generally belong to the IgG_1 and IgG_3 isotypes while the IgG_3 protect from microbes with polysaccharide antigens, such as *S. pneumoniae* and group A and type b *H. influenzae* [153]. Table 22.7 shows normal values for IgG subclasses in subjects aged 0–15. Unlike total IgG concentrations, IgG_1 and IgG_3 reach normal levels within the 1st year, IgG_2 mature more slowly, ensuring an effective antibody response only after the 2nd year, and IgG_4 develop even more slowly. Various authors believe that the role played by IgG subclasses is unique and vital in defending from infections: IgG_2 deficiency is associated with an increased susceptibility to infections by bacteria expressing capsular polysaccharides, such as pneumococci, meningococci, *H. influenzae, Bordetella pertussis*, etc., as well as other factors capable of setting off an inflammation [113, 465]. IgG_4 deficiency instead seems associated with a marked predisposition for RRIs [333]. However, undetectable IgG_4 subclass levels are a common finding in normal individuals and an accurate detection of very low levels of IgG_4 is technically difficult to achieve [450, 465].

Babies aged ≥1 month have levels of circulating *lymphocytes secreting all four subclasses* in a higher number than adults; therefore the capacity to produce antibodies exists well before a full humoral response is developed.

Subnormal IgG subclass concentrations, especially of IgG_2, are also observed in healthy children who do not present an increased susceptibility to infections.

Low subclass levels do not necessarily indicate that the subject will experience immune disorders exclusively linked to these, nor do normal concentrations guarantee that the child will be spared complications. Subjects have been observed both with normal IgG_2 levels and with recurrent infections and with a subclass deficiency, which often do not form other types of antibodies [450].

IgG subclass determination does not indicate what the humoral level restricted to that molecule is: this is a *characteristic in children*, unlike adults, even though research was carried out using the same methods in the two studies [465].

Interesting hints come from studies involving children with RRIs:

Of children aged 2–10, with a confirmed diagnosis of susceptibility to infections, 67/567 (11.8%) had a *IgG subclass deficiency,* almost all concerning IgG_4, with several associations [283].

In other children, the *selective IgG_4 deficiency* was statistically significant compared to atopic controls without RRI, associated not so much with a well-defined state of ID as to a respiratory tract defense mechanism deficiency, in view of the fact that the relative prevalence of this subclass in secretions may indicate a role in the mucosal defense [333].

Other children with *typical symptoms of recurrent infections,* lymphadenopathies, failure to thrive and HgG exhibited low IgG_2 levels, confirming that normal levels of total IgG do not exclude a subclass deficiency [454].

In a cohort of young babies, IgG_4 deficiency was only present in 78/267 subjects (37%) [198]; however, the absence of a control group makes the results incomparable. An IgG subclass deficiency is therefore able to induce or worsen chronic respiratory symptoms in allergic and nonallergic children, especially if predisposed to developing these affections [113], or in subjects with SIgAD [327]. With time these deficiencies, and eventually also those associated with IgA, can normalize [29].

In conclusion, transient and persistent IgA and/or IgG_2 deficiencies have been reported in a small percentage of asymptomatic children [446], but even if IgA and IgG subclasses are not always required as such for a normal immune response, their deficiency may predispose to RRIs [160].

Atopy

As previously illustrated in Chap. 11, the close links between atopy and RRIs are known, and this is confirmed by the observation that asthmatic children have a higher incidence of RRIs than their nonasthmatic siblings. It has been known that RRIs during the early periods of life can play a role in the development of BHR and atopy: in the classic study by Frick et al [173], in 11 out of 13 allergic children sensitization was propitiated by RRIs. With continued observation, the authors noted the presence of high IgE levels, positive RAST and histamine released by leukocytes after infections [172]. In a cohort of 73 asthmatic children aged 0.8–3.1, the 21 affected by

RRIs had a higher incidence of FH positivity (p=0.015), increased IgE (p=0.021), as well as a combined IgA (p=0.038) and IgG (p=0.018) deficiency [296]. IgE hyperproduction could be the result, not only of the well-known association between IgG subclasses and IgE and their coregulation of IL_2 expression [296], but also of a virus-caused unbalanced CD4:CD8 ratio [374]. These results link atopy to RRIs, confirming that the state of chronic inflammation and BHR induced by allergic sensitization is an ideal substratum for the adhesion and chronic evolution of bacterial and/or viral infections.

Clinical Presentation

There are no specific clinical outlines for RRIs. On the contrary, symptoms are extremely varied, with, as previously mentioned, infections caused by bacteria and viruses. URTIs are common at age 4. During the last 12 months, 9.5% of the children experienced more than one bout of acute otitis media, 6.9% had more than one pharyngotonsillitis episode, 47.7% contracted >2 common colds, and 3.2% had rhinitis weekly or monthly [273]. There are children who, during the period of maximum exposure due to *biological immaturity and immunological inexperience,* suffer from one episode each month affecting different organ systems, as well as lymphadenopathies and failure to thrive. The capacity for inducing BHR in normal subjects and worsening the symptoms in those already ill are precisely caused by VRI, also facilitating greater penetration of inhaled viral allergens [530] (Table 11.10); RRIs in turn predispose to sinusitis. Lower IFN-ɣ levels produced by 18 of 53 children at 6 months of age were even greater if the comparison was made between children with RRIs and those with no or maximally one RRI during the follow-up period [382].

Rhinovirus-induced infections (Table 11.11) take the appearance of common rhinitis, but stimulate mastocytes to release histamine, contributing to BHR development and the perspective of delayed reactions.

Diagnosis and Differential Diagnosis

Children with PID

A differentiating feature is the respiratory infections in the ID child that may also result from opportunistic pathogens [80] (Table 22.21). Respiratory infections should be under control. A screening of humoral immunity revealed low Ig levels in 4.6%, low IgA levels in 2.3%, and SIgAD in 1.3% of children [270].

During the last few years, increasingly sophisticated diagnostic techniques have permitted *prenatal diagnosis* in many cases (Table 22.22) [61, 166, 389, 406, 414, 491]: in forms supported by RAG-1 and/or RAG-2 mutations a diagnosis even at the 10th–12th or at the 20th week of pregnancy is possible, so as to evaluate the immune phenotype in the fetal blood [491]. WCCs (white-cell counts) in CB and differential counts can be used to detect the lymphopenia that is commonly present in infants with SCID. However, subset analysis by flow cytometry is necessary to enumerate T, B and NK cells. Subsequently, SCID diagnosis will be suspected when overwhelming opportunistic infections occur [320]. Depending on whether one suspects a humoral, cellular or innate immune deficiency, we begin with the algorithm in Table 22.23 [107], positive if infants or children have ≥2 of these signs, then Tables 22.24–22.26 [101, 478, 522] on laboratory tests can be consulted. However, children with variable levels of antibody ID may end up with different diagnosis [269]. Children with HIgMS presented initially with a history of an increased susceptibility to infection including *Pneumocystis carinii* pneumonia [539] in 43% of children [290]. In PIDs affecting phagocytes, because of the relatively narrow spectrum of disease-specific infections (such as aspergillosis in CGD), careful attention to the microbiology laboratory early in the course of evaluation of a patient suspected of having a PID is crucial to orient the work-up in the appropriate direction [416]. In a male newborn referred to hospital at *27 days of age* for fever, hemodynamic failure and an inflammation syndrome caused by pulmonary infection, culture of tracheal, bronchoalveolar lavage samples and lung biopsy grew positive for *A. fumigatus*, enabling the diagnosis of CGD [337]. To investigate whether patients with undiagnosed ID could be identified in diverse inpatient hospital populations, a scoring algorithm and computer screening method was updated [107] on the basis of ICD-9 codes to survey the discharge diagnoses of all hospitalized patients over periods of time. Thus 17 ID patients were identified, eight of whom were children aged 2–10 (47%), two with neutropenia, two with IgG deficiency, one with LAD, one with DGS, etc. [108]. We also suggest including congenital phagocytic defects in the differential diagnosis of recurrent bacterial or fungal infections in a child [285]. A congenital complement deficiency should be suspected if levels of even one component are reduced [167]. Early diagnosis is essential for choosing the necessary treatment [44].

Differential Diagnosis

The differential diagnosis of PID will emphasize the different characteristics schematized in Table 22.27, to which one must add objective rarity, while FH and child gender become important [10]. In subjects suffering from Omenn syndrome, WAS, severe combined and cellular IDs, the screening of clinical symptoms may be useful at birth and during the first few months after birth (Table 22.28) [61, 80, 399]. The localization of infections is multiple, the ID child usually appears to be ill, and the peripheral lymph nodes and lymphatic

Table 22.22. Prenatal diagnosis in PID

PID	Suggested investigations
A. T lymphocytes	
X SCID	Lymphocyte subsets and function X-chromosome inactivation Nucleic acid sequence
AR SCID	Lymphocyte subsets and function
Nucleic acid sequence	
ADA deficiency	ADA in amnion cells
PID with hyper-IgM	Linkage, nucleic acid sequence
PNP deficiency	PNP in amnion cells
HLA class II deficiency	Absence of HLA class II molecules
ATA	Linkage, nucleic acid sequence
WAS	Fetal platelets, nucleic acid sequence
DiGeorge syndrome	FISH
B. B lymphocytes	
XLA	Mature B cells in fetal blood linkage Nucleic acid sequence X chromosome inactivation
CVID	Nucleic acid sequence
C. Phagocyte function	
LAD deficiency	CD11/CD18 by flow cytometry
CGD, XL	NBT, linkage studies
CGD, AR	NBT, nucleic acid sequence
Chédiak-Higashi syndrome	Giant lysosomal granules in fetal tissue

Data from [61, 166, 389, 406, 414, 491].
CGD chronic granulomatous disease, *FISH* fluorescence *in situ* hybridization, *LAD* leukocyte adhesion deficiency, *NBT* nitroblue tetrazolium, *SCID* severe combined immunodeficiency, *XLA* X linked agammaglobulinemia.

Table 22.23. Clinical algorithm for the screening of PID in infants and children

1. Family history of PID
2. Failure to thrive
3. Oral or cutaneous candidiasis after 1 year of age
4. One or more episodes of cellulitis, meningitis, osteomyelitis, or sepsis
5. Two or more episodes of pneumonia
6. Recurrent deep cutaneous or organ abscesses
7. Two or more episodes of sinusitis in 1 year
8. Two or more months on oral antibiotics with little effect
9. Need for IV antibiotics to clear infections
10. Eight or more episodes of otitis in 1 year

Modified from [107].

pharyngeal tissue are almost imperceptible [102, 196]. The seriously undernourished appearance should be noted, more often observed in children with SCID [162]. RRIs can be observed in other CMI forms [162]: deficiencies of CD3 γ and ε chains [18, 249, 471], ZAP-70 [92, 139] and HLA class II [77, 256]. Finally, children with AIDS will seem to be in severe general condition and this disease is a paradigmatic example of how HIV can overturn the T lymphocyte immune defense with regards to opportunistic infections [79]. In some cases of pediatric AIDS there is hgG that is indistinguishable from PID and that belongs to the differential diagnosis of severe recurrent infections during the first few months after birth [79]. As far as TIH is concerned, the confirmation of a normal presence of the B lymphocytes and low levels of intrinsically produced Ig is resolutive, compared to agammaglobulinemia [61].

Table 22.24. Laboratory tests in children with suspected humoral immunity deficiency

Screening tests
Quantitative IgA, IgG, IgM, IgE serum levels
Isohemagglutinin titers
Antibody responses to prior vaccine antigens (polio, diphtheria, tetanus, rubeola, measles, etc.), Schick test
Advanced tests
Number of circulating B cells (CD19 and/or CD20)
Secretory IgA levels (saliva, tears)
Antibody responses to new vaccine antigens (typhoid, pneumococcal, influenza, etc.)
Lateral pharyngeal X-ray to visualize adenoidal tissue
Specific tests
Advanced B-cell phenotyping
IgA and IgG subclass levels
IgA autoantibodies (selective IgA deficiency)
Lymph node biopsy
Surface markers
Suppressor-inducer cells (CD4/CD45RA)
Helper/inducer cells (CD4/CD29)
CD154 (CD40 ligand) on activated T cells HIgMS
Functional tests
LTT with B-cell mitogens (PWM)
Ig synthesis in vitro
Studies on T-cell function (CVID)
Suppressor cell function:
PWM-Ig synthesis in vitro
Con-A-induced suppression of autologous lymphocytes

Data from [101, 478, 522].
Con-A concanavalin A, *CVID* common variable immune deficiency, *LTT* lymphocyte transformation test, *PWM* pokeweed mitogen.

Table 22.25. Laboratory tests in children with suspected cellular immunity deficiency

Screening tests
Lymphocyte count and morphology
Thymic shadow on chest radiograph
Delayed skin test (tetanus toxoid, Candida, streptokinase, mumps, etc.)
Specific cytotoxicity assay (NK, ADCC, CTL, etc.)
Karyotype
HLA typing
Class I: all cells
Class II: B lymphocytes, monocytes, activated T cells
Advanced tests
Advanced T-cell phenotyping
Number of circulating T-cell subsets
Immature T-cell subsets
Biopsies (lymph nodes, liver, skin, thymus)
Enzyme assays (ADA, PNP)
Specific tests
Surface markers
Mature T cells (CD3)
Major T cell surface marker subsets (CD4, CD8, CD4:CD8 ratio, etc.)
Adhesion molecule typing (CD11a, CD18, selectin ligand)
Functional tests
LTT with mitogens (PHA, anti-CD3, PWM)
LTT with antigens (tetanus, Candida, PPD)
LTT and Ca release with PMA, ionophore, IL_2
Further surface markers (CD7, TcR), CD43, activation markers CD25, CD38
If signal transduction is deficient CD3-γ, CD3-ε, ZAP-70, etc.
Cytokine production (IL_2, IL_3, IL_4, IL_5, IFN-γ, IL_{12})
$IL_2R\ \gamma$ chain (X-linked SCID)
Chromosome fragility (ataxia-telangiectasia, Bloom's syndrome, etc.)

Data from [101, 478, 522].
ADA adenosine-deaminase, *ADCC* antibody dependent cell-mediated cytotoxicity, *CTL* cytotoxic T lymphocytes, *LTT* lymphocyte transformation test, *PHA* phytohemagglutinin, *PMA* phorbol myristate acetate, *PNP* purine nucleoside phosphorylase, *PPD* purified protein derivative.

Children with RRIs

An articulate case history often identifies the familiarity of RRIs, usually with an absent basic pathology and the frequent predisposing environmental factors (Table 22.21), among which passive cigarette smoking stands out. Maximum prevalence occurs during the first 2 years of life or during first contacts with school, the disease is limited in time, and there is usually a single location. In most cases the pseudo-immunodepressed child is clinically normal in all other respects [374]. In ten reported SARS-infected children from Hong Kong, fever, cough, and runny nose were common in the younger children, whereas teenagers presented with symptoms of malaise, myalgia, chill, and rigor [223] similar to those of adults [542]. Thus

Table 22.26. Laboratory tests in children with suspected innate immunity deficiency

Screening tests
PMNs absolute number and morphology, twice weekly over 4 weeks
CH_{50}
C_3
C_4
NBT dye test (now rarely used)
IgE levels
IgG and subclass levels
Cases with neutropenia anti-PMN autoantibodies
Cases with neutropenia without autoantibodies: bone marrow aspiration
Advanced tests
Leukocyte random mobility and chemotaxis
Phagocytosis assays
Bactericidal assays
Opsonic assays
Rebuck skin window
Complement activation assays (C3a, C4a, C5a, etc.)
Complement component assays
Specific tests
Leukocyte turnover
Chemiluminescence
Enzyme assays (MPO, G6PD)
Deformability, adherence and aggregation
Chemotactic factor assays
Complement alternative pathway activity
Functional assays
F actin, 47-kD and 88-kD proteins (regulate actin polymerization)
Defensins, cathepsin G (from specific granules)
Cases with neutropenia
Studies on PMN: hydrocortisone test, G-CSF R
Other studies
Rule out glycogenosis IB
Transcobalamin II
Function of exocrine pancreas
Cases without neutropenia
Killing test
If O_2 production is impaired with soluble and particulate stimuli:
CGD subtypes, G6PD
If O_2 production is impaired with a particulate stimulus only:
Adhesion molecules

Data from [101, 479, 522].
CGD chronic granulomatous disease, *CH_{50}* hemolytic complement 50%, *G-CSF* Granulocyte-colony stimulating factor, *R* recombinant, *G6PD* glucose-6-phosphate dehydrogenase, *MPO* myeloperoxidase, *NBT* nitroblue tetrazolium.

SARS seems to have a less aggressive clinical course in younger children [223].

When in doubt, a broad spectrum of laboratory tests are available: CBC, proteinemia and protidogram, serum Ig levels, or in secretions and IgG subclasses (Table 22.7), immunoelectrophoresis (homogeneous components, κ/λ), dosage of isohemagglutinin, five other natural antibodies, the sweat test [10], in strictly selected cases also a lymphocyte population and subpopulation count (Tables 1.34–1.39), and X-ray of paranasal sinuses. Analysis of the lymphocyte profile sometimes shows a number of deficiencies, statistically differentiated from those found in other children affected by an asthmatic pathology; however, none of the immunological deficiencies indicated (Table 22.29) are characteristic in pseudo-immunodepressed children.

Common diagnostic methods may not be capable of revealing a deficiency of IgG subclasses or of selective IgG_4: the chance that there may be abnormal IgG_2 or IgG_4 levels is not excluded by the normality of IgG serum concentrations [153]. Furthermore, the distribution of IgG into four subclasses makes it difficult to identify these deficiencies simply by measuring total serum IgG levels [113]; only for the past few years have there been highly specific reagents for measuring individual subclass levels and methods such as radial immunodiffusion (RID) [198, 317]. The AAAAI has recommended not relying on subclass levels [10], especially IgG_4 levels, which seem to be unmeasurable in 25% of the population [198]. RID, which has proven to be more sensitive than the ELISA used by the CDC in Atlanta, has shown that 25% of normal children have values below normal for at least one subclass [317]; a similar deficiency was present in 58% of children with RRIs [198]. A recent study measuring the IgG with both methods, has proved that the RID can show higher values of IgG_1 and IgG_2 in low serum levels of both Ig [387], data with an unquestionable negative effect in pediatrics.

In conclusion, at the moment our knowledge suggests that we should also carefully interpret low levels of one or more subclasses, because on the one hand this might indicate a transient or paraphysiological condition, on

Table 22.27. Pediatric clinical differential diagnosis between RRI and PID

Findings	RRI	PID
Family history	+	+ +
Environmental factors	+ +	±
Age <1 year	–	+ +
Sex	Indifferent	Male
Abnormal facial features	–	+
Fever	Short duration	Persistent
Antibiotic therapy	Facultative	Necessary
Recurrent respiratory infections	+ +	+++
Location	Only respiratory	Multiple
Airway localization	Upper	Lower
Pathogens	Common germs	Also opportunistic
Tonsil and lymph node	Normal	Hypoplastic
Course	Normal	Severe, prolonged
Immune abnormalities	Absent or slight and transient	Severe, persistent
Growth	Normal	Retarded
Malnutrition	–	+ +
Prognosis	Good	Short life span[a]

Data from references cited in the text.
PID primary immunodeficiencies, *RRI* recurrent respiratory infections.
[a] If not cured appropriately.

Table 22.28. PID screening in neonates, infants, and young children

Family history	Complement defects
Consanguinity	CMI defects
Early deaths in family	DiGeorge syndrome
Prominent symptoms in the neonatal period	SCID (all forms)
Hypocalcemic seizures	HIV infection and AIDS
Morbilliform rash in the very first days of life	3–6 months
Chronic candidiasis	Agammaglobulinemia
Delayed umbilical cord separation	Hypogammaglobulinemia
Autoimmune hemolytic anemia	Leukocyte adhesion defect
Systemic reactions to live virus or BCG vaccination	6–18 months
Lymphopenia (<1,000 mm^3)	Wiskott-Aldrich syndrome
Eosinophilia	Ataxia-telangiectasia
Cardiopathy	18 months and beyond
Absence or hypoplastic thymic shadow	Common variable immunodeficiency
Onset of symptoms	Hyper-IgE syndrome
Birth to 3 months	Secondary immunodeficiency
Neutrophil defects	

Data from [61, 80, 399].
BCG Bacillus Calmette-Guérin, *CMI* cell-mediated immunity, *SCID* severe combined immune deficiency.

Table 22.29. Differential diagnostic features of PID

Clinical features	Disorders
Autoimmune disease	Selective IgA deficiency, CVID, XLP
Blood	
Aplastic anemia	XLP
Hemolytic anemia	T- or B-cell ID
Neutropenia	HIgMS
Pernicious anemia	SIgAD
Thrombocytopenia	WAS, HIgMS, XLA
Gastroenterology	
Bloody stools	WAS
Diarrhea	SCID, HIgMS
Delayed umbilical cord separation	LAD
Hepatosplenomegaly	T- or B-cell ID, HIgMS, Omenn's syndrome, XLP
Malabsorption	CVID
Mouth ulcers	HIgMS
Thrush	HIgES, SCID
Growth	
Failure to thrive	SCID, T- or B-cell ID, Omenn's syndrome
Head	
Coarse features	HIgES
Oculocutaneous albinism	Chédiak-Higashi syndrome
Unusual facies	DiGeorge syndrome
Lymphadenopathy	Omenn's syndrome, XLP
Recurrent infections	T- or B-cell ID, Chédiak-Higashi syndrome, CGD, CVID, HIgES, HIgMS, LAD, SIgAD, WAS, XLP
Skin and integuments	
Abscesses, recurrent	HIgMS, CGD, LAD
Chronic dermatitis	HIgES, HIgMS
Dermatomyositis-like rash	XLA
Eczema + petechiae	WAS
Fine, hypopigmented hair	Cartilage hair hypoplasia
Lupus-like rash	Complement deficiencies
Maculopapular rash	SCID with GvHD
Oculocutaneous albinism	Chédiak-Higashi syndrome
Teleangiectasia	XLA
Skeletal	
Bony dysplasia	ADA deficiency, Shwachman syndrome

Data from references cited in the text.
CVID Common variable immunodeficiency, *GvHD* graft versus host disease, *LAD* leukocyte adhesion deficiency, *WAS* Wiskott-Aldrich syndrome, *XLA* X linked agammaglobulinemia, *XLP* X-linked lymphoproliferative syndrome.

the other a modest deficiency can result in clear hgG [451]. Subnormal IgG_2 levels can indeed be associated with various manifestations of immune dysfunctions; it is therefore advisable in this case to proceed with specific investigations, measuring the response to polysaccharide antigens and studying the lymphocyte activity in vitro [451]. In children with normal serum levels, who are instead lacking in antibody responses to polysaccharide antigens [143, 430], this is a conclusive investigation [470] (Fig. 22.47). A study of children aged >5, half atopic and half not, has confirmed this thesis, concluding that the answers were similar in both groups, therefore excluding a greater RRI predisposition in the atopic children [344]. Many patients with high IgE levels do not present atopic manifestations: it is thought that an increased concentration is related to a reduced inhibiting activity of the thymus in IgE synthesis [457].

Differential Diagnosis

Recurrent sinopulmonary infections must make one also consider cystic fibrosis and immotile cilia syndrome [457]. Children with malnutrition (Chap. 21) suffer from numerous IDs, prevalently concerning CMI; their vulnerability makes them succumb to severe bacterial ME infections and URTIs, often also risking death. Obese subjects may also be affected by RRIs due to a possible adipose tissue hypovascularization or to a defect in the granulocyte microbicidal activity [457].

Treatment

Antibody Deficiency

In the presence of antibody deficiency, antibiotic treatment is chosen as a preventive therapy in less severe cases, otherwise the *preferable therapy consists in IVIg* (Fig. 22.48). This treatment is restricted to a limited number of diseases, including some forms of ID, secondary or cytopenic ID, in which effectiveness has been proved in DBPC studies [135, 426, 439], like other positive forms of intervention described, while it appears to be of no use in uncomplicated THI [426, 439]. Two children aged 2.5 and 3 with HIgES and Kawasaki disease were administered 400 mg/die of IVIg for 5 days and one 2.5-year-old with HIgES received only one dose, with IgE levels falling from 4,000–14,000 to 600–5,000 UI/ml on the 28th day. Hence there was almost a normalization of IgE production with symptom relapse after 6 months; similar results using a single dose were also obtained in two children with HIgES and severe AD [254].

The following data represent a number of clinical and immunological parameters in children suffering from humoral PID and ATA, with IgG levels <100 mg/dl. Treatment with IVIg, also at a higher dosage, was very well tolerated by patients: all children presented a clear-cut reduction in all clinical parameters, with significant differences compared to IM therapy (Figs. 22.49, 22.50) [174]. IgG levels in all patients also rose considerably compared to previous treatment: the average levels in different determinations was >700 mg [174]. Finally, all children grew normally; the height achieved by each child is between the 3rd and 50th percentile, within the limits of theoretical values calculated on the height of their parents. Substituting therapy with IVIg has allowed patients to return to their normal activities, with a considerable *improvement in quality of life*. In all these years, we have never come across substantial unwelcome reactions or infectious complications [174], as also found by other authors [177, 461]. IVIg could also be effective for reducing the allergic symptoms discussed thus far: presuppositions are not lacking, such as the blocking of allergens and mastocyte FcR thanks to the modest quantities of IgG_4 present in the preparations [196]. In addition, the increased understanding of the IgG transplacental passage (Chap. 2) can absolve the function of timing their transfusion in the case of mothers with antibody ID, so that the fetal defenses can be complete and quantitatively adequate.

In SIgAD common IVIg preparations cannot be used, even if with a low content of IgA, nor enriched, both because of the extremely short IgA life-span, which would therefore suggest IgA administration every 2–3 days, and because the infused IgA do not reach the secretions [507]. Should IVIg be indicated for a deficiency associated with IgG_2, or should transfusions of blood derivatives become necessary, one must first investigate serum antibody anti-IgA levels (IgG and IgE) and, should these be positive, avoid infusions or administer them in a hospital under strict medical supervision, or use washed red blood cells [507]. The same precaution must be taken for subjects with ATA for whom IVIg, if is appropriately administered, also ensure beneficial effects on quality of life, while there are no known therapies for contrasting neurological symptoms. In patients with humoral deficiency, alongside IVIg, if appropriate, an antibiotic prophylaxis is suitable with monthly cycles, alternating amoxicillin, cephalosporin, co-trimoxazole, etc., bearing in mind family compliance. In CVID recurrent infections caused by *Giardia lamblia* should be treated using furazolidone (8 mg/kg/day) or methronidazole (15 mg/kg/day) for 10 days, if necessary to be repeated. CVID treatment in specialized centers involves recombinant IL_2, IL_{10} and cimetidine [456].

T-Cell PID

Some T-cell PIDs represent a severe clinical emergency, such as Omenn syndrome, in which hypovolemic shock and reticular dysgenesis are immanent in the battle for survival. Although precise figures are unavailable, thousands of patients worldwide with different forms of

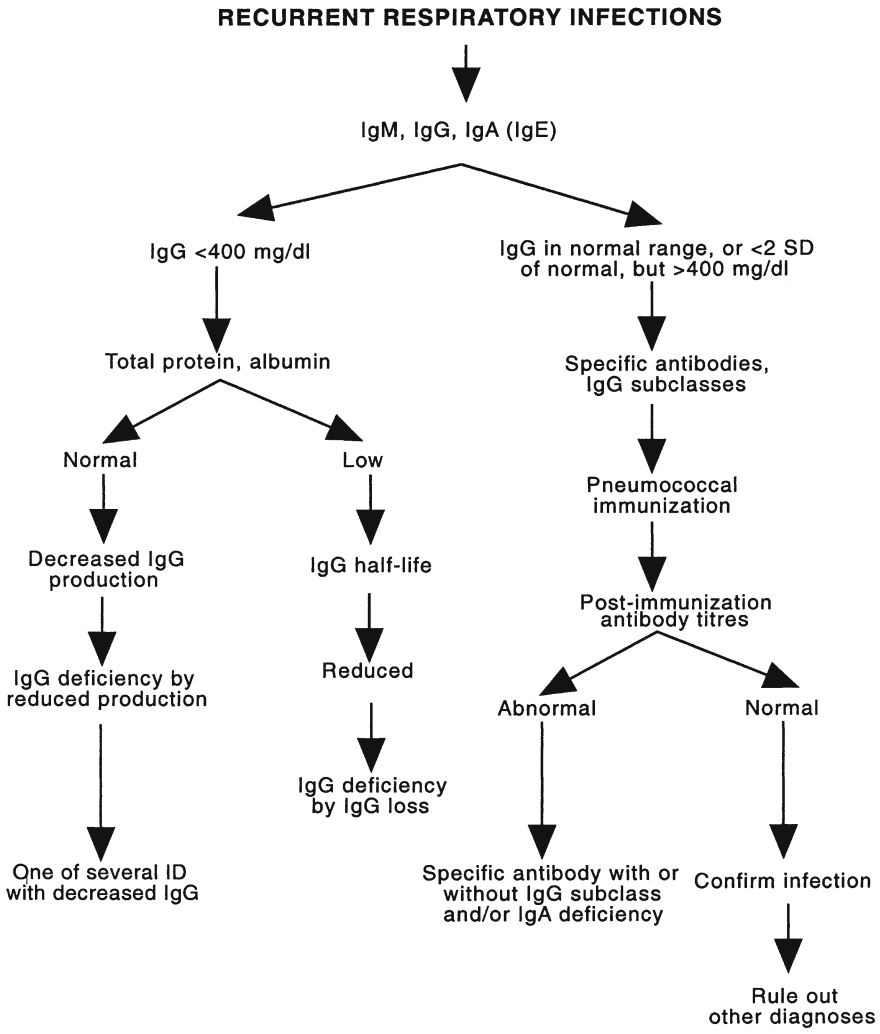

Fig. 22.48. Algorithm for the diagnosis of ID with antibody deficiency in children. The level of 400 mg/dl is arbitrary, but it is the mean value for babies aged 7–12 months (Table 1.15). Calculating IgG half-life after an IgG infusion is helpful to determine an IgG loss in children with diarrhea or nephrotic syndrome. For children with normal or borderline IgG levels, immunizing with pneumococcal vaccine and then measuring antibody titers along with specific pneumococcal antibody titers 4–6 weeks later is most practical. (Modified from [470])

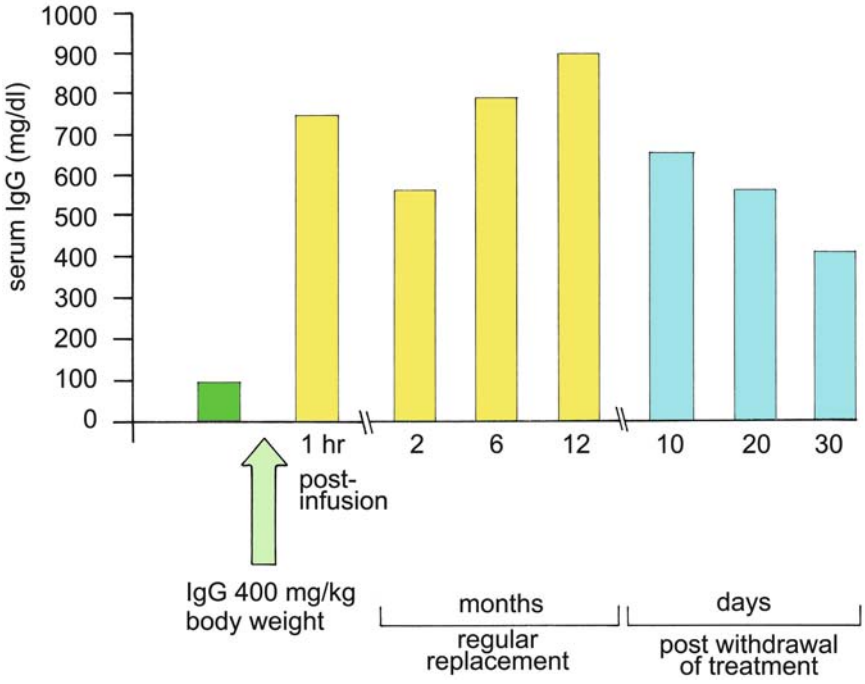

Fig. 22.49. IgG levels in a child with XLA following IVIg replacement therapy. The *first two bars* show IgG levels before and 1 h after receiving replacement therapy, then IgG levels 2, 6 and 12 months after start of therapy; the *last three bars* indicate IgG half-life

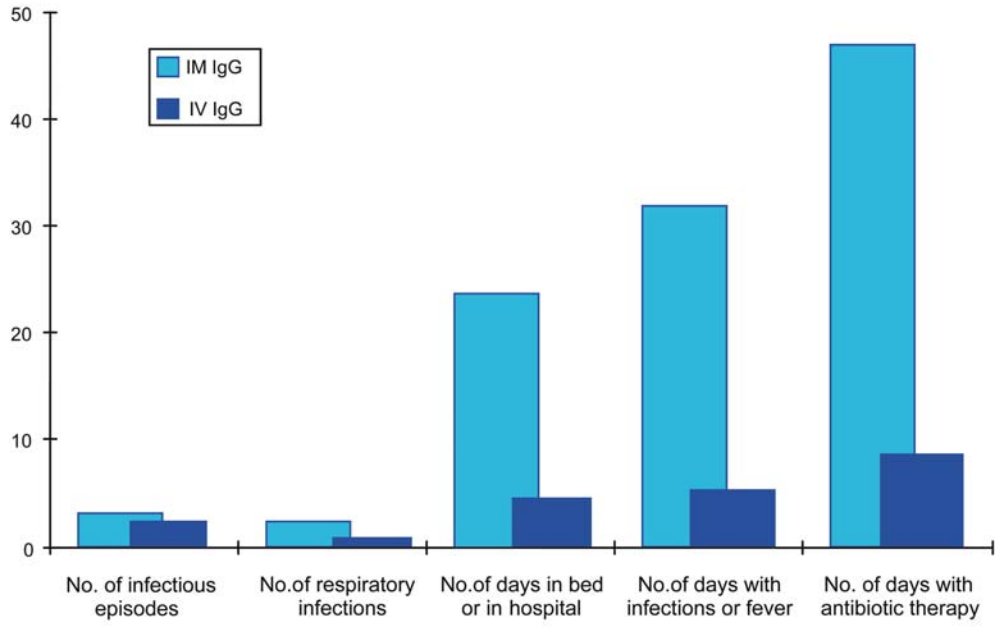

Fig. 22.50. Percent reduction of clinical manifestations (by year/child) in children with antibody deficiency disorders and treated with IM IgG compared to IV IgG-treated children. (Data from [174])

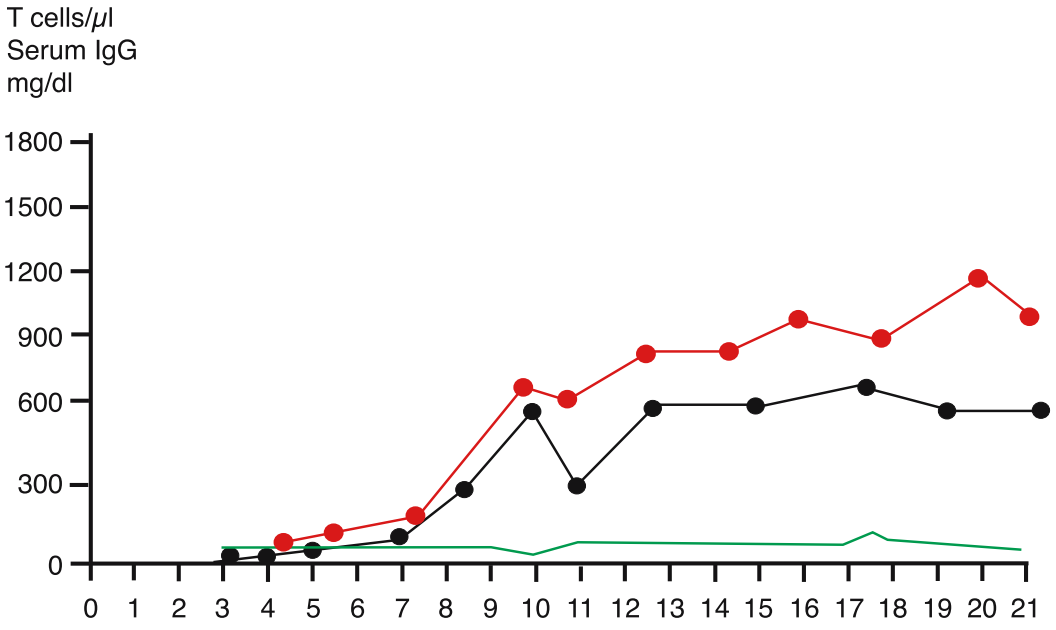

Fig. 22.51. Reconstituting the immune system following TCD haploidentical BMT in an infant with SCID. CD4 (*red line*), CD8 (*black line*), IgM levels (*green line*). (Data from [508])

genetically determined ID have been given BMT in attempts to correct their underlying ID [66], including a recent series [14]. Specific treatment for cellular PID consists in a BMT from a HLA-compatible donor [10]. The ideal SC donor is normally a sibling who shares identical HLA class I and class II *loci*. Without such a donor, these transplantations usually resulted in fatal GvHD. If death did not occur, event-free survival was severely affected by several factors [26]. Either HLA-identical marrow or T-cell-depleted (TCD) haploidentical parental marrow is the standard of care for SCID (Fig. 22.51). When histocompatible related donor BMT is unavailable, a BMT either with HLA-identical unfractionated or TCD haploidentical parental marrow is the standard of care for SCID [338]. All but one (95%) of 21 SCID infants who received TCD identical or haploiden-

tical BMT in the first 28 days of life are currently alive, with the period of survival ranging from 8 months to >19.2 years after transplantation. This compares favorably with a 74% survival rate of 96 infants receiving transplants at a median age of 190 days (range, 45–516 days) [338]. A girl with T^- B^- SCID received a full matched BMT from her sister *at age 2 weeks* [491]. A worldwide survey conducted by Buckley from 1994 through 1997, with subsequent additions of published cases from the literature, revealed that 239 of 302 (79%) patients with PID transplanted with HLA-identical marrow during a period of 34 years were alive [65]. There are >375 patients worldwide who have survived SCID as a result of successful transplantation of HLA-identical or haploidentical BM [67]. Most importantly, 34 of 35 infants (97%) undergoing transplantation *in the first 3.5 months of life* are currently alive [69, 338], compared with a cut-off at 6 months (97% vs 86%, children younger vs those aged >6 months) receiving BMT (OR 5.0 [14]). We stress that neonates developed higher lymphocyte responses to phytohemagglutinin and higher numbers of $CD3^+$ and $CD45RA^+$ T cells in the first 3 years of life than those receiving BMTs late. T-cell antigens peaked earlier and with higher values in the neonatal BMTs (181 days to 1 year) than in the late BMTs (1–3 years) [338]. Over the past 22 years 78% of all SCID patients (110/142) receiving BMT at Duke University Medical Center survive to varying ages up to ≥20 years after BMT. Only 16 had an HLA-identical donor. All others received rigorously TCD haploidentical BM from a parent, most often the mother. The soy lectin, SRBC rosetting technique was used (R. Buckley pers. comm. November 20th, 2004 and April 20th, 2005). An uncommon BMT to treat AR SCID was undertaken in *a 1-month-old girl*. The donor was her HLA-mismatched 6-year-old sister, who had previously received a BMT from her father [479]: presently, they are aged 5 and 13 and are affected by *Molloscum contagiosum* infection [547].

BMT, both HLA identical unfractionated and TCD HLA aploidentical [63]. A recent trial found that because only 10%–15% of affected children have a familial HLA-identical donor (RID), the alternative therapeutic options are BMT from a MUD or a haploidentical BMT or from HLA-mismatched related donors (MMRDs). Only 40% of these children may find a matched donor; therefore, the remaining PID-affected children are candidates for a TCD haploidentical BMT [277]. MUD HSCT is successful in young children [132], but the success rate decreases dramatically above the age of 5–6 years [158] (Table 22.30) [13, 15, 25, 27, 39, 46, 52, 55, 56, 58, 64, 67, 69, 80, 83, 85, 98, 111, 119, 131, 132, 163, 185, 188, 197, 205–208, 231, 233, 235, 237, 245, 252, 256, 257, 259, 260, 277, 280, 286, 288, 290, 305, 307, 334, 360, 366, 380, 405, 408, 428, 440, 448, 452, 456, 466, 474, 491, 496, 499, 503, 534]. Table 22.30 shows the treatment of choice for severe primary T-cell PIDs. Of 94 infants diagnosed as having SCID who received BMT between 1990 and 2004, 66 (70.2%) survived, 12 (92.3%) of 13 infants who received RID BMT, 33 (80.5%) of 41 who received MUD BMT, and 21 (52.5%) of 40 infants who received MMRD

Several different BMT techniques have been adopted. Additional data from [65, 85, 246, 328].
[a] See details in the text for survival rate.
[b] Case reported to Broome et al [58].
[c] Median (1.5–13 years after BMT).
P, at the time of publication.

BMT survived. Compared with MMRD BMT, survival was significantly higher with RID or with MUD (45/54 = 83.3%) [201]. When an HLA-identical sibling as the donor is unavailable, a phenotypic HLA-matched unrelated BMT is needed, also used in CD154 deficiency [290, 499], with a clinical and immune outline normalization [246] and a variable effect on IgG subclasses

[153]. Possibly because of earlier diagnosis before untreatable opportunistic infections develop, the results have improved considerably during the last two decades [65]. BMTs have been successful when applied within the first *7–24 days of life* in 21 infants with SCID, 20 (95%) of those still alive range from 8 months to 19 years, not justifying *in utero* transplants. A completely normal T-cell function was obtained within 82–118 days [338] and in an other 83 patients was still present after 10–17 years [373]. Of the 58 children who received a mismatched parental BMT from 1980 to 1998, 43 (74%) remain alive with T-cell immune reconstitution, a median of 128.8 (range, 13–224.3) months after BMT [362]. Of 96 children out of 117 who received allogeneic BMT after the first 28 days of life, 71 (74%) are alive [69]. Three out of five children who received a HSCT are alive and well after 18–32 months [13]. Breast feeding appeared correlated to an earlier reconstitution when the donor was the mother [338]. *Intra-amniotic gene transfer* has been successfully carried out on a laboratory animal, registering in a dose-dependent manner the fetal gastroenteric and respiratory effects [222]. If confirmed in human beings, this method of treatment will certainly prove useful for prenatal correction of PID.

BMT/HSCT should be completed by conditioning regimens with busulfan and cyclophosphamide, less toxic than total lymphoid irradiation or a combination of nucleoside analogs and anti-lymphocyte antibody preparations [65]. For example, busulfan (16 mg/kg), melphalan (90 mg/m^2) and anti-thymocyte globulin (36 mg/kg) [83]. To enhance the engraftment rate in haploidentical BMT in PID, it was recently suggested to add donor peripheral SCs after mobilization with G-CSF (16 µg/kg for 5 days) and BM cells. With this procedure the cell load is increased, which allows intensification of the conditioning regimen for induction of faster engraftment [277].

In utero BMT suggested advantages include the sterile environment *in utero,* and immaturity of the fetal immune system enabling the prevention of clinical manifestations of the disease in the neonate, and the engraftment without the use of cytotoxic conditioning regimens: a child thus treated was well at age 11 months [164]. Two series of six and four patients [386, 504] and two additional case reports [182, 532] of *in utero* transplants have been published, yet failure of B-cell engraftment and function may result in long-term dependence on IVIg replacement [248]. Better results than those published for *in utero* BMT for SCID were implicit in 13 infants admitted and diagnosed *at a median age of 3 days* because of a FH of a previously affected infant. BMT was successful and all children are alive and well with follow-up to 11.5 years [248] or <30 days vs approximately 4 months [194]. However, it is suggested that in utero transplants may carry the risks associated with injecting the fetus and the inability to detect GvHD during gestation [65].

Umbilical CB transplantation (UCBT) was done in two children affected by a Zap-70 deficiency and an Omenn-like syndrome. Both are alive and well at 4.5 and 2.2 years after UCBT [148]. Unrelated UCBT in eight children with severe T-cell ID [260] and in three with WAS [259] resulted in consistent and stable T$^-$, B$^-$, and NK cell development [259, 260]. Faster availability of UCBTs is a meaningful advantage for patients requiring urgent transplantation: a median of 25 days more rapidly than did those receiving bone marrow [30]. In a large report [423], 40 patients with SCID, seven with WAS, and other unspecified PID received an unrelated UCBT. UCB was evaluated as a SC source for immune reconstitution in children with severe primary T-cell IDs such as SCID, reticular dysgenesis, thymic dysplasia, CID, DGS, and WAS when a matched sibling donor was unavailable, and has been used to date in more than 2,000 patients [194]. Three infants who rejected a TCD-mismatched parental BMT without prior cytoreduction engrafted after infusion of UCBT [69]. A 4.5-year-old girl with HLA class II deficiency had a successful related UCBT for graft failure following TCD nonidentical BMT [52]. A girl with reticular dysgenesis failed to engraft following her first transplant, but fully engrafted after a second unrelated UCBT. Five of six patients showed grade I GvHD, although one child experienced grade IV skin and gut GvHD. Immunological UCBT resulted in consistent and stable T-cell, B-cell, and NK-cell development [260]. Long-term event-free survival (≥27 months) with recovery of antigen-specific responses was reported following an unrelated UCBT in a child with Omenn's syndrome [38].

Gene therapy, which has revolutionized and could revolutionize even more PID treatment in the near future, is analyzed in Table 22.31 [76, 104]. The requisite for applying this form of genetic engineering treatment is that the responsible gene must be cloned; the most common techniques involve knock-out mice and inactivating a particle [104], or employing retroviral vectors (Table 22.32) [263], totally deprived of their genomic factors except for the normal copy of the gene to be inserted. This is indispensable for allowing the vector to reach the human nucleus, where it will integrate with the cellular genome [263]. In this case, PBLs are collected through leukapheresis and cultivated in vitro with retroviral particles containing a normal gene RNA copy: thus the healthy gene is introduced into the cell genome using a vector and the manipulated cells are reinfused, so as to restore normal immune functions. This system has been used to treat two children aged 2 months suffering from SCID [508] and from ADA deficiency by employing autologous PBLs [51], BM cells [54], and CB cells [262]. Three reports [4, 88, 204] of successful gene therapy in infants with X-linked SCID [88, 204] and in T$^-$ B$^-$ SCID [4] are a major step forward among repeated efforts to achieve better immune reconstitution in ADA-SCID with gene therapy than with BMT/SCT [161]. Immediately after the diagnosis had been made in two

children aged 8 and 11 months including a novel splice imitation in the common γc chain [183], haploidentical $CD34^+$ peripheral progenitor cells mobilized with GM-CSF were isolated to a purity of more than 99%. These cells were infused with no prior chemoablation and no prophylaxis against GvHD. Both children showed signs of T-cell reconstitution beginning 3 weeks after the $CD34^+$ infusion and were weaned from continuous cures. They are in excellent health, without GvHD, 34 and 68 months after transplantation. One child does not need replacement Ig. The other received a booster infusion of $CD34^+$ SCs from the original donor 1 year later to improve B-cell function and now receives Ig every 3 months. Both were followed for 10 months after gene transfer [88]. However, retroviral vectors have the capacity of wild-type, replication-competent retroviruses to cause leukemia in immunologically immature neonatal mice [263], and in humans (two children out of 11) [63, 88, 204]. Retroviruses can cause insertional oncogenesis, a long-known potential complication of retroviral gene transfer attempts, because gene integration occurs at random in the genome, thus deregulating the expression of cellular oncogenes [263]. This complication has been thought to be unlikely with such vectors, because they are capable of inserting only once into the cell's chromosomes and cannot repeatedly reproduce and integrate. Lentiviruses may be more effective than murine retroviruses for gene transfer into human hematopoietic SCs and T lymphocytes [263]. In ADA-SCID, *the safety and efficacy of HSC gene therapy* combined with nonmyeloablative conditioning for the treatment of SCID has allowed two children to live at home and clinically well, with normal growth and development [4]. On January 14, 2003, FDA placed on "clinical hold" all active gene therapy trials using retroviral vectors to insert genes into blood SCs after having learned that a second child treated in the French gene therapy trial developed a leukemia-like condition. Gene therapy is on hold despite enormous promise for certain SCID/CID variants.

Survival. In SCID, the European experience with unfractionated HLA-identical and TCD or non-TCD haploidentical or MUD BMTs in patients with SCID reported that between 1968 and 1999, a 3-year survival with sustained engraftment was significantly better after HLA-identical than after mismatched transplantation (77% vs 54%). Within the HLA-identical group, survival after BMT from genotypically or phenotypically identical related or MUDs was 81%, 72%, and 63%, respectively [14]. In non-SCID, 3-year survival after genotypically HLA-matched, phenotypically HLA-matched, MMRD, and MUD BMT was 71%, 42%, 42%, and 59%, respectively [14]. In a retrospective analysis of BMTs performed between 1977 and 1991 at 13 European centers in 149 children as young as 1 month with 11 different PIDs (excluding SCID), the overall survival among 53 recipients of HLA genetically identical BMT was 66%, 45.5% in 22 patients who received closely matched BMT, and 38% in 71 recipients of BMT with two or three mismatched HLA antigens. A significant improvement in survival has been achieved in most PIDs (overall survival, 81.5% vs 51.7%, primarily because of a decrease in the frequency of infectious complications [163]. In the similar analysis performed in 193 children with SCID at 18 European centers between 1982 and 1993, 116 out of 193 (60.1%) patients were alive with evidence of engraftment 6 months after BMT. However, 24 patients died >6 months post-BMT, mainly due to cGVHD and/or viral infection. Thus GvHD 6 months after BMT and B^-SCID vs B^+SCID were the main factors associated with a poor outcome [206]. The disease-free survival was significantly better for patients with B^+SCID (60.7%) than for those with B^-SCID (33.3%) [14]. In a

trial on children with PID receiving BM from HLA-non-identical related donors or from HLA-identical unrelated donors at 13 European centers between August 1990 and June 1993, 22 out of 28 children (76.6%) survived 22–58 months. BM was TCD by use of either erythrocyte rosetting or monoclonal antibodies to prevent GvHD [231]. Additional survival rates were reported previously (Table 22.30). In a series of consecutive UD BMTs 31/33 children with SCID and non-SCID PIDs who received a BMT with reduced-intensity conditioning (RIC) regimen between 1998 and 2001 survived after a 3.3-year follow-up, as well as 10/19 children who received a BMT with myeloablative conditioning (MAT) between 1994 and 1998 and survived after an 8.6-year follow-up. Therefore a RIC regimen results in improved survival and reduced BMT-related mortality compared with MAT in HR children undergoing an UD BMT [396].

In 170 transplanted patients with WAS, the 5-year probability of survival differed according to donor type: 87% with HLA-identical sibling donors, 52% with other related donors, and 71% with MUD. Significantly, boys who had received a MUD transplant before 5 years of age had survival rates similar to those receiving HLA-identical sibling transplants [158]. However, the time required to develop immune function after haploidentical SCTs is quite different from that after unfractionated HLA-identical BM. Lymphocytes with mature T-cell phenotypes and functions fail to rise significantly until 3–4 months after BMT; normal T-cell function is reached between 4 and 7 months [338]. B-cell function develops much more slowly, averaging 2–2.5 years for normalization; many do not have B-cell function, despite normal T-cell function.[338]. *Ex vivo* rigorous depletion of post-thymic T cells from donor marrow that cause GvHD is efficient and feasible, even in haploidentical settings [13], presumably because of more effective infection-control measures and better transplantation strategy [514]. For non-SCID, SCT can provide a cure, and grafts from unrelated donors are almost as beneficial as those from genetically HLA-identical relatives [45]. In most patients, deficient B-cell function persists after transplantation and requires lifelong IVIg therapy [69,207], which is necessary to prevent bacterial and common viral infections [69, 514]. Some patients also have persistent deficiencies of T-cell function after SCT [206, 373].

Children with RRIs

In children with RRIs, depending on the nature of the infection, the pediatrician will prescribe the most appropriate symptomatic and/or antibiotic therapy. In the presence of persistent inflammation, or during the winter, when the risk of close acute recurrent episodes is higher, anti-inflammatory preparations will be prescribed via aerosol, chromones, ketotifen, β_2-adrenergic and if necessary steroids for topical use, strictly depending on the need. We suggest monitoring measures, such as keeping a clinical diary, in which each acute episode should be briefly noted, continuing registration until clinical symptoms have not regressed for at least 15 days and returning to keep notes in the diary each time there is a cough and/or nasal and/or bronchial inflammation, completing this with PEF as well as some respiratory parameters right at the beginning and then every 6 months. It is obvious that if medical intervention is not resolutive a center specialized in infantile respiratory physiopathology should be contacted [47]. Children with SARS were treated with high-dose ribavirin, oral prednisolone, or IV methylprednisolone, with no short-term adverse effects [223].

Antibiotics must be used very carefully in these children because they can influence positively or negatively the innate, cellular or humoral immunity (Chap. 18), interaction with ILs and growth factors are not known, repeated use often causes phenomena involving allergy/intolerance [470], and most infection-prone children suffering from VRIs are given antibiotics unnecessarily.

In Italian children (54.6% of males) aged 6 months to 14 years (median, 4 years) with a history of RRIs, macrolide therapy of acute respiratory infections influenced the natural history of RRIs, probably because of their elective activity on atypical bacteria [508]. Considering the emergence of antibiotic-resistant bacterial stock, as for example *S. pneumoniae*, immunotherapy has been proposed as a means of preventing RRIs by providing children with small doses of inactive bacterial antigens liable to trigger specific and protective immune responses (Table 22.33) [36]. For example, OM-85 BV significantly reduces the URTI rate, particularly in a DBPC study in 232 children aged 3–8 with a history of acute URTIs [448], is active in preventing RRI episodes [36] with a meaningful reduction in the number of days of suffering acute URTIs [448]. Bacterial ribosomal and membrane proteoglycans of *S. pneumoniae*, which stimulate B cells with secretory responses, as well as memory cells, may be used for responding to future infections [36]. Ribosomal immunotherapy appears to be not only well tolerated, but also ideally targeted to induce mucosal responses [37]. Among the preparations reserved for specific use, a study of pidotimod in DBPC trials proved its effectiveness in a sample of 101 children with RRIs, also showing increased CD25, absent in placebo-treated children [72]. The use of immunostimulants should be limited to children with proven high susceptibility to acute URTI, or overexposed children attending daycare facilities, or attending kindergarten or elementary school [508]. However, according to a meta-analysis, immunostimulants are an effective treatment for the prevention of acute URTI in children [40]. Furthermore the *indiscriminate and purely empiric use of IVIg* must be discouraged in every child with RRI, whereas in a prospective, DBPC study of IVIg and co-trimoxazole, 106 of 130 children <8 years referred for recurrent bacterial RRIs became infection-free over a 4-month obser-

vation period [353], in addition to having an extremely unfavorable cost–benefit ratio [426]

Immunization

Children with RRIs and deficient antibody responses to germs expressing a capsular polysaccharide can be successfully vaccinated, but avoiding the administration of live virus vaccines and integrating this if necessary with an IgG replacement therapy [218]. Furthermore, in view of the availability of conjugated vaccines, it will be possible to induce antipneumococcus-IgG_2, providing an effective treatment for children with RRIs, especially if caused by pneumococci. Other kinds of vaccines have provided disappointing results: Fig. 22.52 [340] indicates the immune bases of a specific immunization and the possibility of specific interventions. In children with PID, one should bear in mind all the aforementioned facts.

Pediatricians, PID and RRIs

Until the past few years, there was a busy motion into the fundamental problems underlying a majority of these conditions. Many have now been mapped to specific chromosomal locations, and an impressive number

of the fundamental biological errors have been identified. The pediatrician is entrusted with a more difficult job, that of identifying as early as possible the possible existence of PID, remembering the suggestions for case history in Chap. 6, with the exception of clinical emergencies such as Omenn syndrome and reticular dysgenesis. This specific research becomes a necessity thanks to the new diagnostic and therapeutic advances that have been conceived over the past few years: the earlier one acts, on the one hand with a prenatal diagnosis and on the other with a BMT or SCT therapy, the greater the chance to increase life expectancy for these children, in addition to ensuring *better quality of life*. The discovery and cloning of the genes for these diseases have obvious implications for the potential of gene therapy. The rapidity of these advances suggests that there will soon be many more to come. One of the most common differential diagnoses will occur with a child affected by RRIs, for whom we believe the number of infections must be immediately clarified, although evaluated according to different numeric and epidemiologic factors, not associated with those which instead concern the severity and the site of the infection as well as the type of the pathogenic agent that characterize children with PID. However, antibiotics are banned by the supporters of the hygiene hypothesis (Chap. 24).

Prevention of Allergic Disorders

Preventing Atopic March: A Priority

A heredity component in the pathogenesis of atopic disease has been shown in Chap. 4, and an increased prevalence of atopic disease in Chap. 5, so such diseases represent a very contemporary problem: even a cursory glance at the literature clearly demonstrates the growing prevalence of atopic disorders. In the past two decades, a number of factors have contributed to this increase: urbanization that has brought in pollen-carrying ornamental plants and has generated extensive pollution, excessive smoking that seems to have made inroads everywhere, increased exposure to allergens, and poor ventilation of modern homes, which are outfitted with everything that favors Der p proliferation. These figures alone demonstrate that atopic diseases must not be underestimated, regardless of their manifestations. This is not only because a mild clinical picture can quickly become complicated, but also because in cases that are serious from the outset, only an accurate and timely diagnosis – and a rapid therapeutic conclusion – can effectively resolve this contingency. This would compound the problems of an already difficult area of preventive medicine, although it may be pertinent to move attempts at intervention back into early pregnancy or even preconception. The ability to prevent atopic disease before its occurrence has been a strong desire of physicians dedicated to this pivotal field. In *On Medicine* (2, pp 17–18), Celsus said that *"food and drink... are not only the common aid to all disease but also to good health"*, and Cantani Sr that *"pure air, water and diet are the main and most powerful ways of staying healthy"* [53].

The focus of prevention of pediatric allergy and asthma has recently changed. In Chap. 13 we documented the resolutive effect of the desensitization to both food and inhalant allergens. This is a great opportunity in light of the marked increase in prevalence of the familial allergic diseases of children, including asthma, allergic rhinitis (AR), atopic dermatitis (AD), and food allergy (FA), as shown by our personal experience demonstrating that atopic disease afflicts 95% of infants and children with FHA (family history of atopy), as attested in the table in Chap. 5 illustrating this emergency and in our study on increased prevalence of pediatric asthma from 2001 to 2003.

Definition

Allergic diseases are multifactorial disorders, which are caused by genetic factors that predispose children to atopy and by numerous environmental factors that contribute to their phenotypic expression: given that modifying genotype is not possible, prevention thus focuses on modifying unfavorable environmental factors through appropriate manipulations recommended only for siblings of atopic subjects, therefore defined as genetically at high risk (HR) for allergy.

Methods

Allergic diseases can be prevented in three ways:

- *Primary prevention,* by acting on predisposing factors to prevent or at least delay sensitization before any IgE-mediated disease has occurred.
- *Secondary prevention,* based on the use of drugs as well as other measures, once IgE-mediated disease has developed, means prevention of further sensitization.
- *Tertiary or long-term prevention,* prevents complications and means attempting to reduce allergy expression once IgE-mediated disease has occurred.

Requirements

It has often been noted that prevention has two basic requirements: practicality and cost-effectiveness. On a day-to-day basis, however, the programs for preventing allergic disease may seem impractical and expensive to the families that need to implement them. As a result, they are not always easy to accept, as they often diverge from widespread habits and mentalities. For example, birth shortly before the pollen season is associated with a high prevalence of respiratory allergy during the next developmental stage [360] (Table 4.12), but it would be a difficult task to convince allergic parents to plan the birth of a child for less risky months. The hygiene hypothesis indicates that daycare center attendance by children at risk for atopy helps protect them from subsequent development of allergic diseases and infections. Nevertheless, we must bear in mind that the statistics on ETS (environmental tobacco smoke) [86], extended to

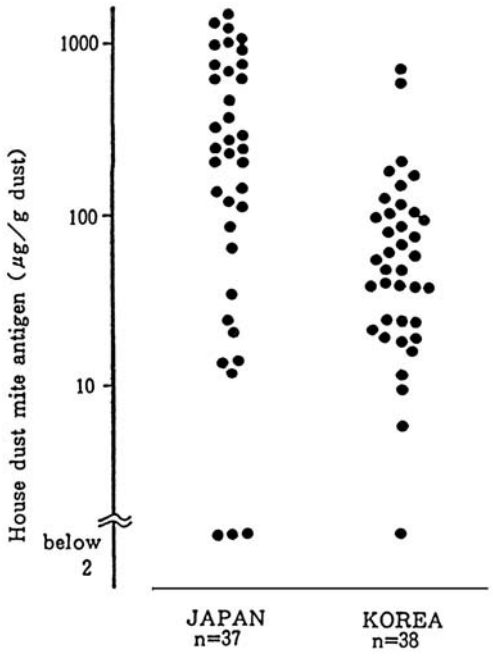

Fig. 24.1. Der p antigen content in dust samples collected from houses in Japan and Korea as measured by ELISA-inhibition method. In Korean houses with a traditional floor heating system and smooth plain flooring a lower Der p concentration was found

the risk of infections of the lower respiratory tract (LRTI) and of development of specific IgE (sIgE) (Table 4.25), involve a significant number of children – up to 100% – attending daycare settings. Fel d 1 and Can f 1 were detected in all daycare settings, evidently brought in by children and/or personnel in contact with cats or dogs, while Der p 1/Der f 1 were noted in 41% of cases [303]. Another observation involved the significant amount of dust that was collected, despite thorough cleaning of the rooms and furnishings [303] (Fig. 24.1) [22].

Exclusive breast-feeding for the first 6 months and delayed weaning over the 6th month of life is often at odds with real problems or with the widespread habit of early weaning. Even the suggestion that nursing mothers restrict the use of strong allergens in their diets – above all cow's milk (CM) – may be accepted reluctantly, due to the common opinion that "milk makes milk." Moreover, a great deal depends not only on the commitment of researchers in this area, but also on incisive campaigns to inform public opinion. Also important is the ability of pediatricians to explain to parents how necessary the proposed dietary–environmental measures are, a concept that cannot be appreciated by everyone. It is vital to emphasize to parents that a range of preventive measures, permitting timely protection against an excess of allergens, can help avoid or delay the appearance of allergic sensitization, or at least ensure that the disease will be less severe. Our studies in this field have been confirmed by the results on 67 children of atopic parents: *none of those exposed to a low allergen load* (<2 μg/g of dust) *became sensitized to airborne allergens* [396].

The prevention of the atopic march is not anecdotal [230] but a reality, as we will demonstrate. Our belief has been strengthened by the need to act positively in the early stages of life [189], by the significant preventive effects of breast-feeding in prospective birth to 7 [39, 123, 484], 11 [477], 15 [162], and 17 years of follow-up [360], also by the dramatic case of a 7-week-old baby for whom no preventive measures were taken despite a positive family history (FH), and who died after several changes in diet (Chap. 9). On this specific subject, we refer to Table 3.8, which summarizes the characteristics of newborns and nursing infants at a HR for atopy, and to Table 4.29, which lists the main genetic and environmental factors that are responsible for or contribute to the development of atopic diseases in HR infants and children.

Primary Prevention

The factors that can modulate the clinical expression of phenotype are as follows(Fig. 4.31):

1. Prenatal factors
2. Perinatal complications
3. Birth period
4. Diet during the first several months and weaning
5. Exposure to environmental factors
6. Immune interventions

Given that we have already discussed points 1–3 in Chap. 4 (summarized in Table 24.1) [23], we will examine the role that other factors play in primary prevention [45, 44, 46].

Role of Diet

Prenatal Role of Diet

Can children be born with allergy? We already answered this question in Chap. 3 by saying that this is a statistically rare possibility. The point we must emphasize, however, is that the fetus starts synthesizing IgE as of the 10th week of intrauterine life, and responds to food allergens that are ingested or inhaled by the mother during pregnancy (Chap. 4).

The theory of intrauterine sensitization has been studied by several authors. Anti-CM cord-blood IgE (CBIgE) was found in 3.3% of HR newborns, and CB lymphocyte stimulation test (LST) with ovalbumin and bovine serum albumin (BSA) was positive in a 2-year follow-up of 8/37 infants when it was repeated twice (Chap. 3). Nevertheless, it was clear that *sensitization does not occur during fetal life,* since CBIgE are the out-

Table 24.1. Environmental modulation of IgE mediated and non-IgE mediated reactivity

Effect of inhaled or ingested allergens
Feeding at-risk neonates/infants with formulas based on heterologous proteins entails an increase in IgE levels and/or of anaphylactic manifestations
Month of birth may be associated with the risk of IgE-mediated hypersensitivity in the subsequent years of life
Exposure to aeroallergens (pollens, house dust mites, molds, pets, etc.) increases the synthesis of specific IgE antibodies
Effect of infections
Viral infections (Epstein-Barr virus, respiratory syncytial virus, etc.) may be temporarily associated with priming of specific IgE antibodies
Effect of medications and other agents
Progesterone taken in pregnancy increased cord blood IgE antibodies
Passive smoking augments total IgE levels
Cortisone reduces the IgE low-affinity receptors on lymphocytes and monocytes of atopic children
Specific immunotherapy reduces specific IgE antibody levels
Hygiene hypothesis
Increased use of antibiotics in childhood, cleaner drinking water, improved sanitation, and widespread vaccination practices could be associated with an increased atopy prevalence

Modified from [23].

come of nonspecific synthesis rather than antigen stimulation. The lack of reactions in the 1st week of life and at initial exposure to CM [195] or hydrolyzed formulas (HF) [50] does not favor this hypothesis but at the same time, it does not exclude it [195].

Several studies have been conducted in different countries to establish whether a special diet during the final months of pregnancy can decrease allergy prevalence in children. Consequently, in atopic families that gave their consent, maternal diets were monitored during pregnancy, reducing the consumption of CM, eggs, fish and so on during the last trimester. Four hundred pregnant women were examined and they followed four different diets during the last trimester: total or partial elimination of the incriminated foods, free diet, or the daily consumption of an egg and 1 l of CM. This study [128] and others reported to date [254, 255, 486] have not revealed any statistically significant differences in either total IgE levels or in atopy development when comparing the offspring of mothers on a restricted diet and those of mothers who did not follow any diet [255]. The results at the 5-year follow-up [129] confirm that no benefits can be gained from this diet, as demonstrated by maternal avoidance of CM and egg during the third trimester of pregnancy and lactation yielding no reduction in AD and CM and egg sensitization in their HR German newborns [181]. We must note that the fetus is already immunologically active starting in the second trimester (Tables 2.4–2.6) and, therefore, the lack of success of the diets during pregnancy may depend on not starting any diet before the third trimester.

The anaphylactic reactions occurring in newborns or infants the first time they ingest CM (Fig. 9.14) imply that evidently it is not easy to protect the predisposed newborn after birth. These reactions may involve the transfer of maternal antigens to the antigen binding sites of anti-idiotype antibodies: if anti-polio anti-idiotype antibodies can be transferred from mother to child, other anti-idiotype antibodies may likewise replace antigens, mimicking their functional properties and thus being transferred from mother to fetus, acting like antigens in the prenatal period or subsequently.

Role of Postnatal Diet

Role of Foods in the Immediate Postnatal Period

In addition to the studies we have cited and those we discussed in Chap. 4 (repeated low doses of allergens can sensitize a predisposed individual), two infants presented anaphylactic shock the first time they were given CM proteins: but it was the second time, since they had received supplements while in maternity wards [45, 253, 265]. Likewise, HFs given to nine newborns at risk triggered anaphylactic reactions when the babies were weaned from the breast [50]. Other studies have shown that nurslings with adverse reactions to CM [196] or with positive skin prick tests (SPTs) to CM and sIgE to egg [256] *were fed CM during the first few days after birth*; moreover, total IgE titers at 5 days of life were significantly related to the amount of supplements *they were given immediately after birth* [371]. All the infants who developed CM allergy (CMA) during exclusive breast-feeding had been exposed to CM at maternity hospital [196]. Between 64 % and 100 % [196, 380, 403] of breast-fed infants who received CM supplements while in maternity wards developed CMA after 7 weeks (mean) [403]. Obviously, early exposure to CM (160 ml) was shown to be sufficient to increase the risk of atopic disease in the first 2 years of life [109]. Among 39 children who developed CMA, a supplement of only 40 ml of CM was adequate [195] (the "low doses," Chap. 3). It is unlikely that immune memory will be suppressed once activated. It is noteworthy that in a cohort of 6,209 newborn infants, significant risk factors of CMA development were full-term exposure to CM at the maternity hospital (87 %) (OR 3.5); long-term breast-feeding (OR

3.9 while breast-feeding supplemented with infrequent small amounts of CM) during the first 8 weeks (OR 5.7) induces the development of IgE-mediated CMA: 2.1% (OR 0.85) in those fed own mother's milk and 2.4% (OR 1.0) in those fed CM formula. More importantly, during the first 8 weeks of life, 54.5% of the infants were exposed to CM at home [358]. Exclusive breast-feeding for 3–4 months yielded statistically significant results [228, 250, 400]. In a trial on 3,903 children, those in the interventional subgroup had a significant protective effect on AD if compared with conventional CM formula (OR[adjusted], 0.64). [250]. Also in the PIAMA birth cohort study, a negative association with AD (OR, 0.6) was noted [228]. Finally, there was an association with an increased risk of AD in children with no parents with allergies (incidence rate ratio, [IRR], 1.29) but not for children with one (IRR, 1.11) or two (IRR, 0.88) parents with allergies [400]. To prevent hidden feeding of allergenic foods in maternity wards, a decision should be taken at a government level, as has been done in Scandinavia [23] and in a London hospital [280], where *supplements have no longer been permitted in maternity wards* for several decades. In contrast, giving supplements is a common practice in Denmark [285] and in Italy [90], and supplements are given to up to 73% of newborns [285] even the children who will be breast-fed receive a CM formula supplement during the night if they cry [90]. Consequently, it would be appropriate for public health agencies to closely supervise the quality of the messages targeting physicians, obstetrical and pediatric nurses and, indirectly, also mothers [141]. Above all, the utmost strictness is required in monitoring maternity wards and hospitals about CM supplements and the harmful use of bottles "by nurses with a pirate bottle ready behind the mother's back" [90]. In the US, since 1935 Ratner recommended to avoid giving CM to breast-fed infants during the neonatal period [340]. The negative effect of CM supplements is that they also shorten the duration of breast-feeding [28, 285], akin to maternal smoking [28, 263, 410], and terminate weaning in advance.

Role of Food in the Days and Month Following Birth

In terms of potential sensitization, the first few weeks of life seem to be particularly critical:

- The mechanisms responsible for *excluding and eliminating antigens* are physiologically immature, permitting protein macromolecules to pass across the intestinal barrier, which is more permeable, particularly if – as demonstrated in newborn rats – intestinal closure is delayed by early CM antigen feeding. This is paralleled by other data [211, 401].
- *A decisive role is played by a sIgA transient decrease* during the first 4 weeks; sIgA plays a protective role by blocking intestinally absorbed antigens, having the highest IgA antibodies concentrations in intestinal secretions [448].

Food allergens represent the most frequent cause of *sensitization early in life,* as they can pass across the intestinal barrier, thus priming IgE antibody generation. Based on this context it is clear that the immune protection imparted to newborns is fundamental:

– *From colostrum,* rich in immunoglobulins (Igs), sIgA and EGF (epidermal growth factor), IgE-suppressing factors [455], which contributes to maturing intestinal defense and to intestinal closure, and EFA (essential fatty acids) (Table 2.19). IgA high levels, of which the newborn – in the first day of life – absorbs about 4 g/l, equivalent to the daily production of a healthy adult, testify to the important immunological protection that comes from breast milk [292]. These IgA have λ chains rather than κ chains, as opposed to serum IgA, and as a result newborns have Igs available that are of vital importance for defense [292].

– *From breast milk* that, as shown in Table 2.12, is rich in crucial cells, important protective anti-inflammatory and immunological defense factors, above all sIgA, as a result of which IgA in breast-fed babies will increase 12%/year until the age of 7 years (p=0.002) [225]. It also contains EFA [377] (Table 2.14), with normal levels [377] that do not depend on gestational age [199] and are only partially dependent on maternal diet, generally containing C18:2ω6 and C22:6ω3, and nucleotides (Tables 2.16, 2.17), which build up the immune system [70], with positive effects on long-chain polyunsaturated fatty acids (LCPUFAs), unlike enriched formulas [471]. Lastly, it performs an immune-modulating action on infantile immune mechanisms, by the transfer of cell-mediated immunity (CMI) and cytokines [24] (Table 2.20). Dietary imbalances such as reduced proportions of regulatory PUFAs (ω3 PUFAs) may be a risk factor for the development of atopic disease [226].

Although breast milk is not as nutritious as adapted formulas, it is *the prototype of hypoallergenic food*, since it provides the *only proteins recognized as homologous by the infant* and they are automatically nonallergenic. Moreover, breast milk ensures an excellent growth standard: based on Bayley's indexes of mental and psychomotor development, breast-fed babies surpass bottle-fed peers in terms of intellectual [262], cognitive and behavioral development [248]. It is the only food that allows such *personal, intimate and emotionally important contact* between mother and child, also promoting breast milk production, impaired by maternal admission to the maternity ward and CM administration there [186].

The erythrocyte concentration of arachidonic acid (20:4ω6) remains the same in breast-fed infants, while it decreases in babies fed EFA-enriched formulas, even if not to the extent of causing undesired effects [269]. The option of feeding HR infants using formulas enriched with ω-6 and ω-3 in the same amounts existent in breast milk is important [276], or with those containing linoleic/α linolenic:10:1 acid (recommended dosage: ω6 0.5–0.7 g/kg/day and ω3 0.07–015 g/kg/day), in case there is a need to replace the missing amounts with an EFA preparation, selected from Table 7.21. Nucleotide addition to CM formulas would promote EFA conversion by enhancing the action of ω6 and, in the long term, making LCP supplements unnecessary.

Breast milk contains very high levels of sCD14 (endotoxin receptor, Table 1.2), which has been postulated to protect against the development of atopy, AD (atopic dermatitis), or both [213].

We stress that IgE-mediated sensitization is possible via breast milk (Table 9.1), due to small quantities of food allergens ingested by the mother that, passing into breast milk, cause atopic manifestations in her child. However, the quantity of β-lactoglobulin (βLG) contained in the CM received in the maternity ward (500–860 ml) is impressive [195, 371] compared to the ng or ng/ml of βLG present in breast milk (Appendix 9.6). To summarize, CM supplements can occasion sensitization in predisposed infants, while small amounts of CM allergen in breast milk can later trigger allergic reactions, labeled as *breast milk allergy* (BMA) or *intrauterine sensitization,* whereas they are caused by CM drunk by lactating mothers [253] (Table 9.1). This possibility must not be cited as a reason to discourage breast-feeding, which is a biological form of nutrition. Instead, it is the reason behind the advice to nursing mothers to avoid or reduce their ingestion of allergenic foods [192]. We feel that inadvertent exposures to CM [195] appear to be far more important than the very small amount of CM transmitted via breast milk, which may rather induce tolerization than allergic sensitization [37].

Late weaning is also important for atopy prevention. Several authors suggest that the protective effect of breast milk seems to be due largely to the delayed weaning of breast-fed children [44, 46, 55]. It is commonly believed that breast-feeding lowers the prevalence of allergic manifestations in children at risk for atopy, being the sole source of nourishment [52, 360], and protracted breast milk-feeding is combined with delayed weaning [134], also because solid food introduction shortens its duration [123]. Data on breast-feeding delayed for up to 9 months of life are controversial, with or without the addition of solids [10, 367]. Others suggest prolonging breast-feeding for up to 12 months if possible [269]. Moreover, the *thymus is significantly larger in volume at 8 months in infants exclusively breast-fed* until that age, and higher in those still being breast-fed at 10 months compared to infants weaned between 8 and 10 months [175]. It was instead emphasized that each month of breast-feeding increased the risk of developing AD in the first 7 years; however, half of the children studied received a CM formula in the very first days of life [19] Kajosaari and Saarinen [221] have demonstrated that introducing solids *in the first 4 months* of life exposes children to the *risk of chronic or recurrent AD*: 35% of 135 children at risk in whom solids were introduced in the 3rd month presented AD by the age of 1 year, with a rate of CM and egg allergy that was fivefold higher than the 14% found in babies exclusively breast-fed until the age of 6 months [221]. The risk of FA is 2.9-fold higher compared to children not weaned in the indicated period ($p<0.005$), increasing in proportion to the number of foods introduced [132, 134] (Table 4.30). While others disagree [19, 137], the confirmation of the benefits of delayed weaning is nevertheless meaningful [84, 466], and these benefits include the prevention of AD [243], FA [484, 486] and asthma [244, 245, 307, 309, 339, 360, 410]. A study on 2,612 infants followed up to age 2 confirmed that a delayed introduction of solids for 4 months of life may prevent AD and sensitization, while a delayed introduction beyond 6 months failed to provide any benefit for the AD prevention [490]. Only 3 studies prolonged the breast-feeding for 9 months [8, 185, 186] with a decrease of atopy.

These data should make us reflect on the disadvantages of certain additions to the diet – at times for no valid reason [485] – during the early days or months of life of nurslings at risk, also without the knowledge of motivated parents [172]. These considerations are reinforced by the observation that radical changes have occurred in the diet, not only because of the introduction of new compounds and the increased use of additives, so that even fresh products have no taste. Nothing is known about the possible effects these modifications can have on children [23]. The best protection is thus afforded by exclusive and extended breast-feeding in children enrolled at birth and followed up prospectively [192]: Table 24.2 [9, 10, 15, 17, 38, 39, 44, 46, 76, 78–81, 133, 162, 165, 166, 167, 170, 176, 183–186, 197, 218, 220, 221, 227, 240, 244, 261, 264, 272, 280, 289, 297, 331, 360, 361, 367, 374, 388, 433, 484, 486–488], or retrospectively: Table 24.3 [27, 156, 157, 161, 235, 238, 267, 470]. The prospective studies in Table 24.2 are further divided based on whether allergen avoidance was included or not in the study. Table 24.4 [44–46] lists dietary and environmental manipulations suggested for HR infants and children.

Hide and Guyer [184] have re-examined the 1981 group [183], Burr et al [39] the 1988 group [289], Chandra and Hamed [57] the 1989 group [81], concluded by Chandra at the 5th year [77], Kajosaari [220] the 1983 group [221], Zeiger et al[484] the 1989 and [486] and 1992 groups [487], Saarinen and Kajosaari [360] the 1979 group [221], Hide et al [186] the study of Arshad et al [10], Sigurs et al [388] the study of Hattevig et al [176]; the number shown represents the total number of children whatever the study (excluding from total the re-examined = 12.8% = 10.587). In the Oddy et al [307] and Kull et al [244] studies, we compared the babies breastfed for ≤4 or ≥4 months. de Jong et al [109] consider as controls BM-fed children who had received CM supplements (see text).

↓ Decrease, ↑ increase, = no difference, *w* weeks, *m* months, *S* study group, *C* controls, *F-U* median follow-up time (years), *FA* food allergy, *AD* atopic dermatitis, *atopy* atopic diseases, *BM* breast milk, *SM* soy milk, *CH* casein hydrolysate, *WH* whey hydrolysate, *SH* soy hydrolysate, *CMA* CM allergy, *CMI* CM intolerance, *NS* not significant, *ND* not done, *OR* odds ratio, *CI* 95% confidence intervals.

[a] At 3 months.

[b] At 8 months.

[c] At the follow-up at 7 years, the decrease was the same as noted in 1989.

[d] Extension up to 18 months.

[e] In this study there was a 71% rate of drop-outs among the breast-fed infants, and among the asthmatics were also included children with wheezy bronchitis. We have considered as reduced wheezing results concluding that the positive prevention regarded wheezy bronchitis (e.g., [167]). See the related discussion in Chap. 4.

[f] The Kaplan Meyer survival functions [307] indicate that the cumulative incidence of both asthma ($p=0.001$) and wheeze ($p<0.001$) was higher if other milk was introduced <4 months. We have included in the study group the children breast-fed >4 months and in the controls those weaned before that age.

The studies have been considered "with environmental prevention" when the pertinent controls were suggested along with the dietetic manipulations; we have taken into account the reviews of Burr [39], Zeiger [481], and Kramer [241] whose remarks we consider.

The mothers of children at genetic risk for atopy were greatly motivated in the above 58 prospective and retrospective studies, and have breast-fed their babies for 136 days (median 135), although breast-feeding was not always exclusive.

↓ Decrease, ↑ increase, = no difference, *w* weeks, *m* months, *S* study group, *C* controls, *F-U* median follow-up time (years), *FA* food allergy, *AD* atopic dermatitis, *atopy* atopic diseases, *BM* breast milk, *SM* soy milk, *CH* casein hydrolysate, *WH* whey hydrolysate, *SH* soy hydrolysate, *CMA* CM allergy, *CMI* CM intolerance, *NS* not significant, *ND* not done, *OR* odds ratio, *CI* 95% confidence intervals, *RR* relative risk.

Table 24.4. Dietary and environmental manipulations suggested for HR infants and children

Environmental
Absolutely no smoking in the house
Strict environmental controls for the elimination of house dust
No pets in the house
Avoidance of air pollution
Avoidance of lifestyle changes
Avoidance of pesticides and consumer products
Dietary
Avoid strict food limitations in pregnant women expecting HR offspring; such mothers must take supplemental calcium (up to 1,500 mg daily)
No CM formula in the maternity ward
Exclusive breast-feeding for the first 6 months of life
Do not introduce solid foods during dietary prevention
CM and dairy products gradually introduced after the 6th month and egg after the first birthday

See the section on the hygiene hypothesis.
Data from [44–46].

Role of Allergen Avoidance

Recent data underscore the importance of *environmental factors* in the sensitization of children to certain allergens that favor the development of asthma. In addition, the timing of the exposure, *in utero* or during the 1st year of life, is crucial. Therefore, primary prevention begins before birth, as we can see from Table 24.5 [44, 46, 60], and it is maximal when preparing the home for the newcomer. The need to ensure a healthy environment prior to the birth of a baby (Table 2.26) is demonstrated by a higher prevalence of severe forms of asthma and a higher number of asthma attacks observed per year in children living in areas with significant environmental pollution, as compared to those living in clean areas [6, 18].

In Chap. 4, we examined the effects of the *energy crisis:* this led to building homes with new features, but it also created a parallel increase in humidity levels above all trapped in rooms [23]. This has indubitably contributed greatly to an increased prevalence of pediatric asthma in Northern Europe and in other areas, and encouraged the development of environmental conditions favorable to Der p/f and mold growth [463]. Home construction year is associated with asthma at the age of 4 [245].

Preventive measures have become mandatory as a result of *high Der p 1 levels detected* in *amniotic fluid samples* at 16–17 weeks of gestation [188], in HR newborns [10] and infants [300, 396, 427] (Fig. 24.1). The measured levels, between 4.3–4.5 and 18.4 µg/g of dust (GM, geometric mean) [10, 396, 427], exceed the lowest limit of 2 µg/g and the highest of 10 µg/g [306, 327]. Sensitization can also occur at levels of <1 [201] or <2 µg of Der p/g [439], while in 25% of homes there were levels >2 µg of Der p/g [18]: this trend can be reversed only by adopting an active preventive strategy [274]. Exposure to 10 µg Der p/g leads to a fourfold increase in the risk of developing asthma in early childhood [397], but even to 1 µg may be associated with a higher incidence of AD; the presence of Der p 1 IgE antibody at 18 months of age was associated with a higher incidence of asthma [201] (Table 24.6) [230, 396, 479]. Environmental measures must be taken against house dust mites (HDM) [463] to reduce the level to <2 µg Der p/g *several months prior to the birth* of at-risk babies or before the family moves to the home, since Der p fecal matter may persist for several months despite strict allergen avoidance. Thus, allergen avoidance must be fulfilled before at-risk children present asthma.

In the *Isle of Wight study* [10, 185, 186] even a modest reduction in HDM allergen amounts in homes of infants at risk reduced the prevalence of sensitization to mites and overall manifestation of atopy during the 1st year of life and some benefits on allergic disease were recorded at age 4 years. At age 8, the results were confirmed with a fivefold reduction of HDM antigen in the preventive group compared to no reduction in the control group (1.28 vs 2.45 µg/g) [12]. Active measures to reduce prenatal and postnatal allergen exposure resulted in HR infants having fewer respiratory symptoms at 1 year of age [102]. Since infants usually spend 80% of their time at home, any home dampness must be considered of the utmost importance, paying attention both to wall stains and to moisture that condenses on glass windows, particularly in bedrooms, as this can represent an additional risk for asthma development [6, 463]. Another measure of primary prevention to be started several months before childbirth or moving elsewhere involves removing any *cats and dogs* in the house [22], without any halfway measures [474]. The dose that can sensitize infants ≥1 year with pets in the house is 3–300 ng/day or 1–100 µg/year, while ng of inhaled allergens/min can cause acute asthma and bronchial hyperreactivity (BHR) [118].

Passive smoke is a particularly harmful environmental factor that can play a leading role in the etiology of early childhood asthma, fostered by a significant rise by smoking parents of children at risk (31%) [165] (Fig. 4.23). A large body of epidemiological evidence emphasizes that *maternal smoking* can raise IgE levels in cord blood (CB) (Table 3.7), it is associated with childhood allergy [266, 267] and the onset of asthma and LRTIs in children <1 year, and lowers EGF [214] and LCP levels [2] in breast milk. Maternal smoking during pregnancy can compromise *the development of the respiratory system* [402] (Table 4.24) *and of the brain* [158], and have important implications for respiratory disease

Table 24.5. Prevention of atopic disease in high-risk children

Before birth
Stop maternal smoking during pregnancy
Free diet for pregnant women (from the allergological point of view)
Remove pets and have the house thoroughly cleaned
Prefer to live on a high storey (if feasible)
If feasible adopt an underfloor heating
Ensure adequate ventilation and humidity (anti-Der p measures)
Perinatally
Nontraumatic delivery
No hidden CM formula at the maternity ward
In infancy
Stop maternal smoking during breast-feeding
Encourage exclusive breast-feeding, prolonged if possible up to the 6th month of life
Consider an elimination diet of nursing mothers (CM, egg)
Clearly explain to parents, especially to grandparents, caregivers and baby-sitters the significance of such avoidance measures
Recommend a soy protein formula (SPF) or homemade meat-based formula (HMMBF) or Rezza's diet. as breast-milk back-up or replacement up to the 6th month of life (two pediatric guidelines prefer to avoid SPFs and suggest extensively HFs [5, 198]). We also use soy + pork collagen formulas
Consider supplemental calcium during restrictive diets
No solid food for the first 6 months; at that age vegetable broth with fresh lamb meat, rice flour, olive oil, and pear may be initiated
Delayed introduction of dairy products until 1 year of life, starting with parmesan at gradually increasing doses
CM- and egg-free pasta and cookies, and bread at 8 months (if the child is not allergic to cereals)
Delayed introduction of eggs up to 2 years, and fish, peanuts and nuts up to 3 years of age
Introduce new foods one at a time
Postpone feeding beef: BSE (Chap. 9) and antibiotics (Chap. 19)
Postpone foods potentially cross-reacting with pollens (Table 9.48)
Do not cook apples, spinach, citrus fruit in stainless steel pots, both new and used, or pressure cookers
Pediatrician or allergist suggestions or skin prick test results shall specify which potentially sensitizing foods could be introduced next
Environmental allergen avoidance
Wash baby with Marseille soap
Use underwear exclusively of white cotton to be washed in a washing machine with Marseille soap at a T >60 °C, wash blankets every 15 days
Absolute ETS cessation at home or in daycare center
Do not allow furred pets in the home
Reduce the early exposure to major allergens especially in the baby's bedroom, and limit any potentially sensitizing factor such as house dust, wool, molds, animal danders, cockroaches, etc.
Remove upholstered furniture and stuffed toys and replace with leather, plastic, vinyl, or wooden furniture and toys, removing plush toys, carpets, wall-to-wall carpeting, bedside rugs, wool and/or feather mattress and pillow
Encase in allergen-impermeable cover but water-permeable fabric, as discussed later, both mattress and pillow in the child's bedroom
Air the child's bedroom daily and vacuum it using a vacuum cleaner with an HEPA filter weekly, scrub bedsprings outside the room
Maintain at home a T of ≈ 20 °C and reduce indoor humidity up to <50 %
Consult pediatrician or allergist about any uncertainty and/or before taking any initiative

Data from [44, 46, 60].

in older children and adults [402]. In 545 HR infants, exposure to maternal smoking during pregnancy or the 1st year was *a risk factor for asthma at 2* [17] and at 4 years [245] and a 13.8 risk factor [12] for children on prevention [12, 17]. ETS is not only a triggering factor of respiratory allergy in babies at risk of atopy, but especially an additional genetic factor, since asthma can be more easily provoked if an atopic parent smokes (more if both parents smoke), and even in children of smoking parents who are not atopic [58]. Therefore, it must be strongly discouraged during pregnancy and following birth. CB cotinine levels were detectable in 61 %–70 % of

Table 24.6. Risk of sensitization to Der p

Threshold value of the risk of sensitization to Der p, of Der p-specific IgE and asthmatic symptoms: 2 µg Der p 1/g dust
Threshold value of the risk of developing acute symptoms: 10 µg Der p 1/g dust
Age of the first episode of wheezing inversely correlated to the greater exposure to Der p 1 allergen during infancy

Data from [230, 396, 479].

HR and low-risk babies [102]. When both cotinine and nicotine were measured in the hair of the newborns of smoking mothers, these values were *6- to 17.5-fold > those in children of non-smokers*; associated with cotinine and nicotine levels in the hair of children of *non-smoking mothers exposed to secondhand smoke during pregnancy* [122]. Moreover, trying to convince the parents of newborns to quit smoking is discouraging [476]: the very high cotinine levels of infants of smoking nursing mothers could not be differentiated from the control levels [86]. *Newborns born to smoking mothers already had a critical level in their CB* of >5 ng/ml; in 50% of newborns there was at least one smoker, and at the age of 1 year, in 51% of the infants the cotinine level was equal to 30 ng/mg of creatinine [18]. Another negative aspect is the reduced propensity for breast-feeding among smoking mothers: 43–51% vs 80% [263] at 6 weeks or 57% vs 70% [470], particularly when ≈11 cigarettes are smoked a day. In the case of a newborn at risk, a powerful appeal must be made to the parents' motivation. Here, encouraging data have come from a valid contribution made by widespread efforts of the Department of Health Services to convince and educate parents, which yielded positive results in 80% of parents (Chap. 4). The possible danger of nicotine contained in commonly consumed foods has been reduced significantly [180].

Causal relationships can also be established between *atmospheric pollutants* (Tables 4.13–4.16) and allergic manifestations possibly associated with felling of several trees in the city or district. Airborne substances can directly sensitize the organism, triggering allergic reactions. In some cases (particulate matters [PM]), they can also act as adjuvants, priming IgE response. Lastly, with an indirect mechanism they are not only able to modulate the host immune response but also act on the shock organ, inducing symptoms in sensitized but asymptomatic subjects [234]: daily life in our cities repeatedly demonstrates this.

Failure to observe these principles can cause inestimable damage to both the child and the entire family's health and well-being. To conclude, ETS, early contact with household dust, humidity, mold and domestic pets, and viral respiratory infections (VRIs) in the 1st year of life can quickly stimulate or not IgE synthesis, which can lead to atopic manifestation even many years later [24].

Immune Interventions

The flourishing investigations into the genetic basis of atopy have identified several candidate genes (Table 4.2), which may provide knowledge that could help in allergy prevention. A special immune intervention strategy, which still requires study, involves the prevention of initial Th2 sensitization to environmental allergens, to induce tolerance or better, immune deviation [189]. This would be achieved through three steps, to identify the allergens that cause atopic disease, the defense mechanism applied by the immune system to overcome the offending agent and the method for administering (vaccination) the allergen or an appropriate analog in a form that can stimulate the defense mechanism best able to induce the development of a protective immunological memory. This procedure would be performed in childhood, before the child is sensitized, so that his or her response to allergens can turn from hypersensitivity to tolerance [189]. Given that a cocktail of allergens is indicated for this purpose [189], we feel it would be difficult to specify the number of potential allergens, which include the pertussis virus, that can act as an adjuvant in promoting IgE. Thus, this procedure should also be scheduled far from whooping cough vaccinations. Other strategies that are still being investigated include CMA prevention, achieved in laboratory animals with a single IV injection of an IgG-βLG conjugate (Chap. 9), and genetically modified fruit to replace SIT via injection (Chap. 13). Dietary nucleic acids may play an important role in promoting a shift in Th1/Th2 balance toward Th1-dominant immunity, also suppressing serum ovalbumin-specific IgE and IgG_1 antibody levels as well as in vitro IL_4 and IL_{10} secretion, while enhancing both serum ovalbumin-specific $IgG_{2\alpha}$ antibody levels and in vitro IFN-ɣ [406] whose deficiency has been shown in children with CMA [328].

Dietary Prevention and Environmental Measures

For 70 years, countless studies have shown that based on breast-feeding and/or feeding with soy protein formulas (SPFs) or Rezza's diet and/or CM delayed introduction, with delayed weaning starting at 6 months, is the rationale underlying the potential benefit of early allergen avoidance to reduce or prevent the prevalence of allergic disease in neonates genetically at risk for atopy: breast milk delays the onset of asthma [245] and AD [243]. The PREVASC study has come to the point: infants in the intervention group were significantly more breast-fed ($p = 0.001$) [242] and/or significantly more received a hypoallergenic formula feeding than infants in the control group. The first intake of solid food was significantly more often postponed to the age of 6 months in the intervention group compared with the control group ($p = 0.0001$) [242, 376]. In 1936, Grulee and Sanford emphasized the protective effect of breast milk in a large population study, and reported that among breast-fed children the frequency of AD was 1,750% lower than in children fed CM [161]. Glaser and Johnstone [154] have demonstrated a significant correlation between feeding children SPF and a lower rate of AD. Since then, there have been both prospective (Table 24.2) and retrospective studies (Table 24.3). The data have been confirmed by a 17-year follow-up, showing statistical significance for respiratory allergy, FA and AD (Fig. 24.2) [360], and

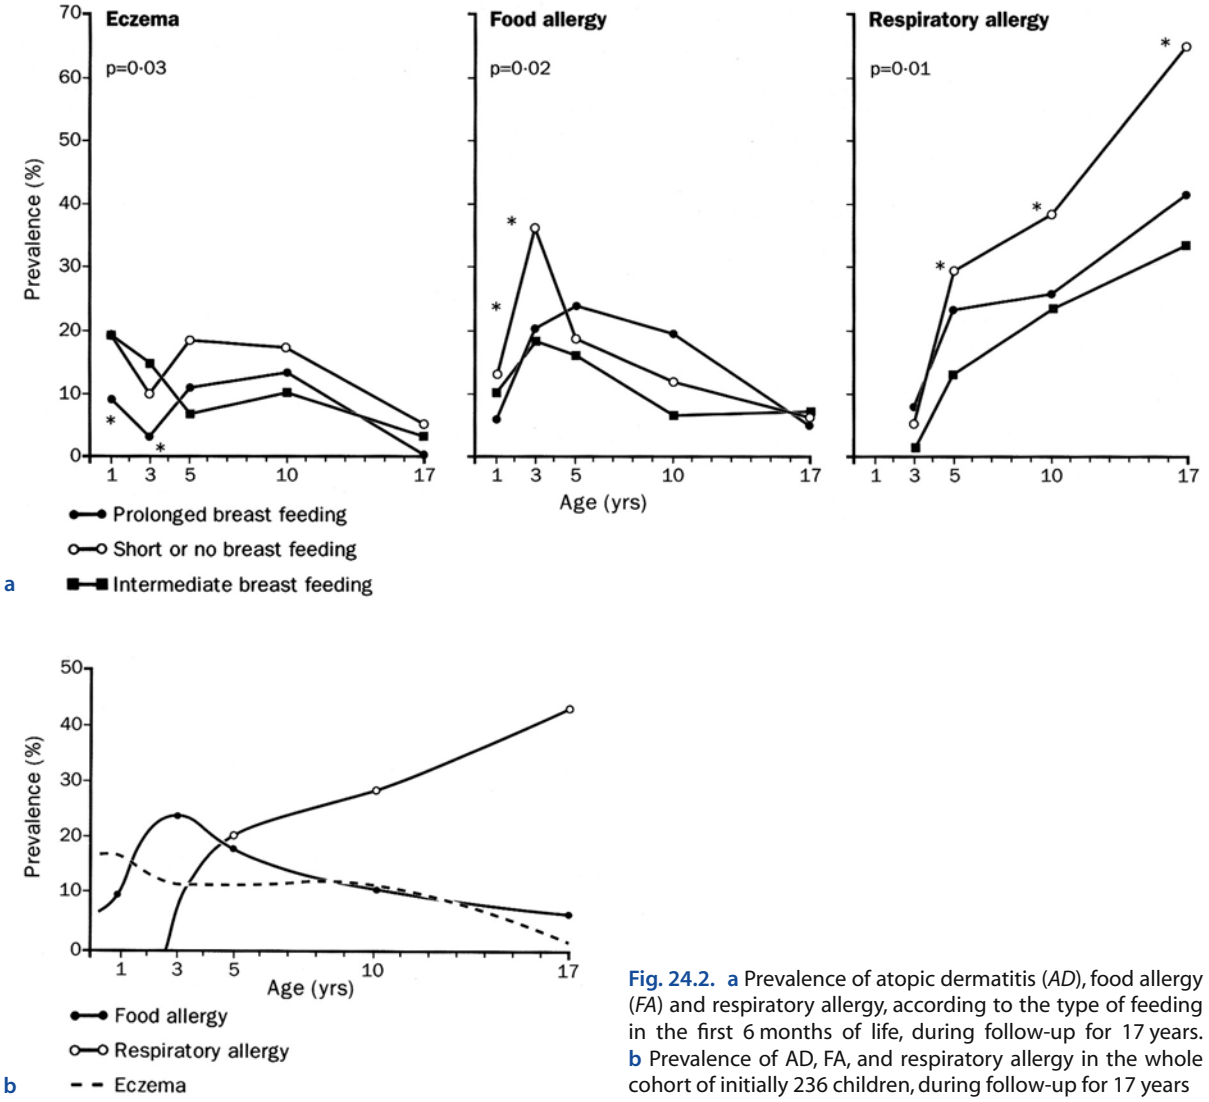

Fig. 24.2. **a** Prevalence of atopic dermatitis (*AD*), food allergy (*FA*) and respiratory allergy, according to the type of feeding in the first 6 months of life, during follow-up for 17 years. **b** Prevalence of AD, FA, and respiratory allergy in the whole cohort of initially 236 children, during follow-up for 17 years

by a 15-year follow-up, in which no breast-fed child developed FA and AD [162]. A 7-year follow-up of 545 children showed a protective effect on respiratory symptoms only if exclusive breast-milk feeding was continued for at least 15 weeks compared to bottle-fed children; solid feeding started before 15 weeks was associated with an increased risk of wheeze during childhood [466]. Table 24.4 shows that CM feeding should be limited, given that after a meal of CM *βLG persists for 3 days* [265]. Allergen avoidance should be enhanced and refined to prevent sensitization to aeroallergens [235] since dietary measures alone are insufficient [481, 484]. In a subsequent Australian study on the same children [307], breastfeeding for >4 months was a significant protective factor for wheezing LRTI, current asthma and atopy, following multivariate adjustment [309]. In a Swedish study in 4,089 babies with a 2-year follow-up, breast-feeding had a significant preventive impact on development of asthma, suspected AR, AD, and suspected allergic respiratory symptoms associated with exposure to pollen and/or pets during the first 2 years of life [244]. Exclusive breast-feeding for ≥4 months reduced the risk for AD (OR, 0.78; 95% CI, 0.63–0.96) [243] and for asthma (OR, 0.72; 95% CI, 0.53–0.97) [245] at the age of 4. In a US retrospective study [339], 7,092 babies were followed up for 6 months: compared with no breast-feeding, full breast-feeding infants had lower OR of coughing or wheezing, vomiting and diarrhea, and lower mean ratios of illness months and sick baby medical visits [339]. Breast-fed children had significantly reduced odds of being diagnosed with asthma or recurrent wheeze before 24 months of age compared with never-breast-fed children [87] A meta-analysis has noted more than a tripling in severe LRTIs resulting in hospitalizations for bottle-fed infants compared to infants exclusively breast-fed for 4 months [143].

The 61 studies on the effects of breast milk have involved over 71,000 children to date. The *protective value*

of breast milk (supplemented with other formulas in 31% of cases) in relation to allergic sensitization has been confirmed by 48/52 (92.3%) of the prospective studies and by 5/9 (55.5%) of the retrospective studies (p=0.0026; Fisher =0.0126). Inversely, 8/61 trials (13.1%) either failed to note any difference or they reported an increase in allergy among breast-fed children as opposed to those fed artificially (Tables 24.2, 24.3).

Important results regard breast milk's positive long-term health outcome on IgE levels in atopic children. In a birth cohort study of 1,246 children studied until the age of 11 years, the children who were breast-fed for >4 months had significantly lower serum IgE levels at both 6 and 11 years if their mothers had low serum IgE levels, whereas the opposite occurred in 16% of children with mothers who had higher serum IgE levels [477]. This result may be explained by individual variations in the levels of breast milk's immunological constituents: exclusively breast-fed children, especially those in the high IgE group, had a statistically lower mean IgE level at 1 and 2 years of age than babies fed adapted or HF formula [272].

Possible Causes of Controversial Results in Prevention Studies

Several controversies can arise from some shortcomings such as the parameters outlined in Table 5.1 or from differences in study design (cohort, case–control, cross-sectional), nonmasked evaluations, unconfirmed diagnoses, no documentation of adherence, short-term breast-feeding, and differential environmental control measures [483]. Kramer et al [237] closely analyzed 636 case histories to monitor whether diagnosis adhered to biological and methodological standards. They found that 34.3% of 470 infants were breast-fed (infant feeding), AD was severe in 17 cases out of 142 (11.9%) (atopic condition), on whom was based the relationship between AD severity and breast-feeding (statistical power). Methodology flaws can be found in other studies. Breast-feeding lasted <3 months [356], for example, in 47% of cases [147], or <6 weeks [170, 261, 382, 404], and solids were introduced early to the children, at 4 months in up to 75% of cases [133] (Table 4.30), with predictable effects [46].

Poor compliance was shown with the recommendation to follow exclusive breast-feeding for 6 months [166]. In Germany, breast-feeding is not widely practiced [18], and in the US it is practiced in 50% of cases, a figure dropping to <20% at 6 months [200]. A significant parameter is the number of dropouts, from 16% to 38% [436, 486] to 57% after 2 years, altering the ratio between breast-fed infants and control subjects [184], an evident contrast with the 11% figure after 7 years [40] and 36% after 17 [360]. As two studies [307, 410] point out, it is the age that CM was introduced rather than the duration of breast-feeding that was more strictly associated with asthma or atopy at 6 years [307]. A *program of allergen avoidance* was disregarded in many studies, or it was not followed adequately (Table 24.7) [46]. There were no such measures in a retrospective study that lasted >30 years, but babies were *breast-fed for ≥1 month* [404]; the criticism was impartial [359]. In a longitudinal study of approximately 1,000 New Zealand children to age 26, information regarding breast-feeding modalities and supplemental milk was assessed retrospectively when the children were 3 years old [382]. *Breastfeeding for ≥1 month* had a higher prevalence of allergen sensitization and asthma [382]. In 926 babies exclusively breast-feeding for <4 months in *13.5%* and >4 months in *16.6%* of cases, breast-feeding was associated with an increased risk of asthma at the age of 6 years, but only *for atopic children with asthmatic mothers* [478].

For example none of the mothers was requested to keep a diary of her child's illness and feeding history [307, 374, 375]: in two studies [382, 478], data were assessed by interviewers evaluating data collected by nurses during their first 2–3 years of life [382] or by physicians' reports or parental questionnaires at 18 months [478]. Similarly, in two Japanese studies breast-feeding was associated with an increased prevalence of allergy according to data gathered from students aged 12–15 and their parents [290] or from students aged 6–15 without their parents [408]. Kramer has shown that retrospective data collection of infant-feed-

Table 24.7. Possible causes of controversial results in studies on atopy prevention

1.	Selection criteria (atopic or nonatopic parents)
2.	Methods used to diagnose the atopic disease (parental diagnosis, general practitioners, pediatricians, allergists, dermatologists, questionnaires)
3.	Lack of supportive immunological data
4.	Lack of statistical analysis of data
5.	Social demographic characteristics
6.	Sex of babies
7.	Drop-out rates
8.	Small number of subjects (possible type 2 error)
9.	Exclusive nature and duration of breast-feeding
10.	Dietary restriction in mothers (cow's milk, egg)
11.	Age of solid food introduction
12.	Type of solid foods
13.	Maternal and child compliance
14.	Attendance at daycare facilities
15.	Allergen avoidance (smoking, dust, pollution)
16.	Duration of follow-up
17.	Prospective vs retrospective studies

Data from [46].

ing history is prone to recall bias, because mothers may forget details about duration and exclusivity of breast-feeding [237]. We know that 32% of fathers and 28% of mothers failed to recollect the feeding procedures [470]. In these studies, no information was given about breast-feeding modalities and supplemental milk, which could not be obtained retrospectively at age 2–3 [382, 478], 7 [404], 10 [470], 6–15 [408], or 12–15 years [290].

The exposure to CM formula in the maternity hospital has been highlighted [382].

In 6,535 children (65% of whom were breast-fed), breast-feeding had no benefit in preventing respiratory allergy, even if breast milk was administered for about 6 months [470]. However, the age at onset of asthma and AD was significantly delayed in breast-fed children and the risk of developing asthma and/or AR was statistically much lower [470]. Breast-feeding is not promoted because it supposedly offers only partial protection, its use is allegedly controversial, and cases have been reported of atopic disease occurring in exclusive breast-feeding [133, 367]. Although the overall beneficial effect of breast-feeding on a child's health *was never questioned,* it is only allegedly cited as ineffective in preventing or reducing atopic symptoms [126, 370].

The problem with the majority of these studies showing controversial findings is that of the confounding factors and that the infants cannot, for ethical reasons, be randomly assigned to breast-feeding or formula-feeding in a double-blind placebo-controlled study (DBPC) [31, 237]. In addition, the lingering discussion on the topic has gained a fresh revival by a reportedly increased risk of asthma and atopy in breast-fed New Zealanders [382] and Tucson, Arizona children who had an asthmatic mother [478]. Logically, these recent adverse reports could have negative public health implications on infant feeding practices [250]. To date, the 61 studies on breast-milk effectiveness – with or without other formulas – have involved over *1,000 children per year* in >70 years: 92% of 61 studies have demonstrated breast milk's advantages, while controversies are raised by 3/61 studies (4.9%), apart from 5/61 failing to show any differences (8.2%) (Tables 24.2, 24.3). This confirms that breast milk contains many immune factors that compensate for the undeveloped defence mechanisms of the gut of the newborn infant (Tables 2.15, 2.16). On the other hand, BMA is a frequently discussed question: The 21 exclusively breast-fed children with BMA were selected among approximately 50,000 children who attended our Division over 10 years. The incidence of BMA may thus range from as low as 0.042% to as low as 0.0042% per year [56] (See Table 9.1). Even if we extend the Kramer et al criticism [237], noting above all the short or very short duration of breast-feeding and the limited size of several cohorts and follow-ups, these studies have involved a large number of children, and convincingly demonstrate the value of breast-milk prophylaxis in neonates genetically at risk for allergy, in a statistically significant percentage of cases. It should not be surprising that infants at risk develop allergic disease (this follows the calculus of probability, Table 4.9) over the long term, above all since highly selected infants are involved.

Studies on the Prevention of Atopic Dermatitis and Food Allergy

In 26 studies, atopic dermatitis (AD) was prevented, four studies established that there was no difference, in seven studies FA/CMA was prevented, and 13 studies prevented atopy in general. Thus 43/52 prospective studies (82.6%) have demonstrated a positive effect of breast-feeding in preventing AD and FA, as well as a study on 4,089 children [243]. A meta-analysis identified 18 prospective studies (818 infants) that met the predefined inclusion criteria and concluded that exclusive breast-feeding during the first 3 months of life is associated with lower incidence rates of AD during childhood in children with a FHA (FH of atopy) (OR 0.84, CI 0.59–1.19). Thus, breast-feeding should be strongly recommended to mothers of infants with FHA as a means of preventing asthma and AD [145]. AD was prevented with asthma in several prospective studies [10, 46, 76, 81, 103, 165, 244, 272, 360, 361, 487]. CMA was specifically prevented in a study on 91 children enrolled at birth but with no control group. No child was sensitized to CM at 6 months and two at 12 months [181].

Studies on the Prevention of Respiratory Allergy

To date, 27 out of 52 prospective studies (51.9%) have noted a reduction in asthma and wheezing and/or AR, but were protected by 16/22 studies (72.7%) with environmental manipulations. The extension at age 8 [12] of the Isle of Wight study [10] showed that after adjusting for confounding variables, the prophylactic group was found to be at a significantly reduced risk for current wheeze, asthma, and atopy (OR: 0.11–0.26) [12]. The Kramer criteria have been applied to 12 studies on the association between breast-feeding and childhood asthma, establishing an OR of 0.70 for the protective effect of breast-feeding and a greater OR (0.52) in children with FHA [146]. In the 17-year study, the effect was positive for respiratory allergy (Fig. 24.2b). Regarding AR, another meta-analysis ascertained that exclusive breast-feeding during the first 3 months after birth is also protective according to six studies, either with positive FHA (OR, 0.87) or negative FHA (OR, 0.74) [288]. In the 20-year retrospective study [27], breast-feeding for >8 weeks ensured a long-term prognostic improvement in the asthmatic children. In the 15-year follow-up, no child developed respiratory allergy, only one child developed AR between 8 and 15 years [162].

In the Third National Health and Nutrition Examination Survey (NHANES III), ever breast-fed children had significantly reduced odds of being diagnosed with asthma and of having recurrent wheeze before 24 months of age [87]. We compared two contrasting studies, one with no effect of dietary manipulation on respiratory diseases [487] and another that instead demonstrated positive results on wheezing and recurrent coughing, with highly significant statistical differences [235]. The data show a significant reduction in asthma at age 4 [245] and at 6 years if exclusive breast-feeding is continued for ≥4 months after birth [245, 307]. The Kaplan-Meier survival functions showed that the cumulative incidence of both asthma and wheeze was significantly higher if other milk was introduced before 4 months [307]. Moreover, breast milk should be recommended to mothers of infants with FHA in first-degree relatives [12, 146]. The study on 16,442 infants [240] breast-fed for 3–6 months has established a solid scientific basis for future interventions to promote breast-feeding. Thus breast-feeding can beneficially impact health care by reducing the need to treat young children for asthma [87].

These observations may suggest that a longer duration of breast-feeding could extend its positive effect to respiratory allergy. Indeed, in a prospective birth cohort study of 2,602 Australian children, the risk of asthma increased if exclusive breast-feeding was stopped (other milk was introduced) before 4 months [308]. In several negative studies, *no dietary–environmental measures were followed* [290, 382, 404, 408, 470, 478], as also found in one study stressing the weight of maternal atopy as a risk factor for AD [356].

The cornerstone of the prevention of respiratory allergy is to discourage maternal smoking during pregnancy and afterwards [9, 10, 46, 49, 55, 58, 67]. Cigarette smoke causes respiratory allergy in an exponential fashion: children exposed to tobacco smoke *in utero* had an earlier onset of sensitization as compared with non-exposed children [205]. The importance of prophylactic measures was underscored in the prevention of asthma [9], in which the risk created by passive smoke must also be given due consideration. As early as the age of 3 months, it shows approximately a fivefold increase in the risk of allergy [10]. There are so many smoking parents as opposed to nonsmoking parents that they represent statistical differences throughout the entire 1st year of life [185].

In this context, important confirmation [10] comes from the fact that *environmental measures*, which have been proposed by many authors for years (Table 24.4), are highly effective in reducing the prevalence of allergic disease: 14% vs 40% depending on whether the group of children (all fed with breast milk and hydrolyzed SPF) applied these measures or not [10]. In a sample of infants divided into two groups in which preventive measures were or were not taken, the prevalence of atopic disease was higher in the group not taking preventive measures: 29.3% and 58.1%, respectively [185] or 20.0% and 46.8% [12]. In a multicenter, randomized study, children were subjected to dietary and environmental controls. At 1 year of age, the overall sensitization rate against the tested allergens (Der p and Der f) and food allergens (egg, CM) in the prophylactic group was 6.21% vs 10.67% in the control group [169]. In an unpublished, retrospective study, 289 children, 169 males and 120 females, aged 3.5–7.5 years, attending our department because they were affected with respiratory allergy, were breast-fed in 94.5% of cases (p=0.0225) for 136 days (mean 125 days, range 33–211). The control children were breast-fed in 69.6% of cases, for a mean of 98 days (range 10–110) (p=0.0001), although also in these children breast-feeding was not always exclusive. In our opinion, the results are positive when both the children and their families were followed up effectively: in 94% of cases, no pets were kept in the house and smoking was avoided in 67% (81% of mothers also during pregnancy) (p=0.0001) [38]. It must be noted that a favorable low allergic environment as occurs in Sweden significantly reduces sensitization rates in children [311].

Dietary Restrictions for Mothers Breast-Feeding Babies at Risk for Atopy

Dietary restrictions have long been implemented with evident success [362], also to minimize the risk of allergenic sensitization through breast milk. In short (Tables 24.4, 24.5):

- The nursing mother should *not freely consume CM and eggs,* or any food that contains them. We and others recommend lowering CM consumption to 150–200 ml/day and eggs to two a week [44, 46, 79, 145].
- If *the nursing infant presents disorders* attributable even to minimum amounts of these or other foods in breast milk, the mother should completely eliminate them from her diet [113].
- *Foods that contain any CM and/or egg* derivatives should be eliminated, as well as casein or sodium caseinate, etc. (Appendix 9.2).
- Meat consumption is permitted, avoiding beef if the nursing infant shows signs of allergy [135].
- *Peanuts, shellfish and mollusks* must be eliminated [362]. Peanuts eaten by a lactating mother provoked an allergic reaction in her 2-week-old infant [113].
- The mother should add *calcium orally* to her diet on a daily basis: Tables 9.23, 9.24.

CM, egg and fish elimination from the mother's diet for 3 months reduces the number of nursing infants who are sensitized in the first 3 months and of those with AD in the first 6 months [177]. At the 4-year follow-up, 19 of 65 (29.2%) children breast-fed by mothers on restriction diets presented AD, with 28 of 50 (56%) among those with no restrictions [388], but the incidence of AD was even lower, 14.2% vs 30.6%, respectively [54], or

10% at 52 months [38], and at 12 months in a study that negatively evaluated maternal diets [181], as opposed to 20% of other case studies [18]. However, one of two children sensitized to CM at 12 months belonged to the group whose mothers did not follow a restricted diet [181].

Allergy-prevention programs should take into account dietary restrictions, to be adopted only in selected cases with a genetically determined risk (Table 24.5). In a cohort of children whose mother did or did not avoid foods during lactation, at the 10-year check-up, the rates of atopic symptoms were the same between both groups [178]. However, a related meta-analysis concluded that an antigen-avoidance diet of mothers during lactation may substantially reduce the AD development in their high-risk child in early childhood [240]. Therefore, restrictive diets should not be recommended indiscriminately, because they can cause emotional and social stress for the family, as well as the danger of suboptimal nutrition for the nursing mother. More severe restrictions are not only unmotivated in many cases, but they also foster poor compliance, social isolation and malnutrition [230]. Poor compliance was more frequent among parents with a low level of education, young mothers, smoking mothers, and those who weaned their infant before the age of 2 months [375]. Doctors should be very precise in explaining all dietary rules to the father too [230], as well as to caregivers. In strictly controlled studies, in four out of five infants with a positive SPT for eggs, *the grandparents had given the infants eggs without the parents' knowledge* [172]. Some children presented sIgE for eggs and CM before these foods were allowed in the diet [176] and others who have never eaten eggs may experience anaphylactic shock at the first ingestion [296]. Infants were given CM, although it was not suggested [485]. Even mothers included in a preventive program can make certain dietary errors, mistakenly eating CM and/or fish [176]. Often, a careful discussion with the parents reveals that children also eat other foods absent in medical prescription, above all if he or she is cared for by several different people.

Results of Our Group's Preventive Studies

In an extensive study we conducted [46], at the median age of 3 years and 8 months (follow-up, 7 months to 8 years), we monitored 347 at-risk newborns, children of atopic parents identified by FH and/or CBIgE. They were part of a preventative program that included the dietary and environmental measures summarized in Table 24.4, including the dietary restrictions for nursing mothers as described above. Fifty-one children presented atopic symptoms during the follow-up: 26/179 (14.5%) fed BM and/or SPF and 25/65 (38.5%) fed CM (p=0.0000).

We conducted a study lasting ≈5 years on the prevention of allergic disease in newborns at risk for atopy, and they were followed up by us *at 1 month,* then *every 3 months up to 12 months,* and subsequently *once a year.* The purpose was to personally check the child's diet, note any atopic manifestations and child growth in weight and height [38]. At the age of 52 months, 19/174 children (11%) presented atopic symptoms. This rate dropped to 10% considering only the children of families who followed the preventative program. The incidence was 9% at 6 months and 4.5% at 36 months, decreasing gradually to 1% at 52 months, while the incidence at 24 and 52 months was much lower [38] (p=0.0001). The application of at least some of the recommendations we proposed helped limit symptom severity and the number of children with total IgE over 2 SDs dropped from 21% at birth to 11% at 3 years [38].

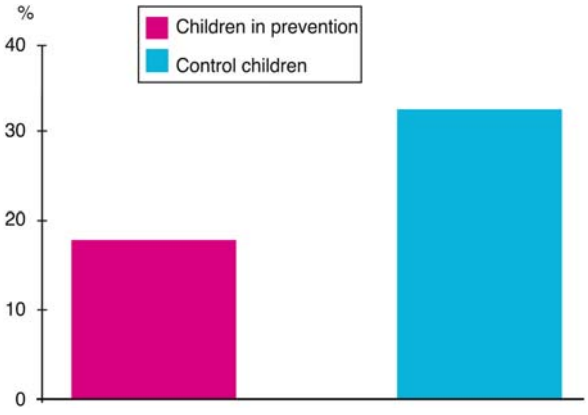

Fig. 24.3. Multicenter study. Prevalence rate of atopic disease in the study children and control children. p=0.0018

We undertook a multicenter study for the prevention of allergic disease in newborns at risk for atopy, based on dietary and environmental prophylaxis [49, 67]. At the last follow-up, 106 of 531 children (20%) had atopic symptoms: 11 (2%) AD; 69 (13%) asthma; five (1%) urticaria, 21 (4%) rhinitis. Of the 106 children, 73 (69%) were males and 34 (31%) females (p=0.0001); 81 (76%) had only one atopic family member and 25 (24%) had at least two (p=0.0001). During the follow-up, the prevalence of AD increased gradually starting at 6 months, peaking at 11% and then dropping to 2% at 4 years, while asthma increased progressively from 1% at 1 year to 13% at 4 years. Very significant statistical differences were found when comparing all types of diet, alone or combined with CM-based diets. The prevention program that was adopted led to a lower incidence of atopic disease in children followed as above, and the rate was significantly lower compared to that observed in the control children (p=0.0018) (Fig. 24.3); Fig. 24.4 shows the ratio of different types of nursing [264]. Figure 24.5 [49, 67, 264] summarizes the cases of atopic disease diagnosed in comparison with the data measured at 2 years, whereas the preventative effects in the 174 children we followed up [38] are summarized in Figs. 24.6 and 24.7. Interestingly, comparing the different rates of

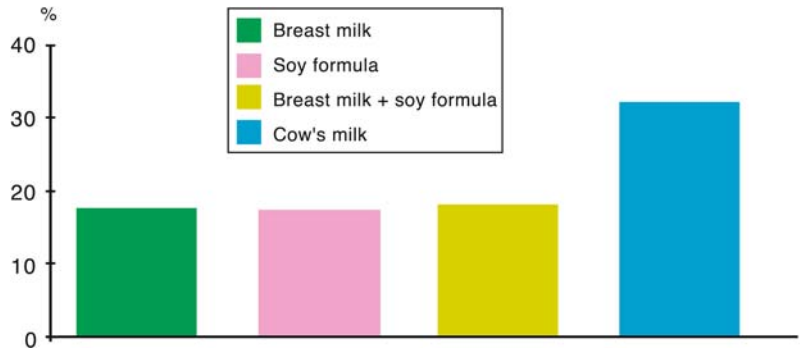

Fig. 24.4. Multicenter study. Relationship between prevalence rate of atopic disease and feeding received. Compared to cow's milk, breast milk p=0.0072, soy formula p=0.0115, breast milk and/or soy formula p=0.0134

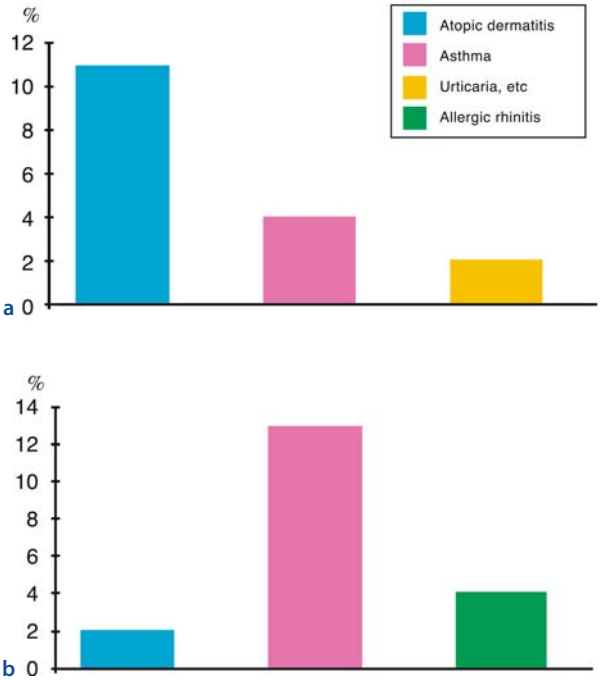

Fig. 24.5 a,b. Multicenter study. Prevalence of atopic disease in children, a at 2 years; b at 4 years. The different reciprocal rate of atopic dermatitis and asthma should be noted. The 3-fold increase of pediatric asthma in two years is evident. (Data from [49, 67, 264])

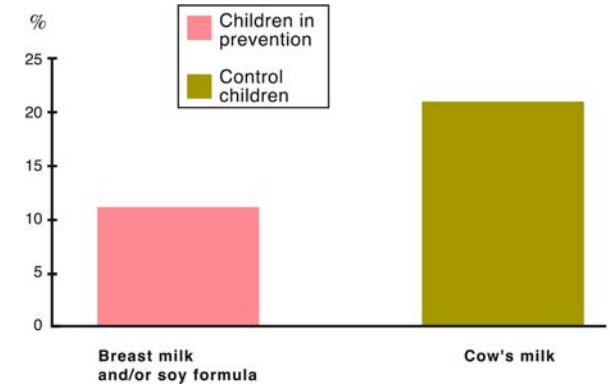

Fig. 24.6. Percentage of the 174 children with atopic disease compared with the control children according to the type of feeding, p=0.0001. (Data from [35])

Table 24.8. Possible causes of failure of allergy prevention programs

Prenatal sensitization
Allergens
Anti-idiotype antibodies?
Poor motivation of nonatopic parents
Lack of maternal compliance, namely, smoking and dietary restrictions
Superficial application of dietetic restrictions
Delayed diagnosis and identification of the offending food
Deliberate or accidental food mistakes
Hidden cow's milk or hydrolyzed bottle in maternity ward
Insufficient intake of important nutrients (such as, calcium)
Solid food introduction during the first 6 months of life
Grandmother effect, such as egg feeding
Cross-reacting allergens
Effect of infections

Data from [230].

Table 24.9. Potential risks of allergy prevention programs

Malnutrition of mother, fetus and infant
Inadequate nutrition
Overprotection of the infant/child
Family dysfunction
Economic consequence for the family
Family social isolation
Feelings of guilt if symptoms do occur despite the efforts
Possible misunderstandings with the clinician

Modified from [230].

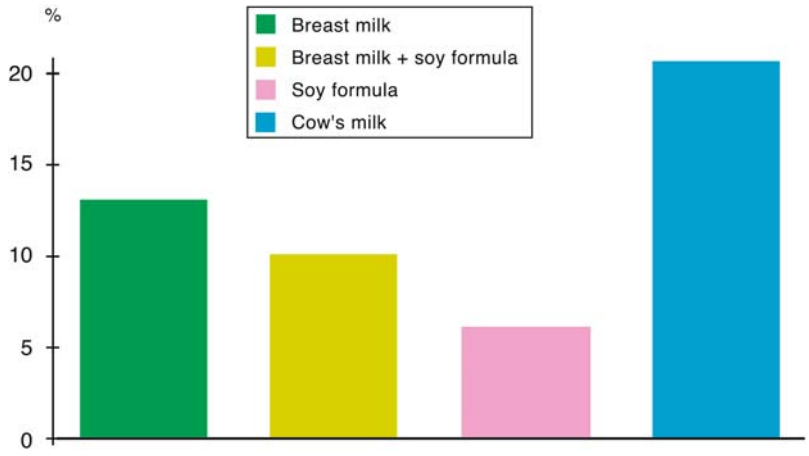

Fig. 24.7. Study of 174 children. Prevalence rate of atopic disease in the study children and control children according to the feeding received. (Modified from [35])

the two studies, in the 174 children followed up exclusively by our staff, the results are clearly lower (Figs. 5.3, 5.4) [38]. Tables 24.2 and 24.3 show that several data confirm our results and that soy allergy is uncommon in atopic children. Our prophylactic studies have regularly demonstrated that all symptoms were mild in children who developed atopic disease and, in general, corticosteroid use was not required. We attribute this to the clinical visits at regular intervals, more frequent in the 1st year of follow-up; moreover, mothers were free to contact us for any clinical manifestation of their babies, as suggested recently [375]. In conclusion, the plague of dropouts was virtually unknown to our studies.

Table 24.5 summarizes the main recommendations for preventing atopic disease in HR children. Similarly, Table 24.8 [230] summarizes the causes that can undermine the outcome of preventative programs, Table 24.9 [230] the possible negative aspects. We must emphasize that inadvertent contact with traces of food or the inhalation of fumes or dust (Table 7.22), through the skin and/or airways, can reach the nursling's immune system [230].

Analysis of Formulas Substituting Breast Milk in Atopic Prevention Programs

Both the Nutritional Committees from the American Academy of Pediatrics (AAP) [5] and jointly the European Society for Pediatric Allergology and Clinical Immunology and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition [198] have published recommendations to prevent and treat FA. The recommendations of these guidelines may have some differences in FA prevention [483].

Soy Protein Formulas

SPFs, as we were the first to demonstrate [61], are the safest and most valid food to use in at-risk newborns, as a substitute or supplement to breast milk if the latter is not available or is insufficient. SPFs are less allergenic than CM and permit regular growth even if used from birth and for a long time [61]. In showing its nutritional [61] (Fig. 9.22) and preventive [38, 44, 46, 61] effectiveness, we do not point to any alterations in the immune response, nor to the increase in morbidity reported by other studies [48]. Therefore, based on previous discussion and data in the literature (Tables 24.2, 24.3) and our 20-year personal experience with more than 3,000 newborns followed-up prospectively for many years [38, 44, 46, 49, 60, 61, 62], we feel that SPFs should be considered a first choice when substituting breast milk in programs for preventing atopy in at-risk newborns [61]. As already noted, the 1953 study [154] yielded highly positive results, but it has been criticized not only because it was retrospective, but also because there was already a high rate of atopy in the control subjects. An extremely low prevalence of SPF allergy has been found by DBPC food challenge (DBPCFC) in children with FA [61] and in infants of atopic parents fed SPFs from birth or very early in life [38, 46, 61]. (See Tables 9.26 and 9.27 including several young children.) Table 24.10 [15, 26, 36, 49, 77, 78, 80, 81, 162, 170, 215, 231, 264, 289] summarizes the results of studies that have specifically compared SPFs with CM in atopy prevention. The study by Bardare et al [15] confirms the *indispensable need for compliance* among subjects at risk and emphasizes the important, lower prevalence of atopic disease with exclusive breastfeeding and a specific diet by nursing mothers [15]. Moreover, in a study usually indicated as negative [36], the rate of atopy in children on an SPF diet was 10.6%, while in controls not on this diet it was 13.3%. Based on this table, we can see that only nonrandomized studies (except [215]) have very statistically significant differences. The prevalence of 74% is notable because it is parent-reported [231].

On the contrary, other authors do not approve of SPF use in preventing atopy and have expressed their criticisms (see [61]), which were overturned by the recent AAP statement (Chap. 9). It may be that in the negative studies, many highly motivated families did not follow the recommendation to avoid CM when nursing HR

children, as in the study by Zeiger et al [485]. A Cochrane Database review based on the analysis of five papers suggests that SPFs should not be recommended for the prevention of allergy or food intolerance in infants at high risk for allergy [312]. A new concern has arisen about the potential hormonal effects from exposure of SPF-fed babies to levels of phytoestrogens or isoflavones [56]. Setchell et al [384] studied 24 male infants aged 1–4 months, seven of whom were SPF-fed. The results of the study stress that the total isoflavone exposure for a SPF-fed 4-month-old infant is 6–9 mg/kg b/w per day. Total plasma levels of isoflavones and genistein in SPF-fed infants range from 2.0 to 6.6 and 1.5 to 4.4 µmol/l, respectively, and were 200-fold greater than plasma levels in infants fed CM formula or human breast milk. They also reported that phytoestrogens circulate in such infants at concentrations 13,000–22,000 times higher than plasma estradiol levels found in early life [384]. However, the isoflavones are commonly present in all SP foods: following ingestion they are absorbed and metabolized by the gut, processed by the liver, and after undergoing enterohepatic recycling are excreted in urine [97, 384].

Largely as a result of research in animal models, concerns have been voiced regarding isoflavones in infant SPFs in relation to nutritional adequacy [385], sexual development and neurobehavioral development [405], immune function and thymus dysfunction [480], but available evidence from infant populations indicates that dietary isoflavones in infant SPFs do not adversely affect human growth, development, or reproduction [56, 284]. Infants fed CM formulas excrete significant amounts of isoflavones in urine, including the bacterially derived metabolite equol, thus confirming the presence of isoflavones in CM [97]. It was suggested that breast milk is a useful source of phytoestrogens (perhaps another advantage of breast-feeding) [391] but recent data [385] do not support this contention.

See Chap. 9 for SAM22 in Bet v 1-allergic patients and for Rezza's diet in FA children.

Hydrolysate Formulas

Studies on HFs nutritional adequacy [481] are lacking, and there are no data from long-term studies apart from three reports [77, 437, 482]. Based on immunological and physiological considerations, we advise against their prophylactic use in the diets of at-risk newborns for atopy [47, 50, 64, 66].

Through breast milk, the GALT (gut-associated lymphoid tissue) of immunodeficient newborns receives sIgA, which plays a decisive role not only in inducing tolerance but also in the defense mechanism for excluding antigens. Moreover, the dietary stimulus and the absorption of various nutrients regulate the production of hormones, some of which – along with high EGF levels in breast milk – appear to be crucial for gut closure. Exposure to allergens when the barrier is immature can predispose the newborn to a deficiency in immunological and other defense mechanisms [13] and in atopic sensitization when allergen concentrations are high [189], promoting the development of Th2-primed IgE [177] within the 1st year. In the first few months, there is active recognition of allergens, and the immune system in maturation reacts with T-cell responses that are initially low-profile and heterogeneous, including allergen-specific Th1- and Th2-like clones that compete reciprocally. After numerous restimulations, one of these Th phenotypes becomes dominant in the response, thus constituting a reserve of CD45 that will then direct the immune response against the individual allergen [189]. At this stage, the genetic predisposition for atopy is also established: the difference between normal and atopic subjects lies in the slow maturation of CD8 affecting the immune deviation and in the absence or reduction of IFN-γ [189]. If allergens step in, if even small peptides (13–17 amino acids) can constitute an epitope associated with class II molecules and thus stimulate specific T-cell clones that can trigger IgE synthesis (Chap. 1), from a biological standpoint it is neither proven nor acceptable to define formulas as hypoallergenic simply because they contain few peptides with MW >6,000 D (Table 9.30). Experimental studies show that HFs cannot induce tolerance, nor can they stimulate defense mechanisms against antigens. Gut closure is delayed among newborns fed HFs in the first 3 days after birth, as compared to newborns not receiving HFs (Fig. 24.8) [211].

To produce HFs that are nonallergenic for the immature GALT and are thus not cross-reactive, intended for atopy prevention in newborns genetically at risk, we must identify enzymes that can fully split the polypeptide chain even of unmasked epitopes of the native HFs. Given that it is technically impossible to destroy all epitopes present on CM proteins using the methods currently adopted to prepare HFs [21], it is easy to understand that these epitopes still have allergenic potency and can be recognized by cell-bound IgE of sensitized children and can trigger even severe allergic reactions [139] due to cross-reactivity. Obviously, the degree of hydrolysis with which CM proteins are processed will significantly influence the presence of residual immunoreactive epitopes: in fact, extensive HF (EHF) have fewer epitopes, while partial HF (PHF) contain a large number. Consequently, the latter should *never be used for prevention in a child who is at risk*, as already specified for CMA therapy. The casein hydrolysate formulas (CHF) produced with a high level of hydrolysis have fewer epitopes that can bind IgE [142], although in many cases they have provoked reactions [139] (Table 9.31). Likewise, if a whey HF (WHF) contains significant quantities of casein, and a CHF contains significant quantities of whey protein that have both escaped enzymatic hydrolysis [260, 345], they can trigger severe reactions in children with IgE-mediated allergy [355] (Tables 9.31, 9.32). We have demonstrated the *direct sensitizing effect of the hydrolysates through breast milk* [43]: 39 nursing mothers of HR infants ingested 400 ml/day of

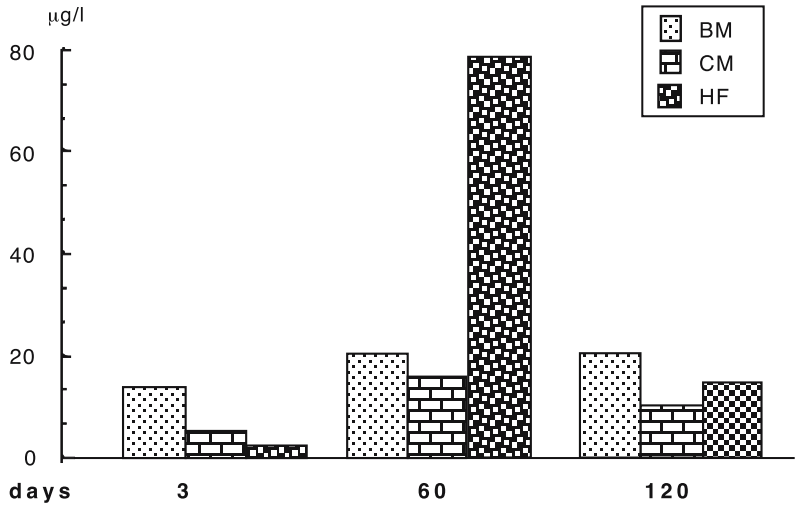

Fig. 24.8. α-Lactalbumin levels in children fed breast milk (*BM*), cow's milk (*CM*) and hydrolyzed formulas (*HF*). (Modified from [211])

a formula of partially WHF (PWHF) for all 6 months of nursing and 39 mothers with the same basic characteristics took 400 ml/day of CM. At the ages of 6 and 12 months, the prevalence of nurslings with total IgE and IgE >2 SDs compared to normal values for this age was significantly higher in children whose mothers had consumed the formula declared as hypoallergenic (p=0.02) [43]. Therefore, all protein epitopes, native or manipulated, are potentially immunogenic, but they can only be defined as such in sensitized individuals. All HFs contain peptides with an MW ranging from 0.5% to 18% greater than 6,000 D (Table 9.30), and variable amounts of residual βLG with allergenic activity (Appendix 9.7). We know that conformational epitopes can be processed through digestion or chemical methods, but if the primary amino acid sequence with at least one epitope persists in peptide fragments, the latter can interact with surface Igs: if two epitopes are intact, they establish a cross-link or they bridge to B-cell receptors, obviously activating them and triggering their clonal proliferation.

The fragments can also contain sequential epitopes that are taken up by APCs and recognized by allergen-specific T lymphocytes [448]; the presence of IgM vs βLG predigested with pepsin and trypsin confirms the persistence of epitopes despite treatment [210]. Naturally, memory lymphocytes can give rise to cross-reactions with these or even noncorrelated epitopes. To get an idea of how difficult it is to eliminate all the epitopes of CM proteins, suffice it to say that in given circumstances, nurslings can become sensitized to these proteins through breast milk. The allergenic molecules in question resist cooking (denaturation). Once ingested by the mother, the proteins are first hydrolyzed in the maternal intestine by gastrointestinal (GI) enzymes and undergo further denaturating and assimilative processes while passing through biological membranes, going to the blood and to the mammary gland (enteromammary axis) (Fig. 2.18). Via breast milk they reach the nursling's intestine, where the peptides undergo digestion again (second hydrolysis), are further absorbed and enter APCs where the hundredth transformation occurs. Despite such treatment, however, CM proteins are still immunogenic and allergenic [1]. If a minute amount of βLG remains in breast milk that can trigger anaphylaxis [253, 265], despite sIgA being there, which contributes to eliminating allergens, it would indeed be singular, on the basis of the peculiarity of the atopic condition – which by definition responds to minute allergen quantities – that a large amount of undegraded proteins contained in HFs can fail to be strongly sensitizing in a genetically predisposed newborn [21]. Even if part of the immunogenicity is destroyed during the various manipulations to which an HF is subjected, epitopes can persist or be unmasked [1] and their immunogenicity *can be just as strong as or even stronger than that of the native protein*. This means that they can thus stimulate the child's immunocompetent cells, induce IgE synthesis and trigger *immediate allergic manifestations* in the HR or sensitized child.

There are EHFs containing very significant quantities of βLG that can thus provoke this effect: we must remember that the products of protein splitting maintain their allergenicity, and that only their antigenicity is reduced [202]. To calculate the amount of βLG contained in a PWHF marketed for allergy prevention, as compared to casein EHF, refer to the data in Appendix 9.7 showing the βLG rate per liter of reconstituted formula compared to CM [21, 43]. βLG allergenicity is highest *in the window period,* as the neonatal intestinal barrier is immature and allows allergenic macromolecules to move into circulation [369]. In fact, βLG is not degraded, resisting proteolysis by pepsin [369], and as a result it goes into the duodenum undigested, where the degradation by pancreatic enzymes may be too slow to prevent absorption of peptide macromolecules and intact proteins into the circulation. This occurs because the *immature intestine is more permeable to macromolecules than in adults* [366, 448], but also because the characteristics of the infantile stomach do not favor

pepsin activity. Pepsin is secreted in very low amounts in nurslings, given the optimal pH of about 2 for most whey proteins, while stomach pH up to the age of 2 months is about 3–4, rising to 6 after meals. Moreover, the production of acid is delayed [311]. The persistence of high levels of whey protein epitopes can bind to preformed IgE or induce an immune response that may represent the process underlying CMA [369]. Experimental data have shown that even by incubating pepsin at pH 4, the residual antigenicity/allergenicity of α-lactalbumin (ALA) and BSA remained high compared to a rate of peptides, with an MW >5–14 kD eliminated by ultrafiltration at 3 kD, a procedure recommended for all HFs intended for children [369].

The data reconfirm the allergenicity of βLG, ALA and casein: therefore, these HFs are at least as sensitizing as CM, if not more so. A casein EHF that, according to the authors, contained only peptides <1,200 kD (Table 9.30), given to newborns for the prevention of diabetes, induced humoral and cellular responses [420]. Nutrition with these HFs also leads to an increase in ICAM-1 (CD54) and CD62L adhesion molecules, which can generate an immune response against bovine proteins, also because of the important costimulatory role of CD54 in activating T lymphocytes [317].

From a clinical standpoint, Chandra et al [77, 78, 81] noted a reduced prevalence of atopic manifestations in nurslings with genetic HR who were fed GS (Good Start) for preventive purposes: SPTs were positive to CM proteins in 4/5 symptomatic nurslings fed GS, as opposed to 2/25 of those given SPF [81] (Fisher, 0.0026), suggesting that sensitization to CM proteins in GS-fed babies is 72% more frequent than in SPF-fed babies. The next study [78] did not specify the number of children who completed the study, nor the allergy diagnosed in symptomatic children – omissions that, to a certain extent, weaken the data. The most recent study [77] reports that there were no statistically significant differences either in the cases of AD or asthma between children fed GS or SPF. In other entrants given HFs, 3.3% presented repeated diarrhea at 4–5 months and 26%–34% developed a respiratory allergy, compared to 15% in breast-fed babies [166]. In a group of 130 healthy newborns, three different types of nursing were established for the first 3 days of life, after which all babies were breast-fed. When the infants were examined at age 4 months, there were two cases of CMA only in CHF-fed babies [219]. In another cohort, the number of children was too small at the 18-month check-up to avoid type II errors [311]: the only significant difference involved the cumulative incidence of atopic disease for the CHF vs CM, while the open food challenge (OFC) for eggs yielded no differences. It must be noted that the highest rate of dropouts was observed in the group fed a PWHF (11.8%) and that only with this formula, there were two reactions to the DBPCFC (4.1%); CMA incidence was 2% [311]. In addition to the five children reported in Table 9.28 [47], we report 14 other cases of HR nurslings presenting nonfatal anaphylaxis at weaning (two instances in one baby) (Table 24.11) [50]. They all received small doses of PWHF at birth, demonstrating the *immunogenicity of HFs prescribed to young infants for prevention* (Table 24.12) [50]. From Tables 9.31 and 9.32, we see that other young infants experienced anaphylaxis or apparent life-threatening reactions when receiving these formulas: $CD45RO^+$ cells proliferate rapidly following sub-

sequent contact with the antigen. It has also been calculated that 80 mg of raw material identifiable as casein (ICRM) in 100 g of HF with the lowest percentages (0.08% Pepti Junior and 0.05% Nutrilon Pepti) is equivalent to what a 2-month-old infant ingests in about 10 days. Nevertheless, there are so-called hypoallergenic (HA) formulas with *ICRM that are 10-fold higher* [327]. These figures clearly indicate that HFs can be immunogenic, triggering an IgE-mediated response in predisposed subjects. Another possibility, even if not directly transferable from animals to humans, is that artificial nursing can alter the function of the intestinal barrier in immature newborns [401], as demonstrated in Fig. 24.8, opening the door to systemic invasion by pathogenic bacteria [401].

Table 24.13 [10, 77, 78, 80, 81, 112, 165–167, 173, 271, 272, 310, 311, 358, 432, 434, 437, 444, 465, 482, 486, 487] outlines the preventative studies based on HFs: Only one study on 3,473 children found an incidence of 1.5% for HF and 2.4% for CM [358]. It should be noted that in various studies, there is a 43%–74% prevalence of CMA in the control group [77, 78, 165, 173, 432, 435, 487], which is not matched in other studies focusing on prevention, apart from the results of Van Asperen et al [423] (42%) in HR children who were not subjected to preventive measures; this is assumed to be based on imprecise inclusion criteria [21]. For example, Halken et al [165] followed 105 HR infants from birth to 18 months, and dietary measures and avoidance measures were strictly followed in 85% of cases. Consequently, the reported prevalence of atopy is unexplainable (32% in the study group and 74% in the control children), while the prevalence of 15% in the 20 children exclusively breast-fed from birth is very low [166]; their IgE levels were significantly lower compared to the other groups [166]. Breast-fed HR babies recruited at birth had a lower development of atopy and of CM IgE levels than those HF-fed [310]. In other HR children *who were not subjected to any preventive measures*, CMA prevalence was 20%, while in HR children undergoing prevention it was 3.6%–5.6% [166], rates decidedly lower than those of 32%–74% [165]. FH positivity was 39% in 92 children nourished with HFs and 35% in the control children, with a high prevalence of atopy at 2 years of age: 24.3% and 62%, respectively [271]. In HR children divided into four groups based on FH and CBIgE, the latter accounted for only 20.5% [465]. Moreover, it was not clear how they were distributed, so that the benefit gained by these dietary manipulations seems to be limited to non-HR children [66].

It is also true that HFs have provoked CMA in at least 25%–40% of cases [77, 78, 112, 165, 310, 311, 432, 452, 482, 487]. In our studies, breast milk was ineffective in 11% (Fig. 24.6)–18% (Fig. 24.3) of cases. Breast milk has never provoked the reactions documented in Tables 9.31, 9.32.

There are few studies documenting the nutritional adequacy of CM-protein HF in HR children fed exclusively with these formulas for an extended period (Tables 24.13, 24.14). In addition, these studies have been meta-analyzed [378], with the conclusion that there were several methodological flaws in the studies, similar to those concerning the protective effect of breast-feeding [237]. Only five studies on PHF [78, 81, 272, 311, 435]

This table includes some groups of children present in Table 24.2, but the authors have not always indicated the content of the two groups; therefore some overlapping data may be noted. *F-U* follow-up period, *HF* hydrolysate formulas, *CM* cow's milk, *CMA* cow's milk allergy, *CI* clinic, *OFC* oral food challenge, *SPT* skin prick tests, *sIgE* specific IgE antibodies, *FA* food allergy, *AD* atopic dermatitis, *C* casein, *SP* soy + pig collagen, *W* whey, high-partial highly or partially hydrolysate formulas, *NS* not significant, *ND* not done.

[a] Fifteen of 30 babies provided with HF received CM formula since the 31st day.

[b] Follow-up at 6, 18 months, and 5 years.

[c] The number of babies who received only HF is not known; the numbers are the same after 2 and 4 years.

[d] The distribution of 25 children (with no FHA) with high IgE levels among four groups is not known.

[e] The cumulative prevalence includes diarrhea and colic as single manifestations of CMA, as previously discussed.

[f] Prevalence at 9–12 months of C is 20%, of W partial is 13%. OFC with CM or egg failed to show statistical differences. There is a significant difference in the cumulative incidence of atopic disease at 9 and 18 months for C vs CM.

[g] In the study of von Berg et al we have reported the mean of the 3 HFs used; AD was not prevented.

were appropriate for comparison [378], among which a study that yielded significant OR results [311]. A recent study [167] fed 79 infants a CHF, 82 an EWHF, and 83 a PWHF, but significant results were only in 232 breast-fed babies (Table 24.2).

The evaluation of growth thus represents a tangible problem: feeding healthy infants a WHF or an adapted formula, from birth to 3 months of age, seems to provide adequate nutrition that is essentially indistinguishable between the two groups, by evaluating weight and length gain and various laboratory parameters, except for cranial circumference [436]. The Fe-binding capacity was higher in the first group and ferritinemia is lacking, which is a more sensitive indicator of any iron deficiency. With regard to an evident reduction in nitrogen retention (p=0.009), the authors cite a study in adults [392], in whom nitrogen use was equally lacking. Nevertheless, a PHF diet ensured greater retention even compared to solid foods [392]. Therefore, we cannot conclude that weight gain was similar in both groups [436].

As compared to breast-fed newborns, healthy newborns fed for a few days with a PWHF demonstrated significant abnormalities in their amino acid profile [347], which dropped on average at the age of 34 days. Threonine values were double, while those for tyrosine, proline and phenylalanine were significantly lower, as were total proteins [348]. In newborns fed as above, the increase in urea nitrogen and the altered distribution of amino acids was again confirmed, in contrast with breast-fed newborns [152]. We should not be surprised, as CM-protein HFs are made exclusively from casein or whey proteins, thus leading to an imbalance in amino acid serum composition. Therefore, to prevent this, adapted formulas should contain an adequate proportion of whey proteins and casein, which should be 60% and 40%, respectively.

Several formulas made with PWHF (Table 9.30) are marketed as preventive against atopic manifestations in general and FA in particular, based on studies that have supposedly demonstrated that a specific tolerance can be induced by early HF feeding (Table 24.14) [49]. The producing industries claim that these formulas may contain undegraded CM proteins or peptides with a high MW of up to >6,000 D, since they are products recommended *for CMA prevention and not for treatment*. What we do not understand is which clinical and experimental data differentiate the doses of allergens triggering symptoms in sensitized babies from those sensitizing not yet allergic babies [21, 43]. The label "HA" can create a false sense of security: this is an ambiguous term that may be erroneously employed [365], but the problem has not been discussed in a proper forum [93]. Instead, in the US the GS producers (Beba HA and Nidina HA in Europe) have been *banned from printing the acronym HA on the label or package*, with the obligation to indicate clearly that if CMA is suspected, GS must be used solely under medical supervision [380]. Re-examining the studies showing the *negative effects of these formulas, regardless of whether they are highly or partially hydrolyzed* (Tables 9.28–9.30), we can see that numerous studies have strongly recommended that their non-immunogenicity be ascertained before using them for preventative purposes or before prescribing them to children with CMA [93, 363]. Cochrane Database Syst Rev. (CD003664) evaluated HFs for prevention of allergy and FA in infants. Based on the analysis of 11 studies, it was concluded that there is *no evidence to support feeding with an HF for the prevention of allergy* in preference to exclusive breast-feeding. However, in HR infants who are unable to be completely breast-fed, there is evidence that prolonged feeding with an HF compared to a CM formula reduces infant and childhood allergy and infant CMA. Incremental costs of formula and the effect on compliance should be measured.

Table 24.14. Properties of hydrolysate formulas

Possible cross-reactivity with CM proteins (more frequent with whey-protein hydrolysate formulas)
Variable levels of unaltered proteins (casein in whey-protein hydrolysate formulas and vice-versa)
Possible allergenicity (partially hydrolysate or whey-protein hydrolysate formulas)
Lower antigenicity than that of CM protein
Nutritional adequacy not known in long-term studies
Unpleasant taste (except partially hydrolysate formulas)
Cost 80% more than a CM formula (except partly hydrolysates)

Data from [63].

The data provided so far are too limited with respect to the need to know definitively whether HFs are safe and nutritionally adequate. To our knowledge, the fair request to clarify – at least to the prescribing doctor – that the HF composition or the hydrolysis method used (which varies from one formula to another) has yet to be met [365]. The opinion has correctly been expressed that, if necessary, HFs could be used to reduce an existing sensitization, not to prevent it [50]. This is confirmed by data demonstrating that several PHF and EHF HA formulas have peptide bands with a high MW [344] (Fig. 9.24) and, if made of whey proteins, they have variable casein contents [345], making them unsuitable for prevention, particularly in sensitized subjects. The indiscriminate labeling of HFs as HA, merely on the basis of the degree of CM hydrolysis, without considering the allergenicity of the residual components and, therefore, their safety in children with CMA, poses the risk of adverse reactions in these children, by the gut detection of residual native or processed components of these HAs [114]. In conclusion, the option of using an HF in HR children should be evaluated on a case-by-case basis, after in vivo tests have been done [54, 363, 380], with data in Table 9.30 at hand. Lastly, the HF unpalatability should be considered, as this has led 50% of expectant

mothers to refuse HFs [128], as well as their cost: for both of these parameters, SPFs offer substantial benefits (Tables 9.20, 9.21). Both the soy + pork collagen HF [368] and Rezza's diet may be available alternatives.

It is evident *per se* that marketing many HA formulas intended for all newborns could pose a further threat to breast-feeding [123]. Mothers should not be led to believe, by expanding on [253] BMA cases, that HF is safer and thus preferable to breast milk from this standpoint. *Subtle propaganda recommending HFs while waiting for commencement of lactation* as a breast-milk supplement or substitute – a practice leading to the *immediate loss of colostrum, the principal immunological defense of the immunodeficient newborn* [292] – could foster the belief that breast-feeding is inferior to artificial milk: if this has occurred [93], the measures that were once invoked are still current today [54]. Giving a newborn any CM formula whatsoever – in 86% of cases in both Milan and Rome – means depriving the child of the immunological factors contained in human colostrum and of anti-infective, anti-inflammatory and immunomodulating factors in breast milk. These foremost effects, associated with allergen avoidance, strengthen breast milk's advantages.

In specialized journals and magazines aimed at the general public, there are frequent advertising inserts that emphasize the advantages of this or that HF: a producer of two baby formulas spent £3 million in England in just 1 year to advertise them [4], while the British Department of Health in turn spent only 1/60 of that amount to promote breast-feeding [4]. The policy of distributing milk formulas for children should not precede upcoming progress in the knowledge concerning children's diets [93]. We can only hope that the agreement reached by European Union (EU) governments, banning advertising that can further jeopardize breast-feeding, will be a long-lived one. In 2001, the prevalence of the initiation of breast-feeding and breast-feeding to 6 months of age in the US reached the highest levels recorded to date, 69.5% and 32.5%, respectively. Comparing rates in 2001 and 1996, increases in the initiation of breast-feeding and continued breast-feeding to 6 months of age were observed across all sociodemographic groups [357]. A recent systematic review shows that community-based trials of breast-feeding promotion and extra support from professionals with special skills in early infant feeding are effective in prolonging breast-feeding [389].

Secondary Prevention

When an atopic disease is manifested, all preventative measures that can avoid relapses must be taken. The cornerstones of this type of prevention can be summarized as follows:

- *Avoiding allergen contact*
- *Preventing allergen entry* or mast cell degranulation
- *Modifying the state of sensitization* using available aids

The usefulness of secondary prevention is demonstrated by the fact that effective measures, intended to identify and eliminate allergens, can represent a valid alternative to drug therapy in children and they are thus virtually ignored [321, 451]. Among strictly pediatric studies [395, 417, 451, 452], only one devotes any attention to avoidance measures [417]. We emphasize that these measures are instead pivotal for prevention.

Avoiding Allergen Contacts

If a child must avoid contact with allergens to which he or she has become sensitized, an elimination diet or environmental measures can be adopted, or even both in some cases. As part of secondary prevention, *establishing effective measures against HDMs has significantly reduced the severity of cutaneous symptoms in children with AD* [409] *and of BHR in asthmatic children* [121]. Above all, it is remarkable that, for the first time, a significant reduction has been noted in AD compared to placebo-treated controls and to Der p 1 concentration [409]. Likewise, Swedish children in the ETAC study, showed the lowest rate of sensitization to Der p and to Fel d 1 compared to other countries [311].

For the atopic child, secondary prevention involves:

- Airborne allergens
- Environmental pollutants
- Food allergens

Airborne Allergens

Effective avoidance is primarily based on physical rather than chemical measures, requires a full regimen in the bedroom(s) and is only relevant to children who are specifically allergic [324].

Dust Mites

The first step is to ascertain the presence of HDMs. To do this, there is an easy-to-use semiquantitative test that is inexpensive and simple to interpret (Acarex). The levels of guanine exhibited by a given sample make it possible to measure the mite infestation level [82, 168, 335]. A simple kit is commercially available.

Other tests measure the number of live HDMs per m^2 of collected samples:

- The mobility test (MT), whereby a rug is covered with a layer of adhesive tape, held in place with a heavy plate and left *in situ* for 24 h at T 21 °C and a humidity of 75%.
- The heat escape method (HEM), in which a flat heating panel is placed on the underside of the rug. It is then heated gradually until the internal layers reach a temperature (T) of 60–70 °C. HDMs tend to move away from the

source of heat, shifting toward the colder upper areas, where they are captured by the adhesive tape.

Depending on the limits of applicability, the following data are obtained [20]:

- MT does not reveal the absolute total, but demonstrates HDM presence in the child's bed, pillows and blankets, with a ratio of 2:1 compared to the mattress, while in the parents' bed the number diminished with virtually the opposite ratio.
- HEM determines the HDM number and is seemingly more sensitive, but it is not applicable to essentially smooth surfaces (carpets, clothing, sweaters, warm-up suits, etc.). It is 6- to 13-fold more sensitive than MT.

These methods measure the live HDMs: *conventional methods reveal 0.3 %–0.6 %* of the above values [20].

The measures applied in the home of a child allergic to Der p 1 will be effective only if they lead to an 80 %–98 % allergenic load reduction [174, 241, 399, 409]. Children benefit from this more quickly than adults [399], suggesting that *histological changes typical of asthma become less reversible* as exposure is prolonged [399]. Environmental manipulations are effective if they are started promptly and completely: surrogates can lead to an improvement in symptoms, but not in pulmonary function testing (PFT) [275]. At the same time, targeted help can come from parents active in adopting an avoidance strategy to reduce allergens [427, 439].

Preventive Measures

The Child's Bedroom

Briefly, the child's bedroom should be sunny, well-ventilated and dry, uncluttered by excess furniture and any items that can act as Der p 1 niches [399, 417], because babies spend a larger proportion of their lives in their bedroom than do adults [398]. If a crib is necessary, this and portable crib mattresses should be encased in mite-proof material [101].

Beds: if possible, there should be *only one bed* in the room, above and below which the child should not be allowed to play, jump, do somersaults, have pillow fights, etc. [306]: Der p also colonizes the floor under the bed [479].

The *mattress* should not be made of latex, wool, horsehair or feathers, but of artificial fibers and polyester. It must be encased with mite-proof covers (with pores ≤2 mm) to permit steam dispersion from transpiration while preventing HDM passage. The slipcover should also be made of dust-proof synthetic fibers. It must be washable and have a *self-sticking closing* for its junctions [456], and it must be covered with another washable slipcover [91]. Commercial mite-proof covers for mattress, pillow, and quilt are effective and inexpensive [101, 321], while cheaper vinyl covers should be avoided as they are totally impermeable [174]. If a second bed in the room is unavoidable, it must be prepared

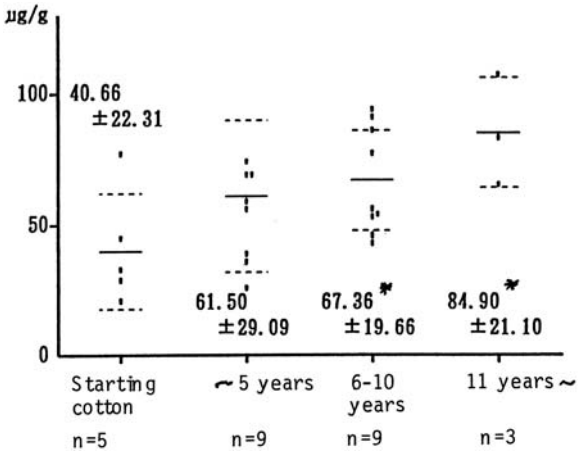

Fig. 24.9. Der p antigen content (μg/g) of traditional beddings by years of use in asthmatic children as measured by ELISA-inhibition method

in the same way [174]. We advise against *zippers* (dust goes through the teeth); if they cannot be replaced, the entire length of the zipper should be covered with adhesive tape. By adopting these measures, after 3 months Der p 1 concentrations in the mattress dust *were reduced to only 1 %* compared to uncased ones [313], and after 6 months the average percentage was significantly lower compared to the base figure [456]. In addition, polyester fibers have proven excellent for reducing not only Der p 1 levels in children, *but also BHR* [121]. According to some, the mattress should be changed every 5 years on the average [91] (Fig. 24.9), while others claim that buying new ones does not offer any benefits, because they quickly accumulate allergens [209] with levels correlated with those of any carpets in the bedroom [100]. The likeliest explanation is Der p 1 and Der f 1 contamination through the clothes of people who handled them, but also Fel d 1 and Can f 1 [107]. Vacuuming the mattress for infants before instalment will remove part of the dust. After installment, regular vacuuming is advisable [107]. Pillows must be treated as above, while sheets, pillowcases, blankets, bedspreads, quilts and so on must be made of synthetic material [241]. One year after the application of HDM impermeable covers on the parents and children's bed the concentration of HDM allergens, measured at the living room floor, the mattress of the parents and the mattress of the baby, was statistically significant decreased in the intervention group, but not in the control group [242, 376].

Furniture should be reduced to a minimum, simple with a regular shape and a smooth surface. Furniture should be wooden, metal, vinyl, and leather, and solid wood is preferable to particle board and laminated wood, as long as the wood is finished with natural paint and not *formaldehyde-based glues.* The objective is to ensure items that do not provide sites for mites to grow [323]. Furniture should be raised from the floor to make the room easier to clean. Avoid upholstered chairs, arm-

chairs and sofas; otherwise, the upholstery must be made of synthetic material. If wardrobes are a must in the room, parents are advised to empty them completely of regularly used clothes, bringing the contents elsewhere and using adhesive tape to seal them. Their function must be minimal, they can become containers to be opened twice a year at the seasonal wardrobe change, nothing more [91]. Books, booklets, magazines, records and so on must be banned, as they can collect HDMs, unless they are kept in dustproof cabinets or boxes, keeping out a book or periodical to read at night, if so desired [417].

If possible, *clothing* should be kept out of the room and stored in boxes or bags made of heavy plastic and prepared as indicated above, which are to be wiped often with a damp cloth. Shoes should be kept elsewhere in tightly closed plastic bags [174]. Likewise, wool blankets and clothing can be kept in sealed wardrobes in the summer, avoiding mothballs or limiting their use, or airing the items in the sun periodically, as with regularly used items.

Curtains, which must be made of synthetic material, must be small and lightweight, and they must be washed frequently [174].

Walls should be as bare as possible and painted. Thus, they should not be covered with unwashable wallpaper, and should not have paintings, prints, posters and other hanging items [417]. Beware of *casein contained in milk paints,* plasters, and wallpaper, since it is not known how commonly organic proteins are used in indoor construction materials [268].

Floors should preferably be smooth and washable (marble, ceramic, tiled, wood, vinyl and linoleum), paying attention to corners and cracks; concrete tends to trap moisture. Make sure that parquets are not glued using *casein or formaldehyde adhesives* [241]. For cleaning, use furniture polish that traps dust, making sure not to raise any dust in the room. Carpets, bedside rugs, wall-to-wall carpeting, animal feather, mats and so on are banned, as they are the most effective dust-collectors and receptacles: if they cannot be removed, for example, wall-to-wall carpeting, they must be covered completely with a polyvinyl sheet fastened at the edges with adhesive tape [306]. Note that synthetic carpeting and rugs have far less Der p than wool ones. Moreover, due to static electricity they tend to trap Der p, preventing its release in the air [333]. A danger for small children is crawling in close contact to house dust probably containing casein [268]. In one study a whey protein *(βLG) was detected in house dust* [469].

Children's *toys*, including dolls, puppets and so on, must be made of washable material and must never be wool, plush or padded. Even if they are new, they become filled with Der p 1 within 4 months [305]. After use, these items must be placed in a closed box. This also hold's for children's favorite bedtime items.

The room must be cleaned thoroughly every day: everything must be wiped carefully with a damp or oily cloth, otherwise room cleaning procedures will promote the circulation of mite-rich dust, increasing its levels in the air [323]. *A high-filtration vacuum cleaner* should be provided with a *HEPA microfilter* (high-efficiency particulate air filter) [306]. While it is true that there are not always significant differences with the use of filters [409], normal filters have no effect on HDMs attached to carpet fibers [306]. Other measures for the child's bedroom and other bedrooms used by children are summarized in Table 24.15 [174, 319, 414, 479]. Cleaning of the bed items must include the seams, where Der p tends to accumulate the most [174].

Other cleaning methods for carpets and similar items include exposing them to direct sunlight for several hours, which is effective for inactivating the allergens [414]. Otherwise, they can be wet-cleaned in the summer using a commercial detergent and applying an acaricide after about 1 month [108]. Radical measures include a T of –20 to –25 °C [108, 319] and the use of a steam cleaner to reach the T of 150 °C [92], but carpets in basements are almost impossible to keep dry [323].

Several strictly necessary measures are recapitulated in Table 24.16 [174, 283, 431, 479]: they are justified because HDMs multiply when T exceeds 25 °C and relative humidity is >75% (for humans, the optimum level is between 25% and 50%), and HDM can survive up to T 60 °C [464]. Therefore, blankets, bedspreads, quilts and so on must be washed at T >60 °C, every 2 weeks on average [283]. T <55 °C does not totally eliminate HDMs, reducing Der p 1 by 95% and Der p 2 by 91% [454], nor is this improved by adding detergents or other chemicals [283]. Instead, dry-cleaning the blankets is effective in 70% of cases [454]. T 60 °C is effective in 50% of cases only if maintained for a full hour. To achieve 100% results also for Der p 2, this would theoretically require T 130 °C for 30 min [319]. *Clothing* must be washed frequently: this is an unsuspected source of high levels of Der p, particularly if the clothes are made of wool, which shows an accumulation ten times higher than cotton [20] and polyester.

Table 24.17 [409, 479] shows a timetable for the measures described here. Two measures are urgent: encasing the mattress, which is truly effective [101, 121, 409] and can reduce the allergenic load by 98% [409], and using mite killers [101, 409].

Environmental Measures

- *To reduce humidity* in the kitchen, bathroom or other rooms, windows may be opened to change the air even during the winter, for 30 min twice a day. Closed windows increase humidity. For the same reason, laundry should not be hung inside the home to dry [426].
- If *the heating system* uses wall radiators, they must always be cleaned with a damp cloth or a high-filtration vacuum cleaner. Radiators collect far more dust that one would imagine and if they are electric this can also pose

Table 24.15. Prevention of atopic disease in high-risk children: rooms in the house

A. In the child's bedroom
Air the bed, blanket, and pillows daily
Scrub mattress and pillows and beat them with a rug beater; if feasible, expose all to sunlight
Clean mattress and pillow covers with a damp cloth and wash in the washing machine every 3–4 months
Change both sheets and pillow slip at least weekly
HEPA air cleaner should be used at least weekly to remove airborne dust particles from mattress and pillow
Air the rooms in the morning when Der p 1 levels are lower
When the room is vacuumed, the child should avoid being in the room while vacuuming is occurring until at least 20 min after it has been completed
The room should remain closed the whole time the child is away
Keep the doors and windows of the bedroom closed as much as possible when not using the room
B. In the other rooms
Do in the same manner:
In the parents' bedroom and the other bedrooms, even if the child does not stay or sleep there daily
In all other rooms where the child frequently goes
In the home of relatives
In holiday houses
If possible in hotel beds the mattress covering should be used
Prepare the other rooms where the child goes, although less frequently, such as, where the child watches television, in the same manner, removing the armchair upholstery, heavy curtains and carpets
Children should stay away from normally damper and not sunny rooms
Remove nonsucculent green plants and domestic pets; leaving them in the garden, courtyard or balcony is not a useful approach
Avoid aspecific irritants, including kerosene, cosmetics, formaldehyde, gas oil, insecticides, turpentine, paints, chemicals and strong odors
An aquarium may increase the humidity level
Prefer synthetic fibers for curtains, blankets, bedcovers and the like; mites burrow in the weft of closely woven cotton or wool fabric and hold on tight; thus they are unlikely to be completely eliminated

Data from [174, 319, 414, 479].

Table 24.16. Additional home avoidance measures

Maintain environmental T ≤20 °C
Uniform heating throughout the home, avoiding T differences
Maintain indoor relative humidity not >50 %
Wash all bedding, including mattress cover, blankets, curtains, etc. at T >60 °C
Dry cleaning of wool clothes, plush, stuffed toys, etc., at T >60 °C, then wash in cold water

Data from [174, 283, 431, 479].

Table 24.17. Suggested chronology for home avoidance measures

A. Primary measures (within 1 month)
Bedroom
Encase mattress and pillow with plastic impermeable covers
Increase T for washing bedding (Table 24.15)
Remove quilted bedcovers and wool blankets or encase as mattress
Remove stuffed toys, clutter and eliminate or encase upholstered furniture
Replace curtains with washable blinds
Remove carpets and wall-to-wall carpeting
Alternatively expose carpets to sunlight
Other rooms
Use HEPA filters
B. Medium- and long-term measures
Bedroom
Replace carpets and wall-to-wall carpeting with smooth floor or vinyl covering
Alternatively spray carpets with acaricides
Change bedrooms to second floor (if feasible)
Other rooms
Remove carpets and upholstered furniture that is not encased
Replace curtains with washable blinds
Reduce humidity by increasing ventilation with fresh air, or using either a dehumidifier or air conditioning
In general
Prefer older buildings with less insulation and better ventilation

Data from [409, 479].
HEPA high-efficiency particulate (or particle arresting) air.

a risk [206]. Hot air rising from radiators promotes airborne allergen dispersion [174]. Some feel that baseboard radiation panels are best [241] (Fig. 24.1).

- *Air conditioning* is helpful for minimizing excessive heat and humidity, which stimulate HDM proliferation. The following rules must be followed: if there is a vent in the room, we recommend covering it with a filter, which can be made of various layers of thick fabric or nylon, to be changed frequently. If there are cracks or holes around the vent, they should be filled with putty. The filters of the heating and/or air-conditioning ducts must be cleaned thoroughly every 2–4 weeks [174]. The effectiveness of this is demonstrated by the significant reduction in HDM number in rooms treated according to these standards [257]. Make sure that pollen does not filter into the models [174].
- An automatic system for *air cleaning* without opening the windows should be installed. In 20 asthmatic children sensitized and exposed to pets in the home, application of air cleaners in living rooms and bedrooms was accompanied by a significant improvement in BHR and a decrease in peak flow amplitude [425].
- If *humidifiers* are used – generally contraindicated [462], particularly in the child's bedroom [206] – verify that the relative humidity is always ≤40%–50%, and clean the tanks regularly.
- *A dehumidifier is* helpful in damp houses or in periods of excessive humidity, and can reduce the allergenic load by >50% [51]. These effects were not confirmed using a portable device [99] and thus their effectiveness is unsure.
- *Acaricides* are effective in reducing environmental HDMs, as long as they are repeatedly applied on carpets and soft furniture [101, 475], as demonstrated by clinical improvement of patients [10, 69, 102, 185, 186, 298, 334, 372, 475]; in fact, the symptoms reappeared in not dust-free rooms, demonstrating that removal of allergens improves clinical manifestations [298]. Antigen avoidance procedures associated with acaricide use reduced the mean concentration of Der p 1 from 25.9 µg/g of dust at birth to 6.0 µg/g at age 9 months [334] and resulted in the development of atopic symptoms at age 1 year in only 13.8% of infants, as opposed to 40.3% of the control subjects [10]. Other authors have failed to note the same effectiveness [121, 399, 456]. It was observed that poor effects on mattresses but significant on living-room upholstery depend on the difference in the thickness of Der p layers and/or the lack of associated cleaning: to be effective, an acaricide must kill not only Der p but also its eggs, denature fecal residue [298] and achieve a tenfold reduction in the allergen quantity per area unit [479]. Several studies [160, 409, 415, 450] tested the validity of Allersearch DMS, composed of a mixture of benzyl alcohol and tannic acid; it is nontoxic and has a dual action, killing HDMs and reducing residual antigenicity. In asthmatic children, a significant reduction was observed in SPT positivity to Der p in their homes [450]; others do not agree [334]. Colloff et al [91] have published a list of producers and/or suppliers of these products: however, many household products may have poor or nonexistent effects on allergens in the air or in dust samples and should be tested objectively before they are commercialized [83]. In addition, a major decrease in allergen was not recorded compared with that seen in the control population [324].

Measures in the Home

The main risk factors for the home are summarized in Table 24.18 [241, 426, 439, 462, 464]: humidity is generally ≥7 g/kg in homes with several floors as opposed to single-story homes, where a higher HDM number thrive well ($p<0.001$) [462]. These measures should best be applied in selecting a new home or before moving, ensuring that the home is insulated from the ground and the apartment is on an upper floor.

Several studies have demonstrated that early intervention may modulate the natural course of atopic disease. We recommend adopting all the above measures – at least the essential ones – several months before the baby is born or the family moves to the home. An antenatal intervention to reduce HDM allergen levels in children's beds had a limited effect since even with expert control measures in place, HDM allergen levels remained high by international standards [286]. In an extension at 18 months, HDM avoidance intervention was ineffective but was associated with a lower use of medications [287]. However, a substantial reduction in Der p 1 levels in beds and in airborne dust in a humid region with naturally high mite allergen levels can be achieved and sustained in children with use of occlusive covers and a rigourous washing routine [438]. HDM sensitization can be reduced by providing school age children with HDM impermeable mattress covers and advice on environmental measures to reduce exposure to HDM allergen. Significantly, three out of 117 (2.56%) children in the prevention group and nine out of 96 (9.38%) controls developed mite sensitization [11]. A pediatric DBPC trial reported no effect of the inter-

Table 24.18. Main home-related risk factors

Solid brick outer walls [426]
Lower storeys [242, 462]
Tight, poorly ventilated homes [242]
Absolute indoor humidity >7 g/kg [464]
Condensation on the inside of double-glazed windows [464]
Concrete slab basement [464]
Wall-to-wall carpets and wooden floor, associated with older floor coverings [426, 439]
Underfloor heating [241]

vention in children aged 2 [236], but at an earlier age the clinical benefits can be barely detectable [37]. In the homes of children born to allergic mothers, use of mite allergen-impermeable mattress covers reduced mite allergen exposure [428]. Active avoidance measures used *during pregnancy and in the 1st year of life* in homes of infants at risk of atopy including dust samples from the parent's bed, the infant's mattress, several floors, and Der p 1 levels demonstrated that recovered Der p 1 from the mother's mattress was reduced by 97.25%, with the effect persisting for 6–12 months [101]. Total Der p 1 from the bedroom floor in the active group was reduced by 53.7%; Der p 1 levels in the crib mattress and nursery floor in the active group were extremely low. The total amount of allergen recovered at age 1 year was 29-fold higher in the control group than in the active group [101]. Another study compared the effect of allergen-impermeable encasings on the mattresses, pillows and bedcovers over 1 year with matching placebo encasings. The use of antiallergic mattress covers resulted in significant reductions in Der p 1 concentrations in carpet-free bedrooms; however, there was no consistent variation in the clinical manifestations of the patients [349]. Others have demonstrated [429] that mite-impermeable mattress encasings have a significant but modest effect on dust and HDM levels of mattresses with low initial HDM levels, compared to placebo. A recently published meta-analysis of mite-preventive measures in mite-sensitive asthmatics suggested that current chemical and physical methods aimed at reducing exposure to allergens from HDMs might be ineffective in the tertiary prophylaxis of asthmatic patients. The authors judged quite ineffective the methods for mite eradication since these methods did not adequately reduce levels of mite antigens [159], but the analysis was contested [98] because there was a diversity of results between different types of treatment to prevent asthma. The use of mite allergen-impermeable mattress encasings was the cornerstone of a pediatric study associated with other mite and food allergen-preventive measures, which substantially lowered the incidence of sensitizations in the 1st year of life [169].

Special Preventive Measures

Holidays in areas patently infested with HDMs are not prudent: spending a vacation of ≥14 days in these places is considered a significant risk [462]. In cities as well, some places are dustier than others, such as theatres, cinemas, etc., Residence in the mountains can cause a range of immunological effects (Table 24.19) [29, 64, 82, 88, 322, 364, 390, 398, 421]: for example, a great difference in mite allergen content in dust of mattress in samples taken from high-altitude areas as opposed to those collected at sea level [85]. If the environment is strictly dust mite-free, an extended mountain stay can lead to appreciable improvement [422]. Nevertheless, parents and doctors should note that these improvements are limited to staying at high altitude, similar to what is achieved in a hospital setting – real or simulated (Chap. 7), but PFT deteriorates and asthma symptoms worsen in children following the return to sea level [88]. Considering the effects as a whole, these stays are sometimes justified by the need to ensure that the airways get a rest. Recently, a critical review was made of the role of certain allergens at high altitudes: even at 2,300 m, sensitization to environmental allergens is possible, including Fel d 1 [398]. Moreover, at 2,600–5,800 m, as many as 112 to 280 Der p/g of dust were noted, independently of T and relative humidity [364]. The study in Los Alamos, New Mexico, a high-altitude desert area and an environment in which there are very few HDMs, shows that in children born and raised there, nearly 17% were diagnosed as having asthma at some time with 14% taking asthma medication [398]. Consequently, although the prevalence of HDM sensitization is reduced in such areas, the prevalence of asthma continues to be a serious problem at altitudes considered free of airborne allergens. At home, other measures require banning smoking and avoiding irritants such as insecticides, mothballs, deodorants in general and so on.

Table 24.19. Results of high-altitude climate therapy

Favorable data
The number and concentration of mites vary inversely with altitude [364]
A t 1,400 m (4,267 ft), SPTs to Der p decrease remarkably (90%) [82]
Serum IgE levels decrease up to 40% and Der p-specific IgE up to 50% after a 9-month stay at 1,400 m [64]
PD_{20} increases after 80 days of allergen avoidance at 1,756 m (5,352 ft) [322]
Reduced histamine release by Der p-specific basophils at 1,756 m [322]
Reduced markers of eosinophil activation at 1,756 m [29]
Reduced peripheral blood CD4 (CD25) T lymphocyte activation (increased CD45RA/CD45RO ratio) and eosinophilia at 1,570 m (4,875 ft) [390]
Unfavorable data
High populations of mites are prevalent at 2,655–5,820 m (8,087–17,727 ft) [364]
At 2,800–3,000 m (8,534–9,144 ft), asthmatic children ranging in age from 8 months to 19 years are most frequently sensitized to Der p and Der f [421]
At 2,360 m (7,189 ft), a sensitization to Fel d 1 is likely [398]
The positive effects decrease invariably after renewed allergen exposure at sea level [88]
Cost/benefit ratio of the change of residence and move to mountain sites

Comment. Comparing the levels of HDMs in the homes of 3- to 15-month-old atopic and nonatopic children, only 50%–56% of parents of atopic children had made any changes to the flooring or beds, and 34%–46% to bedroom carpeting. Among these children, 56%–60% had mattresses and blankets that were not new – as opposed to 61%–68% of nonatopic subjects, although in 80% of these cases the mattresses were encased with an occlusive plastic sheet cover, with a difference compared to non-coverage (2.2 vs 3.1 µg/g) (GM) [427]. However, anti-Der p measures are applied so attentively in Sweden that in the ETAC study sensitization to these allergens was 0% (Fig. 5.22).

Pollens

With pollens, primary prevention is technically impossible, given the pollen ubiquity. It would be best to move to the mountains or out to the open sea for the entire duration of the pollination period, but this would entail a heavy financial investment, as short stays would lead to immediate (and more severe) relapses upon return to the city. Ideally, one should live permanently in a beach town where the wind blowing in from the sea brings pollen-free air, or at an altitude of >1,000 m above sea level if one is monosensitive to *Parietaria*, which does not thrive at these altitudes.

Often, due to the geographic and latitude characteristics that differ from one region to the next, there are pollination periods and types of pollen in the air that vary substantially between areas. To help pollinosis sufferers, sampling points have been set up extensively across the world and they are equipped with counters that take daily or weekly measurements of pollen (and mold) concentrations. As a result, the *aerobiological calendar* of an area of residence and/or study and/or work can be consulted for prevention [104]. Almost everywhere, there are measurement stations that deliver this information weekly via appropriate media (national television, Internet, daily newspapers, medical press, etc.), whereas doctors can obtain more detailed information at the headquarters of local aerobiology associations or from local monitoring centers [104]. Currently, there are short-term previsions of pollen concentrations based on the work done to monitor bioclimatic parameters (T, relative humidity, barometric pressure, wind direction, etc.). A computerized mathematical model correlates the databank of pollen counts for recent years with weather forecast data. A personalized study has also been proposed, with daily monitoring of the pollen count using the IPC (Individual Pollen Collector) or similar, which can furnish data on individual pollen exposure [297].

Preventive Measures

Preventive measures should be adopted essentially during the pollination period that, as should be remembered, is favored by hot, dry climates [104, 413, 479].

- Find out the pollination period of the plants to which the subject is allergic, taking steps when symptoms are most accentuated (for grasses pollination peaks between April and September: from 100 to 500 pollen grains/m^3 of air). We can summarize the other risk periods as follows: when it is windy and/or sunny, and in places such as plains, valleys, the countryside and outdoors in general. Cold and/or rainy days are the most reassuring, as is one's own home if improvements have been instituted.
- As much as possible, avoid spending time outdoors when pollination is peaking. For example, do not go camping or picnicking. Children with grass pollinosis who roll around in the grass can develop contact urticaria (Chap. 8).
- If possible, spend the hotter hours of the day – when pollen air concentration is highest – at home or at work, keeping windows closed. If possible, postpone airing the rooms until the evening.
- If you need to travel, try to leave on cloudy or rainy and windless days. As to rain, heavy and extended rain is ideal, as it can purify the pollen-rich air, while pollen on the ground percolates into the soil.
- Do not ride bicycles, scooters or motorcycles.
- Use air conditioners to reduce pollen concentration in the filtered air. If installing air conditioning in your car is planned, be sure in advance that it is compatible with the child's symptoms [252].
- Do not go in the country or to parks while grass is being mowed or has been mowed recently.
- If possible, put the child in the coolest room on the side least exposed to wind, so he or she can stay closed indoors even in the summer, weather permitting.
- If this is unfeasible, close the windows between noon and sunset, when pollen density peaks.
- Pollen enters through open doors and windows and is found in high concentrations in furniture, beds and carpets [395].
- Avoid eating honey, as it can contain pollen allergens (Chap. 9).
- After the child has been playing outside, have him or her take a shower and then change clothes in a room other than the bedroom.
- Dry laundry indoors, because pollen can adhere to fabrics put outside to dry.
- Avoid staying in rooms or places with an aquarium: pollinosis sufferers show allergic symptoms more often than nonallergic subjects (Chap. 4).
- Grass-sensitive children often have SPTs positive to plant foods. Therefore, when they eat these foods during the pollination period they may have symptoms of oral allergy syndrome (OAS) (Chap. 9).

Specific Measures

- Wear anti-allergy masks in risk situations.
- Scrupulously follow the prescriptions of your pediatrician.
- Before taking the child on a trip or on vacation, check the pollen calendar and pay attention to pollen density bulletins [104].
- Prophylaxis for car asthma [252]: in addition to the measures to be taken during the pollination season, do not allow pets or birds to be transported and ban smoking.

Molds

Some of the reasons that have stirred great interest in fungal allergens (Fig. 1.72) are summarized in Tables 24.20 [105, 330], 24.21 [105, 330], 24.22 [105, 330], 24.23 [330, 479], 24.24 [42, 330, 426, 479] and 24.25 [295], since prevention of mold allergy has gradually become more and more important [105]. Fungi are found both indoors and outside homes (Tables 24.21, 24.22), from which they should be removed by effective prophylaxis. High concentrations are found on school floors, both uncovered and wall-to-wall carpeted [119]. Fungi develop best at T 18–36 °C and a relative humidity of 75%–95%, and are active in spring and autumn, often with the highest concentrations between late summer and early fall [42, 94]. *Alternaria* and *Cladosporium* sensitivity was present in 1.5% and 0.5%, respectively, of children in prevention studies [17]. The *preventive measures* are summed up in Table 24.23 and more comprehensive recommendations for environmental mold avoidance in Table 24.24.

Prahl [330] has confirmed that avoidance measures are significantly effective, underscoring that the main measures to be adopted include:

- Immediate repair of defective insulation in homes or rooms
- Continuous cleaning of air conditioning systems
- Increased airing of rooms where mold growth is noticed (30 min at least twice a day)
- Increased bathroom ventilation
- Uniform heating everywhere
- Increased cleaning and hygiene procedures
- No indoor laundry drying
- Fewer indoor houseplants [330]

Mold spores can contaminate common foods, forming aflatoxins that can cause symptoms of intoxication (Chap. 10) and induce *intestinal and respiratory* symptoms and *skin lesions*. Therefore, an elimination diet is indicated as it can significantly improve symptoms, inducing their relapse (Table 24.25). It should be noted that *Penicillium glaucum* is used to produce gorgonzola or blue cheese, while other varieties are used for camembert, roquefort, etc. Among other possible factors, we must consider that CM pasteurization eliminates possibly 50% of aflatoxins and the UHT method gets rid of 25%.

Table 24.20. Difficulties in prevention studies of mold allergy

1.	Spores are ubiquitous and can be found either indoors or outdoors or both
2.	Fungal growth depends on several substrates
3.	Existence of hundreds of different species
4.	A single mold produces many allergenic substances
5.	Local microclimate, especially humidity, influences mycelia, spore and enzyme growth
6.	No growth of some species in culture media
7.	Saprophyte fungi have the ability to become pathogenic
8.	Skin tests are often weakly positive
9.	Poor correlation between skin tests, RAST and bronchial provocation tests
10.	The more studied molds are the fungi imperfecti, *Alternaria*, *Aspergillus* and *Cladosporium*
11.	Different methods of preparation of mold extracts from one supplier to another
12.	Humans inhale mold spores, unlike the other aeroallergens, whereas the extracts are based on mold mycelia and metabolic products
13.	Fungi are quite different from other aeroallergens, since inhaled particles consist of entire living cells

Data from [105, 330].

Table 24.21. Indoor ecological niches most frequently preferred by molds

Rooms with insufficient ventilation: bathroom, kitchen, woodroom, storerooms	
Other areas where molds collect	
a.	Wall cracks communicating with outside
b.	Window frames where condensation is prominent
c.	Humid floors and walls
d.	Wallpaper on cold walls
e.	Wool, cotton, kapok clothes
f.	Damp fabric or leather (shoes, boots)
g.	Dead leaves of houseplants
h.	Inappropriately stored foods, such as, in refrigerator even at 5 °C
i.	Air conditioning and humidification systems

Data from [105, 330].

Table 24.22. Outdoor ecological niches most frequently preferred by molds

1. Ground
2. Organic material in decomposition (dead leaves, garbage piles, barns, rotten fruit, rotting wood, etc.)
3. Particular work environment
a. Food industry (cheese factory, pork products)
b. Drug industry
c. Large storehouses: depository, docks, silos
d. Paper mill
e. Tree nursery and greenhouse
f. Stable
4. Places remaining closed for a long time
a. Cellar
b. Attic
c. Garage
d. Holiday dwellings

Data from [105, 330].

Table 24.23. Prevention of mold allergy

1. Especially in critical periods do not go to contaminated places, and avoid the following activities:
Going for a walk in the woods, especially with fog or after rain, in recently cut meadows, in harvested fields
Play or work for prolonged amounts of time in basements, cellars, attics, etc.
Mow lawn or make hay
Take dead leaves in the garden or elsewhere
Stay in the vicinity of barn, granary, stables, dunghills, containers with sand, hay, fertilizers
2. Allergic children and teenagers should wear a mask and maximize ventilation when working in areas with high mold growth
3. Decrease sources of mold in house by avoiding overwatering and keeping indoor watered plants or those with dead leaves
4. Air previously closed rooms where children go
5. Prune or cut trees giving shade to the dwelling
6. Reduce general humidity in house (Table 24.17) and water drainage
7. Wash daily air filters on air conditioners, which usually retain spores; these reproduce inside the filter, multiply and cross the filters, and sporulate freely in the environment; wash dehumidifiers with soap and water and nebulizer tubing
8. Supervise that there are no deteriorated or moldy foods in home, pantry, refrigerator, etc., discarding them whenever mold spots appear
9. Remove wallpaper as soon as possible
10. Exposure is reduced by closing windows in the house and car windows
11. Clean humid areas in the kitchen and bathroom, using:
Bleach diluted 1:4–6 parts water or vinegar also diluted
Benzalkonium chloride 1:10,000, or diluted alcohol, or trioxymethylene, which may be left to evaporate in container in closed places, such as, holiday dwellings, basements, cellars, attics or rooms remaining closed for a long time, to discourage fungal growth; the places should be aired by adequate ventilation, avoiding that mold-allergic children enter the spot while the vapor is not wholly dissolved
We do not suggest using formaldehyde regularly; it is a potent skin and airway irritant even in small amounts, above all by being highly hydrosoluble (Chaps. 4 and 8).

Data from [330, 479].

Table 24.24. Plan of a mold-free environment and its maintenance

In house
Buy a hygrometer
Maintain, if feasible, indoor humidity <30%, but never >50%
Ensure adequate ventilation
Increase the ventilation with fresh air where moisture is noted
Use air conditioning during the warmer days and months and at other times of high humidity levels
Use a dehumidifier in the basement or other areas of dampness
The air filters on air conditioners should be washed with soap and water to remove mold and airborne debris, and sprayed with commercially available fungicides as soon as a mold odor is smelled, whereas the dehumidifier should de regularly emptied of the air inside
When the dehumidifier is utilized also in winter:
Avoid excessive humidity
Change the water frequently to discourage mold growth
Clean the inside occasionally with bleach solution as above
No indoor clothes drying (not on indoor clotheshorse), cooking equipment should also be vented to the outside
Household plants should not be watered too much: a common alert of moisture are the circles of a whitish color at the base of the pots, formed by the excessive water used
In the kitchen
Verify the hood efficiency and use a kitchen fan to eliminate the steam formed when cooking
Periodically clean the work surfaces, sink and food containers with vinegar or comparable agents
Bring in firewood for immediate use only
Refrigerator
Molds often proliferate around and under the rubber seal of the door, trays and sinks
Empty the defroster basin regularly
To prevent food deterioration by molds, it is best to put food in impermeable containers or wrap with plastic sheet, aluminium foil, etc.; contaminated foods should be discarded, even if no mold spores are seen the characteristic mold odor is smelled
Clean refrigerator more times a year
Empty and clean the garbage can carefully
Reduce collections of standing water and water leakage
In the bathroom
No bath mat or the like
Apply a window fan to eliminate the steam formed while bathing or showering with hot water
Clean and dry shower curtains, furniture drawers, cabinet inside, and wash-basin, bathtub, shower tubing, etc. using bleach or vinegar as above
Change shower curtains when mold growth is noted
Caulk any possible crack (useful also as anti-cockroach measure)
Bedroom(s)
Eliminate or reduce dust
Remove wall-to-wall or felt carpeting, carpets, bedside rugs, wallpaper if feasible or spray with available fungicides
Mattress and pillows: act as for Der p (bedding is an ideal mold niche)
Condensation on window pane is cause of humidity and favors fungal growth
Hangings, books, upholstered furniture, stuffed toys and the like should be removed
Put shoes and boots back in the closet after an adequate drying
Wood room, store rooms, etc.
Do not allow mold-allergic child in these rooms
Low-wattage bulb lamps may prevent fungal growth
Basements, cellar, garage etc.
Mold-allergic children should not live in basements
Install a dehumidifier
Eliminate water infiltrations or leakage
Miscellaneous
Replace wall-to-wall carpeting with plastic materials
Maintain rooms dust-free, eliminate unnecessary objects that may become mold niches
Solid brick outer walls can be sprayed with fungicide agents
Outdoor activity
Besides what we have mentioned above, greenhouse, antique and embalmer shops, sleeping-bag, sauna, holiday
Dwelling, auto air-conditioners, and hotel rooms are areas where mold reigns

Data from [42, 330, 426, 479].

Table 24.25. Foods to be eliminated in the yeast-sensitive patient

Foods containing yeast as an additive ingredient in preparations
All preparations containing mushrooms and/or yeast extracts
Canned foods not consumed quickly
Breads
Cake and cake mixes
Cookies
Crackers
Foods or substances containing yeast or yeast-like substances because of their manufacture or preparation
Buttermilk
Citric acid, almost always a yeast derivative
Citrus fruit juices not home-squeezed, whether frozen or canned
Dried fruits of all types
Fermented beverages of all types, whether bottled or canned
Fermented cheeses of all types
Malted products of all types
Monosodium glutamate, a potential yeast derivative
Sour cream
Sour milk
Soy sauces
Truffles
Yoghurt
Foods or substances containing vinegar of all types
Apple, pear, grape and distilled, used as such or in the following foods:
Baby cereals
Catsup
Chili
Condiments
French dressings
Green olives
Horseradish
Mayonnaise
Mince pie
Peppers
Pickled beets
Pickles
Salad dressing
Sauerkraut
Tomato sauce
Flour enriched with vitamins from yeast
Hamburger buns
Hot dog buns
Milk, fortified with vitamins
Meat, fish or fowl, fried in cracker crumbs
Pastries
Pretzels
Meat rollé, homemade or canned
Salt-rising bread
Yeast-containing medications
Vitamin B_{12} and all vitamin B_{12}-containing medications
Moreover
All foods stored in the refrigerator for several days

Data from [295].

Pets

Preventive Measures

We are convinced that if the pet is already part of the family, and thus of the child's emotional world (Fig. 4.17), complete removal of the animal is possible only in exceptional cases, as demonstrated by the fact that 36% of asthmatic children complained that they were not allowed to play with pets [416]. If anyone considers these precautions to be excessive in any way, we recall that prevention is always better than taking steps too late: a cat in the house of a newborn or nursling means sensitization by the age of 1 year [9], associated with high IgE titers [311], above all due to the spread of Fel d 1 (Fig. 24.10). An epidemiological study has shown that cats were less frequently kept in families with parental asthma, AR, or pet or pollen allergy (3.5%–5.8%) than in families without FHA (10.8%–11.8%). Dogs were less common in families with (3.3%) than in families without (5.9%) parental AD. Cat ownership decreased from birth to 2 years of age, especially in families with FHA [3].

Although the association between pet ownership in childhood and subsequent allergic disease is controversial [273], the hygiene hypothesis even reversing previous knowledge [33, 41, 182, 314, 325, 343, 353, 489], the main preventive recommendations are as follows [91, 106]:

- Remove the pet from the house or keep it confined away from the child, taking the necessary precautions, given the psychological impact this can have on the child [395].

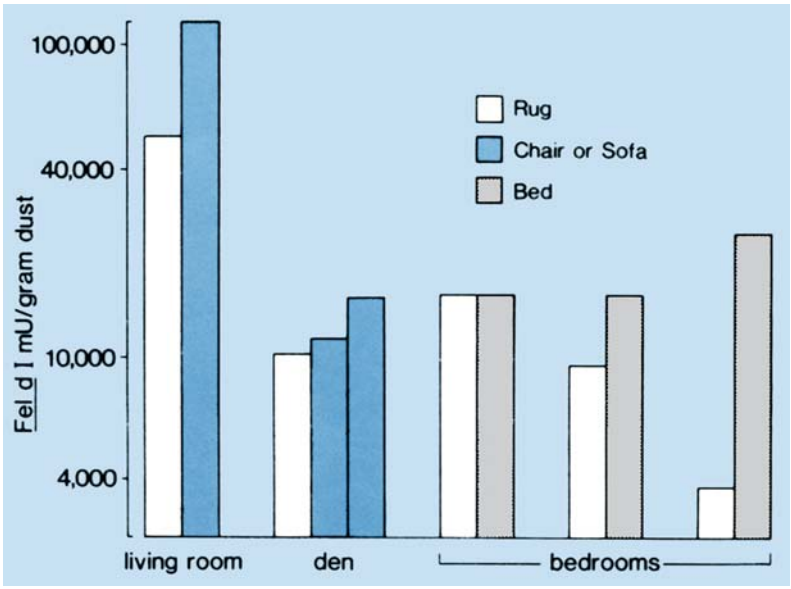

Fig. 24.10. Levels of Fel d 1 from various sites in different rooms of a house. Levels in the living room were five to ten times higher than those in the cat den

• Clean the house thoroughly after the pet has been removed: pet allergens can persist at length in furniture, upholstery, carpets and litters.
• If a cat is involved and the above measures are difficult to carry out, it is fundamental to:
– Bathe the cat as thoroughly and as often as possible: regularly bathing a cat on a weekly basis reduces Fel d 1 levels from 30–90 ng/m^3 to ≤7 ng/m^3 or less, a substantial difference that helps keep BHR away [106]. Other authors feel this is ineffective, on a par with other treatments [233]: because Fel d 1 is in the saliva, obviously a cat spreads it on its coat when it licks itself clean. Therefore, bathing it with cotton balls soaked with distilled or deionized water helps removing the allergens.
– Brushing cats and dogs helps in removing HDMs, which use skin waste as food, abundant in all furry animals.
– Dust or clean home walls thoroughly, allergens concentrate there in 97% of cases, unlike Der p 1 [474].
– Eliminate everything the animal seems to prefer – mattresses, pillows and so on – clearing rugs and upholstered furniture from the room where the pet spends most of its time, also removing a pet's favorite furniture, fixtures and clothing from other rooms as well.
– Air out the home: Fel d 1 levels drop with a ventilation of 0.5 ach, although this does not affect Can f 1 concentrations [301].
– Use a vacuum cleaner only if necessary: as we noted, filters, microfilters and special HEPA filters are not impermeable to allergens [119, 302]. This could be due to the continuous outside allergen supply and not to draperies and walls included in the daily cleaning routine [302].
– Treat rugs, wall-to-wall carpeting and upholstery with tannic acid spray, which is effective against Fel d 1 and Can f 1 [302]. This treatment lasts an average of 1–2 weeks [302, 413, 475] (Figs. 24.11, 24.12 [302]) and can be increased to intervals of <1 week, but other results suggest that only radical measures are effective [475]. It should be noted that while tannic acid is not toxic if used as indicated here, it stains fabrics and carpets [395].
• Do not let the child visit houses with cats, even if the pet is absent or if contact is improbable. If visiting the home is necessary, a pretreatment may be advisable using cromolyn and bronchodilators, or by having the child *wear a filter mask* (Chap. 7).
• In particular cases when epidermal feathers can be left on the pet-owners' clothing, avoid direct contact between the allergic child and these persons [124].
• After visiting houses or other places where cats or dogs are present, at home undress in the room furthest from the child's bedroom, keeping the door closed and the windows open, energetically brushing one's own clothing. For children who attend daycare settings, this can be avoided by changing clothes in special *exchange areas* [304].
• There must not be any animal products in the child's room such as furs, quilts, sleeping bags, skins or pelts, etc. [479].

If these measures do not yield the desired effect, it is clear that this is due to indirect contact [302] such as contamination by visitors and even by inattentive family members [124]: for example, at schools and daycare settings, high levels of Fel d 1 and Can f 1 have been detected, brought in on clothing of classmates, teachers and personnel who own pets. They were found above all on desks, but also on the floor [300, 302, 304], occurring 11-fold more frequently on wall-to-wall carpeting than on uncarpeted ones [304]. RAST inhibition recorded the levels of these allergens, particularly Fel d 1, which can sensitize children and induce perennial symptoms in already asthmatic children [119].

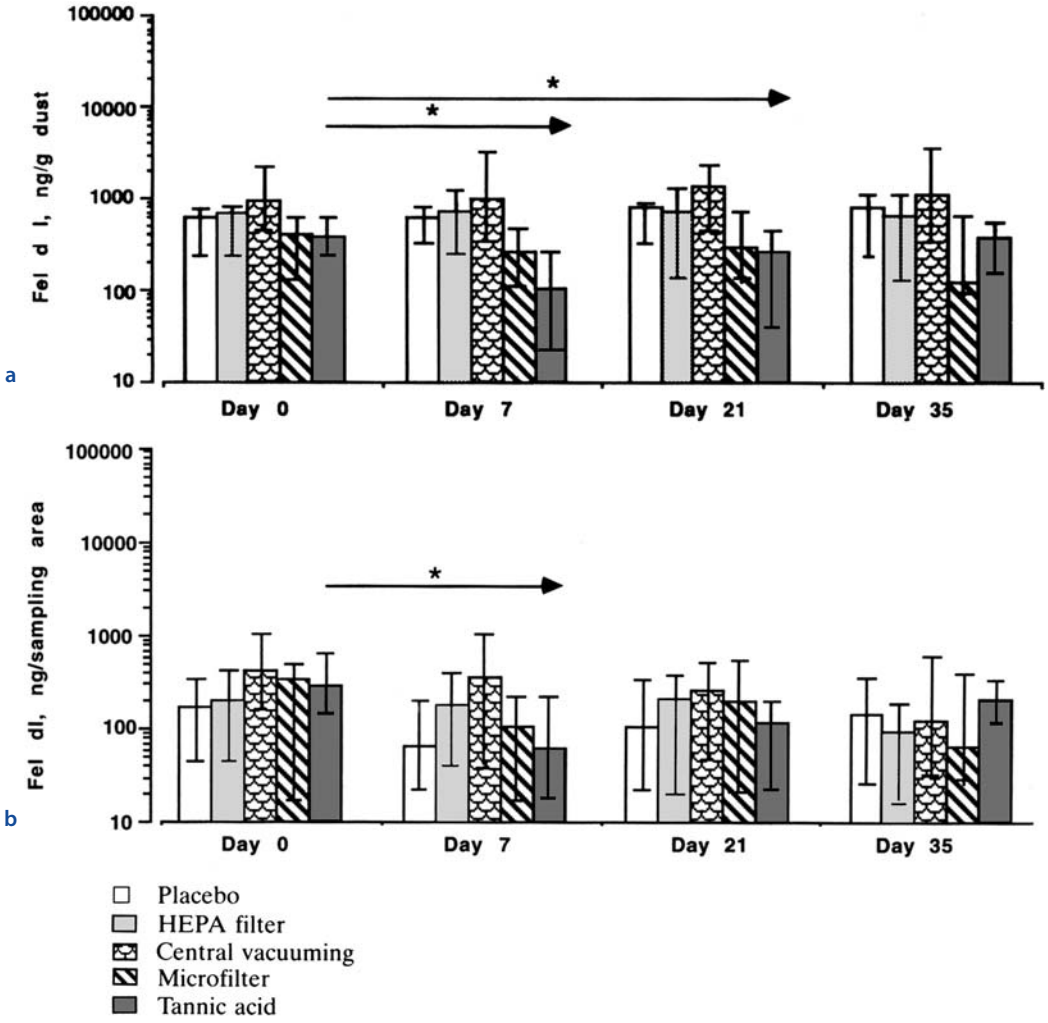

Fig. 24.11 a,b. Cleaning effects on Fel d 1. Influence of different cleaning techniques on **a** concentration of dust and **b** total amount/sampling area of Fel d in dust from living rooms. The *arrow* indicates significant decrease compared to placebo

To summarize, we emphasize that [479]:

- Animal hair has a high allergenic power.
- Current exposure to pets in children in prevention brings about a 43.1 risk factor for cat and a 34.5 for dog [12]. Among children with asthma 3.8% were sensitized to cat and 0.6% to dog [17]. All subjects with respiratory allergy who live in contact with pets can easily become sensitized: 30% of children with asthma/AR have SPTs positive for dog and cat dander [301].
- Being allergic to one species generally means being allergic to all species.
- Even animals not shedding hair can trigger allergy, since the allergens are in the fur as well as the dander.
- Ambient dust, which can easily be conveyed by pets, increases exposure of young patients.
- The more frequent and intense contacts with the animal, the faster sensitization occurs.
- Finding Fel d 1 in many public places (Chap. 4) multiplies the preventative measures.
- Fel d 1 are universally present in UK homes. Levels that have been associated with an increased risk of allergic sensitization were found even in homes without pets [8].
- Given the growing social importance of daycare facilities, extremely low levels of allergenicity can be achieved with a frequent scheduled cleaning [115].

The results of various studies are divergent: 20 weeks following the pet departure, 70% of houses had allergen levels in carpeting equivalent to those of houses without cats [475], or 100% after about 3 years [473], or 75% after 2–6 years [450]. However, it takes >5 years to normalize levels in mattresses [424].

Hymenoptera

Prevention is based above all on measures to avoid places and circumstances that attract these insects.

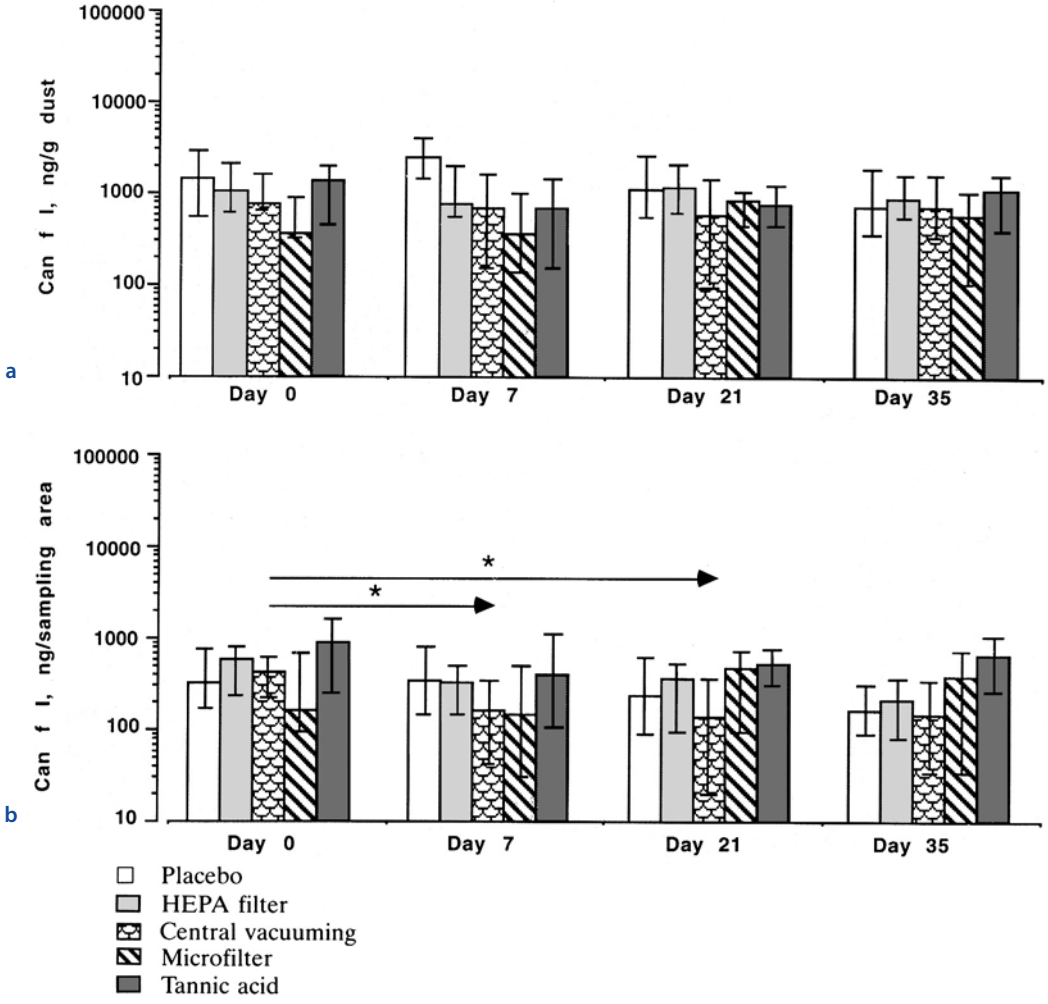

Fig. 24.12 a,b. Cleaning effects on Can f 1. Influence of different cleaning techniques on **a** concentration of dust and **b** total amount/sampling area of Can f in dust from living rooms. The *arrow* indicates significant decrease compared to placebo

Preventive Measures [318, 443]

- If you notice an insect near you, *do not make any sudden movements or try to swat it away*. The insect generally does not sting unless it is stimulated. If you are not wearing a cap, slowly cover your head with your arms or clothing.
- In case of bee stings, try to remove the stinger quickly to prevent anaphylaxis in susceptible subjects. The type of instrument used is not important and *speed is imperative* [443]: wasting time to find the most suitable tool allows the venom to spread [443] (Chap. 17).
- If you are stung near a beehive, move away from it as quickly as possible, because *an alarm pheromone is secreted at the base of the stinger* and, perceived by other worker bees, it helps them locate the victim and trigger their aggressiveness [443].
- When travelling by car, check the inside of the car to be sure there are no insects and keep the windows closed.
- On bicycles or motorcycles, wear gloves, coveralls and a safety helmet.
- When outdoors, particularly during outings, when camping and picnicking, etc., *cover yourself completely,* wearing socks, a long-sleeved shirt, closed shoes, and possibly with gloves and a hat or cap. Do not wear loose clothes, as insects can get trapped in them.
- Avoid wearing *clothes with floral motifs or bright colors,* favoring neutral tones like white, green, khaki, etc.
- Do not wear *perfume and scents* in the broadest sense of the term: scented hair gel, hair lotions and aftershave, shampoo or hairspray, cosmetics, cologne, heavily scented suntan lotion, etc.
- Do not stay *in the sun if you are wet or sweaty* or have rubbed tanning oil on your body.

- When playing or taking walks in the country, do not move rocks, tree trunks or branches lying on the ground with your hands or feet: they often hold wasp nests.
- Likewise, do not go near open flowers, very ripe fruit and/or dry trunks that have fallen from trees, bushes, stacks of wood, bundles of branches.
- In these situations, absolutely *avoid walking barefoot* (many insects are on the ground).
- When eating outdoors, *keep everything closed or covered*. Avoid bringing sweets or ice cream, opening containers with sweetened beverages, leaving food or waste out: they always attract bees and wasps.
- Stay away from fruit stands, as well as mangers or other places where animals are fed.
- During outdoor activities, especially in HR areas or places where trash has collected, consider wearing protective masks, boots and gloves in addition to full-length clothing.
- Hymenoptera are also attracted by perspiration and by the CO_2 produced by hyperventilation during athletic activities.
- Always keep bedroom windows closed or mount insect screens on them.
- Keep trashcans closed.
- If there are nests or beehives next to your home or office, call specialized personnel to remove them.
- Always wear *an ID bracelet* or tag, as recommended; purchase a *cellular phone* if possible.
- Always have an emergency kit with you containing self-injectable epinephrine drugs (that have not expired) and instructions on *emergency treatment*.
- Consult your pediatrician even after performing all the above measures.
- If the history of children with multiple stings of the same insect shows an essentially favorable prognosis, it is suggested to submit only children with severe reactions to SIT [318].

With regard to other insects (Tables 17.11–17.13), attention must be paid above all to *mosquitoes*: the main preventive measure is to avoid overwatering the plants on terraces and balconies and in the yard. Water should not puddle, as this promotes breeding. Similar measures are recommended for the *tiger mosquito*, which lays its eggs not only in stagnant water but also in gutters, manholes and puddles in general. The *fire ant* is found in mounds composed of fresh soil that may be at least several inches high and may extend 30–60 cm in diameter. These ants are very aggressive, particularly if their mounds are disturbed. With regard to available defense systems, children ≤2–3 years should not sleep in rooms where mosquito repellents have been used, given that repeated exposure can turn into sensitization: an *insect screen is safer*. Mosquitoes are also attracted by certain types of perspiration and have receptors for CO_2, through which they identify their prey even 15 m away. It seems that these subjects get bitten more frequently, as do women who use cosmetics containing stearic acid.

Birds

The only prevention is removing them. However, antigens can persist in the home even >18 months, making it necessary that children change bedrooms or, temporarily, even their home, depending on the clinical condition [95].

Horses

Horse allergy can also extend to mules, donkeys and similar animals. Removing the animal responsible for the allergy is imperative. When sensitization is underway this is of clinical importance.

Rodents

Mice and rats have numerous cross-reactive allergens (Table 1.73). Likewise, rabbits, small mice, hamsters and guinea pigs must be removed [413].

Animal fur and/or feathers reviewed so far decompose into a very fine powder that, if inhaled, can trigger asthmatic manifestations in sensitive children. In addition, the dust they generate remains for long periods, thereby prolonging contact.

Cockroaches

Allergen levels are generally low in cold regions with dry winters, prevailing instead in homes with poor ventilation and increased humidity with a 0.6% sensitivity in children in prevention [17, 301]. Cockroach allergen was associated with increased risk for wheezing [258]. Other preventive measures are part of normal cleaning routines [479].

- Keep the *kitchen scrupulously clean* and avoid leaving out leftover food and dirty dishes.
- Keep *food carefully preserved* and protected, or in well-sealed plastic, glass or metal containers.
- Use *specific waste containers.*
- *Caulk holes and cracks* in the walls near faucets, water pipes, bathroom fixtures, etc.
- *Change the seals* on leaky faucets and get rid of humidity on the pipes.
- *Improve ventilation* and remove damp areas.
- Every day, sweep the kitchen and dining room, or any other rooms where food is eaten.
- Use insecticides *monthly.*

After cockroach extermination, it takes 6 months for cockroach allergen levels to decrease by 70%–90%, thus leaving substantial levels of residual allergen [479].

Environmental Pollutants and Irritants

Various factors act as irritants to the air passages and can provoke asthma or aggravate it in subjects with BHR.

1. ETS

A *total ban on smoking* in the house of asthmatic children – and wherever they are – is a vital environmental measure. This measure, which is fundamental not only for prophylaxis but also for therapy, absolutely requires the collaboration of parents, the whole family and any smokers who visit the house of any allergic child. In fact, friends and relatives rarely refrain from smoking when they come to visit, nor are they asked not to smoke, even when the parents are motivated and attentive not to expose their children to ETS. Above all during cold weather, when the windows are kept shut for extended periods of time and asthmatic children spend nearly all day in the house, this creates a highly negative environment for their airways. Anyone who cannot forgo smoking should leave the child's home, closing the door. Many of the misleading methods that are commonly adopted, such as smoking fewer cigarettes, opening the windows or turning on a fan, as well as smoking in another room, out on the balcony or outside the front door, are completely useless and equally pathogenic as far as exposure is concerned. As has clearly been demonstrated, the child's cotinine levels do not change with any of these actions as compared to controls adopting none at all [468]. Maternal smoke during pregnancy has effects *in utero* and postpartum, predisposing the child for developing asthma; see Table 4.25 on pediatric morbidity associated with household smoking. Risk factors for persistent sensitization compared with those for transient early sensitization were maternal smoking during pregnancy, which significantly increased the risk for persistent sensitization (OR, 2.27; 95% CI, 1.14–4.52), also a significant risk factor for asthma at school age (OR, 2.46; 95% CI, 1.28–4.73) [205]. NHANES III stresses that breast-feeding might protect children against ETS-related asthma and recurrent wheeze by promoting postnatal Th2/Th1 switching [87]. However, children were less likely to have been breast-fed if their mothers smoked while pregnant (40.9%) or they lived in households with one or more smokers (36.8%) [87].

Preventive Measures. The asthmatic child must live in ETS-free rooms and/or very far from those visited regularly by smokers: in all restaurants and public buildings, there must be non-smoking areas. Likewise, smoking must be forbidden in cars [252], public transport, trains, ships, tourist buses, airplanes, etc. Smoking a single cigarette produces about 150 g of PM_{10} (particulate matters <10 µm). In a room of 100 m^3, PM_{10} reaches 1,500 when the PM_{10} level to block traffic is 40 µg/m^3/24 h [208]. Prevention becomes even more meaningful for older children and teenagers, and it is not comforting to note that younger generations are taking up smoking (Fig. 4.25). Paradoxically, however, they are also most exposed to ETS. As a specific preventive measure, proposals have been made to tax tobacco companies at twice the revenues generated by sales to young people under the age of 18 [153]. The younger generation is the one that, in fact, is targeted by tobacco companies to recruit new smokers, and the industry has even been accused of increasing cigarette nicotine content to bolster its ability to create a dependency [351]: once a neophyte becomes a slave to tobacco, each one is expected to generate a daily revenue income for at least 20 years [153]. Given the advertising effects, bolstered by widespread failure to remove this advertising from the areas immediately around schools, viewed by these companies as a highly profitable long-term investment [164], any company that prefers to avoid gearing advertising messages to minors and that modifies its marketing and distribution system to reduce tobacco consumption in the pediatric range most at risk would be exempt from this hypothetical tax [153]. An important study indicates that smoking prevalence in New Hampshire declined among middle school students during 2000–2001 and among high school students during 1995–2001 [291].

As we have repeatedly insisted, the actions of pediatricians and teachers are vitally important: it is very helpful for them to explain how important it is for children's health to ban all smoking at home. At times, they will have to use different methods to repeat the imperative measures for preventing infantile asthma, but the time that pediatricians devote to informing the family about the damage caused by ETS will indubitably be rewarded by the therapeutic success that is achieved [444]. In various countries, the number of smoking physicians is as high as 50%–56%: in England, following incisive campaigns it dropped from a 65% rate in 1950 to the current 5% figure [140]. Moreover, parents of at-risk infants and of asthmatic children, as well as older children and teenagers, must be informed about the pathogenic role of smoking. Despite the PREVASC intervention program focussed on avoidance of prenatal and postnatal passive smoking in children at high risk of developing asthma, no difference was found in the intervention compared with the control group concerning the exposure to tobacco smoke except maternal postnatal smoking [242, 376]. Therefore, family smoking of any kind should be strongly discouraged, helping them quit [140]. The action must be extended to urge government agencies *to reinforce nonsmoking measures and ensure that they are enforced* and *to introduce information on the relationship between smoking and disease in university pediatrics courses* [140]. Especially now, since Florentine researches have created the GMO tobacco, with accelerated flowering and bean multiplication (Press report, Feb. 27, 2007).

2. Environmental Pollutants

Environmental pollutants in the air act as adjuvants, irritating the airways, with negative effects on health.

Given the magnitude of the observed effects, a study on 1,759 children has shown that current levels of air pollution have chronic effects on lung development in children from the age of 10 to 18 years. Similar associations were significant in nonasthmatic and nonsmoking children [144]. Prevention is an indispensable measure because exposure at 19–36 months is a significantly higher risk factor (OR, 4.1) than exposure in general [394].

Preventive Measures. *Inside* the home of the asthmatic child, volatile substances with a strong and pungent odor (perfume, toiletry products, scented cosmetics, talcum powder, insecticide spray, cooking fumes, household detergents, cleaning products, room fresheners, fresh dyes and paints, etc.) [230] are to be avoided above all, in addition to other ascertained risk factors such as a humidifier in the child's room and electric heaters [206].

Outside it is more difficult to get away from exhaust fumes, atmospheric dust, industrial smog, SO_2, O_2, NO_2 (Table 2.26) and electrosmog.

- With regard to O_2, farseeing administrators advise parents against taking small children outside during hours that are most at risk based on sample measurements, generally in the afternoon. Therefore, it seems more responsible and sensible to plan morning activities.
- Pediatricians should inform parents of the risks connected with O_2 and, if necessary, recommend the use of special masks [234], suggesting that parents carry their children in their arms if taller strollers are not available, while awaiting more specific measures. The return of older children should be planned so that they avoid benzene in peak traffic hours.

3. Pesticides and Toxins

Infants and children are far more exposed to these products than adults, considering that, by weight, they drink more water, eat more food and breathe more air than adults do. For example, in their first 6 months, nurslings drink three- to fourfold more water kg, children aged 1–6 eat up to twice as much food kg than the average adult, and a resting infant inhales twice as much air as an adult. Considering that infants will put everything in their mouth and play on the floor, this increases their ingestion and/or inhalation of toxins found in dust or on the ground, as well as pesticide and pollutant fumes. The average daily dose (ADD) is drawn from studies on test animals and does not consider pesticide interactions once they are introduced into the body. Furthermore, the calculations are calibrated on adult weight and not on infant and child weight, who thus face greater exposure to pesticides and toxic products (Chap. 4). This is aggravated in France and Italy because they rank high in pesticide consumption (Fig. 10.5). A 1996 study by the Italian Health Ministry estimated the incidence of pesticide residues in fruit and vegetable products, and while it is true that the irregular samples amounted to 2.1%, only 64.5% of the samples were totally residue-free Table 24.26 lists the *foods potentially containing dioxin.*

Table 24.26. Foods potentially containing dioxin

Foods	%
Fish	34
Pork meat	21
Dairy products	20
Eggs	9
Beef, cow's milk, poultry	14[a]

According to WHO, the tolerable dioxin threshold is 1–4 pg/kg/die; the allowed exposure per day is 2 pg/kg.
Source: Istituto Superiore di Sanità, Rome.
[a] Shared with water, air and soil.

Additional Measures. We repeatedly recommend rinsing and rubbing fruit and vegetables under cold or lukewarm running water, if possible with the addition of salt or $NaHCO_2$, then peeling fruit and removing the outer leaves of vegetables. Although most phytomedicines penetrate inside fruit and vegetables, the Environmental Protection Agency of California deems these measures useful. We have warned that a great deal of fruit, including pears, due to prolonged storage far from sunny places and the use of *gas still defined as natural,* can lose their natural characteristics. We already noted that the common use of adding citrus peel to beverages must be given up. Foods treated with ionizing radiation to destroy or deactivate microorganisms may raise problems of nutritional values: the European Union limits this radiation, for example, to potatoes, onions and garlic.

4. Smoke from Gas Heaters, Gas and Wood Stoves and Fireplaces

This type of smoke is listed as a 63.8 risk factor [12]: while it does not fall into the pathogenesis of LRTIs, there is a substantial association with asthma [379]. A meta-analysis ascertained a mean 86% PFT reduction in 40,179 children aged 5–15 exposed to gas from cooking and heating [234].

5. Other Measures

For other predisposing factors, we have cited in several chapters the necessary preventive recommendations (exercise, emotional factors, GER, nocturnal asthma, cough-variant asthma, etc.). Appropriate recommendations for VRIs and sinusitis can be found in the respective chapters.

Table 24.27. Prevention of allergic reactions to drugs

Before prescribing medications
Consider whether
It is definitely necessary
There were no prior adverse reactions to the drug
The child has an increased risk of allergic reactions
Evaluate the option of prophylaxis
During treatment
Method of drug administration
Parent- or child-appropriate information of potential reactions
Oral administration as the safest route
Prescription of concurrent antiallergic drugs
Avoidance of intermittent or multiple therapy
Strict child observation during injection therapy
Facility in place to handle emergency
Potential desensitization
After treatment
Early prediction of the onset of allergic reactions

Data from [203].

6. Drugs and Additives

Among drugs provoking or exacerbating bronchospasm, usually with very severe and difficult-to-control reactions, the most often cited are the drugs listed in Table 19.24. Pediatricians must know whether the drug possibly prescribed can trigger undesired reactions, without waiting for the onset of symptoms following drug intake [203]. A great deal of caution should be exercised in administering antibiotics, antipyretic and anti-inflammatory drugs to asthmatic children [203]. Exposure to antibiotics *in utero* is a potentially important risk factor in the development of asthma and AD in a dose-related manner [282]. Moreover, kanamycin use during infancy promotes a shift in the Th1/Th2 balance towards a Th2-dominant immunity [406]. The indiscriminate use of antibiotics for veterinary and human purposes is the main cause of the appearance of antibiotic resistance in organisms. Adequate probiotic intervention after antibiotic treatment may prevent the Th2-shifted immunity induced by neonatal antibiotic use [406]. However, other evidence finds antibiotic use not associated with a greater prevalence of allergy and asthma [74, 204]. Table 24.27 [203] lists suggestions for prescribing drugs correctly and responding to general prevention criteria.

The type of foods eaten has changed drastically with the introduction of new industrial products with numerous additives, which are detected [203]:

- In all foods unless otherwise specifically indicated: foremost among these are monosodium glutamate, sodium metabisulfite and sodium benzoate.
- In alcoholic beverages including wine and beer, which can contain various excipients, yeasts and other grape components, and metabisulfites, used to stop the wine fermentation process.
- In drugs: again metabisulfites, which can be added to certain bronchodilators, aerosol or nebulizing preparations, and as dyes in oral preparations.
- A US study recorded that 72.5% of 102 oral preparations failed to specify the excipients they contained (natural and synthetic dyes, preservatives, flavorings, sweeteners); sodium benzoate and parabens were introduced, respectively, in 41.2% and 26.5% of cases (Chap. 10). Thus even fresh food items differ in many respects from those available only a few decades ago.

7. Contact Allergens (Tables 8.7, 8.8)

Parents of children allergic to latex must be given a list of all items potentially made of latex (Tables 8.10–8.12), so that they avoid their use. Doctors should be informed of this risk prior to any operation. Parents of sensitized children should be given a list of fruits cross-reacting with natural rubber (Table 8.14). Latex is also considered a hidden allergen: atopic subjects experience episodes resembling anaphylaxis *by eating food prepared and/or served by people wearing latex gloves.* It is impossible to record all possible functions of rubber gloves, some of which are difficult to imagine. For example, they are worn to make metal mesh or to join sheets of wood, which are contained in certain items [57]. Other preventive recommendations include wearing an ID bracelet at all times, always carrying an Epi-pen autoinjector and notifying family members, friends and teachers that epinephrine is required immediately in case of anaphylaxis, and carefully examining items and/or purchases to be sure that they are latex-free [57]. Another material to be avoided is nickel, found in several metal items and common foods. In addition to these items, low-karat gold, silver, white gold and more may contain Ni. For cooking purposes, it is best to use aluminium or teflon-coated pots and pans. For an elimination diet, follow Table 8.5.

Dietary Factors

Unmasking food allergens concealed in the most unobtrusive packages is difficult but vitally important: we are not referring solely to hidden sources of CM (Table 9.34) and numerous other foods (Appendix 9.10), but also the possibility that allergen is hidden in restaurant food, sandwiches, pizza and so on, or in prepackaged preparations whose ingredients fail to list the offending food, triggering severe reactions (Tables 20.5, 20.6), also with the consent of current laws [171]. Therefore, *pay attention when reading package labels*, with the help of Ap-

pendix 9.10: the wording depends on the professionalism of the production industry because by law, they are often considered natural flavorings, vegetable oils or the like [467]. We therefore suggest that labeling be improved with *plain-English terminology and allergen warnings* and parents be meticulously educated about deciphering labels. We recall six cases of fatal anaphylaxis and seven near-fatal cases in 13 children and teenagers aged 2–17 years who had various allergic diseases. Sampson et al reported (Chap. 20) that *no parent was aware* that allergens triggering fatal or nonfatal anaphylactic shock are found in common foods such as sweets, cookies, candy, cereals, sandwiches, and hamburgers. Moreover, precautions are not always successful: although five patients allergic to peanuts carefully avoided eating them, they nevertheless presented acute anaphylaxis (fatal in two cases) because foods served at restaurants contained hidden peanuts, or because the appearance deceived the customer and even the waiter. Severe reactions have also occurred in children with CMA because of the unspecified presence of *CM allergens in foods the producers guarantied were CM-free* [141, 150].

The EU has recently banned the usual jargon of the labels, thus no more casein, ovalbumin, but CM and egg proteins. Moreover, even the unknown ingredients contained in mg doses should be listed, and we hope also the food additives allowed in infant foods.

Four babies aged 4–13 months have been reported with peanut allergy provoked by *peanut oil* contained in the CM formula fed to them and in 11 of 45 (24.5%) of the formulas examined [293]. The authors have ascertained that peanut oil constituted 67%–80% of the total lipids present in two formulas, and thus ingestion amounted to 7 g/day [293]. In England, three of seven of the leading producers of formulas for nursing infants use this oil as a vegetable oil, and the same occurs in vitamin preparations [138]. We have ascertained that in CM formulas made for healthy nurslings, part of the animal fats are replaced with vegetable oils (peanut, sunflower, corn, soy, MCT oils, etc.). Therefore, it would be appropriate for producers to specify if the formulas and the foods they market for allergic children contain them. Peanut oil is an ingredient of various creams and oils used for children as well as of other products for topical application, most often for patients with AD [111]. Recent data of a birth-cohort study showed a significant independent relation of peanut allergy with the use of skin preparations containing peanut oil (OR, 6.8) [247]. The common use of prescribed and over-the-counter preparations containing refined peanut oil, applied to the skin of peanut-sensitized infants may be an important cause of cutaneous sensitization [247]. Heated refined oil would not cause allergic reactions [247]; however, excessive heating may enhance the allergenicity of the residual protein [270]. Peanut oil is also found in certain vitamin D preparations: a cohort of entrants aged 4–35 months who took daily drops containing this oil had positive SPTs to peanuts [111]: OR was high if the product was administered both in the neonatal period (5.47) and later (4.82) [111]. It has been demonstrated that if peanuts are cold-pressed, the oil derived can contain up to 3.3 μg/ml of protein, which can trigger anaphylactic reactions in sensitized subjects [187], who, as mentioned above, can respond to SPTs at a dilution of $1:10^7$. Therefore it is healthier to use olive oil. Unfortunately, it can get blended with hazelnut oil, which shares cross-reactions with walnuts (Table 9.9). Another important chapter covers non-food contaminants such as additives, bacteria, mycetes and excipients potentially added to foods, which can even provoke anaphylactic reactions (Chap. 20). Peanut allergen (Ara h 1) was detected in chocolate-containing food products [442].

A 10-month-old boy with severe AD was found to react to soy oil and was treated with an HF and an amino acid formula (AAF), which were ineffective. The AAF contained a soy lipidic emulsion (in addition to βLG; Appendix 9.4) and was replaced with another AAF; complete recovery was observed 6 weeks later [294]. *Soy lecithin* was positive in an oral challenge test (OCT) in a peanut-sensitive 4-year-old boy; the first case of *egg lecithin* also positive in an OCT occurred in a 15-month old girl [315]. A single reaction to soy lecithin diffused worldwide is a rarity.

Given that onset of atopic disease is usually in early childhood (Table 5.5), often acquiring severe traits, we can understand the importance of scrupulously following dietary and environmental measures. As we have emphasized, establishing avoidance measures should not have the effect of an exaggerated protection of the allergic child, nor should the family feel to be in a constant state of siege, with all the well-known repercussions. The request is that the various parties involved establish *the legal obligation to specify every ingredient in a way that is also understandable to any non-expert* (including the ingredients that are undeclared because they are natural foods). Ambiguous terms are listed in Appendix 9.2. We have noted that HF composition should be listed on the package. Parents cannot always rely on the completeness and accuracy of the ingredient declarations [411]. Accurate interpretation by parents of FA children of the food labels ranged from just 7% for CM to 22% for soy, 54% for peanut, 88% for wheat, and 93% for egg [216]. It is an indispensable intervention – also on a legislative level – to remove CM, eggs and so on from the list of natural foods, which consequently are *not mentioned on food packages.* This provision should be extended to all the examples listed in Appendix 9.10. However, in the greater part of Europe, an ingredient does not even have to appear on a label if it constitutes <25% of the product. As a second line of defense, restaurants, pizzerias, ice cream shops, bakeries and other foodservice operators could be requested to display a list of ingredients at their facilities, and/or to set up a toll-free number to be consulted in case of need

(difficult terminology, possible cross-reactions, etc.). When labels were studied for accuracy by comparison of raw ingredients with finished product labels, 25% of 85 establishments, including bakeries and candy and ice cream manufacturing facilities were found to have omitted raw ingredients, including peanuts and tree nuts, from the final labels [136]. *Pediatric allergy sufferers appear to be a subpopulation of children not always escorted by an adult able to use Epi-Pen.*

Recently, the US has recognized that food recalls can play a role in preventing or reducing the number of allergic reactions that may occur after a product containing an undeclared allergen has been introduced on the market. Three principal factors contributed to the presence of undeclared allergens in the recalled products: ingredient-statement omissions and errors (51% of all recalled products), manufacturing equipment cross-contact (40%), and errors by ingredient suppliers or manufacturing firm employees (5%). Significantly, consumers were the party most often responsible for identifying that an undeclared allergen was present in a product (56% of recalled products) [441]. Unfortunately, these numbers are still likely to be a significant underestimation of the true problem because there are many allergens that are less common but are important for children allergic to those foods [472].

Mad Cow Disease. Mad cow disease (MCD) or bovine spongiform encephalopathy or BSE, or acquired human prion disease, a variant Creutzfeldt-Jakob Disease (vCJD), the human equivalent of BSE, was first reported in 1996; the youngest patient developed symptoms at 16 years of age. Among children there were two fatal cases of definite vCJD and one case of probable vCJD; all reported in 1999. One girl was 12 years old at onset, the youngest ever case of vCJD [440]. Although the nature of the responsible agent of BSE/CJD is uncertain, it is characterized by the pathognomic *accumulation, within the central nervous system of the infected individual, of a normal protein from the host organism,* the PrP (prion protein) (CD230). Differences are noted between the PrP isolated from normal individuals (PrP-c) and PrP isolated from infected individuals (PrP-res) [117]. Apart from neurosurgical procedures, human exposure to prions usually occurs peripherally, especially by ingestion or inadvertent inoculation [68]. Postexposure prophylaxis against transmissible BSE is a necessary step. The absence of an immune response to prions may be related to the fact that these prions lack in nucleic acids. To investigate this, healthy mice were inoculated unmethylated deoxycytidyl-deoxyguanosin dinucleotide (CpG) oligodeoxynucleotides (ODNs). This postexposure prophylaxis resulted in longer survival, and even longer survival after repeated injections [386]. CpG ODNs have been shown to activate both innate and acquired immune responses via a signaling pathway involving toll-like receptor 9 (TLR 9) [419]. CpG-A ODNs induce plasmacytoid dendritic cells (DCs) to secrete very high levels of IFN-α, which secondarily induce purified monocytes to secrete high levels of the Th1-promoting chemokine IFN-γ-inducible protein-10 (IP10), thus creating a Th1-like environment [26]. Development of improved postexposure prophylaxis is urgently needed, given the unknown prevalence of prion exposure associated with the BSE outbreak [68].

Transgenic Foods. In 1998, GMOs gained a world role when Dr. Pusztai was fired from his post when his research discovered that rats fed genetically engineered potatoes experienced jejunal lesions [127]; thus he defined the potatoes, without formality, as *Frankenstein food*. But criticizing reports of research, as the Royal Society did with the Pusztai data, before they were reviewed and properly published, will only intensify *public skepticism about GMOs* [194]. Perhaps the speculation that the lectin GNA (*Galanthus nivalis* agglutinin) caused jejunal crypt hyperplasia is not wholly justified [299]. Possibly the use of transgenic plants expressing GNA to protect food plants highlights that terminal mannose moieties interacting with GNA are synthesized by human glycosylation pathways in white cells [131].

We already examined GMOs in Chap. 1 (Tables 1.78, 1.79 and Fig. 1.81), important above all for the identification and labeling of these GMOs. Currently, about 100 million acres are planted with genetically modified crops, with 72% in the US, 17% in Argentina and 10% in Canada. Considering these data, we can see that they are plants that have been genetically modified to yield products with a longer shelf life but that they lose their natural flavor. Nevertheless, can allergic subjects run the risk of anaphylaxis due to the introduction of new allergens even in very common foods? Virtually nothing is known about the possible influence of such dietary changes on childhood allergy [23]. There are different methods for manipulating food allergenicity, but one thing is to select some with a low allergenic content – for example, different types of apples contain different quantities of allergens that can cause OAS in people allergic to birch – or to reduce the allergenic content by altering the ratios of the individual elements in the food, a procedure that has been achieved with the perfection of hypoallergenic rice, as we discussed in Chap. 9. It is quite another manner to increase allergenicity, such as the introduction of allergens of different provenances by genetic manipulation, thus risking anaphylactic reactions as detailed in Chap. 4. The standardization of the methods used to control potential allergens is required, but this control program for determining the allergenicity of modified foods should be established on an international level. Figure 1.81 illustrates all the necessary steps: both FAO and WHO indubitably monitor the diversity between normal foods and GMOs [130]. On January 20, 2001, the Royal Society of Canada issued a document stating that 53 new procedures should be

fulfilled before new permission to cultivate GMOs could be granted. The use of substantial equivalence as a decision threshold by regulatory agencies is, in the Society's view, scientifically unjustifiable when used to exempt new products from full scientific scrutiny [354]. The BSACI warns that genetic manipulations may cause an inadvertent alteration in allergenicity because a change in an amino acid sequence within the new food might increase the potential of the food to cause sensitization and some neoallergens may evade detection. New allergenic B-cell epitopes and new sensitizing T-cell epitopes may stem from such manipulations; however, the unfolding caused by GMF processing would expose linear T-cell epitopes (Fig. 1.18) to the immune system that would not normally be seen [246]. Similarly, many conventional crosses involve different plant species and/or wild plants that we do not usually consume and thus the genes are new to our organism [418]. Table 20.4 lists 110 foods that can provoke anaphylaxis or anaphylactoid reactions, and several hidden allergens are listed in Tables 20.5 and 20.6. Normally children allergic to a given food avoid its ingestion, but are *unprepared to recognize hidden allergens,* nor are they assisted by food labels. GMO soy-lecithin is so widespread that it escapes any control. Immunoblot results have shown a 25-kD protein of GMO soybean reacting with IgE of some patients, a problem of the hour because 60% of processed foodstuffs contain soy produce [246]. In addition, GMO food labeling would be generic and thus of little value to children with specific FA [412]. So as not to undermine consumer confidence, the label should not only indicate if the food has or has not been genetically modified, but also how much transgenic product it contains. Currently, on a par with fish derived from monosexualization or from doubling maternal DNA [63], the regulations do not specify these characteristics on the labels that accompany products, a failure we have often emphasized in other fields as well. The fact that labels do not include GMO contents equal to 0.9% (EU) poses difficult measurement problems: even *minute doses of allergens* (μg of food) *are enough for primary sensitization* (see Tables 1.78, 1.79). Worried consumers expect that a collaboration between the EU and the US gives them the protection they need [155]. Nobody has evaluated whether intrauterine and infant exposure to GMOs with antibiotic resistance markers can have profound permanent and irreversible consequences even in adult life [63]. Figure 10.6 shows GMO production in European countries.

Hygiene Hypothesis

Our personal everyday experience in the Pediatric Allergy and Immunology Division, where we have worked since its foundation, allows us to conclude that the *hygiene hypothesis may have a very limited effect:* a) >95% of the children cared for have an evident FHA; b) in Table 1.74 we see that 98% of allergens act independently of the hypothesis; c) in taking the child's history, our experience has shown that only 10% of atopic families may have a pet at home; d) ETS is everywhere (Table 4.23) and resistant to any means (see "New Frontiers"). We will also discuss the possible inverse relationship between Th1 and Th2 disorders [217, 387].

A longitudinal study of subjects from age 9 years to age 26 years has found that asthma in early childhood continues with adult asthma. The earlier the age at onset, the greater the risk of relapse (OR, 0.89) per year of increase in the age at onset [381].What is presently known as the hygiene hypothesis is the decline in the infectious environment and in the pattern of microbial exposure during childhood, which consequently is a critical factor underlying the increasing severity and prevalence in allergic diseases in industrialized Western countries [278]. One theory under investigation suggests that increased use of antibiotics in childhood, cleaner drinking water, improved sanitation, and widespread vaccination practices have led to a lower cumulative exposure to microbial pathogens [458]. Thus conditions that are found in industrialized countries could be associated with increased atopy prevalence [259]. Epidemiological studies have shown that atopic diseases are more prevalent in Western industrialized countries [352]. Since it is difficult to change *the water supply and house sanitation,* in theory we should suggest discontinuing necessary antibiotics and no longer immunize children even against life-threatening infection, but *in practice we do the contrary.* In normal children there is a balance between Th1 and Th2 lymphocytes, but abating the protective exposure to infection the Th1 phenotype may be underexpressed and the Th2 phenotype overexpressed [277]. This imbalance forms the basis of the hygiene hypothesis for atopy, so several avoidance measures, for example, those followed by the second part of studies in Table 24.2 should be reversed. According to this hypothesis, immune responses to viruses and perhaps other organisms that generate Th1-like ILs, such as IL_{12} and IFN-γ, down-regulate Th2 responses that predominate in the neonatal immune system. Early exposure to respiratory viral infections through contact with older siblings or by attending daycare centers [14, 207], by the activity of Th1-like ILs, would help T-cell immune responses to mature into a Th1-like phenotype, less likely to favor allergen sensitization, thus *with a protective effect* [204]. Thus, childhood infections might have a key role in stimulating the maturation of the immune system away from the Th2 profile that predominates at birth toward a predominantly Th1-type phenotype [376].

According to data discussed in Chap. 4, the hygiene hypothesis reverses some avoidance measures listed in Table 24.4:

1. One effect of *infection exposure early in life* is to stimulate a shift away from a predominantly Th2 response, but the acquisition of commensal flora might affect up-regulation of Th1 reactivity and thereby affect

down-regulation of Th2 allergy-promoting responses. This immune switching is critical during early postnatal life, when exposure to high levels of antigen first occurs, because the response that evolves is likely to determine life-long reactivity to that antigen. However, early infection also plays an important role in maturation across the immune system, including down-regulation of both Th1 and Th2 responses [25, 259].

2. Along this line is *the suggestion of eating dirt, or moving to a farm:* at best they are theoretical rather than practical clinical recommendations to prevent asthma [458]. Epidemiological reports suggest that there has been a decrease in the frequency of allergy and asthma among children of farmers in Western industrialized countries than in children from nonfarming families, suggesting *a protective effect of the farming environment* against the development of atopic disease [34, 125, 193, 346, 446]. Children exposed to stables and/or farm milk during their 1st year showed substantial protection against the development of asthma, AR, and allergic sensitization [346]. Alterations in gut microbial flora might explain the inverse relationship between exposure to farm animals [25, 32]. Among 300 New Zealand farm and nonfarm children, there was an inverse association between AR, wheeze, and SPT positivity and dairy farming during the 1st year of life, but no such association with contact to specific farm animals. A reason may be found in the temperate climate of New Zealand, which allows animals on large farm holdings to stay outdoors throughout the year [461], as in Crete where animals are kept outdoors all year [16]. In a study on childhood allergy conducted in an urban area and in rural communities of Crete, atopy was twice as common among urban children compared to rural. However, among rural children any difference disappeared between intensity of animal contact and expression of atopy [16].

3. Several results have demonstrated that *cat and dog exposure in early infancy* is associated with later sensitization, but it is intriguing to find some reporting a *protective effect* [33, 41, 182, 314, 325, 343, 353, 489], in children without a maternal history of asthma [72], or with asthma unrelated to pet ownership [249], or in low-risk children without FH of asthma [343]. High-dose cat allergen exposure might induce tolerance to cat allergens and might therefore explain why animals in the house can decrease the risk of allergic diseases [489]. In a recent paper [12] on the *primary prevention of atopy and asthma* the children in prophylactic group had pets at home in 45.2%–51.6% of cases and the children in the control group hat pets in 34.5%–43.1% of cases (NS). The success of the primary prevention was dependent on the pet presence, as advocated by the hypothesis. In farmer's children, current contact with dogs was associated with a reduced risk of AR, asthma, wheezing, and sensitization to cat allergen and prass pollen. The inverse association between exclusive exposure to cats only during the first year of life was limited to wheezing, atopic asthma and grass pollen sensitization. Although higher levels of endotoxin were found in mattress dust of farm children, no significant differences were observed with respect to Fel d1 levels [453]. In 225 cat-sensitized children, we assessed the following atopic manifestations: asthma (38 = 45%), AR (15 = 18%), oculorhinitis (12 = 14%), AD (3 = 4%), FA (1 = 1%), urticaria (2 = 2%) and (14 = 16%) multiple sensitizations, with a high prevalence of respiratory allergy (77%). *Atopy* was present in 42.2% of children and *increased up to 91.7% in children with positive SPTs only for cat epithelium* [62]. A child we have treated reacted with wheezing when in the vicinity of a cat-owner peer. A further meta-analysis concluded that pet exposure increased the risk of wheezing in older children [7]. Some studies were cross-sectional and retrospective, others prospective [62, 249, 314, 343]; moreover, selection bias could not be excluded in two studies reporting that cat ownership was significantly related to a reduced risk of sensitization only in children with positive FH [33, 353]. Three prospective birth cohort studies have demonstrated that early exposure to cats [102] or to cat allergen [447] was associated with an increased risk of manifesting allergy to cat in the 1st year of life [102] and during the first 3 years of life [447] and in contrast, that exposure to > one dog or cat in the 1st year of life may reduce the risk of allergic disease *at age 6–7 years* [314]. Surprisingly, PTF results were better in boys but *not in girls* [314]. Moreover, keeping a single pet provided no protection compared with keeping no pets [459]. In asthmatic children *aged 6–8 cat exposure reached a 27.5% level* and in nonasthmatic a 33.3% level [232]. Thus, keeping a cat in the home is consistent with higher exposure to strong allergic sensitization and can therefore contribute to the *higher risk of atopy in later life and of wheezing episodes* [1]. Additional findings specify a dose-response relation between exposure to cats and specific sensitization within 1 year of age, thus cat ownership was significantly associated with sensitization to cats [102]. Overall, the presence of a cat in the household during the first 3 months of life was associated with an increased risk of sensitization to cats (OR, 2.1) and an interaction between early high-dose exposure to birch pollen and cats in the household was suggested for sensitization to cats [229]. Children exposed to a high concentration of cat allergen made a modified Th2 response characterized by IgG_4 antibody to cat proteins not associated with an IgE response [325], whereas a potential protective effect of high cat allergen levels is caused by increased proportions of $CCR5^+$ $CD8^+$ Th2 cells predominating *in children without FHA* [30]. On the contrary, high cat-induced IL_9 levels were associated with asthma in 12-year-old children [212]. At this stage, we would not advise people who wish to prevent allergic disease in their children to rid their homes of pets. We would also not recommend pet ownership as prophylaxis against asthma [273], especially to families where FHA is prevalent [12, 62]. An inverse association be-

Table 24.28. Evaluation of utility and carrying out procedures of allergen avoidance measures suggested to 96 asthmatic children aged 2–12 years (mean 6.9 years) + control children

	Control group		Study group	
	Yes	No	Yes	No
Pet elimination	27	69	84	12

Measures for humidity reduction	34	62	83	11
Smoke reduction (parents)	52	54	84	12

Study group: skin prick test positive to Der p (66 M, 30 F, p=0.0002). Control group: nonatopic children (56 M, 40 F, age 1–13 years, mean 7.6 years). Statistics: study vs control children in all rows, p=0.0001, smoking, p=0.0302. Unpublished personal data.

tween pet keeping and AD was found in a recent study [344]. Moderate exposure to cat allergen can result in the maximum prevalence of cat sensitization in children who have never lived in a household with a cat [182, 447, 451]. In high-risk families with at least one child or first-degree family member, pets are usually kept outside [242, 376]. Deliberate avoidance of pets might be an explanation for the protective "pet effect" observed in several studies [453]. Current cat possession represents a significant risk for sensitization to cats, *if cats are allowed indoors* [353], and in young children [62]. Contrary to what is normally seen, we show that the parents who wheezed in the first 6 years of life now with asthmatic children successfully organized efficient avoidance measures, especially related to pet elimination (Table 24.28). Cat allergen exposure was significantly lower on parental mattresses in families with allergic mothers [429], since allergic families live in homes with fewer triggers such as pets, no smoking and no carpets than the nonallergic families [37].

4. *Child daycare attendance during the 1st year of life* is an environmental factor possibly protecting against the development of allergies and asthma in childhood [228]. In children with FHA, the protective effect of daycare attendance in early life against the development of atopy begins by 2 years of age, and this protective effect in early life against wheezing may not be observed until after 4 years of age [73]. The development of asthma is less common among children with more exposure to other children at home or in daycare during the first 6 months of life than among children with little or no such exposure [14]. On the contrary, daycare attendance increases the risk of URTI (upper respiratory tract infections) and LRTI in the 1st year of life for children with FHA, especially specific environmental exposures within daycare (presence of pets or having a rug or carpet in the sleeping area) [71]. However, among children with maternal history of asthma, daycare in early life had no protective effect on asthma or recurrent wheezing at the age of 6 years but was instead associated with an increased risk of wheezing in the first 6 years of life [75]. Daycare attendance was a significant risk factor for AD in children born to asthmatic mothers (OR, 2.9) [228]. Concerning the effect of infections, differences have been shown in the microflora from the feces of allergic compared with nonallergic infants [191]. In two prospective studies, allergic infants were GI tract-colonized with more *Clostridia* and *Staphylococcus aureus*, whereas nonallergic infants had more enterococci, bifidobacteria, and bacteroides. If the microbial flora drives the maturation of the immune system, differences in the neonatal gut microflora such as changes in its composition might play a role in the development of atopy, suggesting a crucial role of the balance of indigenous intestinal bacteria in the development of and protection from allergy [25, 222].

5. A large multinational project involving children resident in Germany, Austria, and Switzerland [35, 346] has found that children exposed to stables and/or farm milk during their first year showed *substantial protection* against the development of asthma, AR, and allergic sensitization [346]. In a cross-sectional study involving 812 children aged 6–13 from farming and nonfarming households in rural areas of central Europe, the investigators found a relation between higher levels of *endotoxin* in the mattress dust and a protective effect against the development of AR, allergic asthma, and allergic sensitization in these children [35]. However, three of the four ILs that were down-regulated in the highly exposed children (IL_{10}, IL_{12}, IFN-ɣ) *are among those best known to suppress allergic responses mediated by Th2 T cells* (Table 1.5). In particular, IL_{10} down-regulates the immune responses mediated by both type 1 and type 2 helper T cells [458]. Endotoxin levels in the homes of children suffering from AR were lower than in families without sufferers [461]. However, endotoxin has been shown to be a *double-edged sword*. Longitudinal prospective birth cohort studies suggest that endotoxin exposure in infancy is associated with less AD, as possible evidence of an effect on the allergic march of early childhood [151]. Still, in this and two other birth cohort studies, high endotoxin exposure has a negative effect since it is associated with wheezing in the 1st year of life among infants with a familial predisposition to asthma and allergies [316]

and with an increased risk of physician-diagnosed respiratory infections and cough with respiratory infection, bronchitis, or both during the first 6 months of life, also protecting from AD [149]. Thus can endotoxin not only *prevent the development of atopy and atopic disease* but also down-regulate pre-existing atopic activity [117]? Only one prospective Austrian study involving 11 SPT-positive farm children followed for 3 years suggests that endotoxin might downregulate atopic sensitization [193]. Blood cells from farmer's children expressed significantly higher amounts of CD14 and TLR2 than cells from nonfarmer's children, thus suggesting that the innate immune system responds to the environmental microbial burden and modulates the development of allergic disease [230]. In 609 children of European farmers' and nonfarmer's parents, farmer's children had higher endotoxin concentrations in their homes [120] as in a previous study [346] but TLR genetic variation was a major determinant of their susceptibility to asthma and allergies. However, children of the high-endotoxin group benefited from a genetic variation in TLR4 inversely associated with sIgE to common aeroallergens [120]. High exposure to HDE was associated with an increased risk of wheezing over the period of observation, but this risk rapidly decreased over time [179], and of wheezing episodes, and was independent of the effects of HDE exposure [258]. On the contrary, households with detectable allergen levels but low endotoxin levels may provide a predisposing environment for pet allergen sensitization [149]. The modern metropolitan homes of allergen-sensitized infants had significantly lower levels of HDE compared with homes of nonsensitized infants and compared with farm and rural homes, but levels can still be significant, as well as with farm and rural homes [148]. HDE exposure in 9–24-month-old infants may protect against allergen sensitization by tilting the immune balance in favor of IFN-ɣ producing CD4 T cells (Th1 immunity) [148]; therefore it might shift the developing immune system to a predominantly Th1-type responsiveness postneonatally, thus protecting against asthma and allergies [279]. Whether there is an atopy-reducing benefit to the child *in utero* when the mother is in such an environment remains to be determined.

6. An unexpected result of the emphasis placed on the hygiene hypothesis might be *a prolonged fetal pattern of immune response into the first years of life* [279] when the Th1/Th2 profile is already being shaped [338]. Thus, the first encounter with common aeroallergens commonly occurs in an environment where antigen exposure in a germ-free environment favors the development of Th2 responses [406], which might explain why the newborn shows Th2-skewed reactivity [337]. The response that evolves is likely to determine life-long reactivity to that antigen, programmed into long-term immune memory. Therefore, strategies for primary prevention should be based on reestablishing conditions for the rapid development of Th1 functions during early infancy. This is a necessary step for fetal adaptation to the outside world and for the establishment of a balanced Th1/Th2 response [279].

7. Although endotoxin exposure has been shown to play a bidirectional role in conferring long-lasting protection against asthma as well as increasing the lifelong risk of the asthma onset [110], *muramic acid,* a constituent of peptidoglycan, is present in Gram– and Gram+ bacteria in the environment and may serve as an additional marker of microbial exposure. In a cohort of 553 farm and nonfarm school children from several European countries, children with higher mattress dust muramic acid concentrations had *a significantly lower prevalence of wheezing.* The prevalence of sensitization and respiratory symptoms was not different when comparing the two groups, data that could not be extrapolated to urban children. Independent of the endotoxin concentration, muramic acid can be considered as an independent marker for microbial exposure. Increasing mattress dust muramic acid concentrations are therefore associated with a lower incidence of wheezing, regardless of farming status and endotoxin exposure, and possibly of atopic sensitization among rural school children [430].

Too many paradoxical findings make it difficult to accept the hygiene hypothesis, and it does not explain the increase in asthma incidence in the last 40 years of the twentieth century [326]. Not only is there no credible immune mechanism to explain the hypothesis, but diverse influences on hygiene have been associated with a higher prevalence of atopy [326]. Will the hygiene measures abate the growing worldwide prevalence of allergic disease, as assessed in Chap. 5? A new hypothesis has been proposed in some recently published papers. These suggest that high-dose allergen exposure is associated with a lower risk for specific sensitization compared to moderate exposure to such allergen [170, 325]; similar results were found for cat, horse and pollen allergen [170]. Forerunners of the hygiene hypothesis envisaged that large doses of CM should be popularized, to feed nurslings not at risk of atopy (Chap. 4), and again the only result was that atopy prevalence grew in geometric progression. *Does high-dose pollen exposure induce tolerance* [182]? Thus, is it good hygiene to inhale pollens in early life? Among 592 children with severe asthma seen by us between January 2001 and June 2003, several pollen-sensitized children inhaled so much pollen that they had to be urgently admitted to the ED. Or, does eating dirt protect against mite sensitization [458]?

Changes in family size over the last 30 years do not appear to explain much of the reported increase in asthma or AR prevalence [460]. Increases in asthma mortality in New Zealand reflected a high prevalence of severe asthma in a country where approximately 50% of the homes have cats [276]. Progressive increases in lifestyle changes provide no convincing explanation for the steady increase in asthma hospitalization rate in both

black and white children aged 0–18 years [96]. Moreover, childhood asthma prevalence has increased in several large cities of Africa encompassing the informal settlements of Cape Town, where conditions could not be described as hygienic [457].

The number of siblings is discussed in Chap. 4.

In conclusion, there are prominent challenges to the Th1/Th2 paradigms, which, as currently formulated, might be an oversimplification, as shown by a cohort of 20,043 individuals [387]. The findings in 72 Estonian 4- to 6-year-old children do not even support the hypothesis of an immune deviation with down- and up-regulated Th1 and Th2 responses leading to atopic disease [217]. In a trial on 18,156 subjects, an FHA or FN of asthma was associated with *a higher risk of developing asthma* and a lower chance of remission (HR, 0.79) throughout life. No matter what one's FHA was, *early, acute respiratory infections* were associated with an increased lifelong risk of asthma onset (pooled HR, 3.19) [110]. So the hypothesis is restricted to nonasthmatic children with negative FHA. We feel it is encouraging that the parents of a group of asthmatic children have accepted to carry out successful avoidance measures, with a 52.8 % reduction in the number of smoking parents within the span of 1 year (Table 24.27). Application of the measures suggested in Tables 24.4, 24.16 and 24.17 is sufficient for keeping the levels of Der p constantly low [399]. Table 24.29 [213, 350] summarizes the pros and cons of the hygiene hypothesis. Table 24.30 lists the associations between endotoxin exposure and outcomes in children [35, 147, 251, 346].

Aid to Prevention

An aid to primary prevention comes from *Lactobacillus acidophilus*, possibly advantageous to maturation of the infant's immune system, and effective in preventing atopic disease in HR children [328, 407]. The gut microflora, still largely unexplored, might be a source of natural immunomodulators and *probiotics* [223], which may act by improving the intestinal ecosystem [407]. The use of probiotics in newborns to prevent atopy and atopic disease reduced the prevalence of AD; however, SPT positivity and total and specific IgE levels remained unchanged [223]. Thus the probiotic affected the manifestation of atopic disease but not atopy itself. Others, though, report that oral *lactobacillus* supplementation for mothers of exclusively breast-fed infants in the first 6 months of life offers a safe and effective mode of promoting the immunoprotective potential of breast-feeding and reduced threefold the prevalence of AD by age 2 in children receiving supplementation [342]. *Lactobacillus raises IFN-γ production* of PBMCs in infants with CMA and in infants with IgE-associated AD and may thus provide helpful Th1 immunomodulatory signals [328]. Dietary supplementation with *ω-3 fatty acids* might have a beneficial effect on the prevalence of wheeze during the first 18 months of life [274].

Table 24.29. Factors for and against the hygiene hypothesis

A. Pro
Early infections are inversely associated with atopy
Populations with high prevalence of parasitic infestation have low prevalence of AR and asthma
Exposure to cats, dogs, farm animals decreases the allergy risk
Gastrointestinal flora with high *lactobacillus* counts in children with low prevalence of atopy
Children raised in a farmhouse have fewer allergies than nonfarmers' children in the same area
Early exposure to group daycare is inversely associated with atopy
CD14 gene polymorphism may explain the variable prevalence of atopy
B. Con
Parasitic infestation associated with higher risk of urticaria and atopic eczema
Several microorganisms (*B. pertussis*, *respiratory syncytial virus*) increase IgE production
Active tuberculosis does not decrease Th2 reactivity
Pertussis vaccination can protect children from atopy by preventing pertussis infection
High prevalence of allergy in poor areas of developing countries or inner-city slums'
Air pollution is associated with higher prevalence of respiratory atopy
The striking increase in IgE-mediated diseases (allergy, asthma, AD) that has occurred over the last few decades
Reduced levels of sCD14 in the fetal and neonatal gastrointestinal tract is associated with the development of atopy, AD, or both
Fetuses and neonates show Th2-skewed reactivity

Data from [213, 350].

Table 24.30. Associations between endotoxin exposure and outcomes in children

1. Farm children were exposed to more endotoxins (as measured in house dust, barn dust, and mattress dust) [35, 147]
2. Greater endotoxin exposure was associated with less allergen sensitization, hay fever symptoms, and atopic asthma, in a dose-dependent manner [35]
3. Farm children's blood expressed higher amounts of CD14 and Toll-like receptor 2 [251]
4. Early life exposures to farm barns and unpasteurized milk had strong associations with low asthma and allergy prevalences [346]
5. High levels of endotoxin exposure were associated with an increased prevalence of nonatopic wheeze [35]

Preventing Allergen Entry or Mast Cell Degranulation

Prevention must also deal with infections: VRIs can cooperate with irritants, such as smoke, favoring allergenic invasion as well as increased IgE, as seen in Chap. 4, and thus atopic sensitization [479]. In Chaps. 7, 9 and 11, we illustrated pathogenic mechanisms and preventive properties of cetirizine, levocetirizine, cromolyn, ketotifen and nedocromil sodium. Asthma (including exercise-induced asthma, AIA) and FA are effectively prevented by these prophylactic – not curative – drugs.

Modifying the State of Sensitization Using Available Aids

Once the sensitization condition has set in, if a respiratory allergy is involved it can be modified or cured by *SIT* and if FA is involved by food desensitization, especially in a world in which a large proportion of the population is taking tablets or inhalers every day [324].

In the ETAC study, 795 nurslings with AD for at least 1 month and with an atopic parent were given cetirizine for 18 months, on a DB basis, at a dosage of 0.25 mg/kg twice a day (or placebo), followed by an equivalent observation period [450]: this prevented the development of asthma in 50% of children sensitized to pollen or Der p (Figs. 24.13–24.15). Thus, this study comes to the fore as an urgent priority, given the data illustrated in Tables 5.5, 5.8 and 5.15.

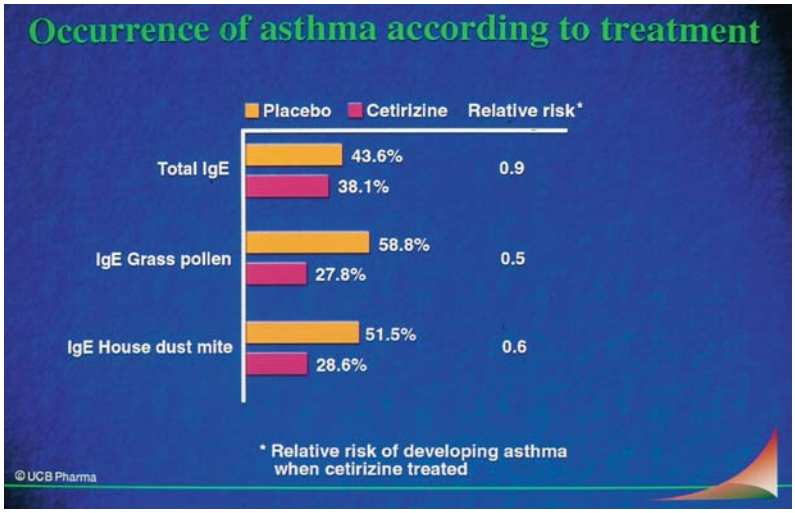

Fig. 24.13. ETAC study group. Occurrence of asthma according to treatment. Children receiving cetirizine who began the study with raised levels of total IgE and specific IgE to grass pollens and/or Der p had a reduced relative risk of developing asthma compared to children who began the study with raised levels of these IgE who received placebo

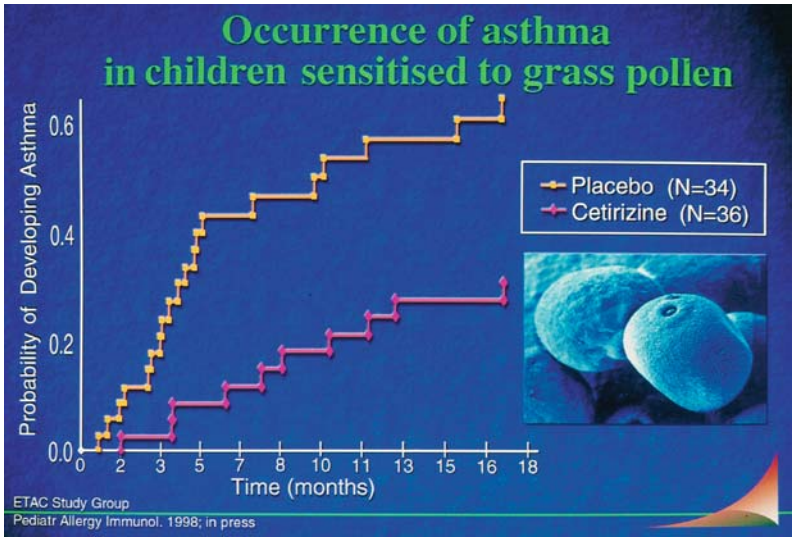

Fig. 24.14. ETAC study group. Occurrence of asthma in children sensitized to grass pollens. Cetirizine prevents asthma from developing in one out of two children who was sensitized to grass pollen and who had AD and a parent or sibling with a history of atopic disease

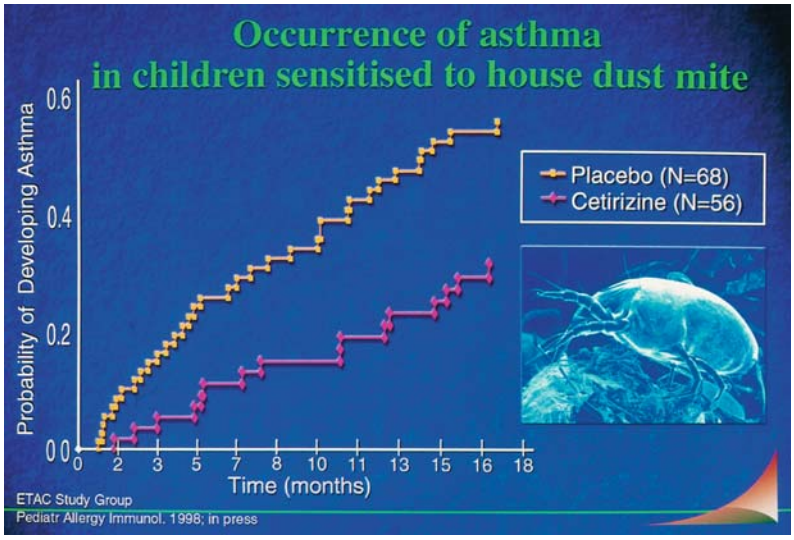

Fig. 24.15. ETAC study group. Occurrence of asthma in children sensitized to Der p. Cetirizine prevents asthma from developing in one out of two children who was sensitized to Der p and who had AD and a parent or sibling with a history of atopic disease

Tertiary Prevention

Tertiary prevention is the stage in which pediatricians treat children and adolescents to stop the atopic march. This goal is best accomplished by avoiding recurrence of symptoms, by using acceptable interventions, minimizing adverse effects, and providing cost-effective outcomes [483]. Parents often turn to their child's pediatrician or allergy specialist to find out if this or that measure they are about to adopt can have a boomerang effect. The advice sought most frequently by parents of allergic children involves the following aspects.

- *Vaccinations:* misunderstanding of the hygiene hypothesis in the lay press should be reversed because the substantial progress and reduction in morbidity and mortality achieved through the introduction of vaccinations should be continued for the benefit of decreasing morbidity from infectious illness. There are no contraindications for allergic children, for example, for the measles vaccine (Appendix 9.11), which should also be given to all atopic children [320]. Likewise, SIT is not contraindicated for coincident immunizations with both viral and bacterial vaccines: the only precaution is that they should not be given on the same day.
- The *choice of the most suitable sport:* we have commented that the asthmatic child feels limited in his or her athletic activities. Instead, even with severe asthma these children can participate in a number of sports: anaphylaxis and EIA can be prevented in most cases. SIT-treated children can also do sports, with the exception of the day they are given their dose of vaccine, due to the greater possible absorption of the allergenic extract during exercise.
- The *choice of vacations:* often (and rightly) parents ask about the most suitable destination. In general, there are no particular limitations: allergic children will benefit from the seaside or the mountains, as long as they spend as much time as possible outdoors. All winter skiing holidays are fine, and they also offer the additional benefit of less pollution, low humidity, and few specific and aspecific asthma-inducing factors. As to the mountains during the summer, children with pollen-induced asthma must avoid staying there in the months of July and August, when grasses are in the middle of their pollination period to varying extents, depending on altitude. With regard to HDMs, whose number seems to increase parallel to height (Table 24.19), the city child allergic to Der p should go to an aseptic house [85], and not to vacation homes that are shut down for the entire off-season period and are often covered with wall-to-wall carpeting. What yields the best results is common sense in the choice and furnishings of the accommodations, which easily helps avoid problems. Based on common experience, most hotels at mountain resorts open up for the season and there is a risk of being assigned a room that has long been closed and, at most, was opened and aired just a few hours in advance. With regard to the beach, parents should bear in mind that, as noted in Chap. 7, children with AD benefit enormously from the beachside sun and that asthmatic children can enjoy the water just like other children, engaging in swimming as we advised. Contrary to popular belief, there is no need to head to the beach at daybreak.
- *Military service:* the atopic boy who has suffered from inhalant-induced asthma, particularly if sensitive to Der p, should be evaluated carefully before being considered fit. The often dusty barracks, long marches often in unfavorable weather and, for subjects with FA, uncontrolled meals are all factors that can cause allergic manifestations, even in young men whose disease has been under control for years. Thanks to SPTs, RAST, PFT, and food and bronchial provocation tests, today it is possible to single out allergic subjects much better than in the past.
- *Laboratory tests or surgery:* it is important that the attending pediatrician be put in touch with the radiologist or surgeons to alert them that the child is atopic. In particular, hereditary angioedema requires special

Table 24.31. Advantages and disadvantages of preventive strategies

Primary prevention	Secondary prevention
Advantages	
Permits prenatal and postnatal prevention	Greater predictive capacity of atopic disease
Optimizes early parental cooperation	More convincing to some parents
Potential prevention of early sensitization/atopy	Prospective follow-up for atopy encouraged
Bridges atopy's window period and critical period	Pediatricians are more informed and motivated
Disadvantages	
Low sensitivity of predictive markers	Potential jeopardy of missing the critical period of prevention
Involves several families not at risk of atopy	Atopic disease may have developed in the meantime
Effective preventive efforts scarcely known	Usual medical care may not encourage prospective follow-up
Prevention costs and effectiveness are undetermined	Prevention costs and effectiveness are undetermined

Modifed from [482].

attention, even for simple dental extractions. We must emphasize that it is not a good idea to discuss hospitalization, surgery and related topics in front of the child: here again, the parent's loving preparation is required, if necessary with the pediatrician's help, particularly if he or she is the child's friend.

- *Travel* requires thorough preparation, and a number of precautions must be taken in addition to the ones indicated so far, depending on the means of transport, travel plans, destination and its microclimate. Pollen sufferers must obtain information on the plants and flowers prevalent in the region or country they are visiting. In Europe there is a special connection module with EAN (European Aeroallergen Network) for this purpose, to permit the exchange of information on aeropollen concentrations in various countries. By car, bus or train, potential allergens other than the ones indicated here include industrial irritants. The windows and/or air vents must be closed tightly: pollen trapped in the closed space of the car (5,000/m^3) or compartment can reach risk levels [252], above all on tree-lined streets and in the country. If you set off on a long car trip, turn on the ventilation/air conditioning 10 min before you leave, to clear the system of these inhalants. If you are travelling by air, check the air quality in the cabin and choose a seat as far as possible from the smoking area. However, if the child has suffered recently from sinusitis, OME and/or nasal blockage, the trip should be postponed. Subjects allergic to Der p must bring a mite-proof mattress cover and pillowcase with them, even if staying with friends or relatives. With FA, the danger lies in foreign foodservice and thus it is imperative to verify that the selected dish does not contain specific allergens. If necessary, bring an auto-injector of epinephrine. If the child is being treated with SIT, we have noted that in England it is difficult to find a doctor willing to give a booster shot. Therefore, when vacationing, it is best to take advantage of the free period. Before leaving, go to your pediatrician, who can draw up a letter for any colleague who may be required to intervene, detailing the diagnosis and current therapy. As far as drugs are concerned, bring a sufficient quantity in the original packaging, keeping a copy of the prescription at hand. If nebulization or peak-flow measurements are required when travelling abroad find out the prevalent voltage in the destination country. If necessary, obtain an adapter if the device does not have one, given that battery-operated models are expensive. As an alternative, there are portable ones that can be plugged into the car cigarette-lighter (only for this use).

Table 24.32. Bill of Rights of atopic disease prevention

Right to be breast-fed, not formula-fed
Right to live in dust-mite-free homes
Right to be free from pets
Right to be free from passive tobacco smoking
Right to breathe clean, unpolluted air
Right to be screened and advised for allergy prevention by the Ministry of Health

Modified from [482].

Table 24.31 [482] lists the advantages and disadvantages of primary and secondary prevention, Table 24.32 [482] outlines the charter of rights for the prevention of allergic disease, both in children at high risk of atopy.

New Frontiers

One of the crucial dilemmas of the allergy world is the endlessly repeated concept of the sensitization window during early infancy. This concept stems from a vast array of epidemiological studies showing that postnatal exposure to high levels of allergens maximizes the risk for subsequent expression of allergic reactivity to those

allergens in adult life. We are now aware that the fetus immune system (FIS) can be immunocompetent from the 18–20th week of intrauterine life, and that from the 22nd week the FIS is able to initiate responses to IgE antibodies and to a wide spectrum of food and inhalant antigens of maternal origin, thus suggesting an advancement of preventive measures. Discovering Der p 1 in the amniotic fluid and the fetal circulation is direct evidence of transamniotic and transplacental allergen exposure [188]. However, at birth the balance is shifted toward a predominance of Th2 T cells and related cytokines. Regardless of when allergen-specific memory first develops, poorly defined factors appear to be operating early to predispose allergen challenge in the immune system during infancy, so that the early formative period may progress toward expression of long-term Th2-skewed allergen-specific immune memory. Development of clinical allergic disease occurs within months of birth in many infants, but the key question is the timing of first exposure to individual allergens, which is likely to be variable before and after birth, generally occurring when the neonatal immune system is immature and more vulnerable to foreign influences [336]. After the report that nucleic acids are contained in breast milk in a much higher quantity than CM, and that these nucleic acids are capable of inhibiting the Th2-mediated responses, the key etiological factor in atopic disease may not be the acquisition of Th2 hegemony, but the efficiency of immune deviation mechanisms [190]; in the breast milk-fed infant the nucleic acids and their relative components may redirect the FIS responses toward the Th1 phenotype [406].

However, the fetus should be protected. Since the incidence of prenatal sensitization in selected infants (0.49%) (Table 3.2) is minimal, there is no advantage to advising expectant mothers to follow a restrictive diet during the last trimester of pregnancy. Maternal smoking in pregnancy may provoke hypoplasia of fetal lungs and reduces the number of alveoli and/or alter passive respiratory mechanics [402]. Pregnant mothers should refrain from corticosteroid treatments since their effects might be transmitted to the fetus, impairing its skeletal growth and development.

The atopic march increases progressively in infants and children, while it is difficult to compare recent epidemiological studies with data published over the past few years. It can be stated that the prevalence is at least 20%–25% in childhood, and that *atopy now rises to second place among the main pediatric pathologies.* Atopy interferes in the pediatric arena at all ages, albeit at varying levels of severity, and also *differs sharply from the adult forms* in etiopathogenesis, prevention, treatment and prognosis. Most cases of pediatric allergy (90% of cases start during this age) have a transitory course and they often go into remission as the child grows. A touchy point is the constant increase in expenses related to special food, drugs, absence from school, time off work and so on, and this underscores the importance of prophylaxis: prevention is always possible, and at a lower cost. Likewise, in the allergy field there have been many positive factors: the ongoing explosion of discoveries and significant research, on both a scientific and clinical level, is undeniable, and this means great progress. So far, these disease have not been endowed with growing importance – as they rightfully should be – in university courses and postgraduate courses, and as a result, greater information in the daily practice of doctors and pediatricians is not guaranteed. We believe that by dedicating ourselves to the young patient with scientific precision, clinical experience, perseverance and love, we can achieve a great deal in the field of diagnosis, treatment and prevention.

The strategy for preventing allergic disorders generally means intruding in the life of the entire family, often confronting deeply rooted habits or mentalities. The dietary-environmental strategy central to our prevention program, as shown in Table 24.4, is sometimes met with perplexity, not only because of the notable psychological and economic burden that these preventive programs entail [44, 46, 172, 176, 470, 485], but also because of the *little attention paid by consensus.* Instead, the active cooperation shown by several families and the encouraging results achieved only serve to *confirm their appropriateness in children at risk of atopy*.

Perhaps sharing a limited view of the unquestionable results that have been achieved, some people question the benefits of these programs, often demanding and complex. This may depend on the annoyance in adhering to a strict protocol and as a result many families with babies at HR of atopy find participation too demanding [310, 481], so that avoiding allergens may simply involve postponement rather than absolute prevention of allergy development [9]. Instead, we deem that dietary-environmental measures are proposed to these families to modify the natural history of allergic disease, reducing an established risk of genetic disorders, and that the possibility of success is tied to the equal involvement of both parents and family members who live with the child or take care of the child outside the home. On our part, the commitment must involve establishing extended supervision through adolescence, to verify if the preventive effect of allergic manifestations continues over the years and becomes extended to respiratory allergy, as recently documented (Fig. 24.2). Returning to the fatal and nonfatal cases reported in Chap. 20, we must theorize that the pediatricians had no knowledge of the preventive measures in children at risk, which have long been known [44, 393], and that, moreover, none of them was present to save dying children.

Jean-Jacques Rousseau once said, "*L'homme naît bon, c'est la société qui le corrompt*" (human beings are born good, it is society that corrupts them). As a pediatrician, and above all as an immunologist-allergist, I agree with the celebrated philosopher that neonates potentially enjoy good health and that the environment corrupts them. Today's world is so rich in pollution and in less

natural foods, which can predispose children to allergy development, that, if we consider the countless portrayals of the Infant Jesus at Mary's breast, we feel we must repeat that *breast-feeding is a measure of incalculable importance for preventing atopic disease.*

Colarizi observed that "no one stimulates mothers to breast-feed" [90]. He saw nurses entering the neonatal ward with a bottle disguised behind their back, because the babies should not be underweight [90]. EU countries have finally agreed to safeguard breast-feeding and in several countries legislation was passed banning both propaganda and distribution of CM formula during the first few months of life. While it is true that any initiative of this kind must be supported, the fact that these messages are being circulated by platforms of international consensus is also an acknowledgment of the active work done along these lines by pediatricians, as we have stressed in all chapters of this book. Oddly enough, the EU has also given all pediatricians a book praising the virtues of CM but not the immunological properties of breat milk, and yet the WHO and UNICEF recommendations should prevent these forms of advertising as well. In several hospitals in Great Britain, hidden forms of advertising have appeared [332] and in several US states, in Europe and in Italy, free samples of formula or coupons for free formula are mailed directly to the homes of nursing and even expectant mothers, and these mailings are repeated when the infant is 1 month old. The campaign is completed by incisive promotions directly targeting the public [200]. The effect is even more serious, considering the significant percentage of young and inexperienced mothers who are logically unable to distinguish advantages from disadvantages, immunological or nonimmunological [281]. It is easy to foresee that the next step will be the arrival in the hospital of false experts who will directly provide the means "to pluck the nipple from the boneless gums" of the newborn. Nonetheless, the work to inform and convince women to breast-feed usually achieves excellent results if it targets expectant mothers, while the results are poor if the message is instead conveyed by pediatricians after the baby is born [357]. This is proof of an initial temporal integration of specialized teams.

We appreciate to the highest degree today's legislation in force in Europe, which protects the working nursing mother: recent data (the ETAC study) show that 66% of European babies are exclusively breast-fed for 1 month (Fig. 24.16) and 42% for 3 months (Fig. 24.17). Even if it is desirable to extend this protection fully, we should point out that several countries in the van of progress in other social fields neglect this aspect of protecting children, to the point that a social-epidemiological trial has revealed that in one of these countries, only 8% of 2-month-old infants and 2% of 6-month-olds are breast-fed [281]. The results of a wealth of studies emphasizing the manifold advantages of breast-feeding [345, 360] should be viewed as a proof that exclusive breast-feeding in the first months of life, the most crucial period in the natural history of asthma [163, 381], should be seen as a true intervention by public health, since it may reduce the morbidity and prevalence of infantile asthma and allied atopic diseases (Tables 24.2, 24.3), with unquestionable benefits for the quality of life.

"An ounce of prevention is worth a pound of cure." It may also be true that a public television advertising campaign to promote breast-feeding and provide strong educational messaging for breast-feeding to expectant mothers was ultimately "watered down" by private interests (personal communication from Organic Consumers Association). We know that a 10- to 20-week fetus is able to advance sensitization to the first trimester of intrauterine life. If we cannot change the atopic inheritance after birth, can we start early and effective preventive measures before birth? In 1922, new frontiers were carved on the portal of our clinic: *in puero homo*, which means "in the infant is the seed of the future man." This ancient philosophy was revisited by the polyspecialistic

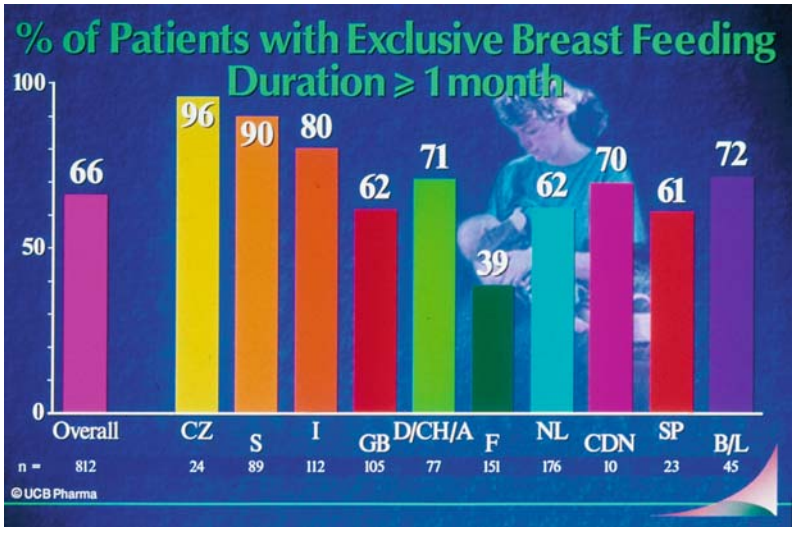

Fig. 24.16. ETAC study group. A mean of 66% of children received exclusive breast-feeding for 1 month or more. The highest frequency was in the Czech Republic (96%), the lowest in France (39%)

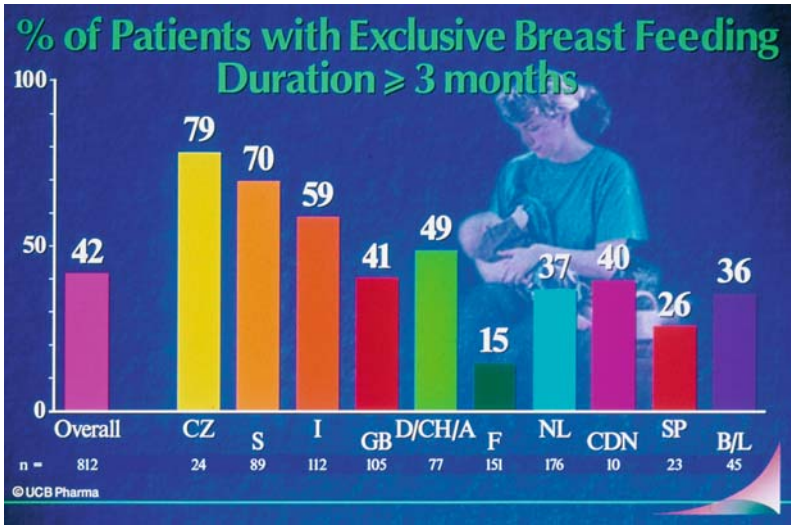

Fig. 24.17. ETAC study group. A mean of 66% of children received an exclusive breast-feeding for 3 months or more. The highest frequency was in the Czech Republic (79%), the lowest in France (15%)

pediatrics of Professor Colarizi. Thus, our goal is not only to reduce morbidity and mortality, but mainly to ensure the best quality of life for both infants and adults, by preventing, diagnosing and curing childhood atopic diseases to avoid their persistence in adults, as Ratner recommended as early as 1951 [341]. If we are unable to modify the genotype by appropriate systems of molecular biology, can we occasion, before birth, successful preventive and defense mechanisms, early and effectively, overall recognized and applied? Such a strategy is given significant impetus by finding specific responses in a domain that can be interpreted as a no-man's land. Mother Nature teaches that in the neonatal immature intestine the first line of defense is made up of a group of specialized factors [393]. It may be that *the first line of defense should be moved forward.* In Vom Kriege (*About the War*) (1832–1834), von Clausewitz (1780–1831) taught that the arrow shot by the bow can be more efficient than a huge gun, and that a company of trained soldiers works better than a haphazard concourse. Therefore, the frontiers of prevention should be moved forward and entrusted to a specialized team of gynecologists, neonatologists, pediatricians and allergists-immunologists. They act one at a time, one doctor for one mother, and should prime a further commitment: atopy prevention. The progress along the frontiers of prevention has been and will continue to be made from individual and collective contributions of these and other disciplines. We hope that the new, bonding relationship will integrate the separate disciplines of gynecology, neonatology, pediatrics and allergy-immunology into a unified intervention directed at moving forward in the prevention of allergic disease, which will ultimately benefit future generations.

Future challenges therefore appear to be centered on the effort to coordinate, through new bonds, the divisions of gynecology, neonatology, pediatrics, allergy and immunology, different as yet, to form a unified partnership, aimed at atopy prophylaxis that will eventually reduce the great demands of atopic disorders in physical, psychological and economic terms. The bonds unifying these disciplines vastly outweigh the ones differentiating them. Much remains to be learned about the mechanisms by which breast-feeding protects against atopy. We are a long way from seeing the complete picture, but the pieces are starting to fit together, and the image is gradually coming into focus. Evidence is already accumulating and we can see what it will look like when it is all put together. It may well be that *the picture is becoming clearer.*

Some not sufficiently defined specificities are indicated with a "w" (workshop).
In several studies previous definitions may be found, which are replaced by the new factor, for example, B27=B*2708, DR1=DR103, DR2=DR15, DR16, DR3=DR17, DR18, DR5=DR11, DR12, DR6=DR13, DR 14, DR1403, DR 1404.
Data from WHO Nomenclature Committee for Factors of the HLA System (January 2004) [640].

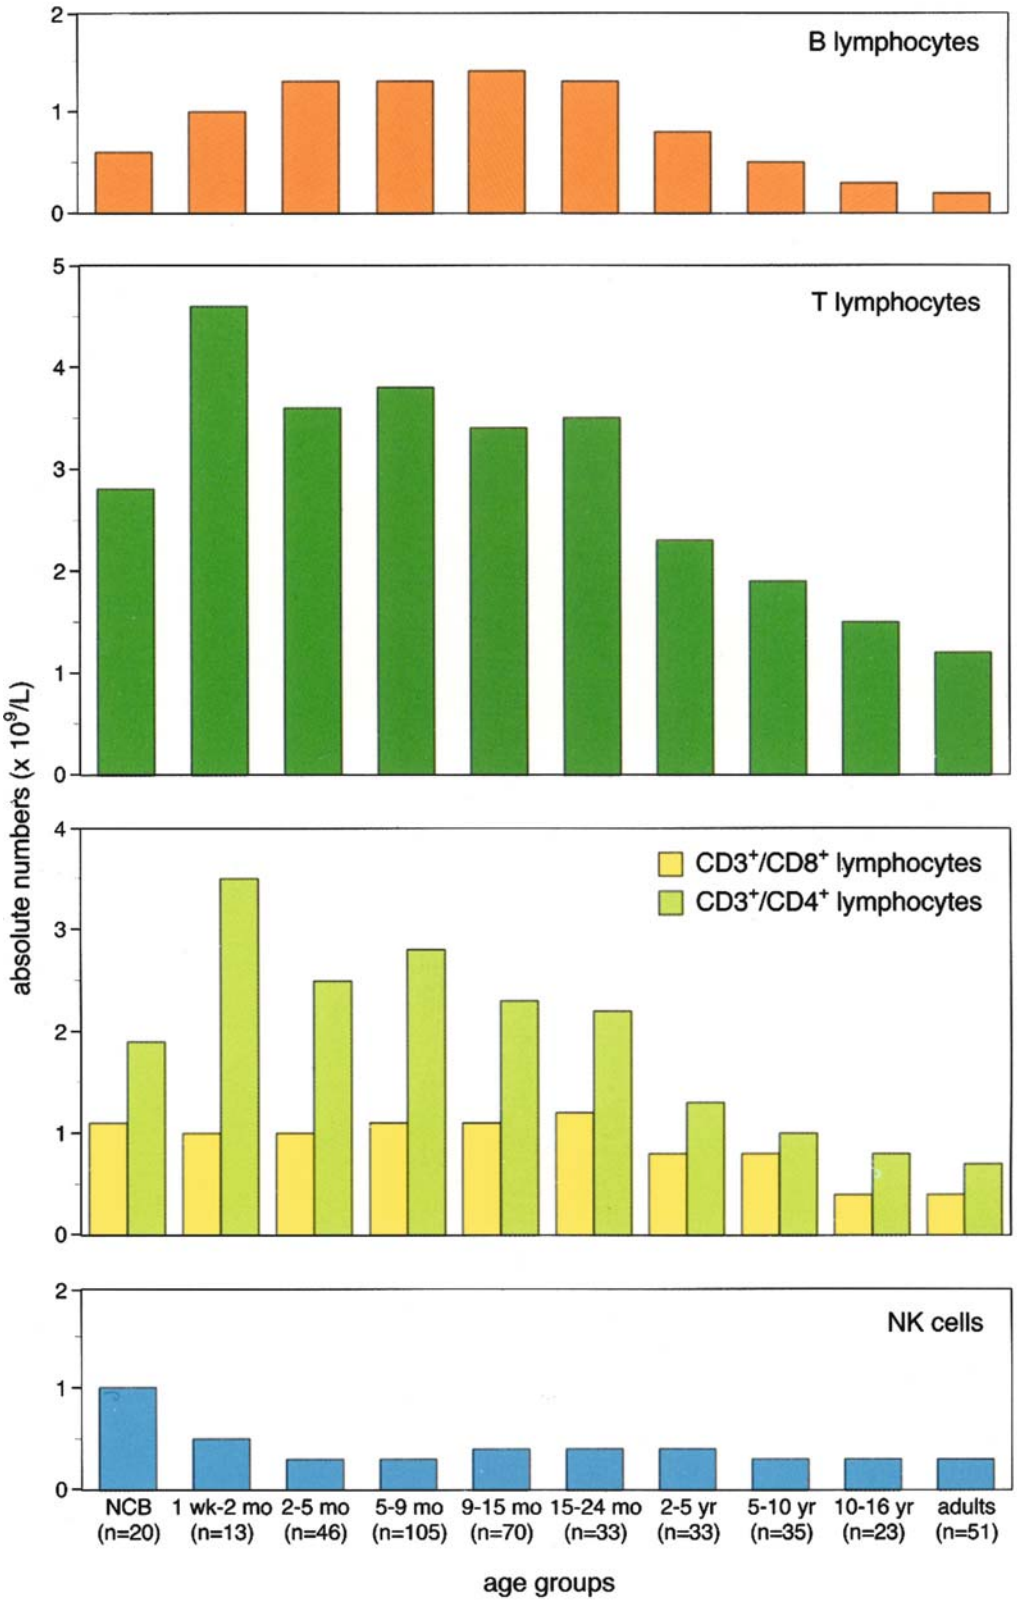
Data from [606].
NA not assigned CD; blank boxes correspond to not tested.



Appendix 1.3. Graphic visualization of data reported in Table 1.34
Histogram showing the median absolute values of the main lymphocyte subpopulation in neonates, children and adults, with the pertinent age limits. *NCB* cord blood, *yr* years, *mo* months, *wk* weeks.
Courtesy of Dr. Comans-Bitter [93].

Appendix 1.4. Interactions of hormones with lymphocytes

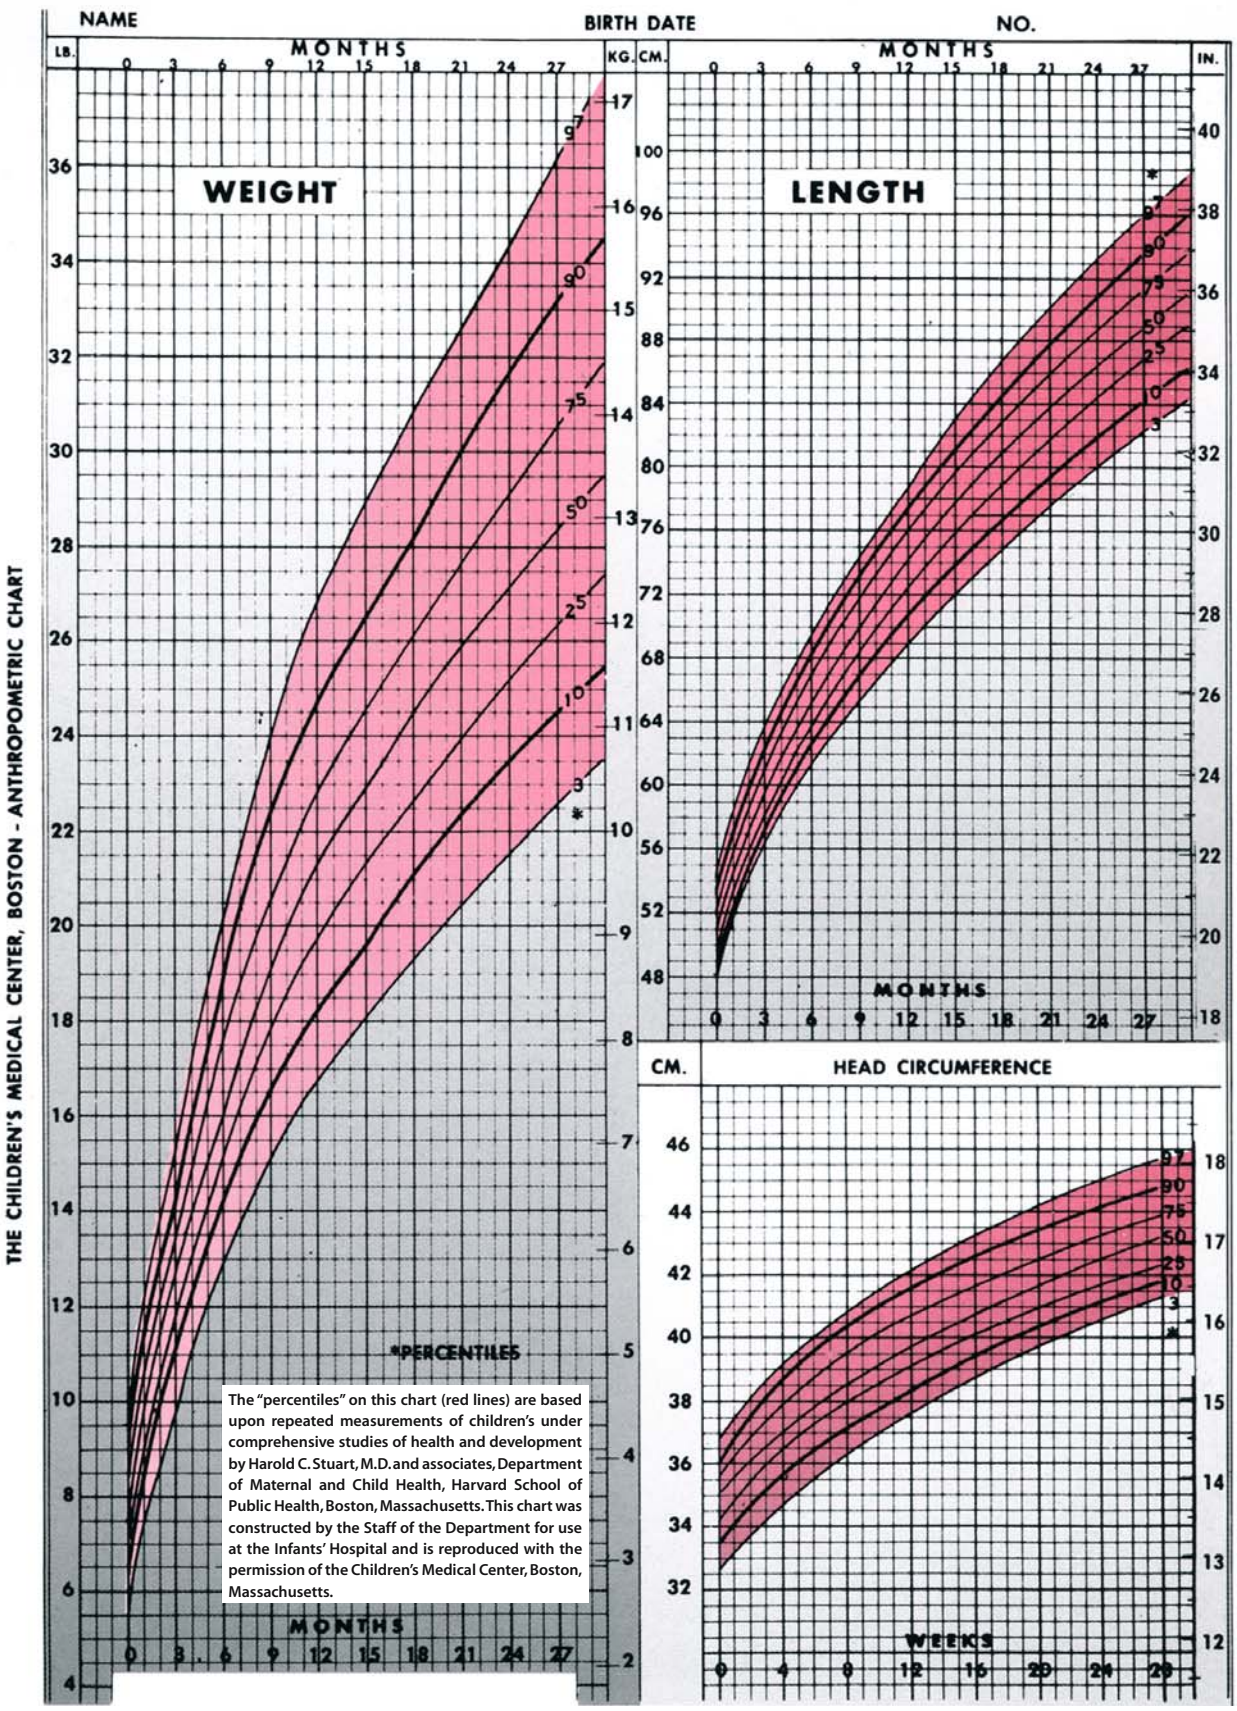
Hormone	Production	Targets	Principal effects
Glucocorticoids	Adrenal cortex	B and T cells	↓ Antibody production, NK activity and cytokine production
ACTH	Pituitary-activated lymphocytes	B and T cells	Glucocorticoid induction, variable effects On: antibody production, cytokine production and proliferation
Enkephalins	Pituitary	B and T cells	Low dose: T cell activation
			High dose: suppression
β-Endorphin	Pituitary	B and T cells	Variable effects: usually suppresses cell activation and antibody synthesis
Melatonin	Pituitary	T cells, thymocytes	↑ Antibody synthesis, cell proliferation
Catecholamines	Adrenal medulla	B and T cells	↑ T cell mobilization, accelerated immune responses sympathetic nerves
Thyroxine	Thyroid	Lymphocytes	↑ T cell activation, plaque-forming cells
Prolactin	Pituitary	B and T cells, macrophages	↑ Macrophage activation ↑ IL2 production
GH	Pituitary	Mononuclear cells	Macrophage activation ↑ Antibody synthesis
Vasopressin and oxytocin		Pituitary	T cells ↑ Proliferation

Modified from [337].

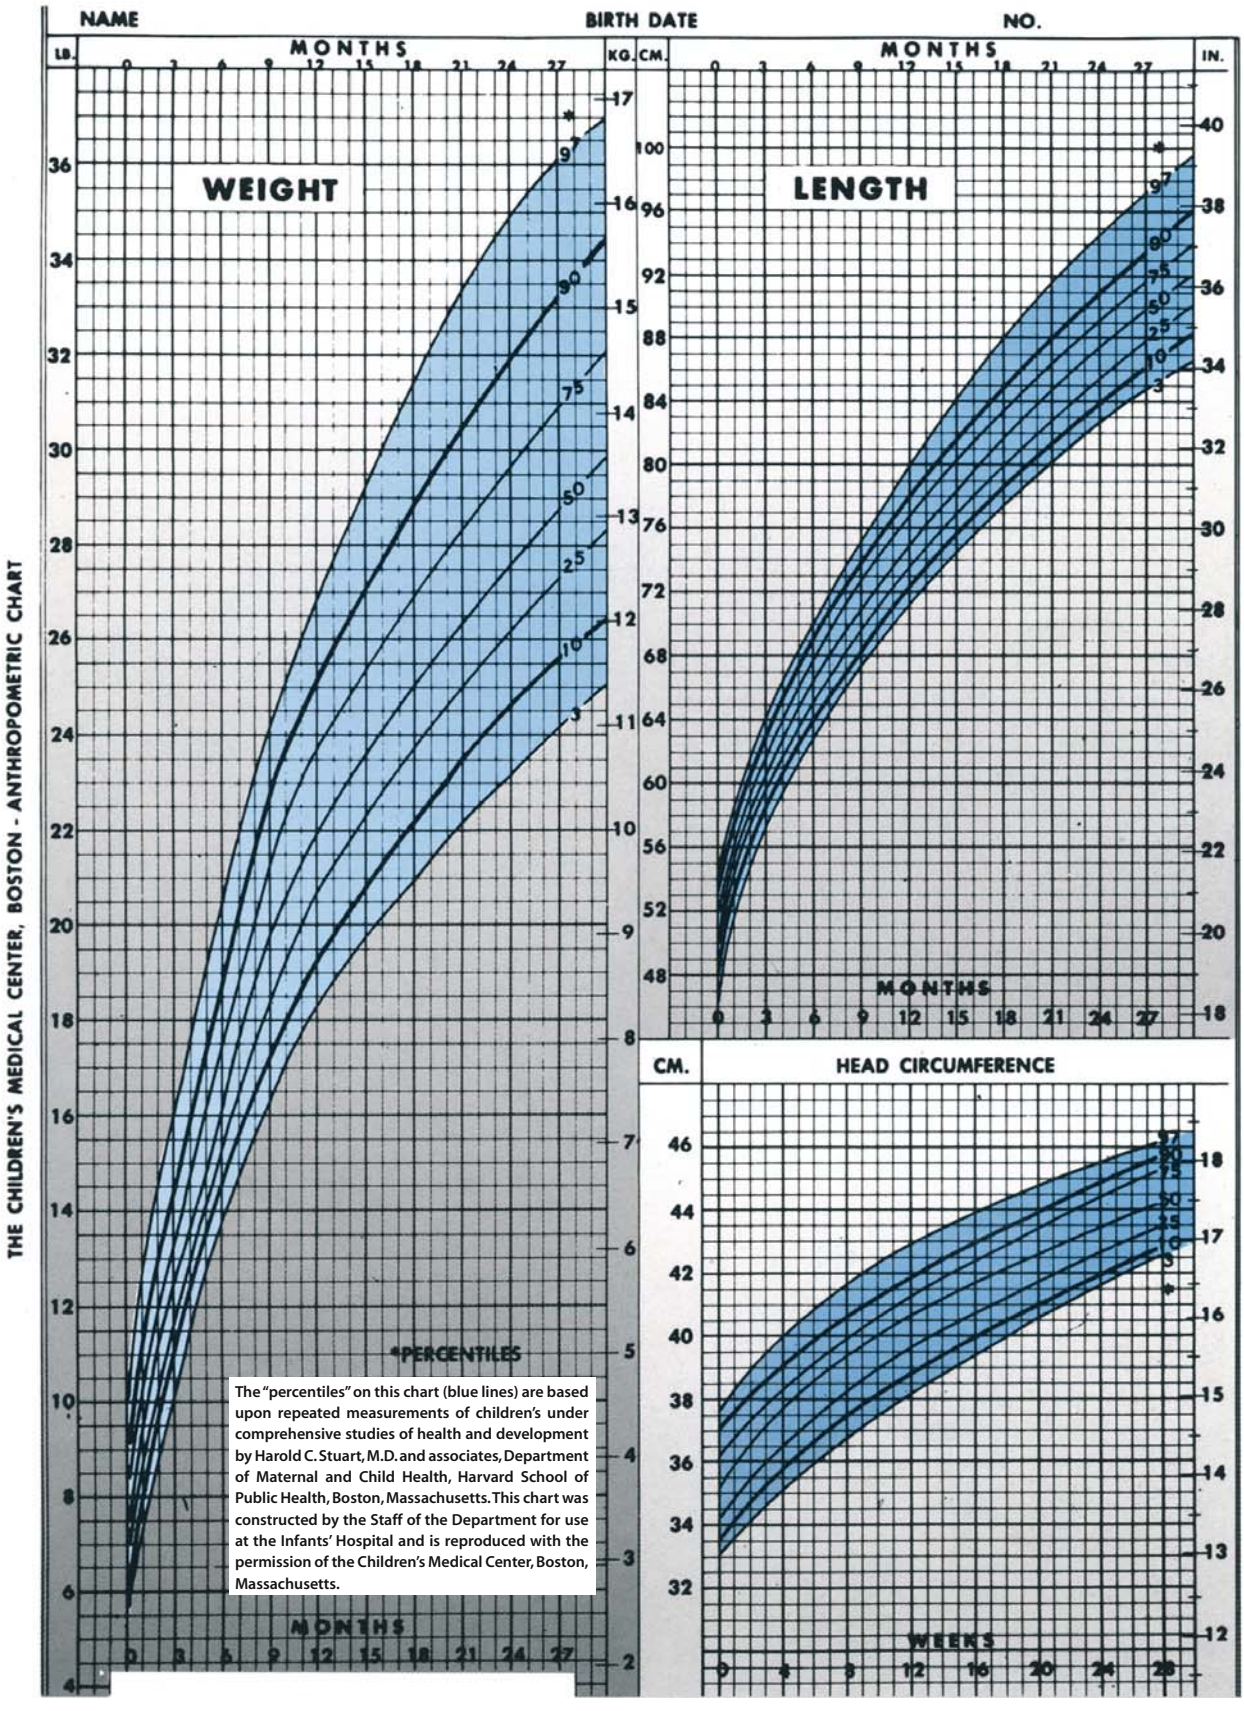
Appendix 4.1. Threshold levels per cubic meter of the main environmental pollutants

	CO	NO_2	O_3	PM_{10}[a]	TSP[a]	SO_2[a]
Alert	15 mg	200 µg	180 µg	50 µg	90 µg	125 µg
Warning	30 mg	400 µg	360 µg	100 µg	180 µg	150 µg

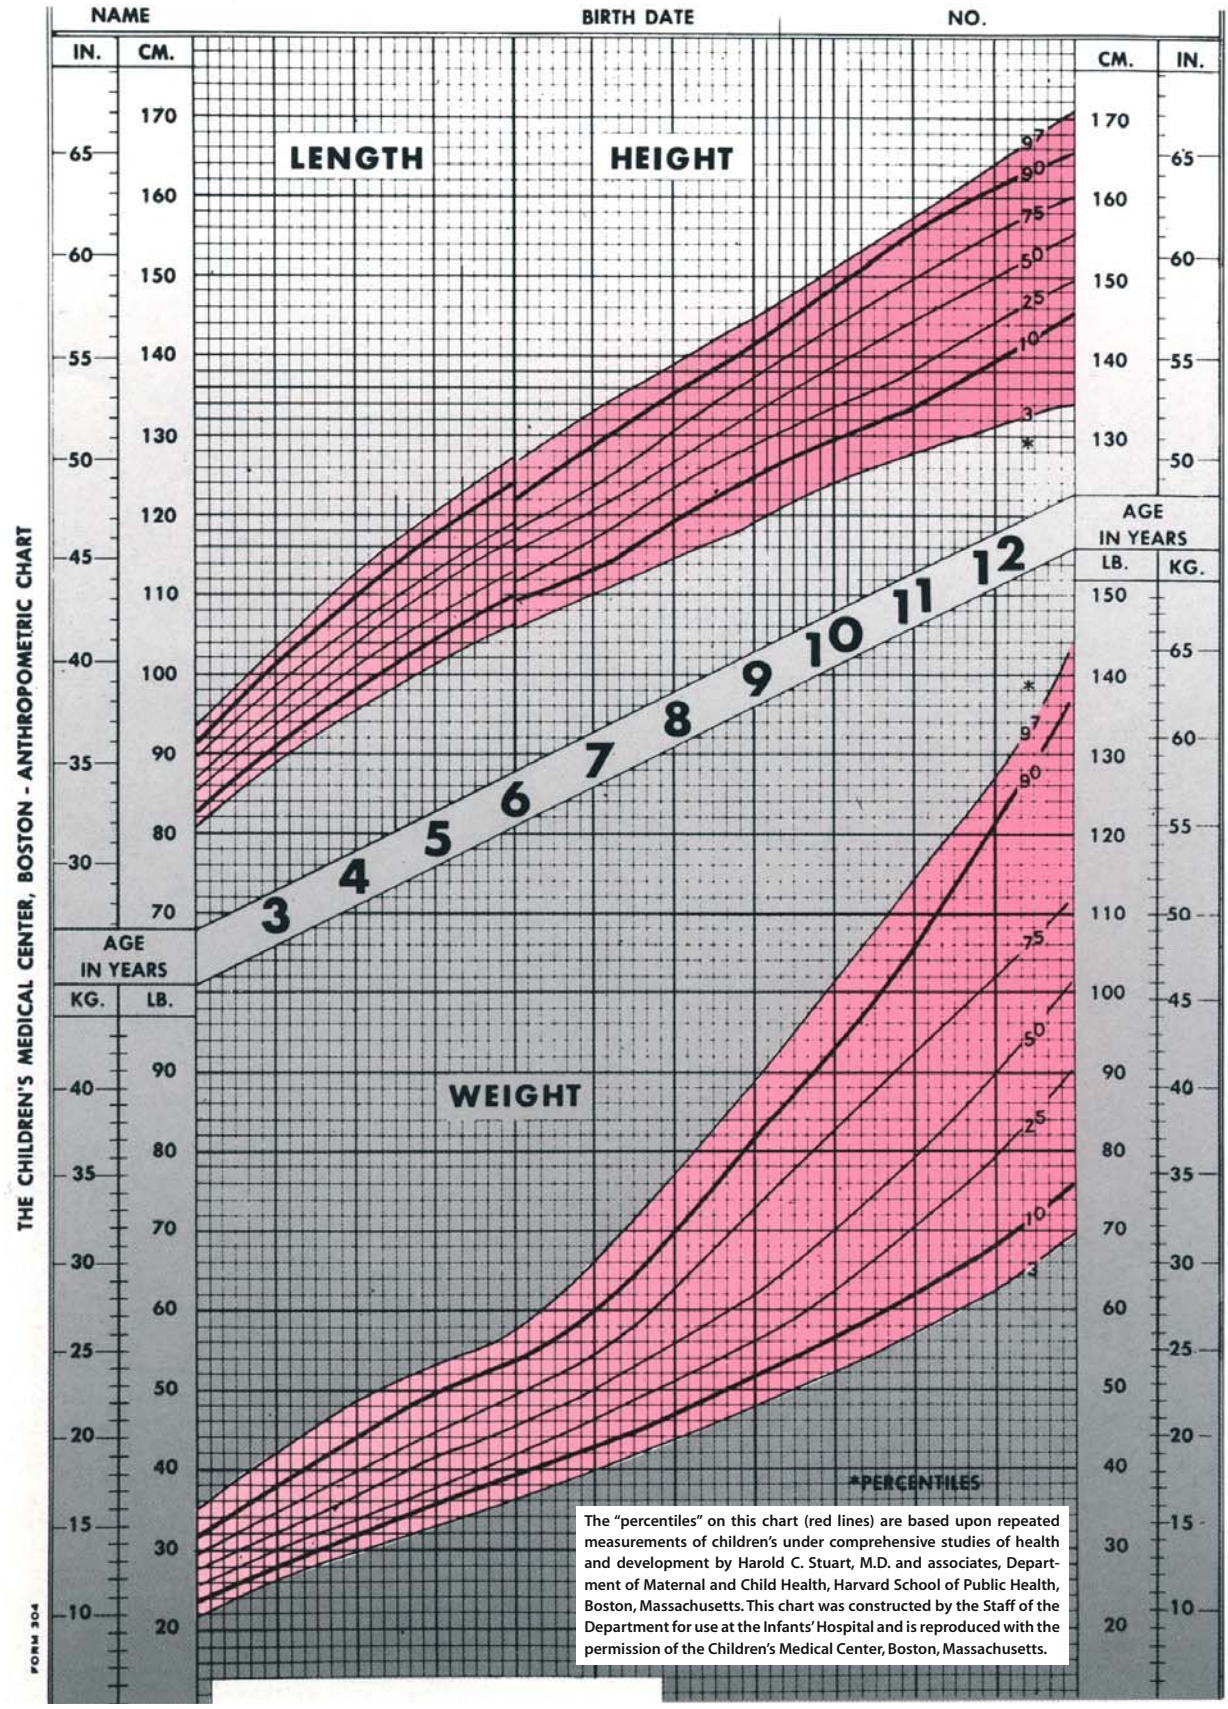
Note that the WHO "alert" value indicates when pollution levels are such that sensitive populations (children and people with respiratory diseases) will begin to feel detrimental health effects. "Unhealthy for Sensitive People": 150–250 µg/m^3.
The WHO "warning" value indicates when pollution has reached a level that everyone will be affected by the pollutant. The USEPA AQI gives different levels only for PM10. "Unhealthy for all People" PM10 levels: 250–350 µg/m^3.
In Europe all cities are "allowed" to register PM_{10} values >50 µg/m^3 for only 35 days/year.
Data from WHO and USEPA AQI (http://www.epa.gov/oar/oaqps/psiaqi.html); WHO Guidelines for Air Quality, WHO, Geneva.
TSP Total suspended particulate.
[a] Daily mean, all others hourly mean.



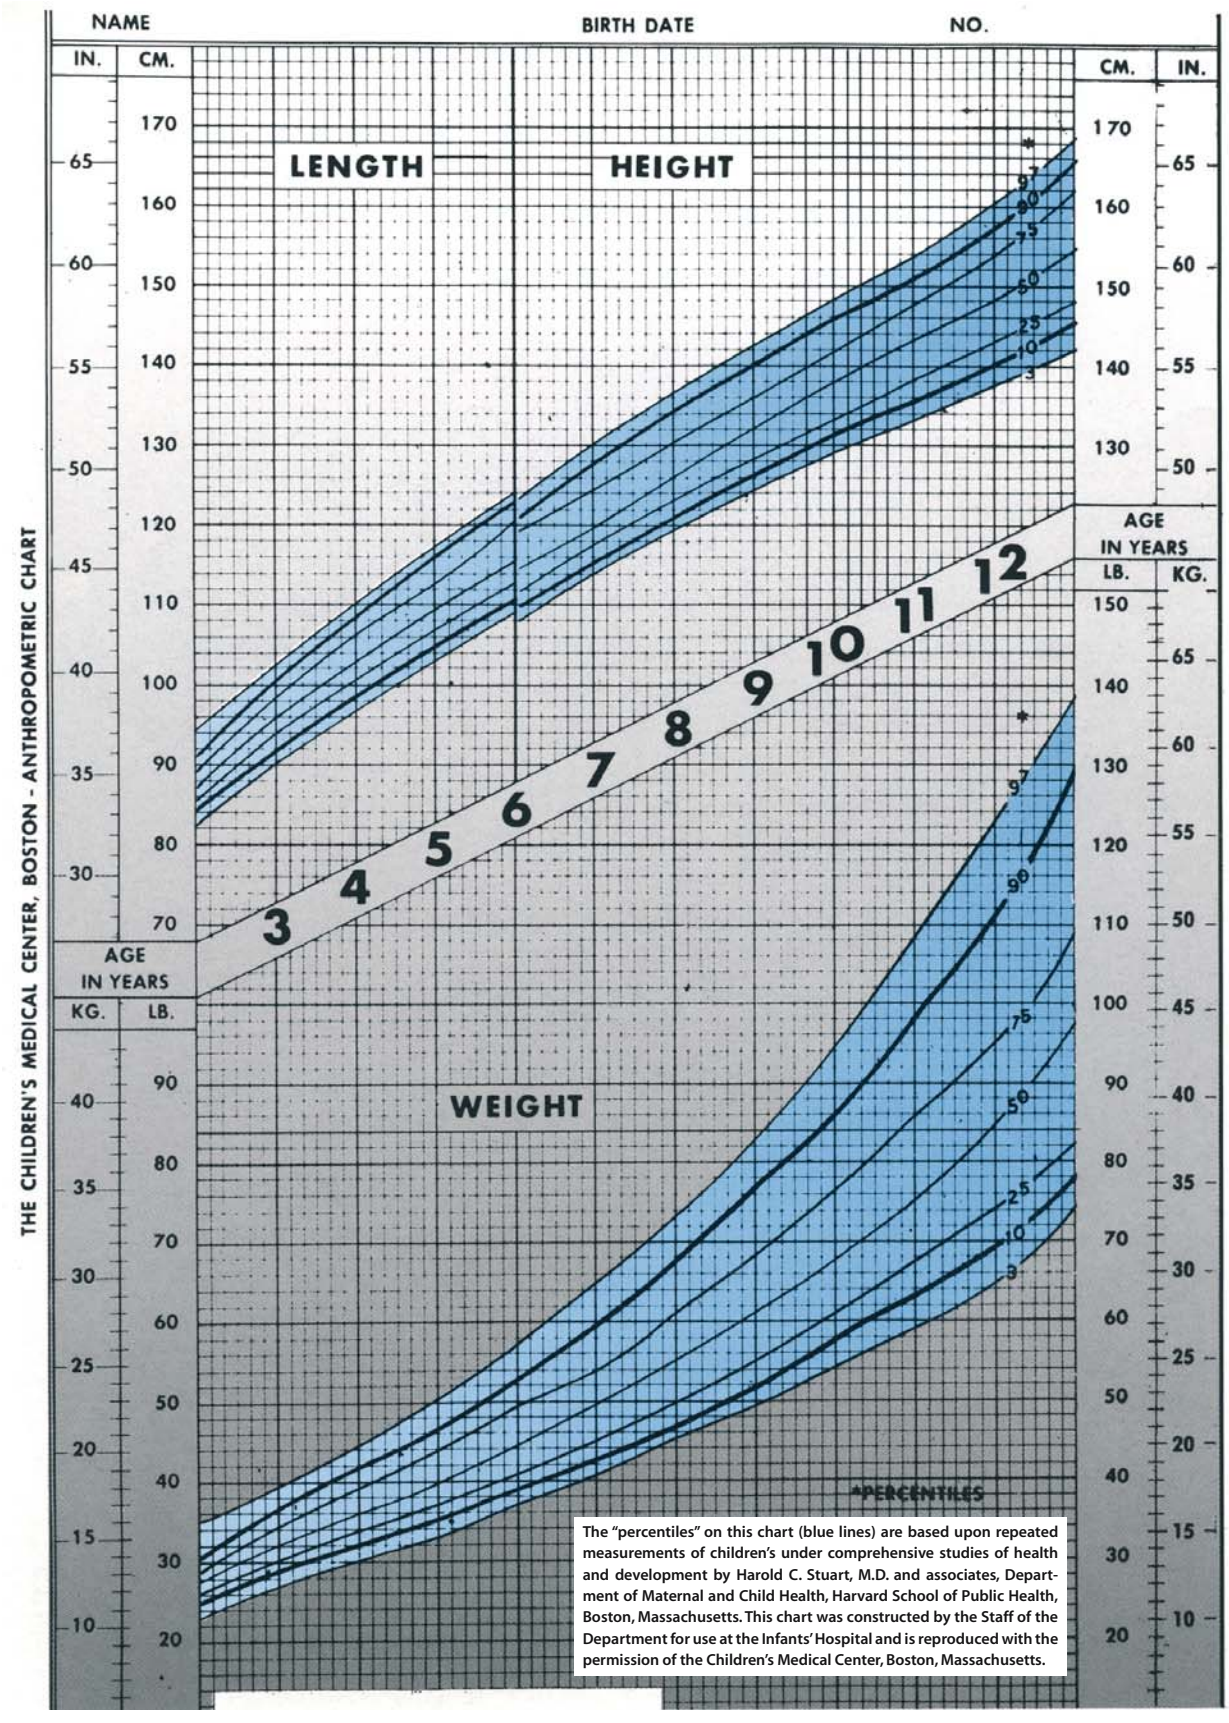
Appendix 6.1. Percentiles for length and weight for age, and for HC. Girls, birth to 2 years



Appendix 6.2. Percentiles for length and weight for age, and for HC. Boys, birth to 2 years



Appendix 6.3. Percentiles for stature and weight for age, girls, 3–12 years



Appendix 6.4. Percentiles for stature and weight for age, boys, 3–12 years

Appendix 6.5. Examination of nasal eosinophils and clinical evaluation

Instruct the child to blow his or her nose directly on a piece of wax paper or on a glass microscope slide, or apply and spread the mucus from the paper to the slide with a cotton-tipped applicator. Otherwise, place a cotton-tipped applicator on the mucosa of the anterior nasal cavity and leave it in place for 2–3 min, then remove, spread the adherent mucus on a glass microscope slide and allow the smear to air dry.

Staining of the nasal smear (the same staining can also be used for conjunctival mucus):

- With the Hansel stain if eosinophils are the only cells of interest
- With the Wright-Giemsa stain if metachromatic cells are also being studied

Examination of the smear. Examine with a microscope under low power (×100) to determine the adequacy of the specimen and individuate the areas of interest. Then examine under a high-power lens (×1,000) and oil immersion. Count the number of eosinophils (pink cytoplasmic granules with blue, bilobed nuclei) and the total number of polymorphonuclear leukocytes (PMNs), which have pale pink cytoplasm and blue, multilobed nuclei. Nasal epithelial cells have abundant pale blue cytoplasm and blue, unlobulated nuclei.

The interpretation of nasal cytograms is best done by the same person.

The percentage of eosinophils is calculated after having examined 1,000 cells, since only 100 cells do not ensure reproducible results. The absolute number of peripheral eosinophils/mm^3 is expressed by the ratio of eosinophils to the total number of peripheral PMNs.

The total number obtained (mean count of the two slides) is evaluated as follows:

No. of eosinophils

- <5%: not significant eosinophilia
- 5%–10%: low eosinophilia
- 10%–50%: increased eosinophilia
- >50%: high eosinophilia

Note that if there are 10% or more eosinophils, allergic rhinitis is suggested (see also Appendix 12.2)

From [14, 59].

Appendix 6.6. Equations for the predictive determination of mean PEF values in children aged 4–16 years, employing Vitalograph Peak Flow Monitor and Wright and Mini Wright Peakflow Meters [181]

Age and length (m) instrument	Sex	C	β1	β2	σ
4–7 years 1.00–1.40 m					
Mini Wright	M	−67.17			
			82.06	27.80	29.9
	F	−90.84			
Vitalograph	M	−55.29			
			59.51	29.15	28.8
	F	−77.47			
7–16 years 1.20–1.80 m					
Mini Wright	M	−46.72			
			97.20	17.38	48.5
	F	−68.96			
Wright	M	−13.84			
			94.72	13.18	43.4
	F	−23.81			
Vitalograph	M	−112.31			
			124.59	17.18	56.5
	F	−136.72			

Equation: $PEFR = C + \beta1 \times (length)^2 + \beta2 \times age$.
See Figs. 6.26–6.31 with ready-made graphs.
The calculations can be made more easily and rapidly with a pocket ruler [181].

Appendix 6.7. Suggestion for an informed consent form

I ..... parent or legal guardian of.....
have been fully and clearly informed by Doctor .....
about mechanisms, administration schedule, purposes and potential side effects of
in vivo diagnostic test .....or[a]
Specific immunotherapy for .....
I agree that my son/my daughter is subjected to this test/treatment[a], am aware that the treating physician will monitor and minimize adverse effects of the treatment. I also confirm that I am aware that I need to follow precautionary measures both before and after the injection/the test, in particular to wait with my son/my daughter in the medical facility for at least 30 minutes following
in vivo diagnostic test .....or[a]
Specific immunotherapy for .....……
dispensing the specialist of every responsibility, in the event I should leave without respecting the necessary observation period and the above-mentioned precautionary measures.
Date .....……
Signature .....……

From [38].
[a] Omit what may be unnecessary.

Appendix 7.1. Clinical evaluation of atopic dermatitis lesions

Severity criteria	Lesion assessment
Mild	Features: erythema, pigmentary changes, mild scaling without significant excoriations (apart from scratching) or lichenifications
	Distribution: relatively little spreading
	Course: episodic, inconstant
Moderate	Intermediate characteristics between mild and severe
Severe	Features: papule, vesicles, crusts, marked erythema, scaling with significant excoriations and/or lichenifications
	Distribution: widespread with face, trunk and limb involvement
	Course: chronic with persistent symptoms independently of local therapy

The SCORAD index (Chap. 6) gives a scoring evaluation.

Appendix 7.2. Levels of free fatty acids in breast milk of European and African mothers

Appendix 8.1. Waxes, gums, spices and flavoring agents that can cause contact urticaria

Waxes and gums
Acacia, beeswax, benzoin, carnauba, guar, karaza, spermaceti, tragacanth
Spices and flavoring agents
Oil of almond, anise, bergamot, camomile, capsicum, caraway, cinnamon, cloves, coconut, ginger, laurel, mace, menthol, minoneme, mustard, nutmeg, palm, peppermint, sesame

Data from [184].

Appendix 8.2. Use of fruit extracts cross-reacting with latex (Table 8.14)

Chymopapain and Papain (from papaya)
Most diffuse use: to tenderize foods (e.g., meat), to clarify drinks (e.g., beer)
Foods
Beer
Cakes
Coca cola
Crackers
Drinks with fruits
Fruit juices and salad
Meat (tenderizes)
Yogurts with fruits
Non-foods and other uses
Cosmetics
Toothpaste
Chemonucleolysis (Chap. 20)
Cleaners for dental prosthesis and soft contact lenses
Drugs: anti-inflammatory, laxatives, gastrointestinal drugs, etc.
Bromelin (pineapple)
Foods
Beer
Cheese
Meat
Other uses
Anti-inflammatory drugs
Diet pills
Ficin (fig)
Foods
Beer
Cheese
Meat
Other uses
Laxative and deworming drugs
Leather and textile industry
Oil of avocado
Cosmetics

Modified from [36].

Appendix 9.1. Dietary products that must be eliminated in children allergic to cow's milk and/or egg proteins

CM and powdered CM
Soups
Cream soups, all soups made with CM/egg, or CM/egg products
Cheese, cottage cheese
Cream of rice cereal
Wheat macaroni and pasta
Breads and cereals
Any prepared with CM or CM products, including biscuits, candy bars, crackers, hot breads, pancakes, rolls, waffles
All cereals precooked and prepared with added CM solids
High-protein cereals
Meat and meat substitutes
Breaded or creamed meat, fish, poultry
Delicatessen meats
Eggs and eggs cooked with CM or CM products
Egg substitutes such as egg beaters
Luncheon meats made with CM
Margarines
Poultry with stuffings
Sausage products such as frankfurters, bologna
Potato and vegetables
Any potato or potato substitute prepared with CM or CM products, including mashed potatoes and macaroni and cheese
Any vegetable prepared or creamed with CM, such as creamed spinach
Salad dressings and mayonnaise containing CM or CM products
Desserts
Any dessert prepared with ingredients that are not allowed
Chocolate (milk chocolate, check plain chocolate)
Commercial cakes, cookies, pies, puddings
Commercial ice cream, sherbet, yogurt
Nondairy whipped topping
Prepared mixes
Fruits and fruit juices

Appendix 9.1. (Continued)

Beverages	
Cocoa, egg nog, malts, milkshakes	
Miscellaneous	
Au gratin dishes	
CM chocolate	
Cream sauce	
Curd, whey	
Special diet preparations	
Egg and powdered egg	
Soups	
Cream soups, all soups made with CM/egg, or CM/egg products	
Macaroni and pasta made with egg	
Mock turtle and egg noodle soup, any egg-cleared stock soup, including consommé, bouillon, etc.	
Breads and cereals	
Commercial doughnuts, French toast, muffins, pancakes, waffles	
Prepared mixes for muffins, pancakes, waffles	
No cereals	
Meat and meat substitutes	
Any serving made with egg as a binding agent, such as casseroles, croquettes, hamburger, meat loaf, sausage, etc.	
Breaded foods in which egg is used as breading	
Canned or stuffed meat	
Cheese fondue, soufflé, cheese puffs	
Meat and fish sauces containing egg butter	
Potato and vegetables	
Any vegetable prepared or combined with egg sauces, including corn custard, hollandaise sauces, spinach omelet	
Duchesse potatoes, croquettes, egg noodles, potato cakes	
Commercial salad dressings and mayonnaise	
Desserts	
Any dessert prepared with ingredients that are not allowed	
Commercial cakes, cookies, frosting, ice creams, icing, pastries, pies, puddings, sherbets and fruit sherbets, yogurts	
Custard	
Meringue, marshmallow, nougat	
Pie crust brushed with egg	
Fruits and fruit juices	
Fruit served with custard sauce	
Fruit whips	
Beverages	
Coffee cleared with egg white	
Commercial candies made without egg may be brushed with egg white	
Ovomaltine and Ovomalt	
Miscellaneous	
All prepared mixes, frozen dinners, etc., unless label clearly indicates egg absence	
Baking powder containing egg white or albumin	
Divinity fudge	
Flour-coated frozen foods	
Thousand Island dressing	
Tartar sauce	

Warning: all labels on foods must be read for products containing milk, egg, and/or soy products: the composition of any food product may be changed without notice.
Lamb meat or products containing it and goat milk may induce cross-reactions in CM-allergic children while chicken or chicken-containing products can induce cross-reactions in egg-allergic children (see text).
The collaboration of M.S. Campostrini in compiling this appendix is acknowledged.
Data from [27, 516].

Appendix 9.2. Dietary products and ingredients with potential hidden forms of cow's milk and/or egg proteins

Ingredients or labels that indicate CM proteins:
Seasonings/flavorings with raw sugar, brown sugar coloring, caramel flavoring/color, natural flavorings, Simplesse [418]
Ingredients that may contain CM proteins:
Artificial butter flavor, butter fat, butter solids, buttermilk, buttermilk also dried or powdered, casein, casein hydrolysate, caseinates (ammonium, calcium, magnesium, potassium, sodium, etc.), cheese, cottage cheese, cream, curds, delactosed whey, demineralized whey, dried or powdered milk, half and half, heavy cream, hydrolysates (casein, milk protein, protein, whey), milk (condensed, dried, evaporated, homogenized, instant nonfat dry milk powder, lactose, lactose-free, low-fat, low-protein milk, low-sodium milk), malted products, margarine, nondairy whipped topping, non-fat butter spread, nougat, protein, rennet casein, skim, sour cream, sour cream solids, sour milk solids, sweet acidophilus, whey, whey protein concentrates, whey protein hydrolysate, yogurt, etc. [8]
Ingredients that indicate masked CM proteins
Brown sugar flavoring, natural flavoring, chocolate, caramel flavoring, high-protein flour, margarine
Potential hidden sources of egg proteins
Bagels
Breads
Coffee
Fillings
Flour-coated frozen foods
Fruit sherbet
Ice creams
Mayonnaise
Meringue
Pastas
Pastries
Pretzels
Root beer
Salads
Sausage
Soups
Egg servings (baked, creamed, deviled, emulsified, fried, frozen, hard- or soft-boiled, poached, scrambled egg, egg salad, egg sandwiches, egg sauces, meringues, omelet, soufflé)
Ingredients or labels that indicate egg proteins:
Albumin, egg (white, yolk, dried, powdered, solids), egg substitutes, eggnog, globulin, livetin (seralbumin, α_2-γ lycoprotein, serum gamma-globulin), ovalbumin, ovomucin, ovomucoid, ovovitellin, Simplesse, yogurts

Products with hidden forms of CM or CM proteins are listed in Table 9.34.
Data from [27, 516].
The collaboration of M. S. Campostrini in compiling this appendix is acknowledged.

Appendix 9.3. Composition of some soy protein formulas

Brand name	Protein	Carbo-hydrates	Fat	PUFA	Minerals	Electrolytes					
						Na	K	Cl	Ca	P	Fe

MCT medium chain triglycerides.

Appendix 9.6. Levels of β-lactoglobulin in cow's milk, breast milk, and some hydrolysate formulas assayed by ELISA and/or RAST inhibition

Food Brand name	β-Lactoglobulin concentration ready-to-use			Ratio CM/ CM/hydrolysate %	RAST inhibition relative potency
	Dry weight µg/g (M±SD)	Product µg/l (M±SD)	Residual %		
CM	117,000	4,000,000	100		100
Beba HA	200				0.06
LHA	200±24	31.200±3.744	0.78	130	
Good Start	83±14	12.438±1.990	0.31	320	
Alfa Ré	0.12±0.016	14.5±1.8	0.00036	280,000	
Profylac	0.066±0.01	8.9±1.3	0.00022	450,000	<0.01
Pregomin	0.065±0.002	9.7±0.29	0.00024	410,000	
Pepti Junior	0.0061±0.0008	0.91±0.12	0.000023	4,400,000	
Alimentum	0.03				<0.01
Nutramigen	0.0056±0.0005	0.84±0.07	0.000021	4,800,000	0.05

A subsequent study shows different values (µg/g): Peptide-Tutteli (EWHF), Nutramigen, Nutri-Junior, Neocate, and Beba HA [235] have values of 0.011, 0.014, 0.031, 0.0016, 84, respectively. The Nutramigen value is greater than 0.4-fold higher in comparison with the above figures.
Data from [235, 317, 318, 368].

Appendix 9.7. β-Lactoglobulin levels in breast milk (ng/ml)

Axelsson et al [17]	5–800
Høst et al [226]	0.9–150 (mean, 4.2)
Jakobsson et al [238]	5–33
Machtinger and Moss [314]	0.1 pg/ml to 6.4 ng/ml
Sorva et al [451]	Basal, 0.0–3.5 (mean, 0.01) 1 h, 0.01–7.84 (mean, 0.12)[a]
	2 h, 0.01–2.34 (mean, 0.07)[a]

[a] After drinking 400 ml of CM.

Appendix 9.8. Nutrient distribution of some special formulas based on amino acids

Brand name	Protein g/dl	Fat g/dl	AA g/dl	Carbohydrate			Energy kcal/l	Osmolarity mosm/l
				g/dl	Type	%		
Neocate	1.95	3.5	2.3	8.1	Glucose		71	342
Neocate Advance	2.5	4.0	3.0	14.6	Glucose	(9)	71	298
Nutri 2000	2.9	3.4	1.7	15.0	Maltodextrin	(99)	100	520
Pepti-Junior	1.8	3.6	–	6.9	Maltodextrin	(90)		
					Glucose		(1)	
					Others	(8)	67	190
Pregomin AS	2.0	3.5	–	8.6	Glucose		73	300

Minerals and trace elements are added to all formulas; α-linolenic acid is added to Neocate and Pepti-Junior.

Appendix 9.9. Calcium-rich foods of the most common cow's milk substitutes for allergic children

Foods	Mg/dl of edible part
Beet	80
Horse	12
Lamb	10
Lean pork	9
Lettuce	50
Pear	13
Potato	9
Rabbit	17
Rice	12
Soy milk	**mg/dl of reconstituted product**

Puvvada et al	1993	8	
Tounian et al	1993	17	
Trotter et al	1994	12	2[a]
Total		1,963	13

[a] The reported reactions have not caused modifications of vital parameters, nor have they required the administration of adrenaline, antihistamines or other medications, and the children completed the normal vaccination.
[b] One child developed anaphylaxis after a subsequent intradermal test.
[c] Two children developed mild generalized urticaria 24 h after MMR vaccination.
[d] The children presented with urticaria, which spontaneously remitted, and were subsequently vaccinated according to the desensitization protocol of Herman.
[e] The children were regularly vaccinated following the above protocol, without reactions.

Appendix 9.11. Number of immediate or anaphylactic-type reactions to measles or MMR vaccination in children not allergic to egg

Authors	Year	Immediate reactions No. of cases	Anaphylactic reactions No. of cases
Aukrust et al	1980	6	0/6

Patja et al	2001	3	2/3[b]
Total		50	3/50

[a] Kelso et al [265] demonstrated by the immunoblotting method the presence of gelatin-specific IgE in an egg-tolerant 17-year-old female who developed anaphylaxis after MMR vaccination.
[b] Two of the three children had sIgE to gelatin.
Data from [94, 243, 378].

Appendix 9.12. Potential hidden sources of wheat, peanuts, corn, nuts, soy, sesame, coconuts and dates, anise, beef, and shellfish

A. Products and ingredients potentially containing wheat
All products made with wheat flour (cake, cookies, ice cream cones, pastries, pie)
Any breaded or floured food or prepared with wheat flour
Bran
Biscuits, doughnuts, dumplings, French toast, muffins, pancakes
Bouillon cubes (some types)
Bread or bread crumbs made with wheat flour, bread and cracker stuffing
Bulgur
Cake flour
Canned meat
Cereal extracts
Cereals containing wheat
Commercial candies containing wheat products
Commercial gravy, gravy made with wheat flour
Commercial salad dressings thickened with wheat flour
Couscous
Cracked wheat flour
Cracker meal, crumbs
Enriched flour, farina flour, gluten flour
Frosting
Kamut
Hydrolyzed vegetable protein
Hyperproteinic floor
Meats containing filler such as meat loaf, bologna, luncheon meats, wieners
Natural flavoring
Noodles, macaroni, spaghetti
Packaged puddings
Pastry flour
Pepper powder (some types)
Phosphated flour
Potatoes or rice prepared with wheat flour (example: escalloped potatoes)
Prepared chocolates and mixes
Pretzels
Rye bread or corn bread made with wheat flour
Sauces of any type prepared with wheat
Seitab
Semolina of all types
Soups containing alphabets, dumplings, noodles, spaghetti
Soy sauce
Strained fruits with added cereals
Vegetable gum, starch
Wheat crackers

Appendix 9.12. (Continued)

Ingredients and labels that indicate masked presence of wheat protein

- All-purpose flour, bread crumbs, cake flour, cereal extract, cracker meal, farina, gelatinized starch, gluten, graham flour, high-gluten flour, high-protein flour, hydrolyzed vegetable protein, mixed grains flour, modified food starch, pastry flour, self-rising flour, semolina flour, triticate, vital starch, wheat bran, wheat germ bran, wheat gluten, wheat meal, wheat starch, whole wheat flour

Ingredients and labels indicating potential presence of wheat protein

- Gelatinized starch, modified food starch, modified starch, natural flavoring, soy sauce, starch, vegetable gum, vegetable starch

B. Products and ingredients potentially containing peanuts

African, Chinese, Thai and other ethnic dishes

Baked goods (pastries, cookies, etc.)

Bakery products

Breakfast cereals (some types)

Candy, cream-filled pastries

Canned fish

Chili

Chocolate (candy, candy bars)

Egg rolls

Ice creams

Margarine (check the ingredients)

Marzipan

Nougat

Pastries (they are often minced and therefore unrecognizable)

Sauces for meats

Sausages

Ingredients and labels that indicate masked presence of peanut protein

- Hydrolyzed plant protein, hydrolyzed vegetable protein
- Cold-pressed peanut oil, ground nuts, mixed nuts, Nu-Nuts (artificial nuts), peanut butter (check the ingredients), peanut flour

NB, Peanuts are employed as peanut oil:

- In CM formulas for babies
- In vitamin oil preparations

C. Products and ingredients potentially containing corn

Foods potentially containing corn starch

- Mixed vegetable creams and/or flours

Any food cooked or fried with corn oil

Baby foods

Bacon

Baking powder biscuits, baking mixes, corn fritters, pancakes

Batters for frying

Breaded or fried foods

Cakes

Candies

Canned or frozen fruits or juices "with sugar added"

Canned peas, frozen vegetables, pork and beans

Cereals for breakfast

Cheese, cheese spreads

Chewing gum

Chili

Chocolate milk

CM, in paper cartons

Coated rice

Coffee, instant

Cold cuts, ham, sausage, wieners, processed meats

Confectioner's sugar, powdered sugar

Cookies

Corn flakes, corn cereals, presweetened cereals

Eggnog

English muffins, tamales, tortillas

Fish sticks, prepared and processed fish

French dressing

Frosting

Fruit juices, fruit pies

Fruits, canned and frozen

Frying fats

Gelatin capsules, gelatin desserts

Glucose and fructose products

Grape juice

Gravies

Ice creams

Instant coffee, instant teas

Jam and jellies

Leavening agents and yeasts

Margarines and shortenings

Peanut butter, butter for frying

Appendix 9.12. (Continued)

- Polenta
- Popcorn
- Potatoes or rice fried in corn oil
- Puddings and custards
- Salad dressings
- Sandwich spreads
- Sauces for fish, meats, sundaes, etc.
- Sausages
- Soy milk
- Soy sauce
- Vegetable soups, commercial soups
- Chemical substances
- Caramel color
- Citric acid
- Dextrin
- Dextrose
- Fructose
- Glucose
- Maltodextrins
- Mannitol
- Monosodium glutamate
- Ingredients and labels that indicate masked presence of corn protein
  - Baking powder, blue corn, corn alcohol, corn bran, corn flour (blue, white, or yellow), corn germ, corn meal (blue, white, or yellow), corn pastas, corn products, corn syrup, corn syrup solids, corn sweetener, cornstarch, dent corn, hominy grits, maize, popcorn, puffed corn, sweet corn, whole dried corn, whole hominy
- Ingredients and labels that indicate peanut protein
  - Food starch, modified food starch[a], vegetable gum, vegetable starch
- Ingredients and labels indicating masked presence of corn protein
  - Corn sugars, corn flour (all types), hydrolyzed vegetable protein, margarine, natural and artificial emulsifiers and stabilizers, thickeners, vegetable broth, vegetable oil

D. Products and ingredients potentially containing nuts (all types), almonds, cashews[b]

- Almond paste
- Artificial nuts
- Baked goods (pastries, cookies, etc.)
- Bakery products
- Brazil nuts
- Cashews
- Chestnuts
- Chocolate with hazelnuts, nut chocolate (chocolate with chopped toasted nuts)
- Commercial sauces for pasta or meats
- Commercial vegetable courses
- Filberts/hazelnuts
- Hickory nuts
- Ice creams
- Macadamia nuts
- Marzipan
- Nougat
- Nut butters (i.e., cashew butter)
- Nut oil
- Nut paste (i.e., almond paste)
- Pecans
- Pine nuts (pinion nuts)
- Pistachios
- Pollack (surimi)
- Sugared almonds
- Torrone paste
- Torrone, chocolate torrone
- Walnuts

E. Products and ingredients potentially containing soybean[c]

- African, Chinese, Thai and other ethnic dishes
- All products made with soy flour
- Baked goods
- Biscuits and biscuit mixes containing soy oil
- Bouillon cubes (some types)
- Breads containing soy oil
- Canned foods
- Canned meat
- Caramel candies
- Cereals containing soy oil, soy flour
- Chocolate
- Commercial ice creams
- Corned beef
- Crackers
- Dietetic food
- Dough mixes
- Filler foods, especially meat-based
- Fish canned in soy oil

Appendix 9.12. (Continued)

Hamburger with soy protein
Hard candies, nut candies
Lecithin (added to biscuits, candies, chocolate and substitutes, ice creams, margarine, spaghetti, etc.)
Luncheon meats
Margarine or shortenings
Meat substitutes
Milk and coffee substitutes
Milkshakes that are not homemade
Minced meat not homemade
Products fried or cooked with soy oil or soy margarine
Salad dressing containing soy oil
Sausages or cold cuts with added soy protein
Soups containing soy or soy products
Soybean oil
Spaghetti prepared with soy flour
Steak sauce
Tea cakes
Toasted soybeans
Tuna canned in soy oil
Vegeburgers made with textured vegetable protein (TVP)
Vegetables served with a soy sauce or dressed with soy oil
Ingredients and labels that indicate masked presence of soy protein
Hydrolyzed vegetable protein, miso, protein fillers, soy flour, soy grits, soy nuts, soy oil, soy protein, soy protein concentrate, soy protein isolate, soy sauce, soy sprouts, soybean (curd, granules), TVP, tofu
Ingredients and labels indicating potential presence of soy protein
Emulsifiers, flavorings, gum arabic, hydrolyzed plant protein, hydrolyzed soy protein, hydrolyzed vegetable protein, natural flavoring, vegetable broth, vegetable gum, vegetable starch
F. Products and ingredients potentially containing sesame
Bread crumbs
Candies
Fillings
Hamburger
Nut and almond substitutes
Restaurant and commercially prepared salads
Vegetable hamburger
G. Products and ingredients potentially containing coconuts or dates
Biscuits
Commercial ice creams
Cookies, pies and puddings that are not homemade
Pastries
H. Products and ingredients potentially containing anise
Candies
Commercial pastries
Cookies, pies and puddings that are not homemade
Liquors
I. Products and ingredients potentially containing beef
Biscuits (containing beef "gelatin")
Bouillon cubes (even if "from poultry")
Canned beef (containing beef "gelatin")
Cheese curd (from calf)
Chopped meat
Commercial Ca preparations (containing beef "gelatin")
Sausages
J. Products and ingredients potentially containing shellfish[d]
There is no particular name masquerading shellfish: see also Table 9.9
The main problem is the use of alternative names, often foreign names:
Calamari for squid
Crevette for shrimp
Escargot for snails
Langouste, langoustine, scampi for lobster
Mollusks for shellfish

Data from [25, 27, 207, 276, 301, 390, 478, 516, 523].

[a] Can also be derived from other ingredients, including potatoes, tapioca, and wheat. Corn may also be used as an adhesive for postage stamps and envelopes, etc. The same problem also concerns fish-allergic children. Corn is used in many medicines and vitamins. Paper containers may contain corn, and the inner surface of plastic food wrappings and waxed paper cartons may be coated with cornstarch. Read every label, some foods may be eaten if checked with the manufacturer and found to be starch-free, best of all is home preparation of all foods.

[b] Nu-Nuts are peanuts first deflavored and then reflavored with a nut like pecan or walnut.

[c] Soybean flour may be added to bakery products to keep them moist; most soy-allergic children may safely eat products containing soy lecithin and/or soy oil. In Chap. 24 a child reacting to soy lecithin is reported.

[d] Beef "gelatin" is made from beef skin and bone; for all commercial products, check whether they effectively contain the offending food.

Appendix 9.13. Clinical and laboratory data to be checked during a more or less prolonged elimination diet

Medical examination of child
Body mass index (BMI), Mid-arm circumference (MAC), Mid-arm muscle circumference (MAMC), plicometry
Control of both the diet and diary
Control of food nutritional value
Height (Appendices 6.1–6.4)
Weight (Appendices 6.1–6.4)
Calcium serum levels
Ferritin serum levels
Iron serum levels
Lipid fractions
Nitrogen balance
Plasma aminoacidemia
Protidemia with electrophoresis
Serum and urine electrolytes
Transferrine serum level
Whole blood count
Zinc serum levels

Data from [516].

Appendix 10.1. Foods and non-foods potentially containing gelatin or vegetable gums

Gelatin	**Arabic gum, acacia gum E 414**
Gelatin of all types	Candy
Brawn	Commercial puddings
Canned beef	Diabetic foods
Chewing gum	Ice creams
Desserts	Iced confectionery
Fruit juices	Sherbet
Fruit yogurt	**Carob seeds, locust gum E410**
Gummy candies	Canned meat
Instant cakes	Chocolate, cocoa and coffee surrogate
Instant pudding	Flour
Instant whipped cream	Fruit juices and preserve
Licorice	Iced confectionery
Pastry	Jam
Pudding	Mustard
Whipped cream	Yogurt
Yogurt	**Nonfoods**
Nonfoods	Cigarettes
Measles vaccine	Cosmetics
	Toothpaste

Appendix 10.1. (Continued)

Guar gum E412	Cosmetics
Canned, commercial soups	Toothpaste
Cheese	**Adragant gum E413**
Dietetic food preparations	Cod-liver oil
Ice creams	Fresh, soft cheese
Salad dressing	Hamburger
Yogurt	Margarine
Non-foods	Mayonnaise
Pharmacological compounds	Soft drinks
Creams	**Non-foods**
Emulsions	Toothpaste
Gummy pills	Vitamin soluble preparations
Lotions	
Suspensions	
Toothpaste	

Gelatin has a widespread use as a stabilizer pharmaceutically and in foods.
Data from [91, 106].

Appendix 11.1. Respiratory rate per minute at different ages in healthy children when awake or asleep

Age	Awake			Asleep		
	Mean	Median	SD	Mean	Median	SD
<2 months	48.0	47	9.1	39.8	39	8.7
2–6 months	44.1	42	9.9	33.4	32	7.0
6–<12 months	39.1	38	8.5	29.6	28	7.0
12–<18 months	34.5	34	5.8	27.2	26	5.6
18–<24 months	32.0	32	4.8	25.3	24	4.6
24–<30 months	30.0	30	6.2	23.1	23	4.6
30–36 months	27.1	28	4.1	21.5	21	3.7
	Mean	Range		Mean	Range	
4–6 years	26	19–30		18	14–23	
6–8years	23	15–30		17	13–23	

Data from [544] (0–3 years) and [302] (4–8 years).

Appendix 11.2. Biological diagnosis of cough in children

Airway obstruction

1. Allergic rhinitis
2. Diphtheria
3. Foreign bodies
4. Maxillary sinusitis
5. Nasal secretions
6. Tonsillitis

Inspiratory stridor

1. Innervation anomalies and malformations
   - Congenital laryngeal malformations
   - Epiglottis or arytenoid cartilage flaccidity
   - Innervation anomalies associated or not with soft palate anomalies
   - Vocal cord dysfunctions
   - Vocal cord traumatic dislocation
2. Epiglottitis
3. Hypertrophied tonsils
4. Laryngeal stenosis
5. Laryngitis
6. Laryngospasm
7. Malformations
8. Acute tracheal stridor
   a. Foreign bodies
   b. Infections
9. Chronic tracheal stridor
   a. Vascular ring
   b. Tracheomalacia
   c. Tumors

Expiratory stridor – dyspnea

1. Bronchiolitis
2. Asthma

Pulmonary dyspnea

1. Congenital cysts
2. Diaphragmatic paralysis
3. Lobar emphysema
4. Pleural disease
5. Pulmonary disease
   a. Bronchopulmonary dysplasia
   b. Pulmonary fibrosis
6. Pulmonary malformations
7. Pickwick syndrome

Cardiogenic dyspnea

Breathing difficulties on expiration and/or inspiration

Dyspnea attributable to metabolic causes

1 Acidosis
   a. Poisoning especially by salicylate-containing drugs
   b. Ketonemia
   c. Uremia

2. Alkalosis
   a. Forced diuresis hypochloremic alkalosis
   b. Hyperaldosteronism
      Primary
      Secondary
      Bartter's syndrome
   c. Hyperventilation syndrome respiratory alkalosis
      Poisoning
      Fever
      Heart failure
   d. Hypokalemia syndrome
   e. Psychogenic hyperventilation
   f. Repeated gastric lavage
   g. Uncontrollable vomiting

Dyspnea due to cerebral cause

1. Biot's breathing
2. Cheyne-Stokes respiration

Dyspnea associated with hypoventilation

1. Birth injury
2. Congenital myotonia
3. Respiratory muscle pareses

Rare causes

1. Alveolar-capillary block syndrome
2. Bland-White-Garland syndrome
3. Endocardial fibroelastosis
4. Generalized arterial calcification
5. Hamann-Rich syndrome
6. Histiocytosis X
7. Idiopathic pulmonary hemosiderosis
8. Kofferath syndrome
9. Kugel-Stoloff syndrome
10. Macleod's syndrome
11. Mounier-Kuhn syndrome
12. Ondine's syndrome
13. Pompe's disease
14. Pulmonary alveolar proteinosis
15. Wilson-Mikity syndrome

Data from [186, 469, 479].

Appendix 12.1. Main causes of chronic nasal blockage in infancy and childhood

Congenital factors	Vasomotor rhinitis
Choanal posterior stenosis	**Allergy**
Congenital choanal atresia	Seasonal allergic rhinitis
Dermoid	Perennial allergic rhinitis
Encephalocele	Recurrent airway symptoms
Glioma	**Drug-induced**
Malformations	Alcohol
Teratoma	Aspirin
Tornwaldt's cyst	β-Adrenergic drugs
Mechanical factors	Cocaine
Adenotonsillar hypertrophy	Guanethidine
Direct or penetrating injury	Methyldopa
Foreign body	Nasal decongestants
Meningocele	Phenothiazine
Nasal polyps	Reserpine
Septal deviation	**Miscellaneous**
Tumors of the nasopharynx	Acromegaly
Infections and Inflammations	Cystic fibrosis
Adenoiditis	Hypothyroidism
Atrophic rhinitis	Pregnancy
Bacterial and viral infection	Sarcoidosis
Chronic rhinitis	Wegener's granulomatosis
Chronic sinusitis	**Iatrogenic causes**
Congenital ciliary dyskinesia	Rhinitis medicamentosa
Immunodeficiency	Stenosis of the nasopharynx
Infectious rhinitis	

Modified from [107].

Appendix 122. Examination of nasal and conjunctival secretions and their interpretation

In interpreting nasal cytograms, the following disorders are suggested in children:
Presence of 10% or more eosinophils:
1. Allergic rhinitis
2. Eosinophilic nonallergic rhinitis (ENR)
3. Nonallergic rhinitis with eosinophils (NARES)
4. Rhinitis associated with non-IgE-mediated asthma
5. Acetylsalicylic acid hypersensitivity
Presence of an increased number of metachromatic cells:
1. Conditions listed above for increased eosinophils
2. Nonallergic basophilic rhinitis
3. Primary nasal mastocytosis
If neutrophils are increased:
1. If associated with intracellular bacteria → infectious rhinopharyngitis or sinusitis
2. If associated with ciliocytophoria (epithelial cells with clumping of chromatin material) → viral upper respiratory infection
In interpreting conjunctival cytograms, the following disorders are suggested in children
Presence of eosinophils, metachromatic cells:
1. Allergic conjunctivitis
2. Vernal conjunctivitis
3. Giant papillary conjunctivitis
4. Keratoconjunctivitis
Presence of neutrophils → infectious or irritant conjunctivitis
Presence of lymphocytes → viral conjunctivitis

Prior to collecting nasal specimens, the child should clear the nose of excess secretions; in infants a rubber bulb might be used to aspirate excess mucus. Then, using a disposable plastic curette, under direct illumination and visualization of the nasal cavity, sample the medial or inferior portion of the anterior turbinate posteriorly, avoiding the anterior bulb area. Gently press the probe cupped tip on the mucosal surface and move outwards 2–3 mm. We suggest repeating the motion twice and withdrawing the probe without touching the nasal vestibule to prevent contamination. Staining is described in Appendix 6.5.

Appendix 131. Schematic dosage schedule for specific immunotherapy for inhalant allergy[a]

A. Start with vial no.1 (1:10,000) with the following doses:		
1st injection	0.10 ml	
2nd injection	0.20 ml	
3rd injection	0.40 ml	At 7-day intervals
4th injection	0.60 ml	
5th injection	0.80 ml	
→ Discontinue vial no. 1 even if there is residual vaccine and		
BContinue with vial no.2 (1:1000) with the following doses:		
1st injection	0.10 ml	
2nd injection	0.20 ml	
3rd injection	0.40 ml	At 7-day intervals
4th injection	0.60 ml	
5th injection	0.80 ml	
→ Discontinue vial no. 2 even if there is residual vaccine and		
C. Continue with vial no.3 (1:100) with the following doses:		
1st injection	0.05 ml	
2nd injection	0.10 ml	
3rd injection	0.15 ml	At 7-day intervals
4th injection	0.20 ml	
Continue with vial no. 3 with the dose of 0.20 ml at 2-week intervals		
→ This maintenance dose, if well tolerated, after a 1-year period will gradually be increased up to 0.50–0.60 ml and the administrations will be first continued at 3-week intervals and then at 4-week intervals.		

[a] SIT for Der p can be started in any season, whereas SIT for grasses should be started in fall (and not during summer) (in Europe) to reach the maximal tolerated dose before the start of the pollinating season. In this period, it is suggested to reduce slightly the maintenance dose in highly sensitive children.

Source: Division of Pediatric Allergy and Immunology, University of Rome "la Sapienza."

Appendix 13.2. Schematic dosage schedule for rush SIT and ultra-SIT for venom

	Rush SIT (in children)		Ultra-rush (in children and adults)	
Week no.	Day no.	Venom dose (in μg)	Minutes	Venom dose (in μg)
1	1	0.01; 0.1; 1; 3[a]	0	0.1
2	8	5	30	1
3	15	10	60	10
4	22	20	90	20
5	29	40	120	30
6	36	70	150	40[b]
7	43	100		

[a] Cumulative dose: 4.11 μg. From [184].
[b] Cumulative dose: 101.1 μg. From [27, 160] for adults and from G. Patriarca (pers. comm.).

Appendix 13.3. Schematic dosage schedule for modified ultra-rush venom immunotherapy

	Modified ultra-rush venom immunotherapy[a]	
Day	Time (h)	Insect venom (μg)
1	0	0.01
	0.5	0.10
	1.0	1.00
	1.5	10.00
	2.0	20.00
	2.5	40.00
	3.0	80.00
2	0	100.00

[a] All children were discharged from the hospital on the second day, with 8 children already discharged 4 hours after the first maintenance dose of 100 μg insect (Dr. Steiß, pers. comm., Dec 19, 2005).

Appendix 13.4. Oral desensitization to cow's milk, egg and fish

Protocol for oral desensitization with cow's milk.
Starting dilution: 10 drops of milk in 10 ml of water

Days	*Daily dose*
1–3	1 drop
4–6	4 drops
7–9	6 drops
10–12	10 drops
13–15	12 drops
16–18	18 drops
Pure milk	
19–21	1 drop
22–24	2 drops
25–27	3 drops
28–30	4 drops
31–33	6 drops
34–36	8 drops
37–40	10 drops
41–44	16 drops
45–48	24 drops
49–52	32 drops
53–56	40 drops
57–60	40 drops × 2
61–64	40 drops × 3
65–68	40 drops × 4
69–72	50 drops × 4
73–76	60 drops × 4
77–80	4.5 ml × 3
81–84	6 ml × 3

Appendix 13.4. (Continued)

85–88	6 ml × 4
89–92	7 ml × 4
93–96	12 ml × 4
97–100	15 ml × 4
101–104	15 ml × 5
105–108	20 ml × 3
Days	*Daily dose*
109–112	30 ml × 3
113–116	40 ml × 3
117–120	50 ml × 2
121–124	65 ml × 2
125–128	80 ml × 2
129–132	100 ml
133–136	120 ml
Maintenance dose: 120 ml of milk (about one glass) at least two or three times a week[a]	

Oral specific desensitization in patients allergic to egg

Starting dilution: 10 drops of shaken egg (albumen and yolk) in 100 ml of water	
Days	*Daily dose*
Days 1–3	4 drops
Days 4–7	4 drops × 2
Days 8–11	4 drops × 3
Days 12–14	8 drops × 3
Days 15–17	16 drops × 3
Days 18–20	36 drops × 3
Pure shaken egg	
Days 21–23	1 drop
Days 24–26	2 drops
Days 27–29	3 drops
Days 30–32	4 drops
Days 33–35	6 drops
Days 36–38	12 drops
Days 39–41	10 drops × 2
Days 42–44	10 drops × 3
Days 45–47	15 drops × 3
Days 48–50	20 drops × 3
Days 51–53	25 drops × 3
Days 54–56	35 drops × 3
Days 57–59	50 drops × 3
Days 60–62	5 ml × 2
Days 63–65	5 ml × 3
Days 66–68	5 ml × 4
Days 69–71	10 ml × 3
Days 72–74	10 ml × 4
Days 75–77	15 ml × 3
Days 78–81	15 ml × 4
Days 82–85	15 ml × 5
Days 86–90	30 ml × 3
Maintenance dose: one egg two or three times a week	
A homogenous dilution was obtained by shaking one egg for 3 min	

Oral specific desensitization in patients allergic to fish

Starting dilution[b]**:**	
Days	*Daily dose*
Days 1–3	4 drops
Days 4–6	8 drops
Days 7–9	12 drops
Days 10–12	24 drops
Days 13–15	32 drops
Days 16–18	48 drops
Days 19–21	72 drops
Days 22–24	108 drops
Pure fish extract	
Days 25–27	15 drops
Days 28–30	30 drops
Days 31–33	45 drops
Days 34–36	60 drops
Days 37–39	5 ml
Days 40–42	10 ml
Days 43–45	15 ml

Appendix 13.4. (Continued)

Cooked fish (boiled cod)		*Days*	*Daily dose*
Days	*Daily dose*	Days 85–87	32 g
Days 46–48	1 g	Days 88–90	40 g
Days 49–51	2 g	Days 91–93	48 g
Days 52–54	3 g	Days 94–96	56 g
Days 55–57	4 g	Days 97–99	64 g
Days 58–60	5 g	Days 100–102	72 g
Days 61–63	6 g	Days 103–105	95 g
Days 64–66	8 g	Days 106–108	110 g
Days 67–69	10 g	Days 109–111	130 g
Days 70–72	12 g	Days 112–114	150 g
Days 73–75	15 g	Days 115–117	175 g
Days 76–78	18 g	Days 118–120	200 g
Days 79–81	22 g	**Maintenance dose:**	
Days 82–84	27 g	200 g of boiled fish almost once a week	

All patients undergo an oral desensitizing treatment; the patients who are allergic to more than one food undergo one desensitizing protocol at a time. The oral desensitizing treatment is given 55 times, according to standardized protocols: at first a diluted food is administered and then is administered the pure food at increasing doses. The starting dilutions used for the desensitization protocols were lower than those used for the DBPCFC. Sometimes, at the beginning of the treatment, sodium chromoglycate (SCG) (250 or 500 mg, according to the patient's age) should be administered 20 min before food ingestion; if no reactions occur, this pretreatment can be dropped out in a few days. After completing the treatment, all patients should be advised to continue eating the allergenic food approximately twice a week, so as not to lose the state of tolerance.
Data from [187] and G. Patriarca, pers. comm.

[a] A recent protocol for oral desensitization in CM-allergic children [138] dilutes CM 1:25 and administers increasing diluted doses until day 42, when undiluted doses may be started under the cover of cetirizine. Overall, 15 of 21 children (71.4%) achieved the daily intake of 200 ml during a 6-month period; 3/21 children (14.3%) tolerated 40–80 ml/day of undiluted CM; 3/21 children (14.3%) failed the desensitization because they presented allergic symptoms after ingesting minimal amounts of diluted CM.

[b] 1.5% eel, 1.5% cod, 1.5% sardine, 1.5% anchovy.

Appendix 13.5. Oral rush desensitization to cow's milk

Day No.	CM dilution (ml)	CM (3.5% fat) (ml)
1	1:100	1
	1:100	2
	1:100	4
	1:100	8
2	1:100	16
	1:100	32
	1:10	1
	1:10	2
	1:10	4
	1:10	8
3	1:10	16
	1:10	32
	Fresh CM	1
	Fresh CM	2
	Fresh CM	4
	Fresh CM	8
4	Fresh CM	16
	Fresh CM	32
	Fresh CM	64
	Fresh CM	100
	Fresh CM	200
5	Fresh CM	200

Continue with daily intakes of 200 ml of fresh CM.
See also the notes for Appendix 13.4.
Data from [20].

Appendix 13.6. SLIT desensitization to latex

Day	Concentration	Dose administered	Total dose
1	From 10^{-18} to 10^{-10}	1 drop of each solution	28×10^{-10} mg of NRL
2	From 10^{-9} to 10^{-1}	1 drop of each solution	2.8 mg of NRL
3	Pure solution (500 mg/ml)	1, 2, 3, 4, 10 drops	500 mg of NRL
4	Pure solution (500 mg/ml)	1 ml	500 mg of NRL

Data from [186].
NRL Natural rubber latex.

Appendix 13.7. Children (<16 years) allergic to latex who successfully underwent SLIT

Children	Sex	Age (mean)
4	2 M/ 2 F	10 (9–11 years)

Data from [186].

Appendix 14.1. Examination of conjunctival secretions and their interpretation

When interpreting conjunctival cytograms, the following disorders are suggested in children
Eosinophils, metachromatic cells
1. Allergic conjunctivitis
2. Atopic keratoconjunctivitis
3. Vernal keratoconjunctivitis
4. Giant papillary conjunctivitis
Neutrophils
1. Infectious conjunctivitis
2. Irritant conjunctivitis
Neutrophils and eosinophils
Allergic conjunctivitis
Lymphocytes
Allergic conjunctivitis
Seromucous secretions
Allergic disease
Mucopurulent secretions
Infectious disease

To obtain conjunctival specimens, invert the inferior lid, have the child look up, and gently scrape the palpebral conjunctiva 1–2 mm with the same type of probe used for nasal specimens. A topical ophthalmic anesthetic can be used for sensitive children. Stain and examine with low-power microscope as shown in Appendix 6.5. Normal epithelium consists of several epithelial cells such as columnar cells both ciliated and nonciliated, and goblet and basal cells. These cells stain light blue, and contain no eosinophils or metachromatic cells (mast cells and basophils). A few neutrophils and bacteria can commonly be observed. Depending on the cells seen, a presumptive diagnosis can be made.

Subject Index

Note: Page numbers in **boldface** show where the topic is treated exhaustively, those in *italics* indicate that there is a figure. If the page number is repeated, there is an illustration on the same page.

Basic concepts are indexed only where they are first mentioned. Common abbreviations are listed as such (e.g., HIV, IgE), less common abbreviations (e.g., PaO_2, SLE) are spelled out. The reader is asked to excuse any repetitions.

Note: For sake of brevity the index lists corticosteroids, interleukins, values, etc. which in the text are also referred to as glucocorticoids, cytokines, levels, etc.; other such terms include cromolyn/disodium chromoglycate, Der p/house dust mite, AIDS/HIV infection, and bronchospasm/wheezing. The names of single medications in widespread use (antihistamines, anti-HIV medications, β2-adrenergics, corticosteroids, etc) are not included, and the reader is referred to the Tables with doses indicated under the single speciality. In infants and children refer to the whole pediatric population. The innumerable drugs cited in Chapter 19 are not included.

Abbreviations:
BHR = Bronchial hyperreactivity
FPT = Food provocation test
MIP = Macrophage inflammatory protein,
NAP-1 and 2 = Neutrophil activating factor-1 and 2
PID = Primary immune deficiency
SDS-PAGE = Sodium dodecylsulfate-polyacrylamide gel electrophoresis
sIgE = specific IgE
TAP-1 and -2 = Transporter associated with antigen presentation 1 and 2
