To my beloved wife
for so much help she has given me
and for so much time I robbed her of.

Preface

Science cannot be restricted
by the narrow frame of a book:
it is generally intolerant of frames

Pediatric Allergy, Asthma and Immunology is a new discipline that finds its foundation in this book, whose roots linke me to Elena and Luisa Businco, with whom I founded the first Italian Pediatric Allergy Division some 30 years ago, now called the Pediatric Allergy and Immunology Division. There I discovered this world, where I had the chance to revive the significance of the three Ss: science, safety and sympathy. Children and their parents consult us in the hope of finding scientific and medical knowledge as well as assurance and understanding sympathy, all necessary prerequisites for the successful outcome of our everyday tasks. Above all, one should appreciate how much the pediatrician–allergist is, more than any other doctor, dedicated to the care of his or her patients, since he or she must either deal with cases of extreme severity, such as anaphylactic shock, or perform ordinary jobs, such as giving suggestions on the diets or the furnishings of the home. The pediatrician–allergist should always find out how to protect the infant, the child and the adolescent against discrimination because of their allergy. With proper prescriptions and appropriate recommendations, such an objective is always within reach, and both the child and his or her parents will profit from a better quality of life.

The earliest roots of this book developed from my everyday work in the Pediatric Allergy and Immunology Division and have grown while preparing lessons and courses to be delivered to medical students and postgraduates in pediatrics. Of course, this ongoing work has found its expression in a host of papers that have inspired several chapters within this book. However, my primary aim was not one of doing something necessary; I have hoped only to do something that is useful to someone. With this book, I hope to have offered convincing proofs and foundations to colleagues committed to pediatric allergy and immunology. Often its main goal is one of *prevention*, in all senses and using all resources, as Arnaldo Cantani Sr. wrote in 1877 in the preface to the first edition of his *Textbook of Clinical Pharmacology*: " … only corresponding with a meticulous study and the greatest exactness to the precise indications of the case, the drugs may be use–ful to the patient … in the belief that air, water, and alimentation are the first and most powerful means to be well."

Pediatric allergy and immunology is a multidisciplinary field of research today, and familiarity with current concepts is important for medical students, for clinicians in every pediatric specialization and for researchers in this attractive area. However, the issue is not benefited by an easy approach, because pediatric allergy and immunology has characteristic features both different and larger in scope than adult allergy. Nor can we disregard significant events such as the *atopic-march*, the inexorably accelerating prevalence of atopic diseases, which develop in 80%–90% of cases within the very first months and years of life, while the intense efforts of research scientists and the greater awareness of pediatricians and of dedicated parents have widened the positive results of prevention and treatment. The avalanche of immunological progress shows no sign of abating in this new millennium. I have therefore begun with the fundamental concepts of basic immunology, whose inferences are relevant to the later chapters. For example, I have attempted to offer an exhaustive discussion in Chap. 1 to the interested reader trying to understand the significance of adhesion molecules from the pathogenic point of view. Therefore, after the chapters on fetal-neonatal immunology and the mucosal immune system, the neonate at risk of atopy, the genetic and environmental predisposing factors and the epidemiology and natural history of atopic diseases, a whole chapter encompasses the diagnosis of allergy, from the clinical history to the provocation tests. The book progresses chapter by chapter to elucidate the spectrum of several diseases, including atopic dermatitis, food allergy, asthma, rhinoconjunctivitis, and to discuss specific immunotherapy (SIT) for these diseases. It also places great emphasis on specialist disorders such as sinusitis and otitis media with effusion, which are frequently associated with allergic diseases. Many pages are devoted to autoimmune diseases, primary immunodeficiencies and to pediatric HIV infection. The last two chapters are comprehensively built on the earlier ones, introducing two emerging important advances, malnutrition and the immune system and another of capital importance, atopy prevention, which sums up the wealth of new data.

Until recently, the expansion of immunology was undervalued. In this breakthrough my major thrust was

to attest to the ferments of activity that have revolutionized, so to say, the exciting new area of research, such as the therapeutic strategies exemplified by the switch from Th2 to Th1 lymphocytes in the immune system manipulations through SIT and anti-IgE therapy, gene therapy of primary immunodeficiencies and the maternofetal treatment of HIV infection. A growing body of literature is shaping our knowledge of the fetal immune system. We are now aware that the fetus can be immunocompetent from the 18th to 20th week of intrauterine life, and that from the 22nd week it can react to food and inhalant allergens of maternal origin, suggesting that heredity and maternal intake of foods or drugs or allergen inhalation may anticipate the foundations of pediatric allergy and immunology in intrauterine life, thus requiring an advancement of preventive measures. In this context, immunology is the new milestone when one refers to the so-called collagen diseases, revisited as a deviation from the normal mechanisms of self-recognition, to the viruses that deceive the immune system, modulating apoptosis at will, and to the immunological components of breast milk, rich in prebiotics and TLRs and protecting infants even from diabetes. From this viewpoint we cannot underestimate the impact of transgenic foods and pesticides, which are revolutionizing foods, and of polluted air breathed by newborns. Among the food offenders, the first level refers to hidden allergens, or those regularly absent from the labels, and the growing number of cross-reactions, with the remarkable latex–fruit syndrome and the mite–mollusc correlations. The role of infectious agents could likely be the opposite of current theories, namely that of protecting infants from the onset of allergic disease, whose higher frequency could be favored by the improvement in the standard of living. The hygiene hypothesis is intriguing, but milk may kill by inhalation, casein may remain active for 2,500 years and egg for 500 years. We move forward in pediatric allergy and immunology: fascinating findings focus on the increasing number of wheezing infants and on the success of desensitization shared by food-allergic and asthmatic children, thus leaving these children without disease. Immunodeficiencies are radically cured by bone marrow transplantation, autoimmune diseases are starting to be cured with stem cell transplantation, diabetes seems to be cured by mother–daughter transplantation of pancreatic cells and immunodeficiencies by bone marrow transplantation. HIV infection can be "cured" by prevention.

In the presentation of the diverse conditions, I have preferred a complete description in a traditional sequence, beginning with an introduction, the definitions and the epidemiology, then continuing with the immunological characteristics, pathogenesis, symptoms, diagnosis and treatment. Further, being compelled to deal with aspects sometimes so distant or different has certainly implied possible errors in measure and a certain degree of overlap. A very hard task was that of selecting, among the relevant literature in an unending stream of data on pathogenic and therapeutic aspects, the most significant ones, especially in the field of pediatrics. It is not always easy and productive to interweave basic and clinical material. I have tried to inform the reader more comprehensively following a logical progression, synthetically reviewing the most recent state of this rapidly advancing specialization, leaving in the background the data pertaining to the basic knowledge of pediatricians and allergist–immunologists.

My purpose was also that of lightening the text with the aid of approximately 1,400 high-quality figures covering basic aspects and tables abounding with practical information facilitating day-to-day diagnosis and management. My approach has been that of utilizing the figures and tables as both a commentary and an extension of the text. The appendices complete the volume, while the abbreviations and acronyms are listed separately. In addition, I have adopted the Système International des Unités (SI) where appropriate. At the end of each chapter a list of references includes leading articles and subspecialty reviews, so that readers are referred to numerous points of departure from which to explore further the subjects closer to their interests.

I have attempted, therefore, to offer to dedicated pediatricians and family practitioners a comprehensive, clear and timely distillation of current information making it possible to keep abreast of recent advances and to acquire the basic principles necessary in their practice. The careful reader will find practical advice on which to base actions that will block the atopic and immunological march by preventing, managing and treating allergic–immunological diseases, and by appropriately informing parents, without neglecting to raise public awareness of the threat posed by the march and to provide the means to stop it. Managing childhood atopic and immune disorders requires a new strategy. Millions of children and their parents expect disease prevention and cure, and allergists or immunologists are challenged to provide interventions that achieve optimal health from childhood to adulthood. I hope that students and postgraduate doctors willing to find a detailed reference for this fascinating and demanding area of pediatrics and willing to develop an allergic–immunological viewpoint will succeed in identifying the diverse pathologies and will be motivated to become more actively involved in the daily health needs of atopic infants, children and adolescents.

I am deeply grateful to my wife, María Susana Campostrini, who assisted me in this challenging enterprise and helped me to add expressive illustrations to the book. I wish to acknowledge the assistance of several colleagues for their helpful discussions and contributions, including Doctors Daniele Ceccoli, Franco Frati, Oreste Marciano and my referees Professors Emanuele Errigo and Massimo Fiorilli. The consultation of numerous journals was of particular help, especially in the libraries of the Pediatric Department of Rome Uni-

versity "La Sapienza" and Rome University "Tor Vergata," the Pediatric Department of Sassari University, the National Council for Scientific Research, the Italian Institute of Public Health and several university libraries of the Hospital Policlinico Umberto I where I work, especially the Department of Experimental Medicine. I extend my gratitude to many colleagues and publishers who have kindly provided many figures including the late Professor Luisa Businco and the UCB that kindly supplied many figures related to the SCORAD and ETAC studies. In particular, I am deeply indebted to Professors Molkhou, Revillard and Wüthrich and their publishers. My thanks to Professors Mogi, Ring and Wüthrich, who presented me with their books and Professors Bernstein, Brandtzaeg, Buckley, Gerrard, Patriarca, Roos and Sullivan for sending me reprints not easily found otherwise. I owe particular gratitude to Springer-Verlag and especially to Ms Ute Bujard for her meticulous editing skills that allowed the publication of this book. I would also like to thank Martha Berg whose excellent assistance helped me very much.

To offer a wide panorama of results, several data have been presented throughout the book and reported in the tables and in the figures, independently of how the children were identified as affected with allergic-immunologic disease. Of course I do not expect that my opinions or my suggestions "to live better with allergy" meet the unconditioned favor of all readers: I would be grateful if they would point out "the errors and the omissions" so that I can correct them in a future edition.

Rome, September 2007
Arnaldo Cantani

Foreword

For those who believe that I may not be the best suited person to present *Pediatric Allergy, Asthma and Immunology* by Arnaldo Cantani, I would like to explain the reasons that encouraged me – a specialist of adult disease of intellectual development, with professional experiences substantially different from those of the author – to agree to his request with great pleasure. These reasons are either of a personal nature or of a more general and ideological nature.

Professor Cantani's knowledge has its deep roots in his extensive work at the Department of Pediatrics of the University of Rome "La Sapienza" and especially at the chair of the late Professor E. Rezza. Only recently, however, when I had more frequent opportunities of collaborating with him, was I struck by the profound "team spirit" that Arnaldo Cantani feels for pediatric allergy and immunology as well as by his exactness and precision in dealing with the commitment necessary to report his own experience.

As Past President of the European Academy of Allergology and Clinical Immunology, I am fully aware of the problems, both general and specific, that pertain to the discipline of "pediatric allergy and immunology." The opportunity to acknowledge this discipline as an autonomous specialization is of primary necessity, especially in north European centers. This orientation is opposed by some pediatric specialists or allergy specialists. However, it should be appreciated that pediatric allergy and immunology differs widely from that of adults, as evidenced by this textbook. This difference is particularly important not only in the newborn period but above all in the diseases typical and specific to the pediatric age as well as in those also common to adult patients, of wholly peculiar physiopathologic, diagnostic and therapeutic characteristics. These current points of view are confirmed by the recent proposal to consider both internal medicine and pediatrics as common branches of the allergology and clinical immunology specialization, as well as the decision of the European Academy of Allergology and Clinical Immunology to create a Section of Pediatric Allergology, thus satisfying the need to gather under a single roof specialists of the "general" discipline, thereby recognizing and warranting the importance and autonomy of the pediatric allergologist.

Professor Cantani's book is a concrete and cogent contribution to the foundation of pediatric allergy–immunology. This book is an impressive and comprehensive documentation of the progress in the understanding and management of allergic–immunologic disorders of infants, children and adolescents, and is divided into 24 chapters illustrated by more than 1,400 tables and figures that are helpful in clarifying complex points. I have greatly appreciated the author's approach of discussing, in addition to the ontogeny of the immune system, mucosal immunology and the typical pathology of infantile immediate hypersensitivity with its very early onset age, the mechanisms underlying specific disease states such as the developing neonatal immune response, autoimmune disease, immune deficiencies and pediatric AIDS, which are increasingly recognized as complex diseases. Such an approach entails, in fact, that one's eyes be kept open to the complexity of clinical allergology and immunology, and widened beyond the limited field of atopic disease and the "atopic march" to the genetic relation to atopy and bone marrow transplantation.

A critical analysis of how this complex and detailed information is condensed into a readable textbook suggests the author's far-sighted attitude: on the one hand the painstaking precision of the scientist (see the list of abbreviations that opens the book), and on the other the more typical Latin inclination to prefer clinical reasoning, which, even in its subjectivity, always represents the essential distinguishing feature between the clinical professor and accurately programmed reasoning.

The findings of several schools and disciplines different from those of Professor Cantani are critically evaluated, and the virtues of single authorship, compared to multi-authored textbooks that often lack sufficient coordination and revision by the editor, are evident throughout the book.

All chapters have reference lists with citations that will be stimulating for those interested in more in-depth study. Moreover, the suggestions at the end of each chapter and the numerous discussions, also in the form of tables and figures, promote an expert starting point for diverse specialists interested in evidence-based medicine, be they allergists, immunologists, pediatricians or practitioners. As a result, the reader has at hand a doubly useful book: one to be studied and consulted, the other to be read with pleasure, a book to be approached critically.

Although he had the excellent collaboration and editorial assistance of Springer-Verlag throughout the preparation of this textbook, Arnaldo Cantani has undertaken alone the fascinating burden of putting together *Pediatric Allergy, Asthma and Immunology*. I therefore compliment the author on assembling an outstanding opus in the interest of pediatric allergy and immunology and in the training of all those concerned with the "march." Anyone who cares for allergic children or wants to learn about immune diseases will surely benefit from frequent consultations of this textbook. I hope that the book will provide pleasure and insight to all prospective readers.

Rome, May 2007
Sergio Bonini

Contents

1 Immunology

2 Fetal and Neonatal Immunology and the Mucosal Immune System

3 Neonatal Immunology: The Neonate at Risk of Atopy

4 Genetic and Environmental Predisposing Factors

5 Epidemiology and Natural History of Atopic Disease

6 Diagnosis of Pediatric Allergy

7 Atopic Dermatitis

8 Other Allergic Skin Disorders

9 Food Allergy

14 Eye Allergy and Immunology

15 Other Allergic Otorhinolaryngological Diseases

16 Allergy and Central Nervous System and Other Allergies

17 Allergy to the Venom of Hymenoptera and Other Insects

18 Autoimmune Diseases

19 Allergic and Pseudoallergic Reactions to Drugs

20 Anaphylaxis

21 Malnutrition and the Immune System

22 Primary Immunodeficiencies

Abbreviations

A	Alimentum
AA	Amino acid
AA	Arachidonic acid
AA	Aspartic acid
α_2M	α_2 Macroglobulin
α_2M-R	α_2 Macroglobulin receptor
AAAAI	American Academy of Allergy, Asthma and Immunology
Aab	Autoantibody
Aag	Autoantigen
AAF	Amino acid formula
AAP	American Association of Pediatrics
AAPSNAD	American Association of Pediatrics Subcommittee of Nutrition and Allergic Disease
ABA	Allergic bronchopulmonary aspergillosis
ABC	Abacavir
AC	Allergic conjunctivitis
ACAAI	American College of Allergy, Asthma and Immunology
ACAT	Automated computerized axial tomography
ACC	1-Aminocyclopropane-1-carboxylic acid
ACD	Allergic contact dermatitis
ACE	Angiotensin-converting enzyme
ACh	Acetylcholine
ACT	Immune-activating cytokine
ACT-2	Immune-activating cytokine-2
AD	Atopic dermatitis
AD	Autosomal dominant
ADA	Adenosine deaminase
ADAM	α Disintegrin and α metalloproteinase
ADCC	Antibody-dependent cell-mediated cytotoxicity
ADD	Average daily dose
ADGL	Dihomo-γ-linolenic acid
ADHD	Attention-deficit hyperactivity disorder
ADH	Antidiuretic hormone
ADNI	Selective antibody deficiency with normal Ig isotypes
ADR	Adrenergic receptor
ADR	Adverse drug reaction
ADRB2	α_2-Adrenergic receptors
AEA	Antiendomysial antibodies
AEA	Antierythrocyte autoantibody
AECA	Antiendothelial cell antibodies
AF	Anchoring filaments
AF	*Aspergillus fumigatus*
AFP	α-Fetoprotein
AGA	Antigliadin antibodies
Ah	Aromatic hydrocarbons
AHS	Anticonvulsant hypersensitivity syndrome
AIC	Amb a 1 immunostimulatory oligodeoxynucleotide conjugate
AICDA	Activation-induced cytidine deaminase
AID	Autoimmune disease
AID	Activation-induced cytidine deaminase
AIDS	Acquired immunodeficiency syndrome
AIHA	Autoimmune hemolytic anemia
AIM	Activation inducer molecule
AIN	Autoimmune neutropenia
AKC	Atopic keratoconjunctivitis
ALA	α -Lactalbumin
ALCAM	Activated leukocyte cell adhesion molecule (CD166)
Alfaré	Alimentation facilement résorbable
Allergen	Allergy generator
ALPS	Autoimmune lymphoproliferative syndrome
AML	Acute myeloblastic leukemia
AMLR	Autologous mixed lymphocyte reaction
ANA	Antinuclear antibody
ANCA	Antineutrophil circulating antibodies
ANF	Antinuclear factor
ANP	Atrial natriuretic peptide
ANS	Autonomic nervous system
AOM	Acute otitis media
AP-1	Activator protein-1

The English medical abbreviations have been cross-referenced using Davis NM Medical Abbreviations, 8th edn, NM Davis Associates, Huntington Valley, 1997. To offer a wide panorama of results, several data have been presented throughout the book and reported in the tables independently of how the children were identified as affected with atopic disease. Drug availability has been assessed. Regarding drug usage, several tables specify the chemical names, types of packaging, administration routes and, where possible, the pediatric doses and schedules of treatment. I have taken care to make sure that the information is correct at the time of publication; however, the ultimate responsibility rests with the prescribing physician.

AP-1	Apolipoprotein 1
Apaf 1	Apoptotic protease activating factor 1
APC	Antigen-presenting cells
APO-1	Apoptosine-1 (CD95)
APP	Acute-phase proteins
APR	Acute-phase response
APT	Aptamil HA
APT	Atopy patch test
APV	Amprenavir
AR	Alfaré
AR	Allergic rhinitis
AR	Autosomal-recessive
AR3	Apoptose receptor 3
ARAM	Antigen recognition activation motif
ARC	Allergic rhinoconjunctivitis
ART	Antiretroviral therapy
ASA	Acetylsalicylic acid
ASAT	Aspartate aminotransaminase
ASCT	Autologous stem cell transplantation
ASO	Allele-specific oligonucleotide
AST	Antistreptolysin titer
ATA	Ataxia-telangiectasia
ATAC	Activation-induced, T cell-derived, and chemokine-related
ATG	Antithymocyte globulin
ATM	Ataxia-telangiectasia mutated
ATP	Deoxyadenosine triphosphate
AU	Allergy unit
AUR	Allergy unit by RAST
AXT	Deoxyadenosine nucleotides
AZT	Azidodeoxythymidine
BaDF	Basophil activating factor
BALF	Bronchoalveolar lavage fluid
BALT	Bronchus-associated lymphoid tissue
BAU	Bioequivalent allergy unit
BCF	Basophil chemotactic factor
BCG	Bacillus Calmette-Guérin
Bcl-2	B cell lymphoma-2
BcR	B cell receptor
BDP	Beclomethasone dipropionate
BE	Base excess
Bf	B factor
BGP-1	Biliary glycoprotein-1
BH1 to BH4	Bcl-2 homology domains
BHA	Butylated hydroxyanisole
β-HCB	β-Hexachlorobenzene
β-HCH	β-Hexachlorocyclohexane
BHR	Bronchial hyperreactivity
BHT	Butylated hydroxytoluene
bid	bis in die, twice a day
b.i.d.	*Bis in die*, twice a day
BIV	Bovine immunodeficiency virus
BK	Bradykinin
βLG	β-Lactoglobulin
β_2-m	β_2-Microglobulin
BM	Basement membrane
BM	Bone marrow
BM	Breast milk
BMA	Breast milk allergy
BMI	Body mass index
BMT	Bone marrow transplant
BP	Blood pressure
bp	base pair
BPI	Bacterial permeability increasing protein
BPO	Benzyl-penicilloyl
BPT	Bronchial provocation test
BSA	B-superantigens
BSA	Bovine serum albumin
BSE	Bovine spongiform encephalopathy
β-TG	β-Thromboglobulin
Btk	*Bacillus thuringiensis* subspp. *kurstaki*
Btk	Bruton's tyrosine kinase
BTS	Benzothiazole bisulfide
Btt	*Bacillus thuringiensis* subspp. *tenebrionis*
BU	Biologic units
BUD	Budesonide
bw	Body weight
C	Constant
c-ANCA	Cytoplasmic antineutrophil circulating antibodies
C/EDPα	CCAAT/enhancer binding protein α
C/EDP	CCAAT/enhancer binding protein η
C1-INH	C1-inhibitor
C4 bp	C4-binding protein
C8 bp	C8-binding protein
CA	Capsid
CAF	CD8 T-cell antiviral factor
CALC	Calcitonin
cALL	Common acute lymphoblastic leukemia
CALLA	Common acute lymphoblastic leukemia antigen
CALT	Conjunctiva-associated lymphoid tissue
cAMP	Cyclic adenosine monophosphate
CAP	Chemiluminescent assay
CAP	Chloramphenicol
CARD	Caspase activation and recruitment domain
CATCH 22	Cardiac abnormalities, Abnormal facies, Thymic hypoplasia, Cleft palate, Hypocalcemia, chromosome 22
CB	Cord blood
CBC	Complete blood count
CBIgE	Cord blood IgE
CBMC	Cord blood mononuclear cells
CCP	Complement control protein
CCR	CC chemokine receptor
CD	Celiac disease
CD	Cluster of differentiation
CD	Crohn's disease
Cd	Cadmium
CD11a/CD18	LFA-1
CD11b/CD18	CR3 Mac-1

CD11c/CD18	CR4 p150,95
CDC	Centers for Disease Control (and Prevention)
CDR	Complementarity-determining regions
CEA	Carcinoembryonic antigen
ced	Cell-death defective
CF	Cystic fibrosis
CFC	Chlorofluorocarbon
CFS	Chronic fatigue syndrome
CFU	Colony-forming unit
CFU-GM	Colony-forming unit, granulocytes and monocytes
CFU-S	Colony-forming unit, spleen
CFU-T	Colony-forming unit, thymus
CGD	Chronic granulomatous disease
CGM1	CEA gene member 1
CGM6	CEA gene member 6
cGMP	Cyclic guanosine monophosphate
CGRP	Calcitonin gene-related peptide
CH_{50}	Hemolytic complement 50%
CHARGE	Coloboma, Heart anomalies, Atresia of choanae, Retardation, Genital hypoplasia, Ear anomalies
CHF	Casein hydrolyzed formula
CI	Confidence intervals
CIC	Circulating immune complexes
CID	Combined immunodeficiency
CIE	Crossed immunoelectrophoresis
CIEV	Caprine infectious encephalitis virus
CIITA	Class II transactivator
CJD	Creutzfeldt-Jakob disease
CKR-SF	Cytokine receptor superfamily
Cl	Chlorine
CLA	Conjugated linoleic acid
CLA	Cutaneous lymphocyte-associated antigen
CLA	System-chemiluminescent immunoassay
CLC	Charcot-Leyden crystals
CLE-0	Consensus lymphokine element-0
CLE-1	Consensus lymphokine element-1
CLE-2	Consensus lymphokine element-2
CLIP	Class II associated invariant chain peptide
CM	Cow's milk
CMA	Cow's milk allergy
CMI	Cell-mediated immunity
CMV	Cytomegalovirus
CN	Calcineurin
CNO	Chronic nasal obstruction
CNS	Central nervous system
CO_2	Carbon dioxide
Con-A	Concanavalin A
COV	Mean coefficient of variation
CpG	Deoxycytidyl-deoxyguanosine dinucleotide
CPK	Creatinine phosphokinase
CPS	Capsaicin
CPT	Conjunctival provocation test
CR	Complement receptor
CR	Crossed reactions
Cr	Chromium
CR3	Complement receptor type 3
CREST	Calcinosis-Raynaud-Esophageal (motility disorders)-Sclerodactyly-Telangiectasia
CRH	Corticotropin-releasing hormone
CRIE	Crossed radioimmunoelectrophoresis
CRP	C reactive protein
CS	Corticosteroids
CsA	Cyclosporin A
CSF	Cerebrospinal fluid
CSF	Colony stimulating factor
CSM	Costimulatory molecule
CT	Computerized tomography
CTAP-III	Connective tissue-activating protein-III
CTL	Cytotoxic T lymphocytes
CTLA-4	Cytotoxic T lymphocyte-associated antigen-4 (CD152)
Cu	Copper
CVID	Common variable immune deficiency
CXCR	CX chemokine receptor
D	Dalton ($1.6605655 \times 10^{-24}$ g)
D	Diversity
d4T	Stavudine
DAF	Decay accelerating factor (CD55)
DAG	Diacylglycerol
DALIA	Distribution-analyzing latex immunoassay
DARC	Duffy antigen receptor complex
DBPC	Double-blind, placebo-controlled
DBPCCT	Double-blind, placebo-controlled challenge test
DBPCFC	Double-blind, placebo-controlled food challenge
DC	Dendritic cells
DC-CK1	Dendritic cell chemokine-1
DCC	Double-blind, controlled
ddC	Zalcitabine
DDE	Dichlorophenyl-dichloroethene
ddI	Dideoxyinosine
ddI	Didanosine
DDT	Dichlorodiphenyltrichloroethane
DEP	Diesel exhaust particles
Der f	*Dermatophagoides farinae*
Der p	*Dermatophagoides pteronyssinus*
DES	Diethylstilbestrol
DGS	DiGeorge syndrome
DGSC	DiGeorge syndrome, complete
DGSP	DiGeorge syndrome, partial
DGST	DiGeorge syndrome, transient
DHA	Docosahexaenoic acid
DHST	Delayed hypersensitivity skin test
DIC	Disseminated intravascular coagulation
DM	Diabetes mellitus
DMARDs	Disease-modifying antirheumatic drugs

DMN	Dimethylnitrosamine
DMV	Daily mean variations
DN	Double negative
DNA	Deoxyribonucleic acid
DNCB	Dinitrochlorobenzene
DP	Double positive
DPG	Diphenylguanidine
DPI	Dry powder inhaler
DPU	Delayed pressure urticaria
DR	D-related
DSCG	Disodium chromoglycate
DTH	Delayed-type hypersensitivity
DYM	Dynorphin
DZ	Dizygotic (twins)
E-L-R	Glutamic acid-leucine-arginine
e-NANC	Excitatory NANC
EA	Erythrocytes, antierythrocyte (antibody)
EAA	Extrinsic allergic alveolitis
EAACI	European Academy of Allergy and Clinical Immunology
EAC	Erythrocytes, antierythrocyte (antibody), complement
EACA	Epsilon aminocaproic acid
EAE	Experimental autoimmune encephalitis
EAEC	Eosinophil adhesion to endothelial cells
EAF	Eosinophil-activating factor
EBI3	Epstein-Barr virus-induced gene 3
EBV	Epstein-Barr virus
ECA	Eosinophil chemotactic activity
ECEF	Eosinophil cytotoxicity enhancing factor
ECF	Eosinophil chemotactic factor
ECHF	Extensively casein hydrolysate formula
ECHO	Enteric cytopathic human orphan (virus)
ECM	Extracellular matrix
ECP	Eosinophil cationic protein
ECU	Extracellular unique
ED	Emergency department
EDIF	Epithelium-derived inhibitory factor
EDN	Eosinophil-derived neurotoxin
EDRF	Endothelium-derived relaxing factor
EDTA	Ethylenediaminetetraacetic acid
EFA	Enhancing factor of allergy
EFA	Essential fatty acids
EFAD	Essential fatty acid dysfunction
EFV	Efavirenz
EGF	Epidermal growth factor
EIA	Enzyme immunoassay
EIA	Exercise-induced anaphylaxis
EIAV	Equine infectious anemia virus
ELA2	Elastase 2
ELAM	Endothelial-leukocyte adhesion molecule (CD62E, LECAM-1)
ELC	EBI1 ligand chemokine
ELISA	Enzyme-linked immunosorbent assay
ELISPOT	Enzyme-linked immunospot
EM	Electron microscope
EM	Erythema multiforme
EMA	Endomysium autoantibodies
ENA-78	Epithelial cell-derived neutrophil-activating protein-78
EMK	Enkephalin
ENR	Eosinophilic nonallergic rhinitis
env	Envelope (of HIV)
EPA	Eicosapentaenoic acid
EPD	Enzyme potentiated desensitization
EPO	Eosinophil peroxidase
EPSPS	5-Enolpyruvylshikimate-3-phosphate synthase
ER	Endoplasmic reticulum
ERV	Expiratory reserve volume
ESL-1	E-selectin ligand 1
ESPACI	European Society of Pediatric Allergy and Immunology
ESPGAN	European Society of Pediatric Gastroenterology and Nutrition
et al.	*et alii*, and others
ET	Eustachian tube
ET-1	Endothelin-1
ET-2	Endothelin-2
ET-3	Endothelin-3
ET-4	Endothelin-4
ETAC	Early treatment of the atopic child
ETAC	European Task Force on Atopic Dermatitis
ETD	Eustachian tube dysfunction
ETO	Eustachian tube obstruction
ETS	Environmental tobacco smoke
EU	European Union
EWHF	Extensively whey hydrolyzed formula
FA	Food allergy
Fab	Fragment antigen binding
FADD	Fas-associated death domain
FAE	Follicle-associated epithelium
Fas	APO-1
FAS	Family atopy score
FAST	Fluoroallergosorbent test
FC	Flux cytometry
Fc	Fragment crystallizable
FcR	Fc-Receptor
FCT	Food challenge test
FDA	Federal Drug Administration

FEF	Forced expiratory flow
FEF_{50}	Forced expiratory flow at 50%
FEIA	Fluoroenzymeimmunoassay
FEIA	Food-associated EIA
FEV_1	Forced expiratory volume in 1 s
FFA	Free fatty acids
FGF	Fibroblast growth factor
FH	Family history
FHA	Family history of atopy

FIC	Fibroblast-induced chemokine
FIS	Fetal immune system
FISH	Fluorescence in situ hybridization
FIV	Feline immunodeficiency virus
FKBP	FK-506 binding proteins
FMLP	Formylmethionyl leucylphenylalanin
FN	Fibronectin
FP	Fluticasone propionate
FR	Framework region
FR	Free radicals
FRC	Functional residual capacity
FSA	Family score of atopy
FVC	Flow-volume curves
FVC	Forced vital capacity
G-CSF	Granulocyte-colony stimulating factor
G6PD	Glucose-6-phosphate dehydrogenase
GA	Gestational age
GABA	γ-Aminobutyric acid
GAD	Glutamic acid decarboxylase
gag	Group-specific antigen
GAG	Glycosaminoglycan
GAL	Galanin
Gal-1	Galectin-1
Gal-3	Galectin-3
GALT	Gut-associated lymphoid tissue
GAPs	GTPase-activating proteins
GC	Germinal center
GCK	Glucokinase
GCP-2	Granulocyte chemotactic protein 2
GDP	Guanosine diphosphate
GE	Gas exhaust
GEF	Glycosylation enhancing factor
GER	Gastroesophageal reflux
GHD	Growth hormone deficiency
GIF	Glycosylation inhibiting factor
GINA	Global initiative for asthma
GLA	γ-Linolenic acid
GLUT-2	Glucose transporter-2 (protein)
GlyCAM-1	Glycosylation-dependent cell adhesion molecule 1
GM	Geometric mean
GM-CSF	Granulocyte macrophage-colony stimulating factor
GM-CSFR	Granulocyte macrophage-colony stimulating factor receptor
GMF	Genetically modified food
GMO	Genetically modified organism
GMP	Granule-associated membrane protein
GNA	*Galanthus nivalis* agglutinin
GPC	Giant papillary conjunctivitis
gps	Glycoproteins
GPM	Genetic polymorphism
GRO	Growth-related gene
GRP	Gastrin-releasing peptide
GS	Good Start
GTP	Guanosine triphosphate
GvHD	Graft-versus-host disease
H	Heavy
H	Humana HA
H/P	Hypolac/Profylac
HA	Hemoagglutination
HA	Hypoallergenic
HAART	Highly active antiretroviral therapy
HAV	Hepatitis A virus
HBV	Hepatitis B virus
H-CAM	Hematopoietic cell adhesion molecule
HC	Head circumference
HCC-1	Hemofiltrate CC chemokine-1
HCV	Hepatitis C virus
HDE	House dust endotoxin
HDM	House dust mite
HE	HIV-exposed
HEM	Heat escape method
HEP	Histamine equivalent potency
HEPA	High-efficiency particulate (or particle arresting) air (filter)
HET	Heterozygote, heterozygous
15-HETE	Hydroxyeicosatetraenoic acid
HEV	High endothelial venules
HF	Hydrolysate formula
HFI	Hydrofluorocarbon inhaler
HHM	Hypogammaglobulinemia with hyper-IgM
HHV	Human herpesvirus
5-HIAA	5-Hydroxyindoleacetic acid
HIES	Hyper IgE syndrome
HIgES	Hyper-IgE syndrome
HIgMS	Hyper-IgM syndrome
HIS	Hyper IgE syndrome
HIV	Human immunodeficiency virus
HIV-1 gp120	HIV-1 glycoprotein 120
HLA	Histocompatibility leukocyte antigens
HLA	Human leukocyte antigens
HML	Human mucosal lymphocytes
HMMBF	Home-made meat-based formula
HNF	Hepatocyte nuclear factor 1α, 4α
HFC	Hydrofluorocarbons
HPA	Hypothalamus-hypophysis-adrenal
HPLC	High-performance liquid chromatography
HR	Hazard risk
HR	(At) high risk (of atopy)
HR	Heart rate
HRF	Histamine release factor
HRF	Homologous restriction factor
HRF-P	Histamine release factor platelets
HRIF	Histamine release inhibition factor
HRQL	Health-related quality of life
HRP	Horseradish peroxidase
HSP	Heat shock proteins
HSCT	Hematopoietic stem cell transplantation
HSV	Herpes simplex virus
5-HT	5-Hydroxytryptamine
HTLV-I	Human T-cell leukemia virus
HVR	Hypervariable region
HZ	Homozygote, homozygous

I-309	I-309 protein
i-NANC	Inhibitory-NANC
I-TAC	Interferon inducible T-cell alpha chemoattractant
IA	Idiopathic anaphylaxis
Ia	I region-associated antigen
IAA	Insulin autoantibodies
IAC	Immunologically active casein levels
IAP	Inhibitors of apoptosis proteins
IAP	Integrin associated protein (CD47)
IAR	Immediate asthmatic reactions (see LAR)
IAW	Immunologically active whey protein levels
IB	Ipratropium bromide
IBD	Inflammatory bowel disease
IBE	Immunoreactive bacterial extracts
IBS	Irritable bowel syndrome
IC	Intracytoplasmatic
ICA	Islet-cell antibodies
ICAM-1 (CD54)	Intracellular adhesion molecule 1
ICAM-2 (CD102)	Intracellular adhesion molecule 2
ICAM-3 (CD50)	Intracellular adhesion molecule 3
ICAM-4 (CD242)	Intracellular adhesion molecule 4
ICD	International classification of diseases
ICD	Irritant contact dermatitis
ICDRG	International contact dermatitis research group
ICE	Interleukin $IL_1\beta$ converting enzyme
ICMA	Intracellular *Mycobacterium avium*
ICRM	Identifiable as casein raw material
ICS	Inhaled corticosteroids
ICT	Ice cube test
ICU	Intensive care unit
ID	Immune deficiency
ID	Intradermally
IDC	Interdigitating dendritic cells
IDDM	Insulin-dependent diabetes mellitus
IDV	Indinavir
IEF	Isoelectrofocalization
IEL	Intraepithelial lymphocytes
IF	Immunofluorescence
IFN	Interferon
IFR	Inspiratory flow rate
Ig	Immunoglobulin
IgA	Immunoglobulin A
IgD	Immunoglobulin D
IgDs	Surface immunoglobulin D
IgE	Immunoglobulin E
IgE-BF	IgE binding factors
IgE-PF	IgE potentiating factor(s)
IgE-SF	IgE suppressive factor(s)
IgG	Immunoglobulin G
IgG-STS	IgG short time sensitization
Igs	Immunoglobulins
IgSC	Ig-secreting cells
IgSF	Immunoglobulin superfamily
IκB	Inhibitor of NF-κB
IκB-α	Inhibitor of NF-κB, type α
IKK	Inhibitor of B kinase
IL	Interleukin
IL_1RA	IL_1 receptor antagonist
IM	Intramuscular
IMN	Infectious mononucleosis
iNOS	Inducible NO synthase
IP-10	Inflammatory protein-10
IP-10	Interferon-inducible protein-10
IPD-1	Insulin promoter factor 1
IP3	Inositol-trisphosphate
IPPB	Intermittent positive pressure breathing
Ir	Immune response
IRAK	IL_1R-activating kinase
IRR	Incidence rate ratio
IRFI	Interferon regulatory factor-1
IRV	Inspiratory reserve volume
ISAAC	International Study of Asthma and Allergy in Children
ISP	Immature single positive
ISS	Immunostimulatory sequences
ITAM	Immunoreceptor tyrosine-based activation motif
IU	International Unit
IUIS	International Union of Immunological Societies
IV	Intravenous
IVAP	In vitro antibody production
IVIg	Intravenous immunoglobulins
J	Junction
JAK	Janus-family kinase
JCA	Juvenile chronic arthritis
JRA	Juvenile rheumatoid arthritis
JSC	Juvenile scleroderma
kb	Kilobase
kD	Kilodalton
KS	Kaposi's sarcoma
L	Light
LA	Linolenic acid
LAD	Leukocyte adhesion deficiency
LAD I	Leukocyte adhesion deficiency, type I
LAD II	Leukocyte adhesion deficiency, type II
LAD III	Leukocyte adhesion deficiency, type III
LAD IV	Leukocyte adhesion deficiency, type IV
LAD V	Leukocyte adhesion deficiency, type V
LAG-3	Lymphocyte activation gene-3
LAK	Lymphokine activated killer
LAM	Leukocyte adhesion molecule (CD62L)
LAMP	Lysosome-associated membrane protein
LAR	Late asthmatic reactions (see IAR)

LARC	Liver and activation-regulated chemokine
LBP	Lipopolysaccharide-binding protein
LBW	Low birth weight
LC	Langerhans cells
LC-SFA	Long-chain saturated fatty acids
LCA	Leukocyte common antigen (CD45)
LCAM	Liver cell adhesion molecule
LCP	Long-chain polyunsaturated fatty acids
LCP	Long-chain PUFA
LD	Lymphocyte-defined
LDH	Lactate-dehydrogenase
LDL	Low-density lipoprotein
LESN	Lupus erythematosus systemic, neonatal
LFA-1	Lymphocyte function-associated antigen-1 (CD11a/CD18)
LFA-2	Lymphocyte function-associated antigen-2 (CD2)
LFA-3	Lymphocyte function-associated antigen-3 (CD58)
LGL	Large granular lymphocytes
li	Invariant chain
LIF	Leukocyte-inhibiting factor
LIP	Lymphocyte (lymphoid) interstitial pneumonitis
LMI	Leukocyte migration inhibition
LMP	Low-molecular-weight polypeptide
LMPT	Lactulose mannitol permeability test
LMW	Low molecular weight
Lod	Logarithm of the odds
LPAM-1	Lymphocyte Peyer's patch HEV adhesion molecule 1
LPAM-2	Lymphocyte Peyer's patch HEV adhesion molecule 2
LPR	Late-phase reaction
LPS	Lipopolysaccharide
LR	(At) low risk (of atopy)
LRTI	Lower respiratory tract infection
LST	Long synthetic overlapping peptide
LST	Lymphocyte stimulation test
LT	Leukotriene
LTB_4	Leukotriene B_4
LTC_4	Leukotriene C_4
LTP	Lipid transfer protein
LTR	Long terminal repeats
LTT	Lymphocyte transformation test
LYST	Lysosomal trafficking
M	Microfold
mAb	Monoclonal antibodies
M-CSF	Monocyte/macrophage-colony stimulating factor
M-CSFR	Myeloid colony stimulating factor receptor
MAC	Membrane attack complex
MAC	Mid-arm circumference
Mac-1, -2	Macrophage-1 (-2) glycoprotein (CD11b/CD18)
MACIF	Membrane attack complex inhibitory factor (CD59)
MAD-2	Monocyte adhesion dependent protein-2
MAdCAM-1	Mucosal addressin cell adhesion molecule-1
MAG	Myelin associated glycoprotein
MALT	Mucosa-associated lymphoid tissue
MAMC	Mid-arm muscle circumference
MAP	Mitogen-activated protein
MAPK	Mitogen-activated protein kinase
MAS	Macrophage activation syndrome
MASP	MBL-associated serine protease
MAST	Multiplied allergosorbent test
MBL	Mannose-binding lectin
MBP	Major basic protein
MBP	Mannose-binding protein
MBP	Myeline basic protein
MBT	Mercaptobenzothiazole
MCAF	Monocyte chemotactic and activating factor (MCP-1)
MCC	Mast cell chymase
MCD	Mad cow disease
MCP	Mast cell protease
MCP	Membrane cofactor protein (CD46)
MCP-1	Monocyte chemotactic protein-1
MCP-2	Monocyte chemotactic protein-2
MCP-3	Monocyte chemotactic protein-3
MCP-4	Monocyte chemotactic protein-4
MCP-5	Monocyte chemotactic protein-5
MCR	Monocyte complement receptor
MCS	Multiple chemical sensitivities
MCT	Medium-chain triglycerides
MDA-7	Melanoma differentiation-associated factor 7
MDC	Macrophage-derived chemokine
MDI	Metered-dose inhaler
MDV	Mean diurnal variation
ME	Middle ear
MEEs	Middle ear effusions
MEF	Mid-expiratory flow
MEF_{25-75}	Maximal expiratory flow at 25 %–75 % VC
MGF	Mast cell growth factor (SCF)
MGSA	Melanocyte growth stimulating activity
MHC	Major histocompatibility complex
MIF	(Monocyte) migration inhibiting factor
mig	Monokine inducible by IFN-γ
mIgD	Membrane IgD
mIgM	Membrane IgM
MIIC	MHC class II-loading compartment
MIP-1α	Macrophage inflammatory protein-1α
MIP-1β	Macrophage inflammatory protein-1β
MIP-2	Macrophage inflammatory protein-2
MIP-3α	Macrophage inflammatory protein-3α
MIP-3β	Macrophage inflammatory protein-3β
MIPF-1	Myeloid inhibitory factor-1
MIPF-2	Myeloid inhibitory factor-2
MLC	Mixed lymphocyte culture

MLR	Mixed lymphocyte reaction
MMEF	Maximal mid-expiratory flow
MMP	Matrix metalloproteinase
MMR	Measles, mumps and rubella (vaccine)
MMWR	Morbidity and Mortality Weekly Report
Mo	Molybdenum
MODY	Maturity-onset diabetes of the young
MP	Monopositive
MPO	Myeloperoxidase
MPS	Mononuclear phagocyte system
MR	Magnetic resonance
MR	Mannose receptor
mRAST	Modified RAST
MS	Multiple sclerosis
MSP-R	Macrophage-stimulating protein receptor
MT	Mantoux test
MUD	Matched unrelated donor
MVM	Microvillus membrane
MXT	Methotrexate
MyD88	Myeloid differentiation protein gene 88
MZ	Monozygous
N	Neutral
N	Nutramigen
N-CAM	Neural cell adhesion molecule
NA	Neutrophil antigen
NACDG	North American Contact Dermatitis Group
NADP	Nicotinamide-adenine dinucleotide phosphate
NADPH	Nicotinamide-adenine dinucleotide phosphate (reduced form)
NALT	Nasal-associated lymphoid tissue
NANC	Nonadrenergic noncholinergic
NAP-1	Neutrophil-activating factor-1
NAP-2	Neutrophil-activating factor-2
NARES	Nonallergic rhinitis, eosinophilic subgroup
NAT	Nucleic acid amplification technology
NBT	Nitroblue tetrazolium (test)
NC	Nucleocapsid
NCA	Neutrophil chemotactic activity
NCA	Non-cross-reactive antigen
NCAM	Neural adhesion molecule
NCF	Neutrophil chemotactic factor
NCF-A	Neutrophil chemotactic factor of anaphylaxis
NE	Norepinephrine
nef	Negative factor
NEMO	NF-κB essential modifier
NEP	Neutral endopeptidase
NFAT	Nuclear factor of activated T cells
NF-κB	Nuclear factor κB
NFV	Nelfinavir
NGF	Nerve growth factor
NGFR-SF	Nerve growth factor receptor superfamily
NHR	Nasal hyperreactivity
NI	Nidina HA
NIDDM	Non-insulin-dependent diabetes mellitus
NeuroD-1	Neurogenic differentiation factor 1
NK	Natural killer cells
NKA	Neurokinin A
NKAR	Natural killer-activating receptor
NKAT	Natural killer-associated transcripts
NKB	Neurokinin B
NKIR	Natural killer inhibitory receptor
NKR	Natural killer receptor
NKRP-1	Natural killer receptor P-1 (CD161)
NKSF	Natural killer cell stimulatory factor
NN	Neonatal neutrophils
NNRTI	Non-nucleoside reverse transcriptase inhibitors
NO	Nitric monoxide
NO_2	Nitric dioxide
NOD	Nonobese diabetics
NOS	Nitric oxide synthase
NP	Nutrilon Pepti
NPP	Nutrilon Pepti Plus
NPT	Nasal provocation test
NPV	Negative predictive value
NPY	Neuropeptide tyrosine (Y)
NRL	Natural rubber latex
NRTI	Nucleoside reverse transcriptase inhibitor
NSAIDs	Nonsteroidal anti-inflammatory drugs
NT	Neurotensin
NVP	Nevirapine
NZB	New Zealand black
NZW	New Zealand white
$O_2^{\bullet-}$	Superoxide anion
O_3	ozone
OAS	Oral allergy syndrome
OCT	Oral challenge test
ODN	Oligodeoxynucleotides
OFC	Open food challenge
OME	Otitis media with effusion
q.i.d.	*Quarter in die*, four times a day
ORL	Otorhinolaryngologist
OVA	Ovalbumin
P	Pregestimil
P	Properdin
P+P	Prick by prick
p-ANCA	Perinuclear anti-neutrophil circulating antibodies
p150,95	CD11c/CD18
PA	Pseudoallergic, pseudoallergy
PAA	Proteins with anti-infective activity
PABA	*P*-aminobenzoic acid
PAC	Perennial allergic conjunctivitis
PACGT	Pediatric AIDS Clinical Trials Group

$PaCO_2$	Partial pressure of CO_2 in arterial blood
PAF	Platelet-activating factor
PALS	Periarteriolar lymphocyte sheath
PAN	Periarteritis nodosa
PaO_2	Partial pressure of O_2 in arterial blood
PAR	Perennial allergic rhinitis
PARC	Pulmonary and activation-regulated chemokine
PAS	*Para*-aminosalicylic (acid)
PBB	Polychlorinated biphenyl compounds
PBL	Peripheral blood lymphocytes
PBMC	Peripheral blood mononuclear cells
PBP	Platelet basic protein
PC	Particle counter
PC	*Pneumocystis carinii*
PC_{20}	Methacholine/histamine provocative concentration causing a fall in FEV_1 of 20%
PCB	Polychlorinated biphenyls
PCD	Programmed cell death
PCD	Protein contact dermatitis
pCi	PicoCurie
PCIIINP	Amino terminal propeptide of type III procollagen
PCIP	Carboxy terminal propeptide of type I procollagen
PCP	Personalized care project
PCP	*Pneumocystis carinii* pneumonia
PCR	Polymerase chain reaction
PD_{20}	Provocation dose 20
PDE	Phosphodiesterase
PDGF	Platelet-derived growth factor
PDGFR	Platelet-derived growth factor receptor (CD140)
PE	Progressive encephalopathy
PECAM 1	Platelet endothelial cell adhesion molecule (CD31)
PEF	Peak expiratory flow
PEFR	Peak expiratory flow rate
PEFV	Partial expiratory flow volume (curve)
PEG	Polyethylene glycol
PEM	Protein-energy malnutrition
PENTA	Pediatric European Network for Treatment of AIDS
PF	Perch fish
PF4	Platelet factor 4
PFC	Plaque-forming cells
PFM	Peak flow meter
PFT	Pulmonary function testing
PG	Polygalacturonase
PG	Prostaglandin
PGD	Prostaglandin D
PGE	Prostaglandin E
PGF	Prostaglandin F
PGL	Persistent generalized lymphadenopathy
PGP9.5	Neuron-specific protein 9.5
PH	Prophylac/Hypolac
PHA	Phytohemagglutinin
PHI	Peptide histidine-isoleucine
PHM	Peptide histidine-methionine
phox	Phagocyte oxidase
PHV	Peptide histidine-valine
PI 3K	Phosphatidylinositol-3-kinase
PID	Primary immune deficiency
pIgA	Polymeric IgA
pIgR	Polymeric Ig receptor
PIP2	Phosphatidylinositol-bisphosphate
PJ	PeptiJunior
PKA	Protein kinase A
PKC	Protein kinase C
PL	Phospholipase
PLA	Phospholipase A
PLC	Phospholipase C
PLCγ1	Phospholipase Cγ1
PLCγ2	Phospholipase Cγ2
PLD	Phospholipase D
PLH	Pulmonary lymphoid hyperplasia
PLP	Proteolipid protein
PM_{10}	Particulate matters <10 µm
PMA	Phorbol myristate acetate
pMDI	Pressurized metered dose inhaler
PMN	Polymorphonuclear (leukocytes)
PNM	Polynucleated neutrophils
PNP	Purine nucleoside phosphorylase
PNU	Protein nitrogen units
pol	Polymerase
poly	Polyarticular
POP	Persistent organic pollutants
PP	Peyer's patches
ppb	Parts per billion
PPD	Purified protein derivative
PPDA	Paraphenylenediamine
ppm	Parts per million
PPV	Positive predictive value
PR	Pregomin
PR	Protease
PR	Protein related to pathogenesis
PR3	Proteinase 3
prn	*pro re nata*, if required
PRIST	Paper radioimmunosorbent test
PrP	Prion protein
PRU	Phadebas RAST unit
PS	Polysaccharides
PSA	Polysaccharide antigen
PSGL-1	P-selectin glycoprotein ligand 1 (CD162)
PT	Patch test(ing)
PT	Provocation testing
PTF	Patch test with foods
PTK	Protein tyrosine kinase
PTP	Protein tyrosine phosphatase
PUFA	Polyunsaturated fatty acids
PUVA	Psoralen ultraviolet A
PV	Pulmonary volume
PVR	Polio virus receptor (CD155)
PWHF	Partial whey hydrolysate formula
PWM	Pokeweed mitogen

RA	Recombinant allergens
RA	Rheumatoid arthritis
RAG	Rice allergen
RAG-1 and -2	Recombination-activating gene-1 and -2
RANTES	Regulated on activation normal T expressed and secreted
RAP	Rapamycin
RAP	Rice allergenic protein
RAST	Radio allergosorbent test
Raw	Airway resistance
RBA	Radio-binding assay
RBC	Red blood cell
RCA	Regulator of complement activation
RDA	Recommended daily allowance
RES	Reticuloendothelial system
REV	Rev responsive element
rev	Regulator of viral expression
RF	Rheumatoid factor
RFLP	Restriction fragment length polymorphism
RFX5	Regulatory factor X5
RGS	Regulators of G protein-signaling
RH	Relative hazard
rHuG-CSF	Recombinant human G-CSF
RIA	Radioimmunological assay
Rint	Interrupter resistance
RLS	Restless legs syndrome
ROC	Receptor-operated channels
RP	Ratio of proportion
RR	Relative risk
RR	Respiratory rate
RRI	Recurrent respiratory infections
RSR	Respiratory system resistance
RSS	Conserved recombination signal sequences
RSV	Respiratory syncytial virus
RSV-IVIg	(Anti)respiratory syncytial virus-intravenous immunoglobulins
RT	Reverse transcriptase
RT-PCR	Reverse transcriptase/polymerase chain reaction
RTC	Rapid thoracoabdominal compression
RTV	Ritonavir
Rx	Radiographic
SA	Superantigen
SAA	Serum amyloid A protein
SAC	Seasonal allergic conjunctivitis
SAFT	Skin application food test
SAH	*S*-adenosylhomocysteine, *S*-adenosylhomocysteine
SALT	Skin-associated lymphoid tissue
SaO_2	Oxygen saturation
SAP	Serum amyloid P component
SAR	Seasonal allergic rhinitis
SARAH	Skin activity reference allergen/ histamine
SARS	Severe acute respiratory syndrome
SBHR	Spontaneous basophil histamine release
SC	Secretory component
SC	Subcutaneous
SC-SFA	Short-chain saturated fatty acids
SCF	Stem cell factor
SCID	Severe combined immunodeficiency
SCN	Severe congenital neutropenia
SCORAD	Scoring of atopic dermatitis
SCT	Stem-cell transplantation
SCY	Small secreted cytokine
SD	Serologically defined (antigens)
SD	Standard deviation
SDF	Stromal cell derived factor
SDS	Standard deviation score
SDS-PAGE	Sodium dodecylsulfate-polyacrylamide gel electrophoresis
SE	Staphylococcal enterotoxin
Se	Selenium
SEA	Staphylococcal enterotoxin A
SEB	Staphylococcal enterotoxin B
SEC	Staphylococcal enterotoxin C
SED	Staphylococcal enterotoxin D
SEE	Staphylococcal enterotoxin E
SEM	Standard error of the mean
SFA	Suppressive factor of allergy
SGOT	Serum glutamic-oxaloacetic transaminase
SH2, 2, 3	Src homology 2, 3
SH2DIA	SH2 domain containing gene 1A
SHS	Schönlein-Henoch syndrome
SI	Système International des Unités
SIAIC	Società Italiana di Allergologia e Immunologia Clinica
SIDS	Sudden infant death syndrome
sIgA	Secretory IgA
SIgAD	Selective IgA defect
sIgE	Specific IgE (food-specific)
sIgG	Specific IgG
sIgM	Secretory IgM
SIS	Skin immune system
SIT	Specific immunotherapy
SIV	Simian immunodeficiency virus
SJS	Stevens-Johnson syndrome
SL	Synovial liquid
SLAM	Signaling lymphocyte activation molecule
SLC	Secondary lymphoid tissue chemokine
SLE	Systemic lupus erythematosus
sLe^x	Sialyl-Lewis x (CD15s)
SLIT	Sublingual immunotherapy
SMOC	Second messenger-operated channels
SO_2	S dioxide
SOD	Superoxide dismutase
SOM	Somatostatin
SP	Single positive
SP	Substance P
SP-A	Surfactant protein A
SP-D	Surfactant protein D

SPA	*Staphylococcus aureus* protein A
SPB	Solid-phase binding
SPEA	Staphylococcal pyrogenic exotoxin A
SPEB	Staphylococcal pyrogenic exotoxin B
SPF	Soy protein formula
SPT	Skin prick test
SQ	Standardized quality unit
SQV	Saquinavir
sRaw	Specific airway resistance
SRBC	Sheep red blood cell
SRCR-SF	Scavenger receptor cysteine-rich superfamily
SSSS	Staphylococcal scalded skin syndrome
Stat	Signal transducers and activators of transcriptions
STCP-1	Stimulated T cell chemotactic protein-1
STS-IgG	Short-term sensitizing IgG
SV	Simian vacuolating (virus)
syk	Spleen tyrosine kinase
T	Tryptase-containing mast cells
T-bet	Transcription factors T-box expressed in T cells
TACTILE	T cell activation increased late expression
TAI	Transient autoimmunity
TAME	Tosylarginine methylester
TAP-1	Transporter associated with antigen presentation 1
TAP-2	Transporter associated with antigen presentation 2
TAPA-1	Target of an antiproliferative antibody 1
Tapr	T cell and airway phenotype regulator
TAR	Transactivation responsive sequence
TARC	Thymus and activation-regulated chemokine
tat	*Trans*-activant
TB	Tubercular
TC	Tryptase and chymase-containing mast cells
TCA	Trichloroacetic acid
TCA3	T cell activation gene 3
TCC	T cell clones
TCDD	Tetrachlorodibenzo-*p*-dioxin
TCL	T cell line
TcR	T cell receptor
TdT	Terminal-deoxynucleotidyl-transferase
TECK	Thymus-expressed chemokine
TEN	Toxic epidermal necrolysis
TF	Transcription factor
TGF	Transforming growth factor
TGFR	Transforming growth factor receptor
TGV	Thoracic gas volume
Th	T helper
ThP	Th precursors
THI	Transient hypogammaglobulinemia of infancy
TIF	(IL_{10}-related) T-cell derived inducible factor
TIM	T-cell immunoglobulin and mucin (domain)
TLC	Total lung capacity
TLR	Toll-like receptor
TM	Transmembrane
TM4-SF	Transmembrane 4 superfamily
Tme/Te	Percentage of expiratory time to reach peak tidal flow
TMJ	Temporomandibular joint
TN	Triple negative
TNF	Tumor necrosis factor
TNFR	Tumor necrosis factor receptor
TNFRSF	Tumor necrosis factor superfamily receptor
TNFRSF6	Tumor necrosis factor receptor superfamily receptor 6
Torr	Torricelli (1 Torr = 1 mmHg)
TPN	Total parenteral nutrition
Tr1	T-regulatory 1
TRADD	TNFR-1-associated death domain
TRUE	Thin-layer, rapid use epicutaneous (test)
Ts	T suppressor
TSP-1	Thrombospondin-1
TSP	Total suspended matter
TSST-1	Toxic shock syndrome toxin-1
tTG	Tissue transglutaminase
TV	Tidal volume
TVP	Tensor veli palatini
TVP	Textured vegetable proteins
TX	Thromboxane
TXA_2	Thromboxane A_2
UC	Ulcerative colitis
UCBT	Umbilical cord blood transplantation
UHT	Ultra-high temperature
UPA-R	Urokinase plasminogen activator receptor
URTI	Upper respiratory tract infection
UV	Ultraviolet
V	Variable
V	Vivena HA
VAP-1	Vascular adhesion protein
VC	Vital capacity
VCAM-1	Vascular cell adhesion molecule (CD106)
vCJD	Variant Creutzfeldt-Jakob Disease
VI	(HIV) virus-infected
vif	Viral infective factor
VIP	Vasoactive intestinal peptide
VKC	Vernal keratoconjunctivitis
VLA	Very late antigens
VNR	Vitronectin receptor
VOC	Volatile organic compounds
VOC	Voltage-operated channels
vpr	Viral protein R

vpu	Viral protein U
vpx	Viral protein X
VRI	Viral respiratory infection
VSV	Vesicular stomatitis virus
vWF	Von Willebrand factor
VZV	Varicella zoster virus
WARI	Wheezing associated respiratory infections
WAS	Wiskott-Aldrich syndrome
WASp	Wiskott-Aldrich syndrome protein
WB	Western blot
WCC	White-cell count
WGAA	Wheat germ agglutinin antibodies β
WHF	Whey hydrolyzed formula
WHO	Word Health Organization
WHO/IUIS	Word Health Organization/International Union of Immunological Societies
XL	X linked
XHIMS	X-recessive hyper-IgM syndrome
XLA	X-linked agammaglobulinemia
XLP	X-linked lymphoproliferative syndrome
XLT	X-linked thrombocytopenia
ZAP-70	Zeta-associated protein 70
ZDV	Zidovudine
Zn	Zinc

Immunology

Historical Milestones

The concept of forbidden foods that should not be eaten goes back to the Garden of Eden and apart from its religious meanings it may also have foreshadowed the concept of foods that can provoke adverse reactions. Thus we could say that allergic diseases have plagued mankind since the beginning of life on earth. The prophet Job was affected by a condition that following the rare symptoms described by the Holy Bible might be identified as a severe form of atopic dermatitis (AD). The earliest record of an apparently allergic reaction is 2621 B.C., when death from stinging insects was first described by hieroglyphics carved into the walls of the tomb of Pharaoh Menes depicting his death following the sting of a wasp. In 79 A.D., the death of the Roman admiral Pliny the Elder was ascribed to the SO_2-rich gases emanating from the eruption of Mount Vesuvius. Hippocrates (460–377 B.C.) was probably the first to describe how cow's milk (CM) could cause gastric upset and hives, proposing dietetic measures including both treatment and prevention for CM allergy. He also coined the term "ασθμα," meaning breathlessness. Subsequently, Thucydides described that during the plague afflicting Athens from 430 to 429 B.C., "those people who recovered from the disease rarely developed the illness a second time and never mortally," an observation that was verified by Panum in 1847 [407]. The Roman poet Lucretius (98–55 B.C.) stated that "what is food to one, is a bitter poison to others." Galen (129–202) was the first to describe allergy to goat's milk and also evidenced the fifth cardinal sign of inflammation, that is the loss of function or *functio laesa* not previously described by Celsus (first century B.C.). Perhaps an example of tolerance could be that of Mithridates (132–63 B.C.), who reportedly acquired immunity against poisons by assuming progressively increasing doses of each poison, a precursor of the oral desensitization by taking small incremental amounts of noxious foods. The concept of immunity, deriving from the Latin *immunitas* (meaning being exempt from), a century ago was linked by early immunologists to the resistance of an individual to infections; therefore immunology probably began its march as acquired immunity [33]. The concepts of immunology have a long history and began primarily as a branch of microbiology. Fracastoro wrote in *De contagione et contagiosis morbis*, published in 1610, that "an infection is the same in both the carrier and newly infected" and postulated the existence of "imperceptible" germs. Since then, several important discoveries have launched a renaissance of research into the field of immunology. Experimental immunology began in 1798 with Jenner [237], Pasteur developed killed and attenuated vaccines, and Miescher later discovered DNA (deoxyribonucleic acid) [33]. In 1875 Cantani Sr stated that the cause of diabetes mellitus was to be sought in a missing *ferment* which in the healthy metabolized glucose. He also demonstrated that dehydration should be cured by *fluid rehydration*. In 1890, Ehrlich expressed the concept of autoimmunity as horror *autotoxicus* [137], amply skimming the etiopathogenetic mechanisms. At the turn of the century, von Pirquet coined the term "allergy" from "αλλος" and "εργος" (meaning altered reaction) [611] and therefore included the development of protective immunity [33], coupled by Coca and Cooke in 1923 with the term "atopy," from "ατοπος" (meaning out of place and thus abnormal) [88]; thus many episodes based on the mechanisms of cause and effect were brilliantly documented [33]. In 1921, Prausnitz and Küstner demonstrated the presence of "reagins" in the serum of allergic patients [436]; in the same year a "Textbook of Immunology" was first published in Italy [75]. In 1966, the Ishizakas attributed a scientific meaning to reagins by identifying IgE as the carrier of reaginic activity in the sera of hay fever sufferers [228]: the first case of immunodeficiency (ID) was reported in 1952 (Chap. 22).

The Immune System

Definitions. The *immune system* was presumably evolved by animals during evolution as a means of self-preservation in a world teeming with microorganisms. It is not selective and immune responses ensue against foreign substances regardless of whether they are bacterial products or not. Therefore the immune system has become exquisitely specialized and highly complex, to protect the host from potentially noxious environmental agents (antigens). The introduction of foreign substances into the host may have an adverse effect on a variety of cells; hence this system synthesizes highly specialized molecules (antibodies), also generating selected cells,

called cytokines, adhesion molecules, chemokines, and the like. Related cells and cell products are consequently a defense system designed to interact with foreign agents to protect the host from any external injury [34].

- *Immunity* is the complex of cellular and/or humoral events following the entry of foreign substances (non-self) into the host. These events are overall free of adverse effects for the majority of subjects, therefore defined as normal.
- *Immunology* is the study of the ways used by the host to maintain homeostasis in the internal environment when confronted with non-self.
- *Allergy* currently implies all forms of hypersensitivity with detrimental consequences for the host and type I, IgE-mediated or cell-mediated reactions.
- *Atopy* is a term underlining the personal or familial hereditary aspects of allergic reactions and is associated usually in childhood or adolescence with increased production of IgE antibodies and/or altered specific reactivity in response to ongoing exposures to allergens, usually proteins.

A thoroughly functioning immune system serves three main functions: (a) defense against invasion of microorganisms and foreign substances, ingested, inhaled or achieved by mucosal contact, or by parenteral injection; (b) homeostasis fulfilling universal requirements of multicellular organisms to preserve uniformity of a given cell type, as well removing worn-out "self" components; and (c) surveillance devoted to perception and destruction of mutant cells [33]. Therefore, inability to relate to *unum* is intrinsic to atopic diseases that depend on hyperproduction of IgE antibodies being IgE-mediated. This is a genetic characteristic, although the mode of transmission is still a matter of debate, and the fact of being atopic does not result automatically in the development of clinical manifestations. Atopy is also polymorphous, manifesting in various forms, starting out as AD or food allergy (FA), to further develop into allergic rhinitis (AR) and/or asthma.

According to the classic theory of clonal selection (Chap. 2), the crucial function of the immune system from the first days of life is to distinguish self from non-self, for example, between what belongs to or is closely correlated to the organism (tolerance to self antigens) and what is foreign, with the goal of eliminating the latter, independent of its potential pathogenicity. This is the quintessential dichotomy of immunology: the *self versus non-self discrimination*. We shall see in Chap. 2 that theories regarding self/non-self are still valid (as long as they are not interpreted literally), with the exception of some recent studies that have clarified how the so-called *neonatal window* period represents an ontogenetic window only as far as tolerance induction is concerned [60]. Immunity is acquired at the first contact with non-self (*antigen recognition*), it is *specific* for a given foreign substance and *acquired,* since it is able to respond to molecules not encountered before. Following an initial antigen stimulus, finally familiar with self and non-self, a series of reactions results, sometimes as if it were reacting to invaders. In virtue of such events, the integrity of the organism, which becomes protected from successive entries of potentially pathogenic substances, is maintained. This is put into practice by the immune memory enabling the immune system to memorize previous exposures to a particular antigen, in a way analogous to natural memory that recalls past experiences. Amongst all defense mechanisms put into action by the host against any external aggressor, we find a network of organs, tissues, cells and molecules responsible for immunity: the *integrated immune system* [36]. The interconnected and coordinated responses following the entry of foreign substances are globally known as *immune reactions.* Relatively small modifications in the delicate and complex molecular and cellular structures of the immune system may cause a functional disequilibrium that is responsible for a cascade of organic perturbations that may become evident alterations, such as atopic diseases varying in nature and severity and primary immune deficiency (PID) [33].

Ideally, the immune reactions determine schematically ordered responses articulated on six levels: processing, presentation and recognition of non-self, cellular activation, elaboration of biologically active chemical substances, mediators, and cellular cooperation. The final outcome of the encounter between host and a foreign invader is now recognized as dependent upon an integrated network of multidirectional communication pathways and signaling, where the mechanisms of memory, effector responses and consequent regulation of secretory proteins and soluble molecules such as the interleukins (ILs) are clarified [34]. Antigen contact starts to form those elements necessary for its recognition, including the cells emitting signals, ILs transducing such signals and target cells receiving them by binding to appropriate receptors; following transduction and amplification of signaling, a detectable physiological response occurs [34]. Thus, immune responses usually culminate in the elimination of provoking agents. The specificity of antigen recognition, as defined in molecular terms, is entrusted to three structures: the variable (V) region of Igs (immunoglobulins), MHC (major histocompatibility complex) V regions and TcR (T-cell receptor) chains. A fourth component of molecular recognition, the cluster of differentiation (CD) markers, differentiates subsets of T from B lymphocytes (from *lympha*, water) and other cell populations [34].

Systems of Immunity

Two general systems of immunity with specialized roles in defending against infection have been selected during evolution [114]:

- *Innate immunity,* an ancient form of host defense, also called natural or congenital immunity, is an attribute of

Table 1.1. Comparison of the innate and acquired immune systems

Properties	Innate immune system	Acquired immune system
Cellular components	Macrophages, PMN, eosinophils, NK cells, DCs, IFN-producing cells, γδ T cells, $CD8^+$ T cells	T and B lymphocytes, macrophages, DCs, $CD4^+$ T cells, $CD8^+$ T cells
Soluble components	Enzymes (lysozyme, complement, etc.), acute-phase proteins, interferon, collectins, defensins, chemokines	Antibodies, interleukins
Memory	No	Yes
Physical barriers	Skin and mucous membranes	None
Recognition	++	+
Self–non-self discrimination	Yes	Yes
Specificity	No	Yes
Speed	tast	slow

Modified from references [115, 184, 537].

every living organism, present at birth, that is, before exposure to foreign agents and consisting of several non-specific factors. Innate responses occur to the same extent as the infectious agent is encountered. Not significantly modified after an encounter with non-self substances, it is void of both a fine-tuned discrimination of such substances and an increased activity following repeated encounters, thereby demonstrating that it does not possess memory. The phagocyte cells (macrophages, neutrophils and monocytes) and alternative complement pathway, although void of specificity, are essential as primary elements of defense against a large number of infectious agents.

- *Acquired immunity,* also called adaptive immunity, becomes involved when the first level of defense fails to fully prevent infection, exemplifying a recent evolutive process, distinct by a particular specificity for offending antigens and by memory. Unlike innate immunity, it is elicited or stimulated by exposures to intruders that escaped early elimination by the innate immune system, insofar as it is armed with a versatile discriminating capacity and potentiated by a successive encounter with such agents.

Table 1.1 [114, 184] shows the major differences between these two types of immunity: the effector mechanisms of innate immunity are activated immediately after infection and rapidly control the replication of infecting pathogens, so the infection is restrained until lymphocytes can accomplish their action. It takes 3–5 days for a sufficient number of clones to be produced and differentiated into effector cells, which allows time for pathogens to damage the host [353]. The greatest difference is that acquired immunity, to compete with genetic variability of microorganisms, has lost the cardinal characteristic seen in innate immunity, that is, the ability to distinguish between potential pathogens and harmless substances. However, innate immunity may have an additional role in determining which antigens the acquired immune system responds to and the nature of that response [148].

Acquired Immunity

As Table 1.1 shows, acquired immunity involves T and B lymphocytes, antibodies and ILs, distinguished schematically into humoral and cell-mediated immunity (CMI), each equipped with various functions, partly different and partly overlapping. Acquired responses involve the proliferation of antigen-specific B and T cells, which occurs when the surface receptors of these cells bind to antigen. Specialized cells, the antigen-presenting cells (APCs), display the antigen to lymphocytes and collaborate with them in the response to the antigen [537].

Humoral-mediated immunity, above all responsible for primary defense against bacterial infections, is passively transferable by serum or plasma, being mediated by antibodies with a specific aptitude for reacting with the configurations responsible for its production, which is typical of B lymphocytes, which in humans differentiate in mammalian bursal equivalent tissue and acquire features of B cells from plasma cells with an endoplasmic reticulum (ER) characterized by an abundant RNA (ribonucleic acid). Specific antibodies are responsible for the reactions of immediate hypersensitivity, cytotoxicity, Arthus reaction and, by means of Fc receptors, phagocytosis.

CMI, as well as being active in the defense against viral infections, is implicated in some cases of autoimmune disease and is characteristically associated with effector–target cell interactions involved in antimicrobial immunity, rejection of allografts, immune surveillance and rejection of tumor cells. This specific immunity is transferable by lymphoid cells and not by serum, where T lymphocytes play a fundamental role [481].

Delayed-type hypersensitivity (DTH) is a typical CMI reaction [33], first discovered by Jenner [237].

Organs and Cells of the Immune System

Several organs and tissues participate in the host defense and are classified into [33, 36, 47]:

- *Primary lymphoid organs* (forming the central lymphoid organs) where both T and B lymphocytes mature into antigen-recognizing cells and developing lymphocytes acquire antigen specific receptors. These cells develop from pluripotent stem cells (SC) *in bone marrow and only during fetal life in the liver* and then circulate throughout the extracellular fluid. B cells reach maturity within the bone marrow, but T cells must travel to the thymus to complete their development. An important and key role in homing-related responses and in the regulation of cell trafficking of stem/progenitor cells (SPC) is played by SDF-1 (stromal cell derived factor-1) bound to G-protein-coupled CXCR4 (chemokine receptor4). Supernatants of leukapheresis products activate SDF-dependent actin polymerization and significantly enhance the homing of human cord blood (CB) and bone marrow-derived CD34 cells in a NOD (nucleotide-binding oligomerization domain)/SCID mouse (severe combined immunodeficiency (ID). CXCR4 plays a critical role in the trafficing of other tissue/organ specific SPCs expressing CXCR4 on their surface, such as during embryo/organogenesis and tissue/organ regeneration [277, 654]. They are represented in mammals by the thymus, bone marrow and only during fetal life by the liver.
- *Secondary lymphoid organs* (forming the peripheral lymphoid organs) including lymph nodes, spleen, tonsils and linings of the digestive, respiratory and genitourinary tracts, skin, conjunctiva and salivary glands. These organs of different size, disseminated throughout the organism, build structures where antigen-driven proliferation and differentiation occur and lymphocytes circulate and recirculate. There T cells interact with foreign configurations by cytotoxicity or releasing nonspecific mediators, with the non-complementary help of ILs, and store, amplify, and disseminate information about macromolecules encountered in various parts of the body [33].

The primary lymphoid organs include the thymus and the bone marrow.

The *thymus* is a lymphoepithelial organ located in the anterosuperior region of mediastinum deriving from the endoderm of the third and fourth pharyngeal pouches. In the 6th week of fetal life, primitive mesenchymal and neural crest cells seed epithelial structures. Remarkably, parathyroids develop about the same time as the same pouches. During fetal development, the thymus size increases, then reaches its greatest relative weight shortly after birth, and its greatest absolute weight at puberty when contrary to other lymphoid organs, it progressively involutes and is replaced by adipose tissue. However, even if lymphocyte numbers progressively decrease, they do not disappear altogether. Apparently, a few fragments are adequate to ensure a compatible T cellularity in peripheral lymphoid tissues. By 8 weeks of gestation, $CD7^+$ hematopoietic SCs migrate from the yolk sac and fetal liver and later from the bone marrow via the bloodstream and enter the thymus through the epithelial cell linings of the cortex. The hematopoietic SC activity is regulated by C/EBPα (CCAAT-enhancer binding protein α) [679]. It has not yet been clarified whether these traveling stem cells are already committed to differentiate along the T-cell (T = thymus-derived) lineage or become committed only after entering the thymus and what excites them to such a gland. It has been hypothesized that these precursors may express certain as yet unidentified surface markers that selectively bind to their corresponding ligands on the thymic vascular endothelial cells. For this reason, the thymus is the central organ where the precursors, bone marrow-derived prothymocytes, undergo intense proliferation and differentiation, as well as do macrophages, epithelial and dendritic cells (DCs) [454]. The gland consists of two lobes surrounded by a thin capsule of connective tissue extending into the lobe, thus forming septa, partially dividing parenchyma into lobules (Fig. 1.1, a) [454]. The peripheral zone of each lobule forms the cortex with immature proliferating cells. The cortex is further subdivided into a superficial and a deeper zone, with a more central area forming the medulla containing more mature cells and Hassall's corpuscles, an aggregate of epithelial cells. While the thymus has a cortex and a medulla, there is no germinal center (GC), or plasma cells, as in normal situations [33]. The thymus, independent of antigen stimulation, may be viewed as a lymphoid organ controlling all peripheral lymphoid organs, by means of expanding immunocompetence of the lymphocytes associated with CMI. The thymus exercises its function in time by secreting several soluble hormones (thymosin, thymopoietin, etc.): in fact, epithelial thymic cells secrete a series of polypeptides (thymic hormones and ILs), contributing to the maturation of T lymphocytes, with which they can interact directly, influencing their differentiation [33]. During fetal cell development, the requirement for STAT5 (signal transducers and activators of transcriptions) in thymopoiesis is developmental stage specific. STAT5 is required for IL_7R-regulated TCR gene transcription, but it is not necessarily essential for TCR gene rearrangement, denoting that factors other than STAT5 activated by the IL_7R-JAK pathway control TCR locus accessibility to VDJ recombinase [246]. One of the major roles of STAT3 in the G-CSF signaling pathway is to augment the function of C/EBPα (CCAAT enhancer binding protein-α), which is essential for myeloid differentiation. Moreover, co-operation of C/EBPα with other STAT3-activated proteins is required for the induction of some G-CSF responsive genes [386]. The close connection between epithelial cells and lymphocytes is confirmed by the presence of large epithelial cells (*nurse cells*) in the superficial cortex, each containing 20–30 blasts in

Fig.1.1. **a** The thymus of a normal newborn. Connective tissue septa, traversed by large blood vessels, divide the thymus into lobules, the very dense peripheral cortex is clearly distinguished from the more central, less dense medulla. **b** Positive and negative selection in the thymus

division. Prothymocytes (pro-T) express CD2 and CD7, immature T cells of the cortex, smaller (pre-T), such as CD1 and once migrated into the medulla, CD3, CD4, CD8, CD38 and CD71 (transferrin receptor) present not only on T cells, but also on cells of other lineages undergoing proliferation. A low number of $CD4^+8^+$ (DP, double positive) T cells located in the medulla learn how to discriminate self from non-self in a process known as education; they interact with stem cells expressing MHC molecules, then $CD4^-8^-$ (DN, double negative) T cells acquire a $CD4^+8^-$ or $CD4^-8^+$ (MP, mono-positive) phenotype. Targeted mutations of CD80 and CD86 substantially reduce the proliferation and survival of DN T cells in the thymus, since the DN development in the thymus is subject to modulation by the CD80–CD28 costimulatory pathway [682]. The earliest immune maturation of any lymphocyte compartment in humans is represented by αβ and γδ TcR and most likely reflects the importance of these cells in controlling pathology due to common environmental challenges. A significant difference between the γδ and αβ T cell lineages is the much earlier activation and conversion to memory of the γδ T cells, which illustrates the central role that γδ T cells have in adressing Ag challenge from birth onward. γδ T cells are distinguished by expression of Vδ1 vs Vδ2 δ-chains. The majority of Vδ2 cells display signs of early activation in neonates. Even in infants <1 year most of Vδ2 nonnaive cells stain for perforin and produce IFN-γ after short-term stimulation, yet nearly all naive Vδ2 cells disappear from blood by 1 year of life. Vδ1 cells predominate during fetal and early life, but represent the minority of γδ cells in healthy adolescents [111]. As regards TcR, only cells with an αβTcR-CD4/CD8 coreceptor combination that is able to bind the same MHC class I or class II molecules will fully mature. Cells with a mismatched combination will die [263]. Positive selection is conditioned by activation of the MAPK (mitogen-activated protein kinase) cascade, although it does not involve $CD4^-8^-$ (DN) T cells [10]. Most lymphocytes not surviving the thymic selection process die by apoptosis (from "απωπτοσις," cellular suicide): they are engulfed and digested by macrophages of the corticomedullary junction within 3–4 days of their last cell division [192] (Fig. 1.1 b). In the deep cortex, T cells interact with macrophages, FCDs and epithelial cells, which during a differentiation process modify expression of cytokeratins such as skin keratinocytes; medullary T cells are found in Hassall's corpuscles [225]. Several immune deficiencies are characterized by selective deficiency of T cells [33].

The *bone marrow* is a structure present in man and in higher mammals considered to be a primary lymphoid organ functionally equivalent to avian bursa. The location of pluripotent hemopoietic stem cells eventually differentiating into stromal cells guides hemopoiesis both by direct cellular contacts with developing lymphocytes (precursors) and by other blood cells, also under the control of growth factors. Many ILs are involved

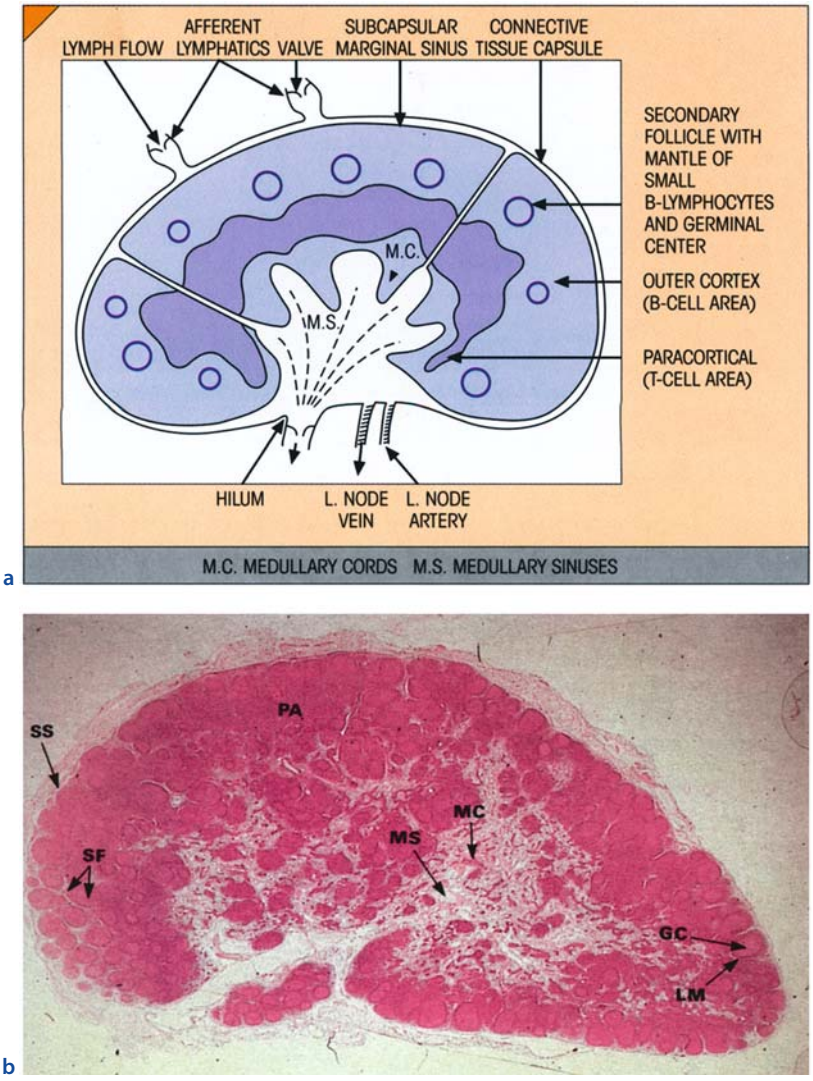

Fig.1.2. **a** Schematic structure of human lymph node. **b** Human lymph node (low magnification). **c** Secondary lymphoid follicle showing GC surrounded by a mantle of B lymphocytes. In the center there are few IgD-positive cells; both areas contain IgM-positive B cells. Lymphocyte mantle stained with anti-human IgD antibody. **d** Section of lymph node medulla stained in methyl green (DNA)/pyronin (RNA) to show the basophilic (*pink*) cytoplasm of plasma cells with abundant ribosomes. **e** Section of lymph node medulla showing macrophages lining the medullary sinus following the uptake of red dye. **f** Lymph node of a mouse immunized with pneumococcal polysaccharide antigen, thymus-independent, revealing a prominent stimulation of SFs with GC. **g** Green stain (methyl/pyronin) of a lymph node draining site of skin stained with the contact sensitizer oxazolone, with the generalized expansion and activation of the paracortical T-cell area, which is clearly noted, since T blasts are strongly basophilic. **h** Lymph node section from a congenitally athymic (nude) mouse showing paracortical depletion with failure of T-cell development. *LM* lymphocyte mantle with SF, *MC* medullary cords, *MS* medullary sinus, *PA* paracortical area, *PC* plasma cells, *PN* primary node, *SF* secondary follicle, *SM* sinus macrophage, *SS* subcapsular sinus

in different pathways; among them IL_4 produced by T cells regulates proliferation of B lymphocytes (B=bone marrow-derived or bursal equivalent). In mammals, B cell maturation occurs in bone marrow: precursor cells (pro- and pre-B; see Chap. 2) multiply when in contact with primitive reticular cells, which generate ILs necessary for cellular multiplication and maturation. As for T cells in the thymus, a great number of B lymphocytes die through apoptosis, while mature B cells leave the bone marrow traversing the walls of venous sinuses [469]. Then they are transported by the circulation to secondary lymphoid organs, where they encounter and respond to invading antigens.

Secondary lymphoid organs include lymph nodes, spleen, tonsils and MALT.

Lymph nodes are lymph filters placed at the junctions of sympathic vessels. They are aggregates of lymphoid tissue strategically positioned to form a complete network throughout the body and carry out the basic functions of filtering foreign material, favoring antigen-dependent differentiation of lymphocytes, and localizing and preventing the spread of infectious processes. Apart from collagenous capsules surrounding lymph nodes, two cortical zones are recognizable within ganglia parenchyma, a more external (cortex or B-cell area) and a deeper one (paracortex or T-cell area) and a central medulla, where parenchyma is organized into medullary cords interdigitating with medullary sinuses. T and B cells, plasma cells and several macrophages are found there (Fig. 1.2) [470]. B cells populate three principal areas, the GCs, with dark and light zones, the follicular mantle zone, including $CD5^+$ and $CD5^-$ with features of virgin cells, and the marginal zone with several subsets also present in the spleen, subepithelial areas of the tonsils and the dome region of Peyer's patches (PP) [63]. B memory cells coming from tonsils colonize subepithelial areas and directly present antigen to T cells by rapid up-regulation of CD80 and CD86 [304]. T lymphocytes reside in T-cell-dependent areas, the deep cortex or paracortical zone together with interdigitating DCs (IDC) and high endothelial venules (HEV) present in lymphoid tissues and possessing cubic epithelial cells

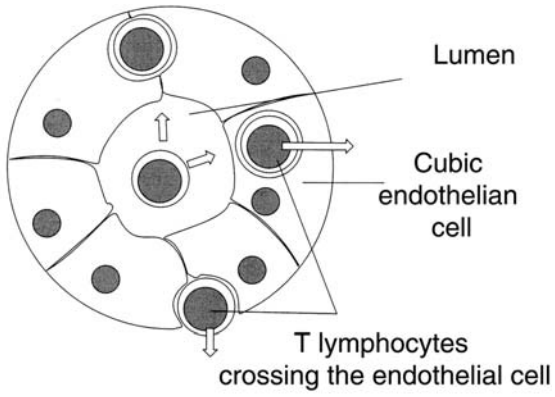
Fig.1.2. (Continued)

(Fig. 1.3). By crossing HEVs, non-antigen stimulated, virgin lymphocytes reach lymph nodes [454], where the paracortical area following antigen stimulation is hypertrophied and contains T lymphocytes and ICDs that are APCs. A specific subset of DCs (originating from circulating CD11c + DCs), which strongly stimulate T cells but not B cells, was recently identified in GCs [191]. Finally, the medullary layer, which is made up of cords separating lymphatic sinuses, contains essentially macrophages and plasma cells.

The *spleen*, in addition to being a filter eliminating senescent or worn-out cells, foreign particles and macromolecules from the circulation, is the only lymphatic tissue specialized in filtering blood as well as in filtering and processing antigens transported into the bloodstream (Fig. 1.4). Similar to lymph nodes, it is divided both from a functional and structural point of view into B and T zones. There are no lymphatic vessels, since blood enters the splenic parenchyma at the hilum via the splenic artery and follows along trabeculae until smaller arterial branches become surrounded by sheaths of lymphocytes, the white pulp. This zone contains lymphoid cells aggregating in lymphoid follicles or lymph nodules, and in *periarteriolar lymphoid sheaths* (PALS), which are similar to the cortex of lymph nodes. The pulp surrounding periarteriolar sheaths is called the marginal zone. In the peripheral area, cortical lymphocytes aggregate into follicles (as can be found in all peripheral lymphoid organs), distinguished into two types, primary and secondary follicles, also designated as GCs (see also "B Lymphocytes"). GCs also contain B cells and macrophages; B cells can also be found in red pulp, which is formed by venous sinuses, reticular fibers (Billroth's cords) and vessels [454]. The PALS mainly



T lymphocytes		Endothelial cell

CD11a	⟷	CD54, 58, 102

Fig.1.3. High endothelial venules

contain mature T lymphocytes with a CD4 phenotype in 65% of cases and CD8 in the remaining 35%. GCs and cells in active proliferation are present; the larger and medium-sized cells predominate in the central part of the GC, while the smaller cells localize at the periphery and form the mantle [454]. The surrounding follicles and marginal zone are composed mostly of B cells in addition to monocytes, plasma cells, red cells, platelets, DCs and several macrophages active in phagocytosis. The main immune function of the spleen is to initiate immune responses against polysaccharide antigens (PSA) traveling in the blood and fixed on the surface of follicular DCs (FDCs), differently from lymph nodes where immune responses to antigens take place if antigens enter via afferent lymphatics [33, 36]. The marginal zone is a natural reserve of memory B cells [48].

The *tonsils* (lingual, palatine and adenoidal) are important immune organs, containing many primary and secondary follicles and GCs, with morphology and cellular composition identical to those in lymph nodes. They are strategically placed for initiating immune responses, as they are continually in contact with inhaled or ingested antigens (Chap. 15).

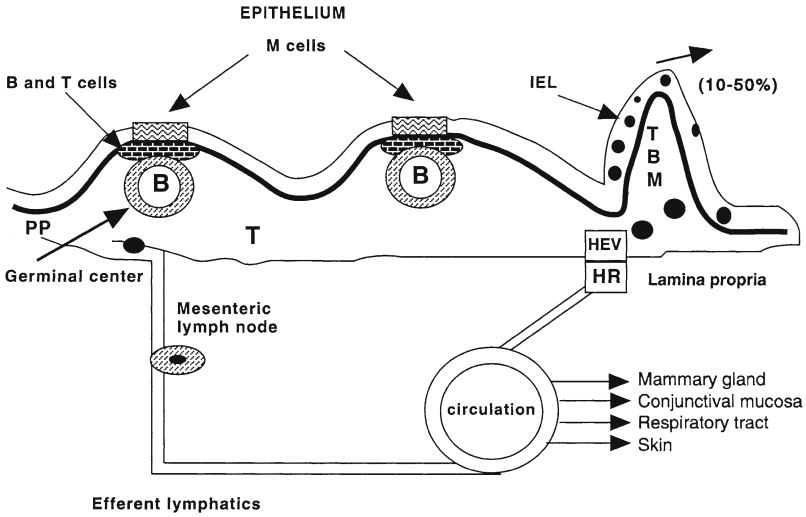

Fig.1.5. Schematic representation of recirculation of lymphocytes showing the relationships with MALT sites. After antigen presentation, T lymphocytes of the organized MALT leave the Peyer's plaques (*PP*) via efferent lymphatics and reach the circulation via mesenteric lymph nodes. Cells derived from the gut preferentially home back to the gut lamina propria via specialized homing receptors (*HR*) and the *HEV*. Cells originating from the gut can also reach other MALT sites: GALT, BALT, SIS, NALT, CALT (see text). *T, B* T and B lymphocytes, *M* macrophages, *IEL* intraepithelial lymphocytes, *HEV* high endothelial venules, *HR* homing receptors. (Modified from [546])

Mucosa-associated lymphoid tissue (MALT) is made of lymphocytes aggregated to form follicles in the lamina propria underlying basement membranes of mucosal epithelia of the respiratory, gastroenteric, cutaneous and urogenital systems. The most prominent of such tissues are termed GALT and BALT (gut- and bronchus-associated lymphoid tissue) (Fig. 1.5) [548]. Such distant anatomical sites not only share common immune effectors such as secretory IgA antibodies (sIgA), but they are also interrelated by a traffic of lymphoid cells.

GALT is represented by PPs in the mucosa of the outer wall of the terminal ileus (up to 200 PPs are present in mammals) and by the appendix, with a similar division into B- and T-dependent areas. Lymphoid tissue is also diffusely distributed in the lamina propria of intestinal villi and crypts and among epithelial cells of gut mucosa. GALT may intervene in differentiating stem cells into B lymphocytes that are mainly committed to IgA synthesis throughout the MALT. Primed B lymphocytes within PPs travel via mesenteric lymph nodes (where they differentiate into mature IgA B cells) and thoracic duct lymph, and subsequently to the systemic circulation, and finally they return mostly to reside at intraepithelial sites in the mucosa and to some extent to the spleen or to more distant sites such as BALT. Studies have shown that T lymphocytes may leave intravascular space via homing receptors on specialized HEVs where vascular adhesion molecules may direct their traffic [548].

BALT is structurally and perhaps functionally similar to GALT, associated with both upper (nasal mucosa) and lower (lungs) respiratory tracts. Lymphocytes are organized into lymphoid aggregates and follicles. They are commonly placed along main bronchi in all lobes that are found especially at bifurcations of bronchi and bronchioli; the so-called M (*microfold*) cells are found in both GALT, over the PP dome, and BALT overlying follicles (see Chaps. 9 and 11).

SIS (skin immune system). The term highlights the skin's immune characteristics, where intraepidermal lymphocytes, DCs, Langerhans' cells (LCs), keratinocytes, etc. are found.

Subsequently, additional lymphoid structures, including *NALT (nasal-associated lymphoid tissue),* corresponding to Waldeyer ring and *CALT (conjunctiva-associated lymphoid tissue)* have been characterized.

Cells of the Immune System

Two Families of Lymphocytes

Both T and B cells can be defined as two lines of immunocompetent cells, morphologically indistinguishable but functionally distinct, having a different origin. The immune response has indeed different functional aspects according to the reciprocal involvement of T or B cells; therefore, this response can be regarded as having two distinct components, the T system of lymphocytes producing immune or sensitized lymphocytes, and the B system of lymphocytes producing Igs. For their identification there is an internationally defined nomenclature, the group of CD antigens (CD followed by a number) (CD1–CD342) (Table 1.2) [4, 6, 16, 23, 34, 49, 70, 82, 85, 102, 103, 109, 112, 120, 132, 147, 158, 175, 242, 262, 343, 373, 407, 428, 437, 442, 484, 501, 515, 559, 571, 584, 608, 604], denoting that a cluster of antibodies will react with a particular antigen (see "Afferent Phase of Immune Response").

These effector cells of specific immunity share two cardinal features:

- They can be induced in that they have the ability to be activated by antigens evoking their formation and can be stimulated to proliferate and differentiate, so as to generate effector and memory cells.

Table 1.2. Leukocyte cell surface proteins: cluster of differentiation (*CD*) and their immune expression

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD1a (R4, Leu 6, VIT6, gp49)	Myeloid progenitors, DCs, LCs, activated T cells	49	Presentation of lipid and glycolipid antigens, antigen presentation to T γ/δ
CD1b (R1, NUT2, 4A76, gp45)	Thymocytes, DCs, LCs, T subpopulation	45	CD1a to C1b, noncovalently bound to β_2-microglobulin, include forms of non-HLA class I-like molecules, with a potential role alternative to known APCs
CD1c (R7, PHM3, M241, gp43)	Thymocytes, DCs, LCs, T subpopulation	43	Presentation of lipid and glycolipid antigens, αβ TcR
CD1d (R3)	Leukocytes, epithelium		Presentation of hydrophobic nonpeptide antigens, αβ TcR
CD1e (R2)			Presentation of lipid and glycolipid antigens, αβ TcR
CD2 (9.6, 35.1, T11, LFA-2)	Murine B, mature T and NK cells, thymocytes	47–58	Associated with CD3ε and ζ, promotes intercellular adhesion via the CD58 ligand, of CTLs to target cells, of T cells to endothelial cells and APCs, signal transduction
CD2R (T11.3, VIT13, D66)	Activated T and NK cells	50	Epitope of restricted CD2, activates thymic, T and NK cells
CD3-α (UCHT1, Leu 4, T3)	Thymocytes, T cells	25–28, 21,	Invariant part of TcR (5 chains), signal transduction for T cell activation
		20, 16, 22	Lineage-specific marker, Ig-SF
CD4 (91.D6, Leu 3, T4)	Thymocytes, T subpopulation, monocytes	59	Th marker, CD3 co-receptor, stabilizes HLA class II–TcR complexes, HIV receptor, signal transduction in association with $p56^{lck}$, Ig-SF
CD5 (T1, UCHT2, T101, gp67)	Mature (murine) B cells and T cells, thymocytes	67	Costimulation of T cells, binds CD 32, CD38, CD45RA, CD45RO, CD72, increases the pool of 2nd messengers, SRCR- SF
CD6 (T12, T411, gp100)	B and T subsets, thymocytes	100–130	Interacts in the TcR-mediated activation of T cells, binds CD166; SRCR-SF
CD7 (3A1, 4A, CL1.3)	Human fetal liver, thymocytes, T and NK cells	40	Signaling, early T-lineage marker, activates T and NK cells, FcR for IgM, Ig-SF
CD8 (α chain: T8, Leu 2a, T811; β chain: T8; gp32)	Most thymocytes, CTLs, intraepithelial lymphocytes, some DCs	34	Stabilizes HLA class II–TcR complexes, coreceptor for HLA class I CTL-restricted, signal transduction, Ig-SF
CD9 (PHN200, FMC56, p24)	Pre-B cells, monocytes, basophils, platelets, activated B and T cells	22–27	Adhesion of pre-B cells, possible role in signal transduction mediated by interaction with GTP-binding proteins, activation and aggregation of platelets, binds CD41/CD61, TM4-SF
CD10 (J5, NEP, BA-3, gp100, CALLA)	B precursors, TN thymocytes, PMNs, fibroblasts	100	Zn-dependent neutral endopeptidase, putative role in B-cell development

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD11a (MHM24, LFA-1, CRIS3, CR1)	Myeloid precursors, monocytes, macrophages, neutrophils, eosinophils, B and T cells	180	β2 Integrin (αL chain), receptor for CD50, CD54 and 102, mediates cell–cell leukocyte adhesion to endothelium (CD54/102), of CTL to target cells, heterotropic among B, T and monocytes and homotropic of neutrophils via CD50
CD11b (Mo1, MAC-1, CR3, gp155/95)	Monocyte-macrophages, neutrophils, NK cells	165	β2 Integrin (αM chain), receptor for CD54, iC3b and fibrinogen, modulates adhesion of neutrophils/monocytes and extravasation via CD54
CD11c (L29, B-LY6, BL-4H4, CR4, gp150/95)	Monocyte-macrophages, neutrophils, NK cells, subsets of activated B and T cells	150	β2 Integrin (αX chain), receptor for CD54, iC3b and fibrinogen, neutrophil/monocyte adhesion to endothelium, receptor for phagocytes
CDw12 (M67)	Eosinophils, monocytes, PMNs, basophils	90–120	Requires further analysis
CD13 (MY7, MCS-2, TÜK1, gp150)	Myeloid progenitors, monocytes, granulocytes	150–170	Aminopeptidase N: inactivates active peptides, receptor for coronaviruses
CD14 (Mo2, VIM 13, MoP15, gp55)	Eosinophils, monocytes, PMNs, basophils	55	Inhibits IgE synthesis on monocytes, receptor for LPS, suggested role in Gram– pathogen clearance, polymorphism in the flanking region, receptor for endotoxin, LPS/LPS binding complex
CD15 (My1, VIM-D5)	Eosinophils, monocytes, PMNs, basophils, LCs	–	Oligosaccharide; binds CD62E; modulates PMN adhesion and phagocytosis
CD15 s (sLe^x)	Granulocytes, NK, T and B cells, monocytes	–	Sialyl-Lewis, binds CD6E, CD62P and CD62L
CD15u			Sulfated CD15, carbohydrate structures
CD16a (BW209/2, HUNK2,3 GB)	Immature fetal T and B cells, monocytes, NK cells, PMN subsets, macrophages	50–65	FcγRIIIa, associated with TcR-ζ and FcεRI-ɣ, promotes signal transduction for NK cells (ADCC) and macrophages (phagocytosis), IgSF
CD16b	Granulocytes	48–60	FcγRIIIb, IgSF
CDw17 (GO35, Huly-m13)	Granulocytes, PMNs, monocytes, eosinophils	–	Lactosylceramide, possible role in phagocytosis, signaling
CD18 (MHM23, M232, 11H6)	All leukocytes	95	Integrin, β2 chain of CD11a, b, c, binds CD54, participates in cell adhesion
CD19 (B4, HD37)	Pan B-cell and pre-B precursors, FDCs	95	Membrane protein: B-cell activation and proliferation, part of signal transduction complex including CD21, CD81 and Leu-13, IgSF
CD20 (B1, IF5, p37/32)	Pan B-cell except pre-B and plasma cells	33, 35, 37	Modulates ionic channels, B-cell activation and proliferation, associated with CD53, CD81, CD82 and HLA

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD21 (B2, HB5, CR2, p140)	Mature B cells, FDCs, normal thymocytes	145	See CD19; binds C3d, EBV and CD23, which is implicated in IgE synthesis; intracellular domain contains potential PKC and PTK sites; RCA
CD22 (HD39, S-HCL1, To15, gp135)	B cells mature, pro- to pre-B cells	130/140	Homologous to MAG, the α-form mediates adhesion to monocytes and RBCs, the β-form to T cells via CD45RO and to B cells via CD75, the cytoplasmic domain has potential PKC sites and 6 tyrosine residues; IgSF
CD23 (Blast-2, MHM6, gp45/50, FcεRII)	Low-affinity IgE receptor (see text)	45	C-type lectin, ligand of CD21, inducible by IL_4 and IL_{13}, modulates cytotoxicity of eosinophils and macrophages, may prevent apoptosis of GC B cells
CD24 (VIBE-3, Ba-1, HSA, gp41/38)	Immature T, B/T cells, PMNs, eosinophils, FDCs	38–70	T-cell costimulation, adhesion and signaling, supports CD80 for T-cell growth
CD25 (7G7/B6, 2A3, Tac p55)	Activated B cells, T, NK, monocyte-macrophages	55	Integrin, IL_2R α chain, associating with β (CD122) and γ chain induces proliferation and activation of T, B and NK cells, and macrophages; CCP-like
CD26 (134–2C2, TS145, gp120)	Memory CD45RO, T and NK cells, macrophages	110	Dipeptidyl-peptidase IV (substrate is the V3 loop of HIV-1 and HIV-2); triggers T cells, to which anchors adenosine deaminase (ADA); binds collagen, fibronectin
CD27 (VIT14, S152, T18A, gp55)	T cells, B cells, subsets of thymocytes, NK cells	55	CD70 ligand, costimulatory signaling activating T cells; TNFR-like protein
CD28 (9.3, KOLT2, B7, gp44)	T-cell subsets, resting T cells, plasma cells	44	Binds CD80 (CD86); costimulatory signal for T cells distinct from TcR signal; IgSF
CD29 (K20, A-1A5)	T, B and NK cells, all leukocytes, monocytes, platelets, endothelial cells	110,130	VLA-β, β1 chain integrin, binds collagen, laminin and fibronectin, or heterodimer of CD49 modulates cell–cell and adhesion to cellular matrix
CD30 (Ki-1, Ber-H2, HSR4)	Activated T, B and NK cells, Reed-Sternberg cells	105	TNFR-like protein for MCP, enhances HIV replication in CD4 T cells, delivering a death signal, expresses Th2-like ILs, binds CD153; TNFRSF, and NGFRSF
CD31 (SG134, TM3, HEC-75, gp140, PECAM-1)	Platelets, monocytes, macrophages, neutrophils, B, naive T and NK cells, Lateral endothelium	140	Platelet antigen GPIIa, $\alpha_V\beta_3$ integrin, binds CD51/CD61, regulates adhesion to endothelium and transmigration of monocytes, PMNs, T and NK cells; IgSF
CD32 (CIKM5, 41H16, 2E1, ex CDw32)	Monocytes, B cells, all leukocytes, platelets	40	FcγRII, implicated in the phagocytosis of neutrophils and monocytes; IgSF
CD33 (My9, H153, L4F3, gp67)	Monocytes, all leukocytes, myeloid precursors	67	Sialoadhesin, binds sialylate glycoproteins

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD34 (My10, Bi-3C5, ICH-3, gp105–120)	Myeloid precursors, vascular endothelium, immature hematopoietic cells	105–120	Sialomucin, lymph node HEVs, CD62L-independent leukocyte adhesion to HEVs, receptor for CD62L, early marker of hematopoietic stem/progenitors cells
CD35 (TO5, CB04, J3D3, CR1)	Monocytes, some B and NK cells, erythrocytes, macrophages, neutrophils, eosinophils, FDCs	250	Receptor for C3b and C4b, RCA, reversible complement inactivation; supports phagocytosis of monocytes and neutrophils, APC putative role on DCs
CD36 (5F1, CIMeg1, ESIVC7, gp90)	Monocyte-macrophages, DCs, platelets, B cells	88	Platelet antigen GPIV (IIIb), binds thrombospondin, collagen, LDL receptor for macrophages (phagocytosis of apoptotic cells)
CD37 (HD28, HH1, G28–1, gp52–40)	Mature B, T and myeloid cells, PMNs, monocytes	40–52	Role in signaling, intercellular traffic with CD53, CD81, CD82, HLA-class II with function of ion channel; modulates B cell activation and proliferation (?), TM4-SF
CD38 (HB7, T10, p45)	Early and activated T, B cells, myeloid progenitors	45	Signal transduction, and cell adhesion
CD39 (AC2, G28–2, gp 80, gp70–100)	T, B and NK cells, monocytes, vascular endothelium	78	Directs NK cell activation, may deliver activating signals from B cells to T cells
CD40 (G28–5, gp50)	Normal and neoplastic B cells, FDCs, macrophages, epithelial and endothelial cells, keratinocytes	50	Ligand for CD40L, important in B cell differentiation and activation, GC formation and isotype switching, prevents apoptosis, TNFRSF
CD40L (see CD154)			
CD41 (PBM6.4, PL 273)	Platelets, megakaryocytes	125/22, 105	Platelet antigens GPIIb/IIIa, mediates platelet aggregation; β3 integrin; associates with CD61; binds fibrinogen, fibronectin, vitronectin, vWF and thrombospondin
CD42a (FMC25, BL-H6, GR-P, gp23)	Platelets, megakaryocytes	22	Platelet antigen GPIX
CD42b (PHN89, AN51, GN287)	Platelets, megakaryocytes	135, 25	Platelet antigen GPIbα
CD42c	Platelets, megakaryocytes	22	Platelet antigen GPIbβ
CD42d	Platelets, megakaryocytes	85	Platelet antigen GPV The a+b+c+d complex promotes platelet adhesion, binds vWF and thrombin
CD43 (OTH71C5, G19–1, gp95)	Hematopoietic precursors, CD4, pre-B, leukocytes	115	Sialomucin, leukosialin; T cell proliferation, costimulation, and adhesion
CD44 (H-CAM, Pgp-1, gp80–95)	Fetal and immature adult thymocytes, memory T	80–95	Binds hyaluronic acid, primes T cell activation, adhesion, HEV homing, apoptosis

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD44R (CD44-restricted or variant)	Expressed in different epithelia	110–250	Possible role in DC migration, binding and presentation of chemokines
CD45 (T29/33, BMAC 1, LCA, T200)	Expressed on all leukocytes	180–220	Tyrosine phosphatase, ligand for CD22; signal transduction for T and B cells
CD45RA (G1–15, F8–11–13, gp220)	Naive T cells, T CD8 subset, B and NK cells	205, 220	T200 with expression restricted to T cells, isoform with A exon
CD45RB (PTD/26/16)	Naive T cells, T, B and NK cells	205, 220	T200 with expression restricted to naive T cells, isoform with B exon
CD45RC			CD45 restricted epitope
CD45RO (UCHL-1, gp180)	Granulocytes, monocytes, T cells	180	T200 with expression restricted to memory T cells, isoform without A/C exons
CD46 (HULYM5, J4B, MCP, gp66/56)	Myeloid precursors, hematopoietic cells and non-myeloid precursors, T, B cells, all leukocytes	56/66	Membrane cofactor protein, prevents C3 breakdown
CD47 (BRIC 125, BRIC 126, gp47–52)	Myeloid precursors, T, B cells, all leukocytes	47–52	β1 integrin associated protein, signaling molecule facilitating adhesion, antigen associated with Rh group
CD47R ex CDw149 (MEM-133)	B and T cells, neutrophils, eosinophils, monocytes	120	Unknown
CD48 (WM68, BCM1, OX-45, Blast-1)	distributed to hematopoietic cells and nonhematopoietic T, NK, capillary, endothelial cells, fibroblasts	45	Binds CD2, involved in T cell adhesion to APCs and their costimulation, may be required by γδ cells for antigen recognition; IgSF
CD49a	T, NK, capillary, endothelial cells, fibroblasts	200–210	α1 Chain associated with CD29 to form VLA-1, binds laminin and collagen I, IV
CD49b (Gi14, CLB/thromb4)	Platelets, B and T cells, endothelia, fibroblasts	155–165	α2 Chain associated with CD29 to form VLA-2, receptors for GPIa, laminin and collagen I-IV, regulates the expression of metallo-proteinase-1
CD49c	B cells, fibroblasts, keratinocytes, epithelia	145–150	α3 Chain associated with CD29 to form VLA-3, binds laminin, collagen and fibronectin
CD49d (B5G10, HP2/1, HP1/3)	Myeloid precursors, thymocytes, NK cells DCs, B- and T-cell lineages	150, 80, 70	α4 Chain associated with CD29 to form VLA-4, binds fibronectin, CD106, MAdCAM-1, role in T cell adhesion/migration to lymph nodes and homing to HEVs
CD49e	Platelets, epithelia, endothelia, thymocytes, monocytes, myocytes, T and B cells	160, 135/25	α5 Chain associated with CD29 to form VLA-5, binds fibronectin and GPIc, T cells, involved in cell adhesion and migration mediates proliferation and differentiation

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD49f (GoH3)	Widespread: T cells, thymocytes, monocytes, platelets, epithelial cells, eosinophils	150, 130	α6 Chain associated with CD29 to form VLA-6, binds laminin; the different α6 isoforms have a distinct developmentally regulated distribution in various tissues
CD50 (101–1D2, 140–11, ICAM-3)	T, B and NK cells, monocytes, PMNs, LCs	116–140	Binds CD11a/CD18, promotes signal transduction and costimulation on T cells; signaling via CD50 stimulates β1 and β2 integrin function on T cells; IgSF
CD51 (13C2, 23C6, NKI-M7)	Platelets, endothelia, monocytes, macrophages	125–24	Complex with CD61, binds fibronectin, vitronectin (α chain) and vWF; role in platelet aggregation, cell-cell adhesion (via CD31) and γδ costimulation
CD52 (O97, YTH66.9, Campath-1)	B and T lymphocytes, monocytes, macrophages	25–29	Target of complement-mediated lysis, may contribute to T lymphocyte depletion and GvHD prevention
CD53 (MEM-53, HI29, HI36, gp32–40)	Granulocytes, B and T lymphocytes	32–40	Bound to phosphoinositol
CD54 (RR7/7F7, ICAM-1)	B (and T) cells, endothelia, epithelia, DCs, fibroblasts	90–115	Protein implicated in B-cell activation, ligand of CD11a/CD18, CD43 and monocytes, Rhinovirus, mediates leukocyte adhesion to epithelium in inflammation sites and in T-cell interactions with APCs and target cells; IgSF
CD55 (BRIC110, BRIC128, DAF)	All leukocytes, activated T cells, endothelium	70	Bound to phosphatidylinositol, RCA, binds CD97 and C3b/C3bBb and C4b/C4b2a convertase, thus accelerating the decay of the C3 convertase and C5
CD56 (Leu19, NKH1, L185, gp220/135)	NK, T and Schwann cells, neurones, astrocytes	200–220	Isoform of NCAM, NK-cell marker, putative role in tissue architecture (during embryogenesis) and in non-restricted cytotoxicity; IgSF
CD57 (Leu 7, L183, L186, gp110)	NK and T cells (CD8), B subpopulation	110	Binds CD62-L, -P, NNK-1, role in non-HLA-restricted cytotoxicity after activation
CD58 (BRIC5, G26, TS2/9, LFA-3)	Myeloid precursors, erythrocytes, all leukocytes	55–70	Role in APCs and T-cell interactions via CD2, bound to phosphatidylinositol; IgSF
CD59 (MEM-43, YTH53.1, p18, gP18)	Many hematopoietic cells and nonhematopoietic cells, T cells	18–20	MACIF, 2nd ligand of CD2, binds C8, C9, phosphatidylinositol, signaling
CD60 (M-T32, M-T21, M-T41)	T-cell and NK-cell subsets, platelets		Carbohydrate with NeuAc-NeuAc-Gal sequence modulates T-cell activation
CD60a			GD3, carbohydrate structures
CD60b			9-*O*-acetyl-GD3, carbohydrate structures

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD60c			7-*O*-acetyl-GD3, carbohydrate structures
CD61 (CLB thromb/1, BL-E6)	Platelets, megakaryocytes, monocytes	105	β3 Chain integrin, receptor for vitronectin (β chain), fibronectin, fibrinogen; platelet antigens GPIIb/IIIa, platelet aggregation, heterodimer with CD41 CD51
CD62E (ELAM-1, LECAM-1, E selectin)	Vascular endothelium	110	C-type lectin, binds ESL-1, promotes tethering and rolling of monocytes, some memory T cells, and for neutrophils also the adhesion to endothelia with CD15s
CD62L (LAM-1, LECAM-2, L selectin)	All circulating leukocytes, except some memory cells	70–90	C-type lectin, migration of lymphocytes to lymph nodes and leukocytes to sites of T cells inflammation, mediates T-cell tethering and rolling and adhesion to HEVs, binds CD34, ESL-1, GlyCAM-1, and MAdCAM
CD62P (gp140, PADGEM, P selectin)	Activated platelets and endothelial cells	140	C-type lectin binds CD162, adhesion of platelets to neutrophils and monocytes, as well as tethering and rolling of leukocytes on activated endothelium
CD63 (CLB gran/12, gp53)	Activated platelets, PMNs, monocyte-macrophages	53	Platelet-activating antigen, associated with con CD9, CD81, VLA 3–6; TM4-SF
CD64 (Mab22, Mab32.2, gp75)	Monocyte-macrophages, DCs, neutrophils	75	FcγRI; high-affinity receptor for IgG Fc, promotes ADCC; IgSF
CD65 (VIM2, VIM8, HE10)	Granulocytes, monocytes, myeloid leukemia cells		Ceramide-dodecasaccharide 4c
CD65 s	Sialylated form of CD65		
CD66a (BGP-1, CEA)	Granulocytes, epithelial cells	140–180	Binds CD62E, adhesion molecule for neutrophils, signaling role; IgSF
CD66b (ex CD 67, CGM6, p100)	Granulocytes	95–100	Adhesion molecule, can activate neutrophils, signaling; IgSF
CD66c (NCA, CEA)	Granulocytes, epithelial cells	90	Binds CD62E, adhesion molecule, capable of activating neutrophils
CD66d (CGM1, CEA)	Granulocytes	30	Adhesion molecule, can activate neutrophils
CD66e (CEA)	Colon epithelium, colon carcinoma	180–200	Adhesion molecule
CD66f	Myeloid lineage cells		
CD67 now CD66b			
CD68 (EBM11, Ki-M7, Ki-M6, gp110)	DCs, PMNs, monocyte-macrophages, basophils	110	Marker of macrophages, lysosomal protein implicated in endocytosis

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD69 (MLR3, VEA, gp 34/28, AIM)	All activated leukocytes, neutrophils, platelets	85	C-type lectin involved in signal transduction for lymphocytes, apoptosis of eosinophils and in early events of T γδ cell cytotoxicity
CD70 (Ki-24, HNE 51, HNC 142)	Activated B and T cells, Reed-Sternberg cells	75, 95, 170	CD27 ligand, implicated in T-cell activation, TNRSF
CD71 (138–18, 120–2A3, T9)	Proliferating, activated T and B cells, macrophages	95	Receptor for transferrin and proteins binding Fe, activated on proliferating cells
CD72 (J3–109, BU-40, BU-41)	pan-B including progenitors, macrophages	43–43	C-type lectin, CD5 ligand, elicits B-cell activation/proliferation, inducible by IL_4
CD73 (AD2, 1E9.28.1, gp69)	B- and T-cell subsets, endothelial/epithelial cells	69	Ecto-5′-nucleotidase, may induce T-cell activation, B-cell interactions with FDCs
CD74 (LN2, BU-43, BU-45)	HLA class II, mature B cells, T cells, monocytes	41–35–33	Invariant chain associated with HLA class II prevents binding of foreign peptides
CD75 (LN1, HH2, EBU-141)	GC and mature B cells, T-cell subpopulation	53	GC B cells, putative ligand for CD22 supports B-B cells interactions
CD75s			α-2,6-Sialylated lactosamines, carbohydrate structures
CD76 (HD66, CRIS-4, ex CD76)	Mature B cells, T-cell subpopulation	53–87	Directs mantle zone and extrafollicular B cells in tonsil areas
CD77 (424/4A11, 424/3D9)	Activated GC and centrofollicular B cells, FDCs	–	Globotriaosylceramide (Gb3), may control transmembrane signals → apoptosis
CDw78 (Anti Ba, Leu21, 1588)	Resting and activated B cells, macrophages	–	Can inhibit or enhance B-cell activation
CD79a (mb-1, Igα)	Specific for B-cell ontogeny, BcR complex	33	BcR component, important for signal transduction comprising ITAM; IgSF
CD79b (B29, Igβ)	Specific for B-cell ontogeny, BcR complex	39	BcR component, important for signal transduction, comprising ITAM; IgSF
CD80 (B7–1, BB1)	Activated B and T cells, DCs, macrophages	60	Early activation marker, binding to CD28 and CD152 (CTLA-4) regulates IL_2 gene expression and activates T lymphocytes
CD81 (TAPA-1)	All B, T, NK cells, FDCs, thymocytes, eosinophils	26	Part of complex including CD19 and CD21: cross-linking CD81 is thought to have a role in signal transduction; TM4-SF
CD82 (R2, IA4, 4F9)	B, T, NK cells, macrophages, monocytes, platelets	60	Participates in T-cell activation, probably in signal transduction; TM4-SF
CD83 (HB15)	GC B cells, B cells, circulating DCs, LCs	43	Mature DC specific marker, may function in antigen presentation; IgSF
CDw84 (GR6, BPC6)	Mature B and T cells, platelets, macrophages	68–80	May be a signaling molecule

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD85 (VMP-55, GH1/75)	Mature circulating and neoplastic B cells	120, 83	ILT/LIR family, dendritic cells (DC)
CD86 (FUN-1, BU63, B7–2)	Activated, mature circulating B cells, DCs, monocytes	80	Rapid expression on activated B cells; interacts with CD28 and CD152 (CTLA-4) to regulate IL_2 gene expression and prevent T-cell anergy; IgSF
CD87 (UPA-R)	Activated PMNs, monocytes, NK and T cells	35–39	Binds vitronectin, receptor for urokinase, role in leukocyte extravasation
CD88 (C5aR)	Monocytes, granulocytes, NK cells, DCs, microglia	43	G-protein-coupled, C5a receptor on phagocytes
CD89 (Fcα-R)	Neutrophils, monocyte-macrophages, eosinophils	45–70	Fc receptor for serum/secretory IgA, signal transduction for phagocytes; IgSF
CD90 (Thy-1)	CD34 subset of bone marrow, CB and fetal liver hematopoietic stem cells, HEV endothelium	25–35	Associated with CD45, participates in T-cell recirculation, adhesion, activation, in cell–cell modulation and cell signaling; IgSF
CD91 (α_2M-R)	Monocyte-macrophages, non hematopoietic cells	600	Binds LDL, receptor for α2M-R mediator of endocytosis
CD92 (CTLL1, GR 9)	Monocytes, granulocytes, B, T, epithelial cells	70	Unknown
CDw93 (GR 11)	Monocytes, granulocytes, endothelial cells	110	Unknown
CD94 (kp43)	γ/δ T subsets, human NK cells and αβ CD8	70–43	Implicated in signal transduction for NK and T cells; the CD94 receptor (43kD) can inhibit HLA class I molecules; CD94 with a new associated protein (94AP) forms a NK receptor involved in the recognition of HLA-A, HLA-B, HLA-C molecules
CD95 (Fas/Apo-1)	Thymocytes, activated B and T cells	36–45	Transduces apoptosis signal, role in T-cell clonal deletion, TNFRSF
CD96 (TACTILE)	Activated T and NK cells	160	Promotes T and NK cells activation; IgSF
CD97 (GR1, BL-KDD/F12)	Monocytes, granulocytes, NK cells	74, 80, 89	Receptor for CD55 (?) and TNF; TNFR
CD98 (4F2, 2F3)	Monocytes, B and T cells, several cell lines	85, 40	Actin-associated, modulates intracellular Ca^{++} levels and cell proliferation (?)
CD99 (E2, MIC2)	All hematopoietic cells, thymocytes, T and B cells	32	T-cell rosette formation with erythrocytes, DP thymocytes adhesion to T cells
CD99R (CD99-mAb restricted)	B and T cells	32	Restricted CD99 hematopoietic cells
CD100 (BB18, A8, GR3, ST-003, -005)	Most hematopoietic cells, activated B, T, NK cells	150	Semaphorin, associated with CD45, PBMC proliferation, role in T-cell adhesion
CD101 (BB27, BA27, GR14, ST-004)	Monocytes, granulocytes, mucosal T cells	140	Inhibition of T-cell proliferation, possible role in T-cell signaling, IgSF

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD102 (ICAM-2)	Lymphocytes, monocytes, vascular endothelia, NK cells, HEVs, platelets	55–65	Binds CD11a/CD18 on endothelial cells, mediates T-cell recirculation, trafficking and activation, and stimulates leukocyte activity in inflammation; IgSF
CD103 (HML-1, M290)	Intraepithelial T cells, activated CD8 T cells	175–105	Integrin, $\alpha_E\beta_7$ subunit, binds E-cadherin, role in mucosal lymphocyte adhesion
CD104 (β1)	Epithelia, monocytes, T cells, keratinocytes	150–125	β4 Chain integrin, binds laminin
CD105 (GR7, CELL-CAM)	Endothelia, PMNs, activated monocyte-macrophages	90	Endoglin, receptor for TGF-β1 and TGF- β3; TGF-βR type III and ectoATPase
CD106 (VCAM-1, INCAM-110)	IL-activated vascular endothelia, bone marrow stromal cells, embryonic tissues, APCs	90–110	Binds CD49d/CD29; lymphocyte migration, recruitment, activation/stimulation by APCs, PBMC and eosinophil adhesion stimulated by endothelial ILs; IgSF
CD107a (LAMP-1)	Activated platelets, T cells, neutrophils	110	Lysosome-associated protein
CD107b (LAMP-2)	Activated platelets, T cells, neutrophils	120	Lysosome-associated protein
CD108 (SEMA7A)	Splenic T lymphocytes, some stromal cells	80	Human blood group antigen
CD109 (8A3, 7D1, PAF)	Endothelial cells, T cells, activated platelets	170/150	Possible role in activation, proliferation and signal transduction
CD110 (MPL, TPO-R)	Platelets		
CD111 (PRR1/Nectin1)	Myeloid cells		
CD112 (HVER, PRR2)			
CD113 (PRR2)	Myeloid cells		
CD114 (CSF3R, G-CSFR)	Monocytes, granulocytes, endothelial cells, platelets	130	G-CSF receptor; CSF3R
CD115 (CSF-1R, M-CSFR)	Monocyte-macrophages and progenitors, placenta	150	M-CSF receptor (CSF-1) promotes phagocyte proliferation/ differentiation
CD116 (GM-CSF)	Macrophages, eosinophils, PMNs, DCs, fibroblasts	75–85	Binds GM-CSF, with higher affinity if coexpressed with CD131, supports proliferation and differentiation; class CSFR
CD117 (SCF-R, c-kit)	TN thymocytes, hematopoietic progenitors	145–150	SCF receptor, signal transduction, differentiation and adhesion; IgSF
CD118 (IFN-α/βR)	Broad cell expression	–	Receptor for IFN-α and IFN-β; CSFR
CD119 (IFN-γR)	Macrophages, B, T, NK and epithelial cells	90	IFN-γα chain receptor induces macrophage activation, B-cell differentiation; A CSFR

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD120a (TNFR.I, p55)	Granulocytes, epithelial cells, FDCs, monocytes	55	Type 1 TNFR, up-regulates leukocyte adhesion molecules and inflammation; TNFRSF1A
CD120b (TNFR.II, p75)	Granulocytes, myeloid cells, monocyte-macrophages	75	Type 2 TNFR, signaling triggers biological effects TNFRS1B
CD121a (IL_1R 1)	Thymocytes, fibroblasts, T cells, endothelial cells	75–85	Type 1 IL_1R, promotes cell growth in synergy with IL_2 and IL_4, protects against intracellular pathogens, inhibits the IL_{12} protective effects; IgSF
CD121b (IL_1R 2)	Neutrophils, monocytes, bone marrow and B cells	68	Type 2 IL_1R; IgSF
CD122 ($IL_2R\beta$)	Activated T cells (α, β, γc), $\beta\gamma$ chain on NK cells, CD8 T cells	70–64	β Chain of IL_2R, responsible for all the effects induced by IL_2, γc chain could prevent induction of anergy, the complex IL_2 + CD122 + CD25 forms a high-affinity receptor for the activation of thymocytes, B, T and NK cells and macrophages, incrementing the NK cytolysis and Ig synthesis; CKR-SF
CD123 ($IL_3R\alpha$)	Bone marrow stem cells, megakaryocytes, granulocytes		$IL_3R\alpha$ CKR-SF (cytokine receptor-superfamily)
CD124 (IL_4R)	Mature B and T cells, hematopoietic precursors, fibroblasts, epithelial and endothelial cells, pre-B, B and T lymphocytes	130–150	Activates B cells increasing CD23 and IgM expression; is a switch factor implicated in IgE regulation. Associates with $IL_{13}R\alpha$ to form $IL_{13}R$ complex; CKR-SF
CDw125 ($IL_5R\alpha$)	B cells, eosinophils, basophils	80	Combines with CDw131 to form the high-affinity receptor for IL_5; CKR-SF
CD126 ($IL_6R\alpha$)	T and B cells, monocytes, fibroblasts, hepatocytes	60	α Subunit, forms with CD130 the high-affinity receptor for IL_6; CKR-SF
CD127 (IL_7R, $IL_7R\alpha$)	Thymocytes, T/B cell progenitors, mature T cells, monocytes, lymphoid and myeloid cell lines	68–64	The two chains associate to form the high-affinity receptor for IL_7, triggers proliferation of pro- and pre-B cells and immature T-cell growth; CKR-SF
CDw128 (IL_8R)	NK cells, neutrophils, monocytes	58–67	Receptor for IL_8 and α chemokines
CD129 (IL_9R)	T and B cells, macrophages, megakaryoblasts	64	Receptor for IL_9, 40% homology with $IL_2R\beta$, inhibits apoptosis; CKR-SF
CD130 (gp130, SIG, IL_6R)	All hematopoietic cells, many other cell lines	130–140	β Subunit; signal transduction chain for IL_6 receptors; CKR-SF
CD131	Widespread on myeloid cell types	120–140	Common β subunit associated with α subunit of IL_3R (CD123), IL_5R (CDw125) and GM-CSFR (CD116) ; class BCSFR (see Table 1.5: it links to IL_6R)

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD132	B, T, NK cells, monocytes, PMNs, macrophages	65–70	IL_2R γc (common) chain, subunit of IL_2R, IL_4R, IL_7R, IL_9R, $IL_{15}R$, $IL_{21}R$ and similar signaling components of receptors; associated with JAK3; CKR-SF
CD133 (AC133)	Stem/progenitor cells		Prominin1 (PROM1)
CD134 (OX40)	Expressed on activated T cells and macrophages	50	Adhesion of activated T cells to vascular endothelial cells via gp 34, TNFRSF4
CD135 (Flt3, Flk2)	All hematopoietic stem cells, B-cell progenitors	130	Tyrosine kinase receptor, growth factor for hematopoietic progenitors, IgSF
CDw136 (MSP-R)	Tissue macrophages, some epithelial cell lines	180	Receptor for macrophage-stimulating protein (MSP-R)
CD137 (4–1BBL)	B and T cells, macrophages		T-cell activation and differentiation, distinguishes between IgE- and non-IgE-mediated atopic dermatitis and asthma, TNFRSF9
CD138	B cells		Glycosaminoglycan, binds fibronectin, collagen, thrombospondin
CD139	B cells, granulocytes, monocyte-macrophages		
CD140a (PDGF-Rα)	Endothelial cell lines		Receptor for PDGF α chain; CKR-SF
CD140b (PDGF-Rβ)	Monocytes, PMNs, fibroblasts, smooth muscle cells	160	Receptor for PDGF β chain, tyrosine kinase directing signal transduction
CD141	PMNs, monocyte-macrophages, endothelia, platelets, smooth muscle cells, keratinocytes, megakaryocytes	75	C-type lectin, thrombomodulin
CD142	Monocytes, vascular endothelial cells, fibroblasts, keratinocytes, stromal cells	45–47	Serine protease cofactor, binds factors VIIa and Xa coagulation factor III
CD143 (ACE)	Endothelial cell lines		Peptidylpeptidase, binds angiotensin
CD144	Vascular endothelial cell lines		Cadherin-5 or VE-cadherin, binds β-cadherin
CDw145	Endothelial cell lines (?)		
CD146 (MUCI8, 5-endo)	All leukocytes, endothelial cells, platelets	50–60	Likely adhesion molecule; IgSF
CD147	Widespread cell diffusion		Neurotelin, basigin; IgSF
CD148 (HPTP-η)	Granulocytes, monocytes, DCs, Kupffer cells	240–260	Proteintyrosinphosphatase (PTP)
CD150 (SLAM, IPO-3)	B and T cells		SLAMF1, IgSF
CD151 (PETA-3)	Macrophages, platelets		TM4-SF

SLAM signaling lymphocytic activation molecule.

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD152 (CTLA-4)	Activated cytotoxic T cells molecule, modulates lymphocyte homeostasis		CTLA-4; 70% similarity with CD28, binds CD80 and CD86, costimulatory; killer cell Ig-like receptors IgSF
CD153 (CD30L)	Activated T cells, B cells, neutrophils, macrophages		CD30L; cross-linking supports T-cell proliferation and IL production; TNFSF5
CD154 (CD40L, T-BAM, gp39)	T and NK cells, basophils, mast cells, eosinophils production; CD154 deletion results in the ID with hyper-IgM	33	Ligand for CD40, activates B cells, costimulates T-cell proliferation and IL production, CD154 deletion results in the hyper-IgM syndrome, TNFSF5, belongs to the family of TNF-α and -β, NGF, and of Fas, CD27, CD30 ligands
CD155 (PVR)	Monocytes	80–90	Poliovirus receptor; IgSF
CD156 (ADAM-8, MS2)	Neutrophils, monocytes	69	Metalloprotease, binds peptidase, possibly involved in leukocyte extravasation
CD156b (TACE/ADAM17)	Adhesion structures		Snake venom-like protease
CD157 (BST-1, MO-5)	B and T lines, monocyte-macrophages, granulocytes	50	Unclear function in myeloid cells
CD158e, i, k (KIR family)	NK cells		NK receptors specific for class I HLA; IgSF
CD159a (NKG2A)	NK cells		Killer cell lectin-like receptor subfamiliy C
CD160 (BY55, NK1, NK25)	NK cells		
CD161 (NKR-P1)	NK cells		Killer cell lectin-like receptor subfamiliy B, binds NK cells
CD162 (PSGL-1)	Myeloid cells, granulocytes, monocytes	120	Sialomucin, binds CD62P
CD162R (PEN5)	NK cells		
CD163 (M130)	Tissue macrophages, LPS-stimulated monocytes	110	Unknown function; SRCR-SF
CD164 (MGC-24)	Epithelium, monocytes, bone marrow stromal cells	80	Potential adhesion molecule
CD165 (GP37/AD2)	T cells		Potential adhesion molecule
CD166 (ALCAM)	Activated T cells and monocytes, epithelium, fibroblasts	100–105	Adhesion molecule binding CD6; IgSF
CD167 (DDR1)	Adhesion structures		Discoidin
CD168 (RHAMM)	Adhesion structures		
CD169	Adhesion structures		Sialoadhesin
CD170 (Siglec-5)	Adhesion structures		
CD171 (L1)	Adhesion structures		
CD172a (SIRP α)	Adhesion structures		

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD173	Carbohydrate structures		
CD174 (Lewis y)	Carbohydrate structures		
CD175 (Tn)	Carbohydrate structures		Tn antigen (T antigen novelle)
CD175s	Carbohydrate structures		Sialyl-Tn
CD176 (TF)	Carbohydrate structures		
CD177 (NB1)	Myeloid cells		
CD178	Cytokine/chemokine receptors		Fas ligand (CD95L), TNFSF6
CD179a	B cells		Vpre-B
CD179b (×5)	B cells		
CD180 (RP105)	B cells		
CD183	Cytokine/chemokine receptors		CXCR3
CD184	Cytokine/chemokine receptors		CXCR4
CD195	Cytokine/chemokine receptors		CCR5
CDw197	Cytokine/chemokine receptors		CCR7
CD200 (OX2)	Thymocytes, B cells, T cells		
CD200R	Monocyte/macrophage, DCs		
CD201 (EPC R)	Endothelial cells		
CD202b	Endothelial cells		Tie2 (Tek)
CD203c (NPP3/PDNP3)	Myeloid cells		Expressed on blood basophils but not on other blood leukocytes
CD204	Myeloid cells		Macrophage scavenger R
CD205 (DEC205)	Dendritic cells		
CD206	Dendritic cells		Macrophage mannose R
CD207	Dendritic cells		Langerin
CD208 (DC-LAMP)	Dendritic cells		
CD209 (DC-SIGN)	Dendritic cells		
CDw210 (IL_{10} R)	Cytokine/chemokine receptor		$IL_{10}RA$, $IL_{10}RB$
CD212 (IL_{12} R)	Cytokine/chemokine receptor		$IL_{12}R\beta$

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD213a1	Cytokine/chemokine receptor		$IL_{13}R\alpha1$
CD213a2	Cytokine/chemokine receptor		$IL_{13}R\alpha2$
CDw217	Cytokine/chemokine receptor		$IL_{17}R$
CD220	Non-lineage molecules		Insulin R
CD221 (IGF1R)	Non-lineage molecules		
CD222	Non-lineage molecules		Mannose-6-phosphate/RIGF2 R
CD223 (LAG-3)	Non-lineage molecules		Lymphocyte activation gene 3
CD224	Non-lineage molecules		γ-Glutamyl transferase
CD225 (Leu13)	Non-lineage molecules		
CD226 (DNAM-1 PTA1)	T cells		
CD227 (MUC.1)	Non-lineage molecules		
CD228	Non-lineage molecules		Melanotransferrin
CD229 (Ly9)	Non-lineage molecules		
CD230	Non-lineage molecules		Prion protein
CD231 (TALLA-1/A15)	Non-lineage molecules		
CD232 (VESPR)	Non-lineage molecules		
CD233 (Band 3)	Erythroid cells		
CD234	Erythroid cells		fy-Glycoprotein (DARC)
CD235a	Erythroid cells		Glycophorin A
CD235b	Erythroid cells		Glycophorin B
CD235ab	Erythroid cells		Glycophorin A/B cross-reactive mabs
CD236	Erythroid cells		Glycophorin C/D
CD236R	Erythroid cells		Glycophorin C
CD238 (Kell)	Erythroid cells		
CD239 (B-CAM)	Erythroid cells		
CD240CE (Rh30CE)	Erythroid cells		Cross-reactive mabs
CD240D (Rh30D)	Erythroid cells		

Table 1.2. (Continued)

CD (synonyms)	Main cellular distribution	MW in kD	Main functions and properties/ligands/receptors/superfamily
CD240DCE (Rh30D/CE)	Erythroid cells		
CD241 (RhAg)	Erythroid cells		
CD242 (ICAM-4)	Erythroid cells		
CD243 (MDR-1)	stem/progenitor cells		
CD244 (2B4)	NK cells eosinophils		Elicites ERK, activates NK cells and causes eosinophils to release EPO, IL_4 and IFN-γ
CD245 (p220/240)	T cells		
CD246	T cells		Anaplastic lymphoma kinase
CD247	T cells		ζ Chain of TcR

CDw128 has been divided into CDw128a (CXCR1, IL_8RA) and CDw128b (CXCR2, IL_8RB). The main cells are underlined following the Immune Receptor Supplements [4, 6, 262] and International Workshops on Human Leukocyte Differentiation Antigens [501]. Data from the 5th International Workshops on Human Leukocyte Differentiation Antigens [453], Immune Receptor Supplement, 1st [4] and 2nd ed [5], 1997, CD antigens 1996 [257], CD Designations, 7th HLDA Workshop [331] and new CD designations (2002) [691] and from [4, 6, 16, 23, 34, 47, 70, 82, 85, 102, 103, 109, 112, 120, 132, 147, 158, 175, 242, 262, 343, 407, 428, 437, 442, 484, 501, 515, 559, 571, 584, 608, 688, 691]. The 8th HLDA Workshop has extended the CD nomenclature up to CD339 (S. Zola pers. com., March 5, 2005). Abbreviations are in the list.

- They are committed to specific, initial antigen recognition by interacting with a restricted part of the macromolecule called epitope by means of specific membrane receptors present on both B and T cells [326].

There are two major sets of lymphocytes. The antibodies produced by B lymphocytes play a crucial role in interacting with extracellular antigens, when found outside the cell (for example, when viruses are encountered in the blood), whereas these antibodies are ineffective against endocellular antigens, because overall they are unable to penetrate the cells. Accordingly, T lymphocytes are probably originally derived to ensure a high specificity in the critical phase of immune responses to pathogens of various sources. *Antigen recognition takes place in a different way for each phenotype,* since T cells respond to antigens only when encountered inside or on the target cell surface, thereby showing that T-cell antigen recognition is fundamentally different from B-cell antigen recognition. Such properties are gradually acquired during ontogenesis when lymphocytes undergo a series of differentiation events, each characterized by sequential expansion or regression of the genes coding for expression of membrane proteins and glycoproteins (gps) [35, 481, 647].

Structure and Molecular Framework

Igs or antibodies are molecules of specific immunity, present in soluble form in biological fluids or as membrane receptors at BcR (B-cell receptor) and TcR surface. The immune system consists on the whole of $\approx 10^{12}$ T cells and of $\approx 10^{20}$ B cells: in the bloodstream ≈80% of lymphocytes are T, 10%–15% are B cells and 10%–15% are *null cells* known as LGLs (*large granular lymphocytes*), non-T non-B since they lack markers of B and T cells. The Ig N-terminal part has a binding site or paratope providing specific recognition. The C-terminal transmits biological signals following epitope-paratope binding. TcR, BcR, and Ig polypeptide chains are composed of subunits, each made up of ≈100 amino acids, bound to disulfide (-S-S) bonds, termed domains or regions. Such striking similarities are also found in molecules belonging to the *Ig superfamily (IgSF):* although these proteins are found in diverse tissues, they all appear to share a common primordial origin.

B Lymphocytes

B cell precursors, the first cells to be appraised in ontogenesis, originate from hemopoietic bone marrow stem cells and complete developmental and maturative processes that began in the fetal liver. Briefly, the earliest distinguishable cells in the B repertoire are known as pro-B cells and pre-B cells with no surface Igs but with surrogate light (L) chains. At this stage the cells express RAG-1 and RAG-2 (recombination-activating genes),

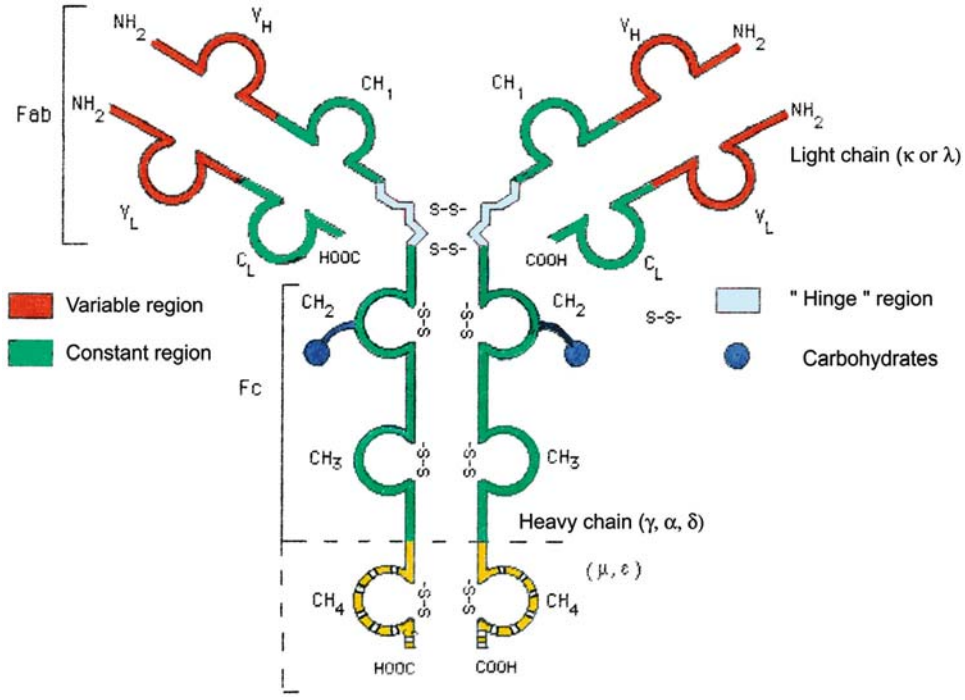

Fig. 1.6. Immunoglobulin basic structure. VH + VL Antigen binding site, which is located in the V (variable) domain. CH_1 + CL Covalent and noncovalent binding between the H (heavy and L (light) chains; spacer between the antigen binding site and effector functions. Intrachain -S-S bonds regulate the molecular flexibility and determine the spatial conformation. CH_2 C1q fixing site (complement activation). CH_2 + CH_3 Binding site for Fc receptor of monocytes, macrophages, neutrophils, streptococcus A protein, syncytial trophoblasts (placenta crossing). CH_3 binding site for Fc receptor of lymphocytes and mast cells

whose deficiency is responsible for one form of SCID; affected patients are unable to produce functional lymphocytes bearing antigen receptors [508]. The next cells in the B-cell lineage bearing monomeric surface IgM (IgMs or mμ) are referred to as immature B cells. In the following stages of maturation, a mature B cell expresses IgM, IgD, and Fc receptors (FcR) for IgGs. Up to this point, all maturative steps take place in the bone marrow and are antigen-independent (Chap. 2). It has been suggested that bursal epithelial cells might produce polypeptides, triggering maturation of lymphoid stem cells into immunocompetent B cells, similarly to what occurs in the thymus. These short-lived lymphocytes colonize typical zones of lymph nodes and the spleen. Each cellular clone synthesized in a GC produces isotypes of the same class, specific for a given antigen. During the evolution of immune responses, there is a switch in Ig classes from IgM to IgG, IgA and IgE. If IgG and IgA antibodies are produced last, this could account for an associated defect of the two Ig classes. Babies with X-linked Hyper-IgM Syndrome (HIgMS) have little or no IgG and IgA [96, 544].

The Igs are structurally similar. A typical antibody molecule has a Y-shaped configuration when viewed schematically (Fig. 1.6) and consists of a basic unit of four polypeptide chains, two identical L and two identical H (heavy) held together by interchain -S-S bonds also present on single chains and by hydrogen bonds. As the figure shows, NH_2 and COOH indicate amino and carboxy terminals, respectively. L chains are common to the diverse Igs, which instead differ from their H chains that determine class type, hence IgA H chains are α, those of IgG are γ, etc. Each L chain is made up of two domains: a V region that varies from antibody to antibody and a constant (C) region, essentially identical among L chains of a given type (Fig. 1.7). For this reason, the molecules are practically identical, except in amino-terminal domains where variability differentiating V domains of both L and H chains is most pronounced [18]. In man, C regions are encoded by one of four C_H genes for H chains and by one of two C_L genes for L chains (Lλ and Lκ). H chains therefore consist of four C and one V domains and L chains of one C and one V region. Both chains, organized in sequence, are distinguished by their succession of amino acids: L chains consist of 211–217 amino acids and H chains of 450 for γ and α chains, and of 614 for μ and ε chains [3]. One noteworthy characterization of Igs lies in their *bifunctional aspects,* in that they bind antigens and, in addition, elicit biological processes that are independent of antibody specificity. Each of these functions is localized to a different part of protein: C domains have various effector activities (complement activation, opsonization, etc.) via IgG, IgE and IgG_4 FcRs, while V do-

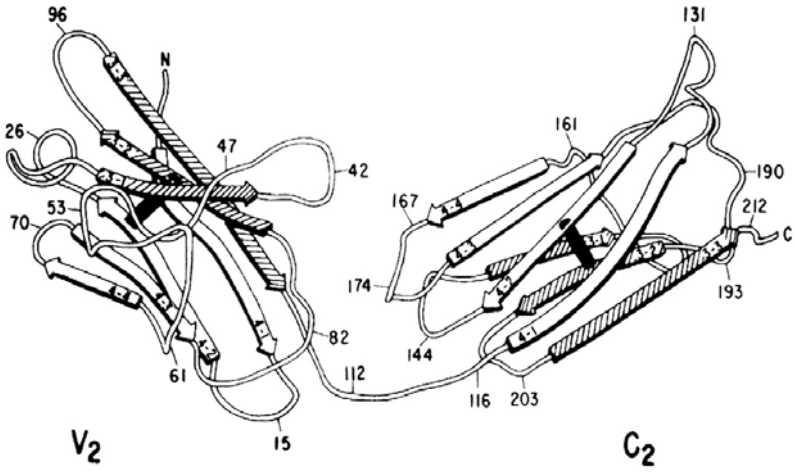

Fig. 1.7. Structure of V and C domains of a light chain. The -S-S bridges in each domain are indicated by *thick black lines*. The hypervariable regions that form the antibody combining site or paratope correspond to the loops around positions 26, 53 and 96

mains are committed to the specificity of antigen recognition. V regions within any group are not uniformly variable across their whole 110 amino acid span. Instead, the greatest amount of variability of V domains of each chain (genes V_H and V_L) is concentrated in three regions of both L and H chains called hypervariable regions: the less variable stretches interspersed within these hypervariable regions are called *framework regions* (FR) of 15–30 amino acids. The six hypervariable regions, which are each 9–12 amino acids long, participate in antigen binding and form a region that is complementary in structure to antigen epitopes, accordingly designated *complementarity determining regions* (CDRs) principally involved in antigen contact, three in V_H domains and three in V_L domains [86]. H chains γ, α and δ are formed by four C_H (C_H1, C_H2, C_H3 end C_H4) domains, μ and ε by five. Only γ, α and δ chains have a hinge region located between two C_H domains; however, for the other two chains there is the C_H2 region. The C domain of H chains is dictated by one gene (C_γ, C_μ, C_ε, etc.) dictating isotypes [474].

To understand the diversity of antibody repertoires, recent evidence shows that coding information of a typical human gene, that is the sequences coding regions to be transduced into amino acid sequences, does not exist as intact, functional genes. Therefore a single, uninterrupted DNA stretch in germ cells is broken up along the chromosome and dispersed along the DNA strand into multiple, shorter discrete entities (exons), widely separated by noncoding DNA regions (introns). Eventually, exons coding for V domains may be broken down in still smaller segments, each lacking some features needed for proper RNA splicing and unable to function separately [470]. Consequently, a V domain of a V_L chain is encoded by two separate DNA gene segments, exons separated by introns: the first 95 amino acids of V_κ domains are dictated by a V exon, the shorter exon J_κ (joining) codes the remaining 13 amino acids (96–108) of C-terminal domains [414]. H chains are dictated by V_H, J_H, D_H (diversity) and C_H exons; the D exon, absent in L chains, dictates a few amino acids and is in charge of the higher H chains variability compared to L chains [3]. An L chain gene is assembled from three types of gene segments: V_L and J_L are transferred on their genome (total inherited DNA) and integrated with a C_L segment. This machinery, known as *gene rearrangement*, necessary for transcription of gene information (mRNA synthesis) is employed only for genes dictating Ig L and H chains or TcR. After genes are transcribed into RNA, introns are removed from transcripts and exons are joined together by RNA splicing. As will be seen later, this rearrangement is the core of the capability shown by the immune system to recognize an incredible variety of antigen structures in nature [18].

Genetic Rearrangements for Ig Synthesis

Antibody molecules are encoded by three independent groups of genes. Two genes dictate λ chains: one comprises V_λ and C_λ genes, κ comprises V_κ and C_κ, genes, while the third group dictates H chains and has V_H and C_H genes. Before synthesizing Ig chains, however, Ig genes must be assembled within a genome of differentiating cells (rearrangement). Briefly, a V region gene can be located in a DNA position of an inherited chromosome (*germline*), and can then move to another position on the chromosome during lymphocyte differentiation. For example, five J segments of a κ chain are clustered near C exon, whereas at least 30–35 different V segments lie scattered widely over many DNA kilobases (kb). Rearrangements follow an order fixed in advance: H chain first, then L κ, finally L λ, encoded by chromosomes *14q32*, *2p12* and *22q12*, respectively (Fig. 1.8), with resulting deletion of intervening genetic materials and consequent realignment according to a configuration calling for Ig generation [186].

In the rearrangement of H chains, selection of one each from ten D, five J genes, and ≈200 or more V regions will produce a tripartite gene complex VDJ recombination for V_H regions. VDJ recombination is the process by which the V region exons encoding the antigen recogni-

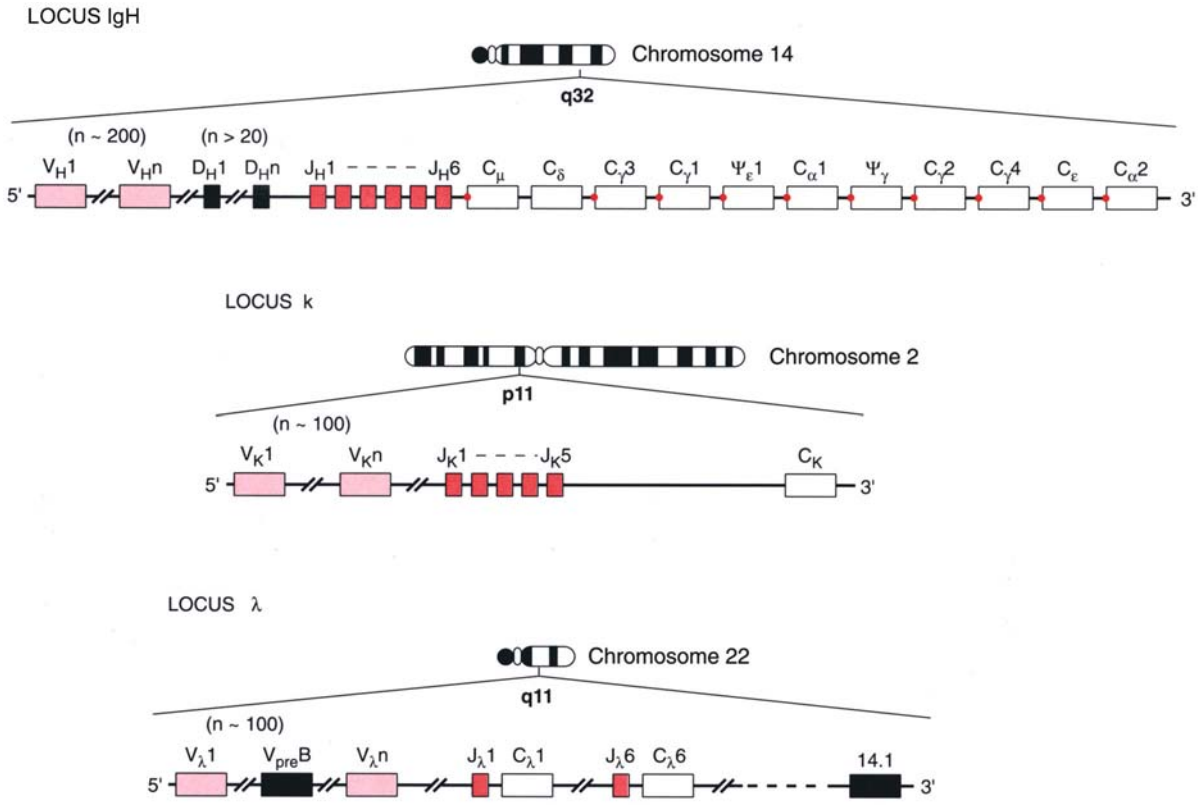

Fig. 1.8. Schematic representation of chromosomes 14, 2 and 22

tion sites of receptors expressed on B and T lymphocytes are generated during early development via somatic assembly of component gene segments [128]. During maturation of B and T lymphocytes, the first rearrangement involves H *locus* with the juxtaposition of D and J genes (DJ rearrangement) by the deletion of intervening DNA. This rearrangement occurs in a very early stage of maturation, when precursors are not yet clearly committed to B lineage; indeed it is also observed in 20% of T cells [474]. The second rearrangement involves subsequent translocation of DJ segments to selected V region genes (VDJ rearrangement) (Fig. 1.9), which occurs in pre-B cells, already committed to B lymphocyte family. As a consequence, the VDJ segment joins the C_H gene [591]. However, recombination can be somewhat imprecise, since during this process several nucleotides may be removed from or added to a junction, so combination of VDJ segments of H chains results in a large number (10 D_H × 4 J_H × 200 V_H) of possible sequences (that is, antibodies). This reshuffling process, known as *combinatorial joining,* is the prevalent source of protein diversity. For example, when organizing κ genes, as there is only one Cκ exon, all κ proteins must have identical C domain sequences, while cells can choose among several Vκ and Jκ segments, with the result of joining such segments in diverse combinations. Thus, a large number of different V region sequences can result and when combined with 50 κ chain V domains could form 400,000 different V_H genes. Considering a necessary heterogeneity of gene segments and combining 400,000 with 200 V_κ and four J_κ genes (200×4) × 10 equal to flexibility of VJ rearrangement, we have *at least* $3{\times}10^8$ *different antigen-binding sites*. Such an outstanding recombinant capacity is further increased by somatic mutations to 10^{10}–10^{15} [18]. Nonetheless, even using a relatively small amount of gene segments, the immune system can secrete an impressive antibody diversity through combinatorial joining [414].

In the most common scenario, a VDJ segment joins first with C_μ genes, and subsequently with C_γ, C_ε, C_α genes, with synthesis of a complete H IgM chain, etc. Without an associated L chain, surface expression is not possible and only cytoplasmic μ is found (pre-B cells). Isotype switching requires DNA rearrangements. Consequently, a single V gene is associated in successive phases with different C genes on the same chromosome, thereby allowing each cell to produce antibodies of different isotypes with the same paratope. Several components that are involved in this process have been identified. Among them, a complex system of enzymes and other proteins jointly known as *recombinase activity* appear to be necessary for gene rearrangements. Thus the enzyme VDJ recombinase catalyzes recombination processes, during which intervening DNA is usually excised. However, since similar sequences are found also

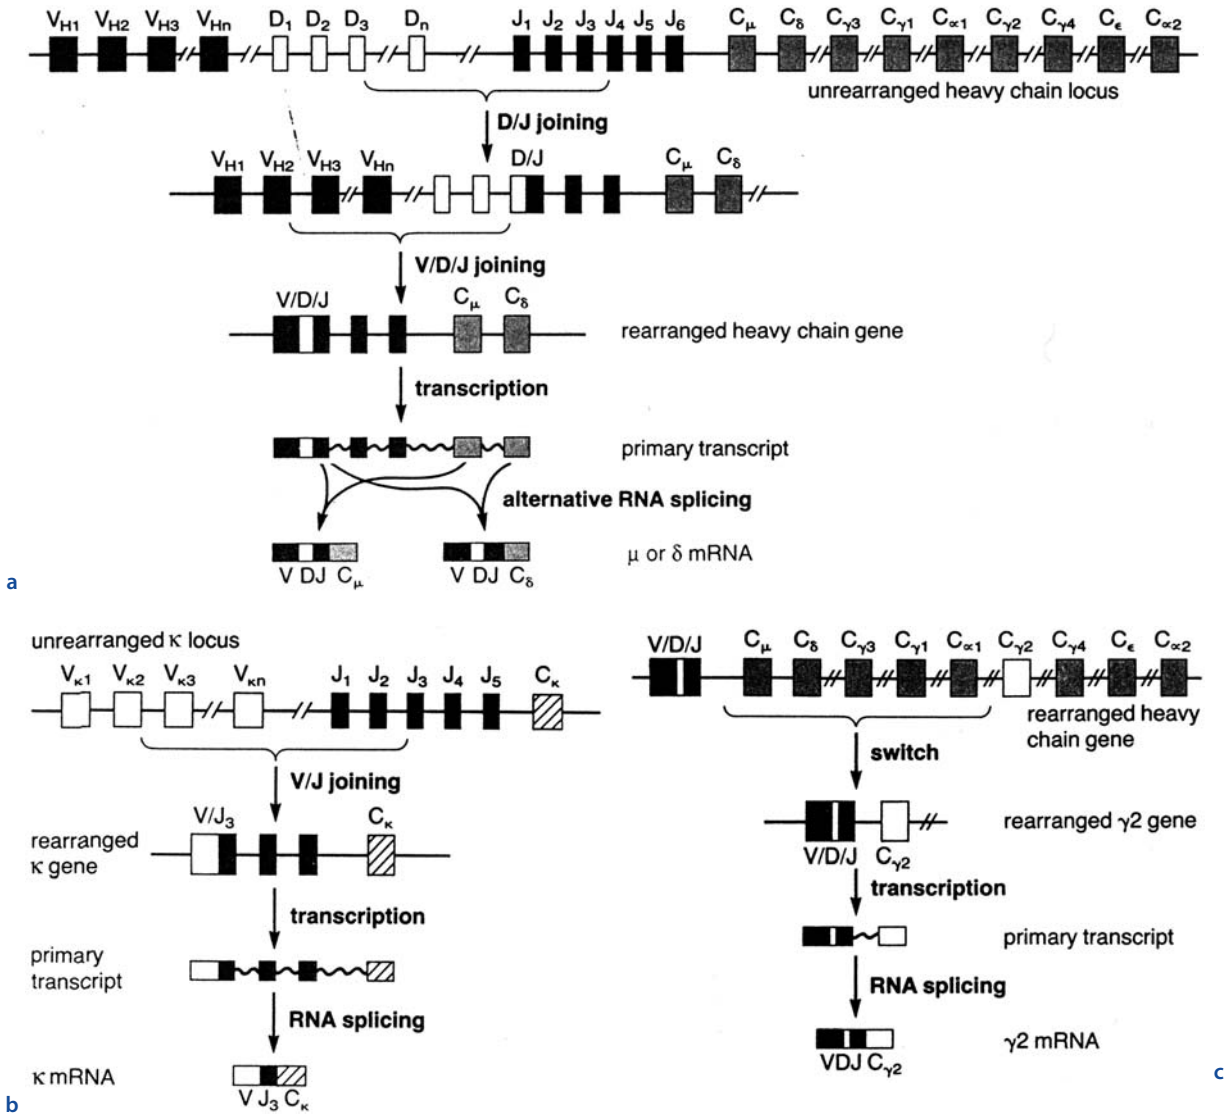

Fig. 1.9. **a** Schematic depiction of transcription, rearrangement and splicing of an H chain (Hμ or Hδ). **b** Schematic depiction of transcription, rearrangement and splicing of an L chain (Lκ or Lλ). **c** H-chain isotype switching

in TcR T-cell regions, it appears that VDJ recombinase is used by both B and T cells. VDJ recombination proceeds via precise DNA cleavage initiated by the RAG proteins at short conserved signal sequences [128]. Whatever their precise role, the coordinated expression in pre-B and pre-T cells is essential for the rearrangement of Ig genes and TcR αβ chains, but RAG activity is switched off in mature lymphocytes [299]. Mutations of such genes consisting in imprecise gene segment joining of coding sequences during VDJ recombination appear to cause SCID with B and T cells severely impaired [299].

After hierarchical H-chain rearrangement, L-chain rearrangement occurs (Fig. 1.9): when a D segment is absent, V domain is encoded by VJ genes (VJ rearrangement), with subsequent juxtaposition to respective C segment; λ genes are rearranged only in the event of a nonproductive κ rearrangement. This procedure continues until efficient V genes are generated for H and L chains and ends with synthesis of functional polypeptides.

Rearrangements are carefully orchestrated, following the principle of *allelic exclusion,* that is, in each B cell is transcribed the gene product of only one of each chromosome pair. The gene located on the second chromosome typically is not used, to prevent contemporary synthesis of H chains with differing V domains in any given cell; it is an *allele*, a term designating two genes or two or more alternate forms of a single gene occupying the same *locus* [591]. The gene on the second chromosome is not rearranged unless a nonproductive rearrangement occurs; when rearrangements are nonproductive on both chromosomes, cell death ensues, there-

by clarifying why the same B lymphocytes within their entire life span can produce only a single type of L chain (κ or λ) [474].

Precombination of gene segments implies further elements of diversity, due to either an imprecise DNA rearrangement of nucleotides that are believed to be inserted at V–J junction, which increases junctional diversity of L chains, or of H chains by mechanisms amplifying diversity, including the possible joining of two D genes, with or without inversion of one rearranging gene segment, as well as disparities in recombination of chromosome 14 [263]. Another very important mechanism generating variations is somatic mutations, which are able to introduce a heterogeneity even higher in nucleotide sequences. Insertions of such nucleotides are carried out by the enzyme terminal-deoxynucleotidyl-transferase (TdT), a terminal-independent DNA polymerase expressed in B lymphocytes early during their development, but also in thymocytes of all species. The variations in gene sequences resulting from imprecise joining or from insertion of N regions, via addition of nucleotide sequences, absent in germline, provide a supplemental diversity at VDJ junctions designated "N-region diversity." Moreover, these processes affect sequences within each VDJ exon coding for CDR3 of L- or H-chain V domain. Hence, TdT can be viewed as another component of the VDJ recombinase system [263]. This implies that all these mechanisms engendering a disproportionate antibody diversity leave an unknown fraction of B cells to aberrant Ig gene rearrangements, probably >50% [47]. Recent data show that TcR and Ig V, D, and J gene segments are flanked by conserved *recombination signal sequences* (RSS), consisting of a heptamer and a nonamer separated by a nonconserved spacer of either 12 or 23 nucleotides. The 12–23 base pair rule first postulated to explain Ig gene rearrangement also governs TcR gene recombination. Virtually, during a rearrangement, a gene with a flanking sequence containing a 12-base pair spacer can only join to a gene whose flanking sequence has a 23-base pair spacer and vice versa, thereby elucidating the precise order of Ig gene transcriptions [337].

In conclusion, because of the very efficient DNA usage displayed in gene rearrangements, as well as RNA transcription and joining machinery described above, B lymphocytes can produce an isotype switching conserving antigen specificity, although utilizing an assembly of about 300 gene segments, there would be several million different antibodies in the same subject [3]. Once the recombination process is completed, C region genes of both H and L chains are associated with the VDJ or VJ complex. In this way, the VDJ complex becomes joined to C region genes of other isotypes located downstream on the same chromosome. The conclusion of such rearrangements is the production of different isotypes of the same antibody. Such antibodies capable of recognizing a specific antigen will be on the whole clone, on the whole progeny originating from a single B cell precursor. In that way, each lymphocyte clone can respond only to antigens able to bind to its unique pair of H and L chains, and all antibodies synthesized by an activated clone are directed against that particular antigen, as in the case of B lymphocytes, or has receptors ready for the antigen, as in the case of T lymphocytes [470].

On the other hand, papain digestion splits Ig molecules yielding three fragments of roughly similar size (50 kD), two monovalent Fab (fragment antigen binding) fragments with a whole L chain and half H chain (retaining ability to combine with antigen), and an Fc fragment (fragment crystallizable) comprising carboxy-terminal portions of both H chains. On B cell membrane, Igs are disposed as follows: the tail of Y is the Fc fragment, while the arms correspond to Fab fragment (Fig. 1.6).

Pepsin digestion yields a single large fragment called $F(ab)'_2$, roughly corresponding to two -S-S linked Fab fragments with bivalent antigen-binding activity. Antibody ability to fix on several cell types with Fc region of H chains takes place via FcRs, present on different cells. FcR molecules appear to exemplify a point of contact and cooperation between humoral and CMI. The main FcR for H chains of different Igs are summarized in Table 1.3 [186, 486].

In addition to the variability related to paratope diversity for antigen molecules, under appropriate circumstances antibodies deliver three main forms of Ig epitopes as defined by their location on antibody molecules, that is isotype, allotype, and idiotype determinants [18].

The term *"isotype"* is often used as equivalent to the terms "class" and "subclass;" isotypes are Ig epitopes codified by identical gene segments found in all healthy individuals of the same species. Individuals of a different species have different isotypes, since each isotype is located on a distinct gene locus on the pertinent genome. Antibody isotypes are defined principally in relation to H- or L-chain C regions and in some instances to V_H and V_L invariable regions, as are Ig epitopes that characterize classes, subclasses and types of H and L chains. As a general rule, isotypes are recognized by antibodies produced by different species.

The *allotypes,* or genetic markers, a form of variation in Ig structure, are allelic forms of the same protein as a result of different forms of the same gene at a given locus. They are located in C regions of both L and H chains: allotypes of L chains are named Km, those of H chains Gm, Am, and Mm. Inherited as dominant mendelian traits, they stem from genetic differences in amino acid sequences of C genes (*genetic polymorphism,* GPM). Allotypes are accepted in some countries as legal evidence in paternity disputes. As in other allelic systems, variants are not present in all healthy subjects and therefore distinguish Igs of one subject from Igs of another, as do blood groups.

The *idiotypes* (from Greek "ιδιος," personal or private), are as many as B-cell clones, 10^8 in adults [186], and are formed by single idiotopes building a given paratope with its characteristics and binding idiotypes

Table 1.3. Immunoglobulin (*Ig*) receptors

Receptors	CD	Immunoglobulins	Cells
FcαR	89	IgA	Neutrophils, lymphocytes, monocyte-macrophages, eosinophils
FcεRI	–	IgE	Mast cells, basophils, eosinophils, LC
FcεRIIa	23	IgE	B cells
FcεRIIb	23	IgE	B and T cells, eosinophils, LCs, NK cells, platelets
FcγRI	64	IgG_1 +++, IgG_3 +++, IgG_4 ++	LCs, monocytes, neutrophils
FcγRII	32	IgG_1 +, IgG_3 +	B, T and NK cells, monocytes, macrophages, eosinophils, neutrophils, platelets, basophils, LC, FDC, epithelial and stromal cells
FcγRIII a, b	16	IgG_1 +, IgG_3 +	T and NK cells, neutrophils, macrophages

FcαR consists of an α chain linked to IgA and a dimeric chain FcγR for transduction of signals [470].
Modified from [186, 470].
LC Langerhans' cells, *FDC* follicular dendritic cells.

to antibody specificity [469]. Being determined by antibody V regions in hypervariable regions, *they are not linked to the class*: each idiotype is defined by association of V_H and V_L domains and therefore distinguishes one V domain from the others. There are two types, those associated with paratopes are located very near CDRs and those recognizing structures outside the binding site are carried by hypervariable and V regions, respectively. Based on such definitions, we can see two ways to evaluate V regions: by serologic aspects (idiotype) or by antigen-binding properties (paratope) [58].

The IgSF (Table 1.4) [4, 23, 34, 109, 139, 186, 323, 557, 693] (Fig. 1.10) is formed by polygenic groups of genes and single genes, structurally correlated but not necessarily functionally, but whose structural features recall those of Igs; they belong to families sharing an evolutionary homology, probably originating from a few ancestral genes. It is presumed that V regions of such molecules may have a role in intercellular interactions, or as receptors for soluble ligands [186].

T Lymphocytes

T cells especially, but also B cells and other immune cells, synthesize ILs, proteins with a molecular weight (MW) of 15–25 kD governing intensity and duration of immune reactions, mediating cellular proliferation and maturation, and also wound healing (Tables 1.5–1.8) [4, 14, 34, 45, 50, 52, 55, 66, 68, 78, 92, 98, 118, 119, 126, 128–130, 140, 141, 152–154, 156, 158, 167, 172, 181, 213, 219, 220, 240, 245, 249, 258, 272, 278, 318, 326, 372, 377, 383, 387, 398, 399, 412, 413, 421, 426, 437, 455, 461, 474, 480, 481, 487, 517, 523, 526, 528, 532, 534, 560, 562, 607, 641, 669, 693]. In parallel, there is a leukocyte superfamily (Table 1.9) [27], less extensively represented as the IgSF.

Table 1.4. Constituents of the IgSF

H and L chains
Class I and II HLA molecules (correlated)
β_2-Microglobulin
TcR, CD3, CD2, CD7, CD4 and CD8
BcR, CD79a, CD79b
Poly-IgR (receptor of IgM and IgA antibodies), a fragment of poly-IgR constitute the SC of sIgA
Adhesion molecules, integrins, selectins, etc. (see below)
Additional molecules: CD1, CD16, CD19, CD22, CD28, CD32, CD47, CD48, CD58, CD64, CD66a-e, CD80, CD83, CD86, CD89, CD90, CD96, CD101, CD117, CDw150, CD152, CD155, CD158 a, b, CD166
Receptors of: IL_1 (IL_1R, I and .II, CD121a and 121b) IL_6 (IL_6R, CD126) GM-CSF (GM-CSFR, CD116) M-CSF (M-CSFR, CD115) PDGF, etc.

Table 1.4. (Continued)

Adhesion molecules as part of the IgSF		
Molecules	**Ligands**	**Distribution**
CD1	?	Thymocytes and DCs
CD2	CD58 (LFA-3], CD48, CD59	T and NK cells, endothelial and epithelial cells
CD3/TcR	Nominal antigen	T cells
CD4	HLA-II	T cells, monocytes
CD7	?	T and NK cells
CD8	HLA-I	T and NK cells
CD22	CD45RO	B cells
CD28	CD80, CD86	T cells and plasma cells
CD31 (PECAM-1])	CD31, heparin	T cells, endothelial cells, monocytes, platelets, neutrophils
CD48	CD2	Hematopoietic and not hematopoietic cells
CD50 (ICAM-3)	CD11a/CD18	T cells, monocytes, neutrophils
CD54 (ICAM-1)	CD11a/CD18, CD11b/CD18, CD43	Activated T and parenchymal cells, NK cells, endothelial and epithelial cells, fibroblasts, monocytes, chondrocytes, DCs
CD56 (N-CAM)	CD56	T, B, NK cells, endothelial and epithelial cells, keratinocytes, DCs
CD102 (ICAM-2])	CD11a/CD18	Endothelial cells (high expression), epithelial, T, and NK cells, monocytes, DCs, platelets (low expression)
CD106 (VCAM-1)	CD49d/CD29, $\alpha_4\beta_7$	Endothelial cells, monocytes, DCs, fibroblasts, stromal medullary cells, myoblasts
HLA-I	CD8	APCs
HLA-II	CD4	APCs
Ig	Nominal antigen	B cells
MAdCAM-1	CD62L	Mucosal and lymphoid HEVs

CD2, CD48, CD58 form a family, although they are located in pericentric loci of two different chromosomes: 1p13 for the first two and *1q21–23* for the third one; a correlated family is CEA, with CD66b (ex CD67) and CD66e (NCA).
Data from [4, 6, 23, 34, 109, 139, 186, 323, 557, 693] and International Workshops on Human Leukocyte Differentiation Antigens [501].
APCs antigen-presenting cells, *CEA* carcinoembryonic antigen, *DCs* dendritic cells, *ICAM-1, 2, 3* intracellular adhesion molecules-1, 2, 3, *IgSF* immunoglobulin superfamily, *LFA-3* lymphocyte function-associated antigen-3, *MAdCAM-1* mucosal addressin cell adhesion molecule-1, *N-CAM* neural cell adhesion molecule, *PECAM-1* platelet endothelial cell adhesion molecule, *SC* secretory component, *VCAM-1* vascular cell adhesion molecule-1.

A tentative nomenclature may divide ILs into five main types:
a) Interleukins (IL_1–IL_{33})
b) Hematopoietic growth factors (CSF)
c) IFN
d) TNF
e) Growth factors: EGF (epidermal growth factor), FGF (fibroblast growth factor), PDGF (platelet derived growth factor), TGF, etc.
ILs are released from several inflammatory effector cells [151] (Table 1.5):
1) From *Th1 T cells* IL_2, IL_3, IL_{12}, IL_{18}, IL_{22}, IL_{23} IL_{27}, IL_{32}, TNF-α (tumor necrosis factor-α) and -β, IFN-γ, and GM-CSF
2) From *Th2 T cells* IL_3, IL_4, IL_5, IL_9, IL_{10}, IL_{11} IL_{13}, IL_{18}, IL_{25}, IL_{27}, IL_{31}, GM-CSF, whose genes are associated with the chromosome 5 gene cluster in region q31–q33, together with IL_6, IL_9, IL_{12}, IL_{13}, M-CSF and CD14 (IL_4, IL_5, IL_9, IL_{11}, IL_{13}, IL_{16}, IL_{17}, IL_{25} induce asthma)
3) From Th1 and Th2 lymphocytes IL_{14}, IL_{28}, IL_{29}, GM-CSF, IFN-γ, BaDF, NGF
4) From B lymphocytes IL_{10}, IL_{12}, IL_{14}, IL_{19}
5) From endothelial cells GM-CSF, TNF, IL_1, IL_3, IL_6
6) From fibroblasts GM-CSF, G-CSF, M-CSF, IL_1, IL_3, IL_6, IL_{15}
7) From hemopoietic cells IL_{23}
8) From mast cells IL_3–IL_6, GM-CSF and TNF-α
9) From monocyte-macrophages IL_1, IL_6, IL_8, IL_{10}, IL_{12}, IL_{15}, IL_{18}, IL_{19}, GM-CSF and TNF-α
10) From NK cells GM-CSF, M-CSF, IFN-γ, IL_2, IL_{15} and TNF-α
11) From PBMCs IL_{24}
12) From skin and trachea IL_{20}
13) From thymus and medullary stromal cells IL_7, IL_{11}.

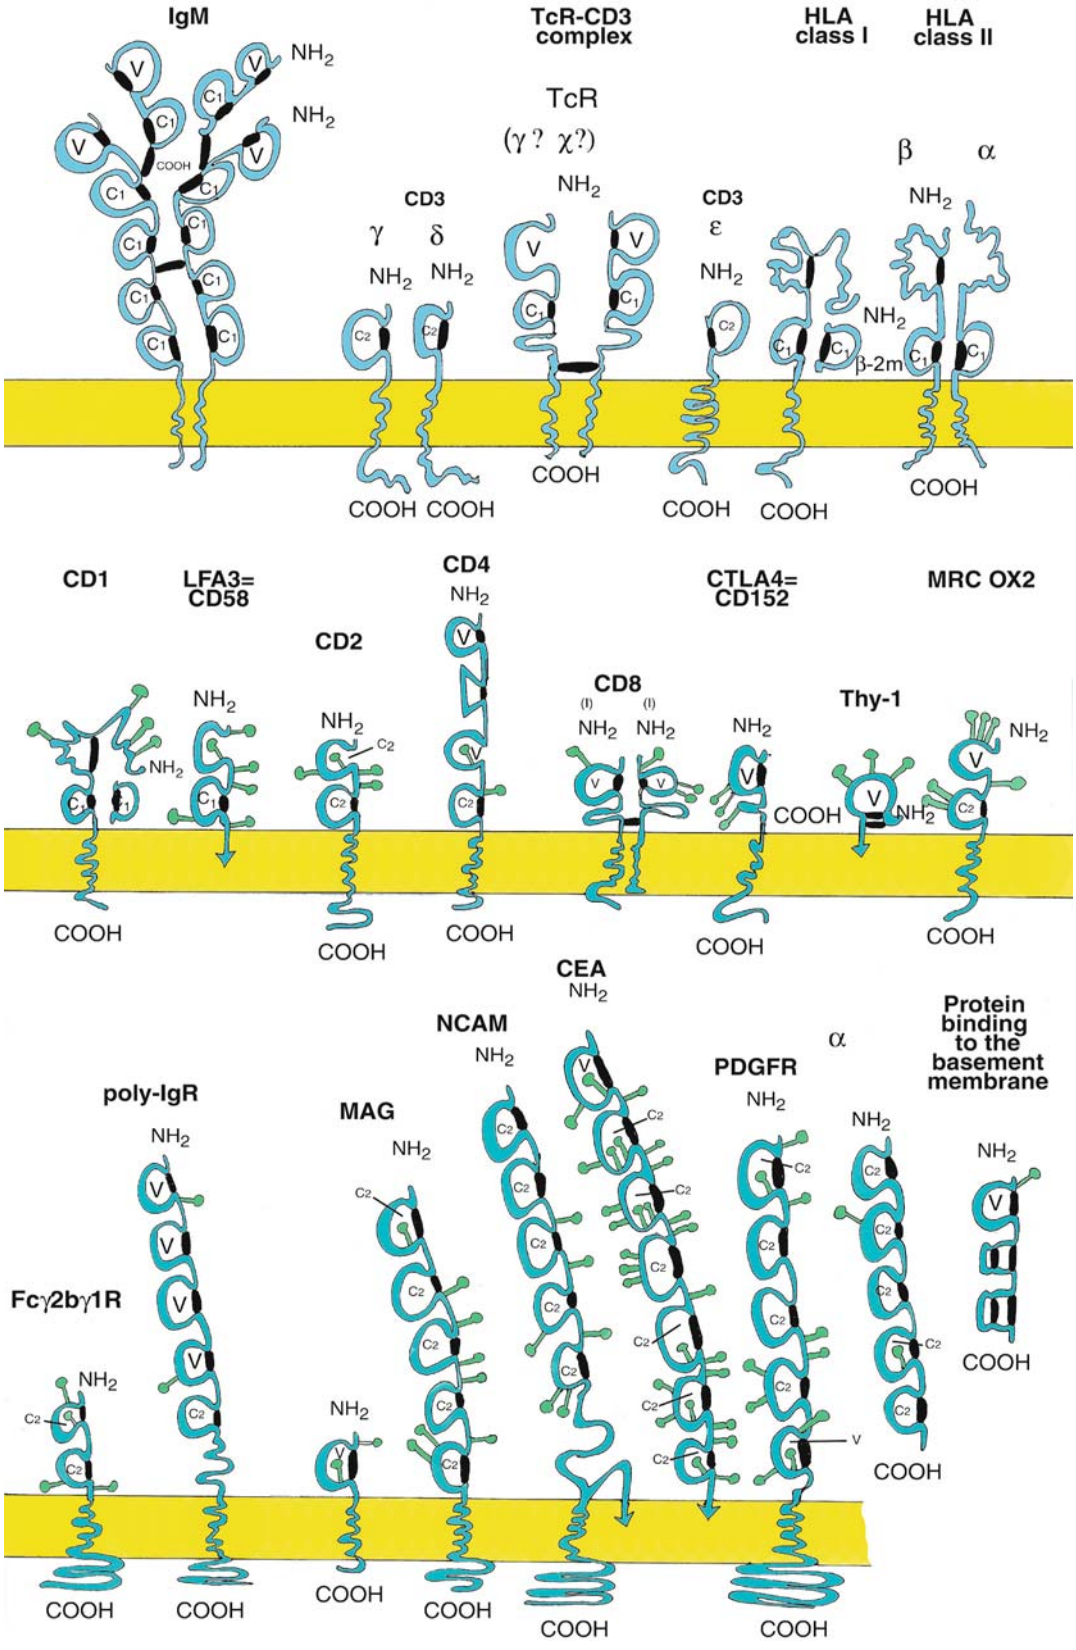

Fig. 1.10. Immunoglobulin superfamily (IgSF). Protein binding to the basement membrane. A model is shown for each molecular type from one species, the *circles* show sequence segments that form Ig domains. α *1Bgp* non-cell surface glycoprotein, β_2-*m* β-microglobulin, *CEA* carcinoembryonic antigen, *MAG* myelin associated glycoprotein, *poly-IgR* immunoglobulin receptors, *NCAM* neural adhesion molecule, *PDGFR* platelet-derived growth factor receptor = CD140, *Po* myelin protein, *Thy-1* and *MRC OX2* brain/lymphoid antigens

Table 1.5. Main characteristics of interleukins (*ILs*; cytokines)

Name	MW (kD); chromosomes, primary sources and targets, principal biological effects
IL_1	α and β (17 and 15–17; *2q13–21*) and IL_1RA [27] with a structure similar to that of IL_1, however, competes for binding of type I receptors $IL_1α$ Sources: Several different cell types, especially monocytes and macrophages, T and B cells, NK cells pluripotent stem cells: proliferation T lymphocytes, primarily Th2, but also Th1: stimulate to express IL_2 B and NK cells: activation, differentiation and proliferation Macrophages: activation Basophils: differentiation $IL_1β$ Sources: T and B lymphocytes, dendritic cells (DCs), endothelial, and epithelial cells, fibroblasts, etc. Effects: Induces acute-phase responses of liver (thus playing an important pro-inflammatory role) Stimulates the production of IL_2, IL_3, IL_6, IFN-γ by activated, antigen-specific T lymphocytes IL_1 and IL_{18} have an analogue signaling pathway, are key molecules in both the innate and adaptive immunity, and are members of a larger family of related receptors, some of which contribute to host defense TRAF6 participates in IL_1 signaling
IL_1R	$IL_1α$ and β bind with about the same affinity to the same cell surface receptors IL_1R-activating kinase (IRAK), leads to translocation of NF-κB
IL_1R type-I	(80) T and endothelial cells, fibroblasts, hepatocytes and other cells, has an extended amino acid cytoplasmic tail and after binding IL_1 transmits signals intracellularly
IL_1R type-II	(6) Defined as inactive, can function as a precursors of soluble forms binding IL_1
IL_2	(15–20; *4q26–28*) Sources: Exclusively Th1, NK, B cells, and mast cells Effects: Stimulates antigen activation of TcR T lymphocytes stimulated by IL_1 (CD4 and cytotoxic cells = TCT, NK cells and TCT IL-activated cells = LAK): Growth, activation, and differentiation B lymphocytes a) Proliferation and differentiation b) Isotypic selection of IgG_2 Basophils and macrophages: differentiation, increase of TNF-α expression and/or production of IL_3, IL_4, GM-CSF (colony-stimulating factor) and IFN-γ
IL_2R	Formed by three chains: α (55; 10) one affinity-modulating subunit, and β (75; 22) and γ (64; X), two essential signaling subunits Mediates the functions and activities of IL_2 (see above); resting NK cells express its β and γc receptor; the β chain associates with JAK1 and γc associates with JAK3 JAK1/JAK3 (and STAT3/STAT5): induce IL_{15}-like activities $IL_2Rγ$ gene (*Xq13*) encodes the γc-chain of the IL_2, IL_4, IL_7, IL_9, IL_{13}, IL_{15} receptors that are essential for the development of T and NK lymphocyte subsets
IL_3	(14–30; *5q31–33*, where linkage to human asthma has been demonstrated) Sources: Bone marrow stromal cells, activated Th cells, mast cells, keratinocytes Effects: Hematopoietic stem cells (all lines): growth factor and differentiation B and T cell early precursors: growth factor Basophils and mast cells (mostly of mucosal type): proliferation, differentiation, activation, degranulation Basophils: mediator release NK cells and LAK: stimulation Eosinophils: pro-inflammatory alterations

Table 1.5. (Continued)

Name	MW (kD); chromosomes, primary sources and targets, principal biological effects
IL_3R	Has α and β chains, the β chain is common to IL_5R and GM-CSFR
IL_4	(18–20; *5q31–33* on gene cluster) Sources: Progenitor cells, B and Th2 subsets, and mast cells Effects: Hematopoietic stem cells: differentiation, proliferation B and T lymphocytes: activation, proliferation and differentiation B lymphocytes a) Isotype switching of IgG_1 and IgE antibodies b) Up-regulation of HLA class II and of FcεRI for IgE antibodies c) Induction of ε-germline transcription in B cells T lymphocytes: a) Differentiation of naive T cells to Th2 cells producing Th2-like ILs b) Proliferation of Th2 cells c) Stimulation of antigen activation of TcR Th1 lymphocytes: inhibits switch of T cell differentiation from Th0 to Th1 and IFN-γ production Eosinophils: transendothelial migration Macrophages: inhibit activation Mast cells: growth factor (in experimental animals, in synergy with IL_3), up-regulates FcεRI and CD54 Basophils: up-regulates FcεRI Mononuclear phagocytes: up-regulates FcεRII and HLA class II Neutrophils: activation (see also IL_{13}) Fibroblasts: up-regulates chemokine production Epithelial cells: up-regulates mucin gene expression Endothelial cells: up-regulates CD106 Additional effects: Is thought to exert its effects through the FcεRI present on several cell lines (see text) Induces the expression of FceRII by eosinophils, monocytes and platelets Down-regulates the production of IL_8 by monocytes, of $IL_1α$, IL_6 and TNF-α by macrophages and of IL synthesis by Th1 subsets Activates STAT3 and STAT6
IL_4R	(CD124) (*16p12*) hematopoietic precursors, B and T cells, fibroblasts The receptors signaling triggers the activation of JAK-1 (via the receptor α) and JAK-3 (via the common γc chain, part of this receptor Stimulates T-cell growth, and B-cell activation to promote IgE isotype switching and T–B interactions, induces CD8 cells to produce IL_4
IL_5	(25–50; *5q31–33* on gene cluster) Has α and β chains, the β chain is shared by IL_3 and GM-CSF receptors, explaining the overlapping biological activities Sources: Th2 subsets, mast cells and eosinophils Effects: Activated B lymphocytes: a) Differentiation b) IgA and secretory IgM (sIgM) production c) Expression of IL_6 receptors T lymphocytes: a) Cytotoxic activity b) Expression of IL_2 receptors c) Antigen activation of TcR Eosinophils: a key role in augmenting activation, differentiation, vascular adhesion (CD11b), life span *in vitro* (eosinophilopoietic IL) and IgA-mediated degranulation Basophils: histamine release
IL_5R	(60) The α chain (CD125) (60 kD) has non-binding β chain (CD131) (95 kD) shared with IL_3R and GM-CSFR α chains to form the high-affinity IL_5R [62] Distribution: eosinophils and basophils Binding to IL_5 promotes growth and differentiation of eosinophil precursors, activating mature cells

Table 1.5. (Continued)

Name	MW (kD); chromosomes, primary sources and targets, principal biological effects
IL_6	(21–28; *7q15–21*) Pleiotropic cytokine induced by IL_1, IL_2, TNF, PDGF and IFN and inhibited by IL_4 and IL_{13} Forms a family with IL_{11}; they have overlapping effector profiles and multimeric receptor complexes in which the promiscuous gp130 molecule serves as a signaling subunit Sources: T and B lymphocytes, monocytes, macrophages, fibroblasts, keratinocytes, hepatocytes, epithelial and endothelial cells Effects: Th2 cells: synergize with IL_1 or TNF to promote growth of immature thymocytes and activation of mature T cells B cells: a) Growth and differentiation b) Ig production: synthesis of IgA, of IgG subclasses, and of IgE induced by IL_4 NK cells: activation TCT: differentiation Additional effects: Antiviral activity Hepatocytes: synthesis of acute phase proteins up-regulating the gene transcription Interacts with CSFs in the proliferation and cell differentiation of pluripotent stem cells Inhibits the inducer and effector phases of delayed-type hypersensitivity
$IL_6R\alpha, \beta$	The α chain is CD126 (80 kD), and the β chain CD130 (130 kD) (gp130), high-affinity IL_6R is formed with CD130 Distribution: resting or activated B cells, plasma cells, T cells, monocytes, fibroblasts, hepatocytes, neural cells $IL_6R\beta$ has signaling chains for receptors for IL_{11}, keratinocytes, LIF, oncostatin M (OSM), and ciliary neutrophil factor (CNF) Overlapping actions: induction of differentiation and proliferation of hematopoietic precursors, and of acute phase proteins
IL_7	(25; *8q12–13*) Sources: Chiefly thymic, bone marrow and stromal cells, but also human keratinocytes Effects: T precursors: proliferation and differentiation of early thymocytes Mature T cells: enhancement to produce IL_2 and IL_2R IL_2 and IL_6 synergize with IL_7 effects on T cells TCT and LAK cells: generation, proliferation and activation Pro- and pre-B lymphocytes: proliferation and differentiation of progenitor cells Megakaryocytes: maturation Monocytes: IL_1, IL_6 and TNF secretion $\gamma\delta$: Proliferation
IL_7R	CDw127 (68 kD) associated with the γ common chain of CD132 (64 kD) to form the high-affinity IL_7R The common γc chain is part of this receptor Distribution: immature thymocytes, pre-B cells, mature T cells, monocytes, $\gamma\delta$ IEL Induction/promotion of immature T-cell growth, expression of CD25 on T cells, proliferation of pre-B/B cells, and monocyte activation, critical for T lineage but not for B lineage development
IL_8	(8–10; *4q12–21*), neutrophil-activating peptide (NAP) Sources: Activated monocytes and macrophages, in addition to monocytes, endothelial and epithelial cells, T lymphocytes, fibroblasts, keratinocytes, hepatocytes, and chondrocytes IL_8 production is stimulated by LPS, IL_1, TNF and virus

Table 1.5. (Continued)

Name	MW (kD); chromosomes, primary sources and targets, principal biological effects
	Effects: Neutrophils: a) Potent chemoattractant b) Activation and induction of degranulation, respiratory burst and adhesion to endothelium via CD11b/CD18 T lymphocytes: chemotactic activity and directed migration Basophils: inhibits histamine release
	Additional effects: Together with TGF-β inhibits IgE synthesis Promotes angiogenesis by blood vessels
IL_8R	(44–59/67–70; 2) (CDw128)
	Distribution: CD8 T cells, neutrophils, monocytes, NK-cell subsets
	Receptor of α chemokines
IL_9	(32–39; *5q31–33*) growth factor for clones of CD4 cells which also produce it
	Sources: T lymphocytes (especially Th2, but not CD8) and B lymphocytes, mast cells, and eosinophils, and potentially involved in allergy and asthma
	Effects: Mast cells, megakaryocytes: enhances proliferation Basophils: proliferation, increases the sensitivity to IL_3 B lymphocytes: enhances IL_4-induced production of IgE antibodies
	Additional effects: Enhances the synthesis of IL_6 Induces IL_{22} activity Substantial promoter of myeloid and erythroid precursor
IL_9R	(CD129) T and B cells, macrophages, megakaryoblasts
	The common γc chain is part of this receptor
IL_{10}	(19; *1q32*), several IL synthesis inhibitory factor (CSIF)
	The genes for IL_{10}, IL_{19}, IL_{20}, IL_{22}, IL_{24}, IL_{26} are found within a 200-kb region of chromosome 1q32, whereas genes encoding the two other IL_{10} family members, IL_{22} and IL_{26}, are found within 30 kb of each other and less than 100 kb from the IFN gene on chromosome 12q15; the family can be further divided into two groups. IL_{19}, IL_{20}, and IL_{24} belong to one group, whereas IL_{10}, IL_{22}, and IL_{26} form another group. Moreover, IL_{19}, IL_{20}, and IL_{24} use the common $IL_{20}R2$ chain for signaling, and IL_{10}, IL_{22}, and IL_{26} may also share a common R2 chain
	Pleiotropic IL with important immunoregulatory functions whose actions influence activities of many of the cell types in the immune system
	Sources: $IL_1β$, IL_6, IL_8, IL_{12}, G-CSF, GM-CSF, IFN-γ, TNF-α produced by activated monocytes, IL_4 and IL_5 by Th2 subsets, leukocytes and skin
	IL_2 and IFN-γ produced by Th1 subsets, thus eliciting the generation of IL_4
	$IL_1α$ and β and TNF-α by Th1 and NK cells
	IFN-γ and TNF-α by NK cells
	Negatively regulates its own synthesis by monocytes
	IFN-γ inhibition results in the switch of T cell differentiation from Th0 to Th2
	B cells, Th1, Th2 and suppressor T subsets, DCs, mast cells, monocyte-macrophages, eosinophils and keratinocytes
	Effects: Macrophages: inhibition of differentiation and expression of HLA class II and adhesion molecules Monocytes: inhibition of differentiation into macrophages CD4 lymphocytes: Inhibits IL_8-induced migration Down-regulates Th1 responses, thus suggesting an anti-inflammatory activity

Table 1.5. (Continued)

Name	MW (kD); chromosomes, primary sources and targets, principal biological effects
	Suppressor CD8 T cells: Favors differentiation and chemotaxis Inhibitory factor at the maternofetal interface (Chap. 2) TCT precursors: enhances the number and the function B lymphocytes: has a significant effect opposite to the SCIF activity stimulating: a) Growth of progenitors of the erythroblast series and of mast cells b) Differentiation and expression of HLA class II c) Isotype switching to IgA_1 and IgA_2 secretion along with TGF-β, and to IgG_1, IgG_3 and IgG_4 On IL synthesis, in particular inducing IFN-γ on NK cells by IL_{12} On APCs function down-regulating HLA class II expression, an effect reversed by IL_4 On production of reactive oxygen and nitrogen species d) Isotype switching to IgE e) Modulation of IL_4-induced B-cell IgE production in favor of IgG_4 f) Inhibition of IgE-dependent mast cell activation ILs: inhibits $IL_1\alpha$, $IL_1\beta$, IL_2, IL_6, IL_6, IL_{18}, TNF-α Langerhans' cells (LCs): tolerogen effects in addition to suppressing their APC function STAT1, 3, 5: activation, such as IL_{22}
$IL_{10}R1$	(110 kD) Distribution: thymocytes, B cells, mast cell and macrophage cell lines After binding to B cells induces B-cell proliferation, differentiation and isotype switching to IgA secretion with CD40L = CD154 and TGF-β
$IL_{10}R2$	Intact second chain of the human IL_{10} R complex, which may be shared by receptors for the other IL_{10} homologs A distinct feature of the $IL_{10}R$ complex is that both chains can independently bind ligand, whereas in the IL_{10} and IFN–R complexes, only one chain (the R1 chain) can bind ligand in the absence of the other: in all of these receptors, the second (R2) chains are necessary for signaling through the JAK-STAT complex Recognizes IL_{10} and IL_{22}
IL_{11}	(23; *19q13.3–q13.4* and *7* centromeric region) Sources: Bone marrow stromal cells Effects: Hematopoietic progenitor cells of megakaryocytes and macrophages/monocytes: growth factor B lymphocytes: increases Ig secretion independently of T lymphocytes Hepatocytes: synthesis of acute phase proteins cooperating with IL_1 and IL_6 Modulates Th1/Th2 IL production from activated $CD4^+$ T cells, and augments T-cell IL_{10} elaboration Additional effects: Acts synergically with IL_3 in megakaryocyte differentiation Sharing several biological activities with IL_6, it is likely that they use similar signal transduction mechanisms
$IL_{11}R$	Belongs to the receptor family, also including IL_6R, etc.; IL_{11} initiates signaling via binding to a unique IL_{11} receptor chain ($IL_{11}R$). Isoforms of $IL_{11}R$ have been described that contain $IL_{11}R1$ and do not contain $IL_{11}R2$, a cytoplasmic domain. The binding of IL_{11} to $IL_{11}R$ forms a complex that binds to and induces gp130 molecule homodimerization, resulting in the assembly of the active $IL_{11}R$ trimer
IL_{12}	(*5q31–33*) Heterodimeric IL manifests some effects almost reciprocal to those of IL_{10}; an IL_{12}-family is composed of IL_{23} and IL_{27} Has two covalently bound 35- and 40-kD chains (and thus designated p35 and p40 subunits), encoded by two separate genes regulated independently and inactive if expressed separately – the p40 subunit is expessed in large excess of the p35 subunit – p35 is among the early inducers of Th1 responses, while it inhibits Th2 lymphocytes – when p35 associates with p40, a soluble member of the cytokine receptor superfamily, it forms IL_{12}, which induces Th1 differentiation and the release of IFN from Th1 and NK cells – CD40 cross-linking up-regulates IL_{12} p40 mRNA in monocytic and B-cell lines and in human monocyte-derived DCs – the two subunits act as signal transducer by providing a cytoplasmic STAT4 binding sit which enables STAT4-mediated responses to IL_{12} to occur DCs; The gene encoding the p40 subunit is located in the region of chromosome 5 – the duo $IL_{12}p35/IL_{12}p40$ is called IL_{12} p70

Table 1.5. (Continued)

Name	MW (kD); chromosomes, primary sources and targets, principal biological effects
	Sources: B cells and monocyte-macrophages (via CD40–CD154 interactions) Effects: Allergen-specific T cells Crucial role in selective switch of T cell differentiation into Th0 or Th1 Stimulation of adhesion molecules Th1-inducing and Th1-maintaining B lymphocytes Induction of STAT1 activation, T-bet expression and IgG2α class switching NK cells a) Activation, proliferation and cytotoxicity b) Expression of CD2, CD56 and CD11a c) Stimulates production of IFN-γ from Th1 cells and NK cells NK cells, macrophages and Th1 subsets: production of IFN-γ – p40 is expressed by some cells such as nonprofessional APCs and only after activation Has homology with the soluble receptor of IL_6 Costimulates proliferation of peripheral lymphocytes Promotes cell-mediated immunity (CMI) Protection against infectious diseases
$IL_{12}R$	(α chain or R1, 120 kD, and β chain or R2, 140 kD) Sources: CD4, CD8 activated T cells, NK cells, and B cells Effects: Stimulates their proliferation as well as the peripheral hematopoiesis R2 is a key Th1 commitment step when naive Th precursor cells commence differentiation into Th1 cells
$IL_{12}Rβ1$	(*5q31–33*) Encodes the p40 subunit
IL_{13}	(9–17; *5q31*) The gene encoding IL_{13} is only 25 kb upstream of the IL_4 gene and in the same orientation Has a receptor different from that of IL_4 possibly a subunit in common with IL_4R Sources: CD4 (Th 0, 1 and 2) and CD8 T cells stimulated by antigens, monocytes and mast cells Effects: Up-regulates HLA class II and adhesion molecules such as CD11b, 11c, 18, 28, 49e Down-regulates CD16, CD31, and CD 64 Manifests no growth effects on T cells, unlike IL_4 Human B lymphocytes: a) Expression of CD23 (also on monocytes), CD71, CD72, sIgM and HLA class II b) Class switching to IgE and IgG_4 c) Expression of ε-germline transcripts independently of IL_4 even if two to five times less powerful Monocyte-macrophages: IL_4-like effects (inhibits HIV replication in monocytes and ADCC in both cells) Additional effects: Has a persisting activity unlike IL_4, which is activated only 8–12 h Together with IL_4 induces VCAM-1 = CD106 on endothelial cells Its polymorphism is associated with high total serum IgE levels and increased risk of atopic asthma
$IL_{13}R$	Appears to be heterotrimer, and formed by $IL_4Rα$, $IL_2Rγ$ and $IL_{13}Rα1$- or $IL_{13}Rα2$-binding Associates with CD124 to form the $IL_{13}R$ complex; the common γc chain is part of this receptor Distributed to human B cells, endothelial cells, several non-hematopoietic cells, including monocyte-macrophage populations, B cells, basophils, eosinophils, mast cells, fibroblasts, smooth muscle, and airway epithelium Crucial role in inducing human B-cell proliferation and class switching to IgE in presence of CD40; suppresses the induction of inflammatory ILs, activates STAT6

Table 1.5. (Continued)

Name	MW (kD); chromosomes, primary sources and targets, principal biological effects
IL_{14}	(53) Sources: T and B lymphocytes Effects: Activated B lymphocytes: a) Expands clones b) Suppresses antibody secretion c) Enhances selected subpopulations d) Promotes long term growth in vitro Monocytes: release of ILs
$IL_{14}R$	Binding of IL_{14} increases expression of $IL_{14}R$, as well as in intracellular cAMP, DAG and Ca^{++} levels
IL_{15}	(*15*; *4q31*) Sources: Stromal cells, monocyte-macrophages, fibroblast cell lines, epithelial cells, and in various tissues such as muscle, placenta, etc. Effects: T lymphocytes: growth factor Powerful chemoattractant Stimulates proliferation sharing its functions with IL_2R β and γ chains and the only α chain possessed T- and NK-cell clones: proliferation LAK, NK and CTL cells: activation and differentiation B cells: proliferation and differentiation Human tonsillar B cells stimulated by CD154: proliferation and Ig synthesis γδ subpopulations: proliferation and differentiation Mast cells: stimulation STAT3/STAT5 and JAK1/JAK3: phosphorylation Additional effects: IL_{15} presence in several fetal tissues suggests a role in differentiation and maturation of fetal immune system Shows several biological activities similar to IL_2, for example the capacity to stimulate T-cell proliferation and induction of cytotoxic T lymphocyte and IL-activated killer cells
$IL_{15}R$	(58–60) Forms a new family with CD25; the common γc chain is part of this receptor Sources: T-cell lines, macrophage lines, diffused in non-lymphoid cells and tissues Induces proliferation and differentiation of activated B cells
IL_{16}	(50–60) Sources: Activated CD8 lymphocytes, airway epithelial cells Effects: T lymphocytes: chemotactic action binding to CD4 receptor Eosinophils: chemotaxis Additional effects: Expression of HLA class II and IL_2R Suppresses HIV replication
IL_{17}	Has 5 members, $IL_{17}A$, $IL_{17}B$, $IL_{17}C$, $IL_{17}E$ (IL_{25}), and $IL_{17}F$ (ML-1) Sources: a) CD4 memory and CD8 lymphocytes and TcR-αβ b) Spleen $CD4^+$ cells and neutrophils c) IL_{15} able to induce IL_{17} release from purified spleen $CD4^+$ cells and airway neutrophils and could lead to IL_{17} production following bacterial infection Effects: T cells: proliferation Fibroblast: proliferation Stimulates production and expression of ILs by macrophages, epithelial and endothelial cells, and fibroblasts

Table 1.5. (Continued)

Name	MW (kD); chromosomes, primary sources and targets, principal biological effects
$IL_{17}R$	(98, 22) Sources: Triple negative thymocytes, T-cell clones and cell lines Effects: Enhances T-cell proliferation induced by PHA, activation of NF-κB, IL_6, IL_8 and expression of CD54; the soluble form instead inhibits T-cell proliferation and IL_2 production
IL_{18}	(24; *11q22.2–22.3*) Initially described as an IFN-γ-inducing factor; is closely related to the IL_1 family in terms of structure and pro-inflammatory properties Sources: Activated macrophages, airway epithelial cells, Kupffer cells, dermal keratinocytes, osteoblasts, adrenal cortex cells, and intestinal epithelial cells Effects: Activation of both CCL and CXCL chemokines Activates NF-κB, expresses Fas ligand, induces human HIV Synergizes with IL_{12} and anti-CD40 to induce B cells to express IFN-γ Stimulates T cells for IFN-γ production and growth promotion, also in the absence of T cell antigen receptor engagement Stimulates T-cell proliferation and potentiates the Th1-driving capacity of IL_{12}p70 With IL_1 is a key molecule in both the innate and adaptive immunity and is member of a larger family of related receptors, some of which contribute to host defense Also enhances Th2 cytokine production (IL_4 and IL_{13}) and regulates IgE production in vivo in the absence of allergen
$IL_{18}R$	Recruits IRAK and IL_1R-activating kinase and NF-κB-inducing kinase (see above) One of the IL_{18}R chains is the IL_1R-related protein, a member of the IL_1R/Toll-like receptor (TLR) superfamily
IL_{19}	(*1q32*) Shares 21% amino acid identity with IL_{10} and binds to IL_{20}R Signals through a receptor complex that is also utilized by IL_{20} and IL_{24} Two distinct IL_{19} mRNA species differ in their 5′-sequences IL_{19}, IL_{20}, IL_{22}, and probably also IL_{24} could form a single subfamily of helical ILs Sources: B cells and monocytes Effects: Signaling via STAT3, induce JAK-STAT signal transduction pathway through a specific receptor complex IL_4 and IL_{13} potentiate IL_{19} gene expression in LPS-stimulated monocytes GM-CSF directly induces IL_{19} gene expression in monocytes
$IL_{19}R$	
IL_{20}	(*1q32*) a new member of the IL_{10} family Sources: Skin (where its overexpression leads to skin abnormalities) and trachea Effects: Activates a STAT3-containing signal transduction pathway Skin differentiation and keratin expression Pro-inflammatory effects on keratinocytes and possible central role in the epidermal response to inflammation Stimulates chemotaxis and antimicrobial activity of myeloid cells
$IL_{20}R1$	Both its subunits are expressed in keratinocytes throughout the epidermis, recognizes IL_{19} and IL_{24}
$IL_{20}R2$	Also on certain endothelial and mononuclear cells, recognizes IL_{10} and IL_{22}
IL_{21}	(4q26–q27), IL_9-induced factor maps to the same locus as the IL_2 gene, separated by roughly 180 kb Sources: Activated peripheral T cells

Table 1.5. (Continued)

Name	MW (kD); chromosomes, primary sources and targets, principal biological effects
	Effects: Proliferation and maturation of NK cells populations from bone marrow Proliferation of mature B-cell populations costimulated with anti-CD40 Proliferation of T cells with or without anti-CD3 costimulation in concert with IL_2, IL_{15} and, to a lesser extent, with IL_7
$IL_{21}R$	(*16p11*) With the first exon situated just 39 kb from the $IL_4R\alpha$ locus, the common γc chain is part of this receptor Sources: Stromal cells in the bone marrow or thymus Resting B cells Cell lines of B, T, and NK lineages Human $CD23^+$ and $CD56^+$ Associated with JAK1, JAK3 and Tyk2
IL_{22}	(*12q15*), or IL-TIF, another member of the family of IL_{10} homologs, located on human chromosome *12q*, where several *loci* potentially linked to asthma and atopy have been identified by genetic studies, particularly in the *12q13.12–q23.3* region. More precisely, it is located on chromosome *12q15*, at 90 kb from the IFN-γ gene, and at 27 kb from the IL_{26} gene, which codes for another IL_{10}-related cytokine. In the mouse, the IL_{22} gene is located on chromosome 10, also in the same region as the IFN-γ gene Sources: Th1 cells, IL_9 Pleiotropic effects: Activates STAT1, 3, 5; as IL_{10}, stimulates monocytes to make TNF Can activate IFN-γ-like biological responses such as HLA class I induction and STAT activation Target tissue is the liver, where it induces acute-phase reactants and is active in the innate immunity In keratinocytes IL_{22} activated STAT3 and directly increased the expression of β-defensin and β-defensin 3
$IL_{22}R$	(1) Complex composed of two subunits, the $IL_{22}R\alpha$ chain and the second $IL_{10}R\beta$ chain: both chains are required for signaling, each chain alone is capable of binding IL_{22}
$IL_{22}BP$	(*6q24.1–25.2*). This receptor, named IL_{22} binding protein, inhibits IL_{22} activity by binding IL_{22} and preventing its interaction with the functional $IL_{22}R$ complex, but $IL_{22}BP$ often fails to block IL_{22} activity Both chains of the $IL_{22}R$ complex are ligand binding chains; however, none of them is capable of transducing IL_{22}-signaling alone. Both chains are necessary to assemble the functional receptor complex able to induce signaling after binding IL_{22}
IL_{23}	A p19-p40 heterodimer structurally related to IL_6, G-CSF, and the p35 subunit of IL_{12} sharing homology with members of the IL_6/IL_{12} family of ILs, also combining the IL_{12p40} subunit with its subunit p19, requires interaction with $IL_{12}R1$ and $IL_{23}R$ with a cytoplasmic STAT4 binding domain Source: Hemopoietic cells, bone-marrow-derived DCs Effects: Th1 activation T-cell memory Activates $IL_{17}E$ and STAT4 in blast T cells Induces exclusively the proliferation of naive and CD45RO memory T cells and of related IFN-γ
$IL_{23}R$	Associates with $IL_{12}R\beta1$ in a combined deficiency
IL_{24}	(*1q32*) (melanoma differentiation-associated factor MDA-7) Sources: PBMCs and melanoma (MDA-7) Induced by: IFN-β and mezerein Effects: Signaling by STAT3 Targets: tumor cells Biological effects: Tumor and apoptosis inhibition

Table 1.5. (Continued)

Name	MW (kD); chromosomes, primary sources and targets, principal biological effects
IL_{25}	Also called $IL_{17}E$ Sources: Th2 cells Effects: Induces Th2-like IL_4, IL_5, and IL_{13} gene expression through a subset of APCs expressing high levels of HLA class II Amplifies systemic and localized allergic-type inflammatory responses by its actions on several cell types Increases serum IgE, IgG, and IgA levels, induces blood eosinophilia and pathological changes in the lungs and digestive tract
IL_{26}	(*12q15*) (= AK155) (a factor discovered after overexpression in human T lymphocytes after transformation by the simian rhadinovirus herpesvirus saimiri) Sources: T cells Mast cells after FcεRI cross-linkage Effects: IL_{26} and IL_{19} bind to the $IL_{20}R$ complex, composed of cytokine receptor family 2–8/$IL_{20}R\alpha$ and $IL_{20}R\beta$ (type I). IL_{26} or $IL_{10}R$ 2 chains and $IL_{20}R1$, but not IL_{21}, bind to the receptor complex, composed of $IL_{22}R$ and $IL_{20}R\beta$ (type II) Enhances secretion of IL_8 and IL_{10}, and cell surface expression of CD54 Activates the JAK/STAT signaling pathway, inducing a rapid tyrosine phosphorylation of STAT1 and STAT3 in cells expressing $IL_{20}R1$ and $IL_{10}R2$ IL_{26} may play a role in local mechanisms of mucosal and cutaneous immunity
$IL_{26}R$	Formed by a combination of two receptor subunits, $IL_{20}R1$ and $IL_{10}R2$, which dimerize to generate the receptor engagement and results in phosphorylation of STAT1 and STAT3
IL_{27}	p28 protein, a further member of the IL_{12} family involved in Th1 initiation A heterodimer composed of two chains, p28 (IL_{30}) and EBI3, analogous to $IL_{12}p40$ and $IL_{12}p35$ (p28-related protein), respectively, and a p40-related protein The heterodimer is expressed by APCs Sources: Activated APCs, macrophages and DCs Effects: Involved in Th1 initiation Triggers clonal proliferation of antigen-specific naïve but not memory $CD4^+$ T cells and synergizes with IL_{12} in IFN-γ production by naïve $CD4^+$ T cells Activates STAT-1, -2, -3, and -5, JAK-1 and -2 in naïve $CD4^+$ T cells Promotes polarization towards a Th1 phenotype with expression of IFN-γ IL_{27} stimulation induced phosphorylation of STAT-1 and expression of T-bet and $IL_{12}RB2$ in naïve $CD4^+$ T cells. Together with IL_{12}, IL_{27} augmented IFN-γ secretion in naïve $CD4^+$ T cells Suppresses $CD4^+$ T cell proliferation and Th2-II-like production Activates Th0 and Th1 cells Activates STAT-1 and induces T-bet expression and IgG2a in stimulated B cells, together with WSX-1 limits innate and adaptive components of type 2 immunity at mucosal sites
$IL_{27}R$	One subunit is WSX-1 Its engagement results in IFN-γ production
$IL_{28}A$	(19) IFN-λ2 mediates antiviral activity in cells in response to viral infection
$IL_{28}R$	Includes receptors for type I and type II IFNs (IFN-αR1, IFN-αR2, IFN-γR1, and IFN-γR2) and receptors for $IL_{10}R$, $IL_{20}R$, and $IL_{22}R$
$IL_{28}B$	(19) IFN-λ3 mediates antiviral activity in cells in response to viral infection
IL_{29}	(19) IFN-λ1 mediates antiviral activity in cells in response to viral infection
IL_{30}	(16p11) a member of the long-chain 4-helix bundle IL family, and EBI3, form the IL_{27} heterodimer Termed p28 because of its molecular mass

Table 1.5. (Continued)

Name	MW (kD); chromosomes, primary sources and targets, principal biological effects
IL_{31}	The oncostatin M receptor (OSMR) is part of receptor complexes for OSM and IL_{31} a four-helix bundle IL Sources: Preferentially Th2 cells Effects: Skin tropism Signaling events are triggered by JAKs constitutively binding to membrane-proximal receptor regions
$IL_{31}R$	Gp130-like receptor (GPL) recruits JAK1, JAK2, STAT-1, STAT-3, STAT-5 signaling pathways, as well as the Pi3 kinase/AKt cascade
IL_{32}	Exists as four splice variants Sources: Human peripheral lymphocyte cells after mitogen stimulation, human epithelial cells by IFN-γ, and NK cells after exposure to the combination of IL_{12} and IL_{18} Effects: Induces human TNF-α, and IL_8 in THP (Th precursors) monocytic cells Activates nuclear factor-κB (NF-κB) and p38 mitogen-activated protein kinase (MAPK); may play a role in inflammatory/autoimmune diseases
IL_{33}	Sources: Member of the IL_1 family Effects: Mediated via IL_1R ST 2 Activates NF-κB and MAP kinases Drives production of Th2-associated ILs
G-CSF	(18–22; *17q11–21*) Granulocyte colony-stimulating factor Favors growth of myeloid progenitor cells
GM-CSF	(22; *5q31–33*) Sources: Activated T cells, monocytes, macrophages, fibroblasts, bone marrow stromal cells Effects: Stimulates growth of hematopoietic precursor cells, mostly of granulocytes/monocytes; modifies the functions of mature granulocytes Enhances neutrophils (inhibiting migration), macrophages and eosinophils (paraeosinophil IL) Induces phagocytosis, production of eicosanoids, ADCC, platelet production by megakaryocytes Promotes growth and maturation of LCs to APCs
IFN α, β, γ (interferons) produced by Th1 cells;	Common properties Hematopoietic stem cell growth B cells: proliferation NK cells, TCT: activation Macrophages: phagocytosis and accessory activities (IFN-γ > IFN-α, β) Additional effects: IL_1 and IL_2 synthesis (IFN-γ > IFN-α, β) Induction of HLA molecules of class I (IFN-γ > IFN-α, β) and class II Production of FcR Production of Igs Antiviral activity (IFN-γ < IFN-α, β): inhibition of viral replication and of tumor growth Differentiation of leukemia cells of promyelocytic and monoblastic origin Additional actions (IFN-γ > IFN-α, β) Differentiation of erythroleukemia cells Antibody production Influence on CMI
IFN-α	(16–27) (*9p22*) Sources: Mainly monocytes, macrophages, and lymphocytes, secondarily B cells, NK cells Stimulates macrophages and B differentiation Has activities similar to IL_{12} inducing the differentiation of allergen-specific T cells into Th0 or Th1 cells Inhibits virus-infected cells

Table 1.5. (Continued)

Name	MW (kD); chromosomes, primary sources and targets, principal biological effects
IFN-β	(20) Sources: Macrophages and granulocytes, and also fibroblasts Effects: On B proliferation
IFN-γ	(20×25; *12q22–24*) Sources: Th1 and T γδ lymphocytes, CD8 cells, activated NK cells and macrophages Has a central role in the immune response, since stimuli activating T lymphocytes induce IFN-γ synthesis Effects: T lymphocytes a) Inhibits Th2 proliferation inducing their shift to Th1 b) TCT and NK cells: induction and proliferation B lymphocytes a) Differentiation inhibiting IgE antibodies production either directly or down-regulating FcεRI expression by B cells and of CD23 by IL_4 b) Expression of IgG Fc Activated B lymphocytes: proliferation and differentiation, in synergy with IL_2 Additional cells: Monocytes, macrophages, mast cells, DCs, fibroblasts, and T lymphocytes: induces or increases the expression of HLA class II Eosinophils: increases the cytotoxic activity and the adhesion to endothelium via the expression of CD54 Macrophages and neutrophils: activates and enhances their phagocytic and bactericidal activities Macrophages: induces chemotaxis and increases survival Mast cells: prolongs the life span Neutrophils, monocytes and macrophages: activation to promote ADCC reactions NK cells: activation Pluripotent stem cells: growth and activation Additional effects: Antagonizes the action of IL_4 and inhibits the IL_4-induced IgE production by B lymphocytes Inhibits secretion of IL_{10}
IFN-κ	Expressed in epidermal keratinocytes Sources: Resting DCs and monocytes Effects: Release of several cytokines from both monocytes and DCs Inhibits inducible IL_{12} release from monocytes
IFN-λ 1–3	Correspond to $IL_{28}A$, $IL_{28}B$ and IL_{29}
IFN-λR1	One of the two receptors utilized by all three IFN-λ proteins, the other is $IL_{10}R2$
IFN-τ	Suppression of proliferation and inhibition of IgE production
IFN-ω limitin	Sources: Mature T lymphocytes in spleen and thymus Bronchial epithelial and salivary duct cells Effects: Induces apoptosis in pre-B cell lines Reduces the proportion of CD45R-positive cells Enhances the antigen-induced cytotoxic lymphocytes Suppresses the antigen-induced T-cell proliferation
IFN-αβR	Consists of two subunits, IFNAR-1 and IFNAR-2
IFN-γR	Receptors 1 (*6q23–24*) and 2 Expressed on nearly all cell types Coupled to the JAK-STAT signaling pathway Mice lacking this receptor or STAT1 display a profound disruption of both innate and adaptive immunity

Table 1.5. (Continued)

Name	MW (kD); chromosomes, primary sources and targets, principal biological effects
M-CSF	(45–70; *5q31–33*) Monocyte/macrophage-colony stimulating factor Promotes proliferation and differentiation of monocyte/macrophages and the activation of NK cells
TGF-α	(5, 6) transforming growth factor, eosinophil generation
TGF-β	(12.5–25) the TGF-β family contains five homologous members, TGF-β 1 and 3 are encoded by single genes on chromosomes 19.1, and 14, respectively; TGF-β may be a Th3 IL Sources: Activated B and T cells, macrophages, platelets; has opposing actions: a) Promotes proliferation of fibroblasts and collagen synthesis, increases IgA production by B cells b) Inhibits almost all other cells, including T and B lymphocytes, blocks IgM and IgG synthesis, IL_1R production and HLA molecules expression c) Eosinophil generation
TGF-βRI	Recognizes Smad-2 and -3 that transduces TGF-β-triggered signals together with Smad-TGF-βR
TGF-βRII	Causes recruitment and phosphorylation of TGF-βRI and formation of a receptor complex
TGFR-1	CD120a
TGFR-2	CD120b
TNF α, β	Tumor necrosis factors Effects: Express HLA class I and II and manifest antiviral activity Epithelial cells: induce the proliferation by G-CSF Endothelial cells: interact to produce CD54 Monocytes: stimulate both motility and production of IL_6 and IL_8 Neutrophils: potent activators and adhesion-inducing, promote chemotaxis and degranulation B cells: modulate immune responses mediated by IL_4
TNF-α	(17–51) (*6p21.3*) Sources: Monocyte-macrophages, mast cells, PMNs, endothelial, NK and activated T cells Effects: Macrophages, neutrophils, eosinophils: activation and expression of HLA class I and adhesion molecules B cells: activation Hepatocytes: synthesis of acute phase proteins Muscle cells: induces endotoxic shock Additional effects: Favors delayed-type and contact hypersensitivity Manifests an inhibiting effect on LCs
TNF-β	(20–25) Sources: Activated B and T (Th1] lymphocytes Effects: On neutrophils and on the proliferation and differentiation of B lymphocytes Favors the expression of adhesion molecules
TNFR-SF	Includes CD30, CD40, CD95, CD97

Several other molecules have been described: *BaDF* basophil differentiation activating factor, *EAF* eosinophil activating factor, *ECEF* eosinophil cytotoxicity enhancing factor, *EGF* epidermal growth factor, FGF fibroblast growth factor; *MIF* (monocytes) migration inhibiting factor, *NGF* nerve growth factor, *PDGF* (30–32) platelet derived growth factor, *SCF* stem cell factor.
IL_4R, IL_7R, IL_9R, $IL_{13}R$, $IL_{15}R$, and $IL_{21}R$ have the common γc chain; cytokine receptors are dealt with also in Table 1.2.
EBI3 Epstein-Barr virus-induced gene 3, * chemokines, see below, *WXS-1* WSXWS (Trp-Ser-X-Trp-Ser).
Data from [4, 14, 34, 45, 50, 52, 55, 66, 68, 78, 92, 99, 118, 119, 126, 128–130, 140, 141, 152–154, 156, 158, 167, 172, 181, 213, 219, 220, 240, 245, 249, 258, 272, 278, 318, 326, 372, 377, 383, 387, 398, 399, 412, 413, 421, 426, 437, 455, 461, 474, 480, 481, 487, 517, 523, 526, 528, 532, 534, 560, 562, 607, 641, 669, 693] and PubMed ID: 14764690.

Table 1.6. Regulation of isotype switching and HLA expression by some ILs

ILs	Immunoglobulins	HLA class
IL_3		II
IL_4	IgG_1 and IgE	II
IL_5	IgA	I
IL_{10}		II
IL_{12}	IgE	
IFN-α and -β		I/II
IFN-γ	$IgG_{2α}$	I/II
TGF-β	IgA	II
TNF-α and -β		I

Table 1.7. Synergic activities of ILs

Synergy	Cytokine synergic effects
IL_1, IL_3, IL_5	Production of granulocytes, eosinophilopoiesis
IL_2, IL_4	Enhancement of T lymphocytes
IL_2, IL_5, IL_6	Synergy with IL_4 and IL_{13} in promoting IgE production
IL_2, IL_{12}	Generation of TCT and LAK
IL_3, IL_{11}	Megakaryocytopoiesis
IL_3, IL_4, IL_{10}	Differentiation of B lymphocytes, production of mast cells
IL_3, IL_6	Hemopoiesis
IL_3, IL_4, IL_{11}	Cooperation in several functions
IL_3, IL_9	Promotion of the growth of some mast cell lines
IL_4, IL_6	Hemopoiesis
IL_4, IL_{13}	Isotype switching ε
IL_5, NGF	Production of basophils/mast cells and eosinophils
IL_{10}, IL_2, IL_4	Growth of immature thymocytes
GM-CSF, NGF	Production of granulocytes

Table 1.8. Activity of ILs and chemokines in atopic diseases

Effects	Cytokines and chemokines	Activity
IgE regulation	IL_4, IL_{13}	ε Isotype switching
	IL_4	Generation of IL_4 producing CD4
	IL_2, IL_5, IL_6	Synergy with IL_4 and IL_{13}
	IFN-γ, TGF-β	Inhibit IL_4 and IL_{13}
	IL_{12}	Enhances production of IFN-γ by T cells and NK cells
IgA regulation	TGF-β	α Isotype switching
Eosinophils	IL_3, IL_5, GM-CSF, RANTES*, MIP-1α*, eotaxin, MCP-3* IL_1, TNF	Eosinophilopoiesis Eosinophil chemotaxis and activation Eosinophil activation
Mast cells: development and activation of GM-CSF	IL_3, IL_9, IL_{10}, NGF, H-CSF	Mast cell growth factors Inhibits mast cell proliferation
	MIP-1α*, MCP-1*, MCP-3*, RANTES*	Basophil chemotaxis, histamine release
	IL_8	Inhibition of histamine release
Inflammation	IL_1, IL_4, IL_6, IL_8, GM-CSF, G-CSF, TNF, IFN-γ	Activation of neutrophils
	IL_1, IL_3, IL_5, TNF, GM-CSF	Activation of eosinophils
	IL_1–IL_4, GM-CSF, M-CSF, TNF, IFN-γ	Activation of macrophages
Anti-inflammatory	IL_{10}, TGF-β	Inhibit IL production and T cell and/or monocyte function

EBI3 Epstein-Barr virus-induced gene 3, * chemokines, see below.
Data from [4, 14, 34, 45, 50, 52, 55, 66, 68, 78, 92, 99, 118, 119, 126, 128–130, 140, 141, 152–154, 156, 158, 167, 172, 181, 213, 219, 220, 240, 245, 249, 258, 272, 278, 318, 326, 372, 377, 383, 387, 398, 399, 412, 413, 421, 426, 437, 455, 461, 474, 480, 481, 487, 517, 523, 476, 528, 532, 534, 560, 562, 607, 641, 669, 693] and PubMed ID: 14764690.

Table 1.9. Leukocyte surface molecule superfamilies

Superfamily domains	Examples	Common functions in immune system
Complement control proteins	CD21, CD35, CD62P	Control of complement cascade
IL receptors	$IL_2R\beta$ (CD122), $IL_6R\alpha$ (CD126)	Growth factor receptors
Epidermal growth factor (EGF)	CD62L, CD62P	Cell surface ligand binding
Fibronectin type II	Mannose receptor	Polyvalent functions
Fibronectin type III	Integrin β4 (CD104), IL_7R (CDw127)	Polyvalent functions
Immunoglobulin V set	IgV, TcRV, CDw90	Adhesion, recognition
Immunoglobulin C1 set	β_2M, HLA class I α3 domain	Adhesion, recognition
Immunoglobulin C2 set	CD2 domain 2, CD3ε	Adhesion, recognition
Integrins	CD11/CD18, CD49	Adhesion
Lectin C-type	Mannose receptor, CD23, CD62L	Carbohydrate binding
Lectin S-type	CD11b/CD18	Carbohydrate binding
Leucine-rich glycoprotein repeats	CD42a, CD42b	Protein–protein or –lipid interactions
Link	CD44	Hyaluronic acid/chondroitin sulfate binding site
LDL receptor	LDL receptor	Lipoprotein binding, NN function
Ly-6	CD59	NN
HLA	Class I α1, α2, II α1, β1 domains	Recognition
NGF receptor	CD27, CD40	NN
Rhodopsin (serpentine receptor)	IL_8R (CDw128), C5aR, CD5, CD6	G-protein coupled receptor
Somatomedin	PC-1	NN
Transmembrane 4 pass	CD9, CD37, CD53	NN
Phosphotyrosine phosphatase	CD45	Signal transduction
Tyrosine kinase	M-CSFR, c-kit (CD117), lck	Signal transduction

Modified from [27].
IL interleukins, *LDL* low-density lipoproteins, *M-CSFR* Monocyte/macrophage-colony stimulating factor receptor, *NN* not known, *PC-1* plasma cell surface antigen-1.

PubMed ID: 12734330 has given a full description of IL_{30}: according to the HUGO Gene Nomenclature Committee, the symbol p28 (IL_{27}) should be used. It was finally identified as one subunit of $IL_{27}R$ [664].

Recently, the IFN family has been enriched by several new acquisitions (Table 1.5): type I IFN family contains IFN-α, IFN-β, IFN-κ, IFN-λ, IFN-ω, IFN-τ and IFN-ζ. Limitin is IFN-ω, an IFN-like IL that has approximately 30% sequence identity with IFN-α, IFN-β, and IFN-τ [398, 399]. IFN-κ, like IFN-β, induced the release of several ILs such as IL_{28} and IL_{29} from both monocytes and DCs, without the requirement of a costimulatory signal [390]. TLR-9 (Toll-like receptor-9) stimulation by CpG (cytosine-phosphate guanine) DNA induced the expression of all IFN-α, -β, -ω and -λ subtypes in PDCs (plasmacytoid dendritic cells), whereas TLR-4 stimulation by LPS (lipopolysaccharide), or TLR-3 stimulation by poly I:C, induced only IFN-β and IFN-λ gene expression [88]. A new IFN, STAT1-induced FLN29, might be involved in the termination of LPS signaling [335]. Three genes on human chromosome 19 have been found to encode distinct but similar proteins, which are called IFN-λ1, IFN-λ2 and IFN-λ3, and are designated as $IL_{28}A$, $IL_{28}B$ and IL_{29}, respectively. It is suggested that these ILs are functionally referred to as type III IFNs because of their unique primary sequence homology and receptor usage [88]. A distinct receptor complex is utilized by all three IFN-λ proteins for signaling and is composed of two subunits, a receptor designated as IFN-λR1 and a second known as $IL_{10}R2$, which signal through the JAK-STAT pathway [274, 519].

This receptor mediates the tyrosine phosphorylation of STAT1, STAT2, STAT3, and STAT5 (signal transducers and activators of transcriptions). Activation of this receptor by IFN-λ can also inhibit cell proliferation and induce STAT4 phosphorylation, further extending functional similarities with type I IFNs [88]. T lymphocyte origin is from pluripotent stem cells, initially arising during embryonic development from hemopoietic tissues of the yolk sac, then the early stages continue in the

fetal liver. Unlike B cells, maturation does not occur *in situ,* but from bone marrow-derived progenitors undergoing maturation in the thymus, where the greater part of cells multiply and differentiate into immunocompetent lymphocytes. In the thymus, functionally competent cells are exported into peripheral lymphoid compartments in accordance either with thymus ability to produce different soluble factors or with particular intercellular interactions. Early in development, thymocytes express several cell surface molecules, including CD2 and CD7 (CD7 deficiency is described in Chap. 22), but lack both DN CD4/CD8 and CD3. Precisely in the thymus, via a series of intermediate steps, DN cells change into DP $CD4^+8^+$ thymocytes. As thymocytes mature into T cells, they express increasing levels of TcR, finally turning into $CD4^+8^-$ and $CD4^-8^+$, becoming MP. Therefore, during early stages of thymus phases, thymocytes express indifferently both CD4 and CD8; the association of either subset with TcR will show whether cells recognize MHC class I or II molecules, thus regulating subsequent differentiations [255]. IKK (inhibitor of κB kinase)-induced NF-κB (nuclear factor κB) activation, mediated by either IKK1 or IKK2, is a pivoral factor for the generation and survival of mature T cells, and IKK2 has a crucial role in regulatory and memory T cell development [503]. NF-κB is also activated by IL_{32} [258].

T cells have been identified by their ability to bind sheep erythrocytes to form E rosettes (red cells), and more sensitive binding of monoclonal antibodies (mABs) identifies their TcR, referred to as CD2. However, the most commonly used marker for T cells is CD3 associated with TcR. Further definition of cell surface protein antigens derives from rDNA technology. The molecules expressed on lymphocyte membranes, characterizing diverse phases of the differentiation process of T subsets, allow their identification and are overall assayed by means of lymphocyte differentiation antigens designated with CD terminology (CD1–CD342) defining cellular antigens. Such markers also distinguish nonhematopoietic cells involved in both innate and acquired immunity, permitting their recognition via analysis of cell surface molecules expressed on lymphocytes during stages of cell development and/or activation. CDs constitute a group still under definition and classification [470, 501] and recently revisited [4, 262, 343, 604]. These CD cell surface markers have been grouped into T cells, B cells, and NK cells, among others. The grouping is somewhat arbitrary because essentially none of such CD markers is restricted to a single cellular lineage.

Uniformity of *nomenclature* is assessed via monoclonal antibody technology, which unlike polyclonal ones prepared from immunized animals all have the same antigen specificity, and are immunologically completely homogeneous since each antibody is synthesized from cells derived from a single clone. Briefly, a hybridoma can readily be formed by fusing a single normal B cell suspension from immunized mice to cells of continuously replicating tumor cells: hybrid cells so obtained show a unique association of antibody specificity and proliferate indefinitely. The cells can also be grown as individually cloned and screened to produce antibodies with desired specificity [414]. Periodically specialists meet in international workshops to compare specific reagents.

The CD4–CD8 dichotomy is considered out-of-date, because a few CD4 have suppressor/cytotoxic and a few CD8 have helper functions [30]. We refer to CD4 or CD8 cells to specify either helper or suppressor/cytotoxic functions, unless otherwise specified [30]. CD4 cells express a CD4 surface antigen, a monomer of 60 kD with four extracellular Ig-like domains, while CD8 is associated with CD8 molecules, αα or αβ dimers each of 34 kD, linked by -S-S bonds, both cells with a short cytoplasmic tail interacting with $p56^{lck}$ [4]. CD4 and CD8 are encoded not by MHC, but by genes on chromosomes 12 and 2, respectively; quantitative and qualitative differences make it possible to distinguish CD4 from CD8 cells present in the bloodstream with a 2:1 ratio [481]. However, CD4 and CD8 functions are at least twofold, since their extracellular portions bind to MHC molecules on the APC surface, thus acting as adhesion molecules. Another major function of CD4 and CD8 is to act as signal transducers in T cells due to their intracellular portions linked to specific kinases; thus CD4 and CD8 are phosphorylated following antigen binding to TcR [36].

Unlike B cells, T cells can interact with antigens directly, even in solution. Antigen recognition by T lymphocytes occurs only when antigens are inside or on the surface of a cell, more precisely when antigens are presented by APCs associated in man with HLA (human leukocyte antigens). Such *double* recognition of both antigens and HLA molecules is critical for T-cell activation, whether immunoregulatory or cytotoxic. We can therefore conclude that in the thymus T lymphocytes are committed to recognizing HLA antigens, and also that tolerance starts in the thymus following TcR affinity for HLA molecules, attributing to HLA a crucial role in the *recognition* process.

Originally described in mice, two phenotypes were defined showing that T dichotomy is actually the heterogeneity of CD4 cells. However in man there are three subpopulations (Tables 1.10–1.12) [52, 69, 130, 158, 220, 249, 455, 470, 650], divided into three helper (h) subsets based on different patterns of ILs they secrete [643].

These subsets are: Th1 T cells predominantly involved in DTH reactions, Th2 T cells apparently specialized in IgE-mediated reactions, and Th0 T cells [159, 455]. Th0 cells represent a heterogeneous population of effector cells, mostly naive lymphocytes that in the absence of signals clearly driving differentiation into Th1/Th2 T cells have never before been activated and thus have not acquired the ability to secrete a mature profile of ILs, modulating their effects with respect to

Th2	–	<0.1	<0.1	<3.0
	+	31.9	0.2	39.9
Th1	–	<0.1	<0.1	<3.0
	+	<0.1	24.8	0.8

Data from [642].

the type and quantity of ILs produced in the microenvironment and the nature of responsive cells [643].

The conventional definition of a Th1 or Th2 cell depends strictly on the secretion of IFN-γ or IL_4. Th1 cells secrete IFN-γ but do not secrete IL_4, whereas Th2 cells secrete IL_4 but not IFN-γ. T cells secreting neither IFN-γ nor IL_4 are neither Th1 nor Th2 cells [470]. A subset of $CD4^+$ T-cell lines, which secrete TGF-β but not IL_4 or IFN-γ, has been termed a Th3 cell [470]. In addition to Smad-2/4 of TGF-βRI, there is Smad-7 which blocks activated receptors and interferes with phosphorylation of both Smad-2 and Smad-3 (G. Monteleone, pers. comm. 15. 2. 2005) [156]. An IL_{10}-producing subset has been termed Tr1 (T-regulatory 1) [470]. Another family, that of T-cell Ig domain and mucin domain (TIM) proteins, is identified to be expressed on T cells [320]. The quantitative difference of ILs synthesized by T cells is remarkable, as demonstrated either by production of high levels of IL_4 and IL_5 by Th2 T cells (GATA-3 is critical for expression of the IL_5 gene in Th2 cells) [678], while that of IFN-γ is significantly lower, or by nearly specular IL secretion by γδ Th1 T cells [665]. Thus, either GATA-3 or single-nucleotide polymorphisms in the IL_{18} gene might be relevant in inducing the very broad Th2 phenotype observed in atopic subjects [278]. A specific factor triggering differentiation into Th1 lymphocytes has been identified in IL_{12}, which in a dose-dependent manner increases IFN-γ levels in TcR of antigen-specific T cells while antagonizing an IL_4-induced B-cell switch to IgE production. It also appears that IFN-γ IL_{12}-mediated production is necessary to stimulate complete expression of Th1 phenotype [105]. For the outcome of CD4 T cell differentiation, the balance between T-bet (TFs T-box expressed in T cells) and GATA-3 is critical [665]. However, T-bet initiates Th1 lineage development from naive *Thp (Th precursors)* cells, both by activating Th1 genetic programs and by repressing the opposing Th2 programs [556].

CD4 T cells coming from thymus, although they can differentiate either into Th1 or Th2 T cells, are not predestined to IL production [644]: the current theory is that only at the moment of antigen presentation do uncommitted cells begin to secrete ILs, with polarization of immune processes into a model of type I or IV reactions [290]. As yet, it is not clear how CD4 T cells distinguish the antigens they encounter, because there is no proof that such antigens are endowed with specific structural features allowing CD4 to recognize them [469]. Since T-cell antigen specificity is prearranged in the thymus apparently at random, it is challenging to imagine how CD4 cells on the point of recognizing a given antigen can be programmed at this stage of development, so that they can express a defined set of ILs at the subsequent encounter. To undo the Gordian knot, the present dogma is that in any inflammatory site both Th1 and Th2 lymphocytes differentiate from common post-thymic antigen-specific ThP, while an intermediate point between ThP from one side and Th1/Th2 T cells from the other is represented by Th0 [473]. Hitherto, cell surface marker analysis for Th1-Th2 T-cell subset identification has yielded unconvincing results. Recent studies show that Th1-Th2 T cells differentiate in conformity with CD30 expression, with CD27, CD40, CD95/Fas, OX40 and other molecules belonging to the receptor superfamily of TNF/NGF (TNF-R = CD120a, CD120b and NGF-R), with low or hardly noticeable levels of Th1 and high levels of Th2 cells (and of CD8) [388]. CD30 is therefore viewed as a specific marker and if stimulated as a cofactor of T lymphocyte differentiation, preferentially toward the Th2 T-cell phenotype, which expresses CD30 on its membrane [113]. An interesting observation is that a biologically significant number of CD30 markers are present in the bloodstream of patients allergic to grasses (and not in controls) in concomitance with pollination periods [113]. A soluble CD30 (sCD30) (88 kD) is increased in serum of HIV (human immunodeficiency virus) seropositive patients [4]. Recent data show that the LAG-3 molecule (lymphocyte activation gene-3), an IgSF member binding to the nonpolymorphic part of HLA class II molecules, is selectively transcribed into activated Th1 and NK cells, since its expression is correlated with IFN-γ production by Th1 cells and not with that of IL_4 [457]. Of particular

interest is the role of the STAT family of molecules, including SH2 and SH3 (src homology 2, 3) [248], activated by an additional TF, PTK (protein tyrosine kinase) [224]. Two classes of SH2-containing inhibitory signaling effector molecules have been identified: the tyrosine phosphatase SHP-1 and the inositol phosphatase SHIP (SH2-containing inositol polyphosphate 5-phosphatase) interacting with the immunoreceptor tyrosine based inhibitory motif (ITIM) [446]. *STAT6,* activated by IL_4 and IL_{13}, *plays a crucial function related to genes regulating differentiation into Th2 T cells* [248, 523], similarly to *STAT4 phosphorylated* by IL_{12} *for Th1 T cells* [523]. Th2 T cells are thought to have a defect of STAT4 phosphorylation [401]. Thereby STAT4 and STAT6 appear to control Th1 T-cell differentiation [523], while IL_2 and IL_{15} activate phosphorylating STAT3 and STAT5, and IL_4 and IL_{12} activate phosphorylating STAT3 [240].

CD 8 T cells. IL_7 and IL_{15} are crucial for the development of $CD8^-$ T cells within the thymus, and SOCS1 (supressor of cytokine signaling-1) regulates this process by regulating both ILs [441]. CD8 T cells are the main type of effector T lymphocytes, as suppressor and cytotoxic cells. In the first case, they bind one HLA class I/peptide molecule also contacting β_2-microglobulin (β_2-m). A flexible loop of the α3 HLA domain is clamped between the CDR-like loops of two CD8 subunits in the classic manner of an antibody-antigen interaction, precluding the binding of a second HLA molecule [170]. The binding of CD8 to HLA can prime CD8 T-cell precursors that depend on IL_2 (cytotoxic T-cell differentiation factor) (Table 1.5) produced by Th1 cells to be transformed into active cells [349]. CD8 T cells thus activated secrete soluble factors suppressing both Th1 and Th2 T cells, as well as growth of Th2 T cells enhanced by IL_4, thereby down-regulating immune responses and inhibiting activation of B cells [255]. Consequently, eliminating CD8 T cells in immunized mice, the synthesis of IgE antibodies was amplified, whereas it was inhibited when CD8 T cells were deleted prior to treatment, suggesting that there are two different subsets of T suppressors, also because IL_4 inhibits CD8 T cells producing IL_2 and IL_6 and stimulates those secreting IL_4 and IL_5 [255]. CD8 T cells have two distinct patterns with different effects: *type 1 of Th1 T cells (Tc1)* and *type 2 of Th2 T cells (Tc2)* [456, 469]. CD8 Tc1 produces IFN-γ, so the highest production of IL_4 is supported by CD8 absence and anti-IFN-γ presence [349] and IL_4 may encourage Tc2 [470]. Animal data suggest that functionally distinct subsets of CD8 Tc2 T cells may play a significant role in IgE regulation [255, 349]; also in humans, such CD8 trigger isotype switching of B cells to IgE antibodies [105]. In addition, virus-specific CD8 can eventually generate IL_5 with an implicit increase of eosinophilia in airways [100], thus providing key elements to explain clinical links between viral infections and asthmatic exacerbations [105]. As we shall discuss subsequently, infantile atopy is associated with a deficiency of T suppressor cells [142] (Chap. 4).

Once activated by antigens or lectins, *cytotoxic T CD8 lymphocytes* (CTLs) play a prominent role when antibodies are unable to block cytolytic viruses, circulating or present on cell membranes. CTLs associated with HLA class I molecules via a specific receptor recognize viral peptides expressed on target cell surfaces, lysing them independently of antibodies or complement [123]. A first signal causes translocation and secretion of cytotoxic cell granules containing proteins named cytolysins, also known as *perforins* (which perforate target cell membranes) and granzymes also present in NK cell cytoplasmic granules: secretion of such Ca++-dependent proteins leads to cell lysis [322]. Typical is the granule speed when they are directionally released to make contact with target cells [189]. A second signal may induce death via a self-destructive mechanism mediated by Fas/Apo-1 (apoptosine-1) (CD95) [559], activated by contact between effector and target cells [322]. Fas and Apo-1 are identical molecules localized on murine and human cells, respectively [559]. Both are encoded by TNFRSF6 on chromosome *10q24.1* and are based on TcR-mediated recognition of target cells [189] and on increased membrane permeability of target cells: the increase in intracellular fluid polarizes to lysis [421]. The lytic process can be outlined in four steps:

- *TcR-CD8-mediated recognition* in the context of HLA class I molecules, CTL adhesion to antibody coated plasma membrane of target cells forming a CTL-target cell conjugate persisting for a few minutes and mediated by CD11a/CD18/LFA-1 (lymphocyte function-associated antigen-1) interactions with pertinent ligands CD54/ICAM-1 (intercellular adhesion molecule-1) and CD58/LFA-3 and possibly CD2/CD80 molecules
- *Irreversible programming* of lytic equipment with release of perforins, which, when in the contact area of conjugates, form 5- to 16-nm pores, upon which mobilized granules deposit their contents into intercellular clefts by exocytosis
- *Lethal hit* in unidirectional fashion mediated by the release of granule contents
- *Cellular death* by osmotic lysis, or more likely by enhanced fragmentation of nuclear DNA, a process characteristic of programmed cell death (PCD) or ritual suicide, or apoptosis [421]

The lytic process is in perspective unremitting, because cell recycling is activated by new TcR stimulations [189].

NK (natural killer) *cells* (non-T non-B) are morphologically similar to lymphocytes, but somewhat larger with a reniform nucleolus and a cytoplasm rich in large granules, assuming therefore an LGL phenotype [460]. NK cells make up about 15% of peripheral blood lymphocytes, and 3%–4% of splenic lymphocytes, while notable amounts are found in lung interstices, gut mucosa, and liver. IL_{21} and $IL_{21}R$ play a role in NK cell proliferation and maturation from bone marrow [412]. Deriving from precursor cells common to T lymphocytes residing in the fetal liver and bone marrow [193],

together with HLA-restricted CTLs, naturally occurring NK cells lyse a variety of targets with no prior specific sensitization of the host (unlike T cells), regardless of HLA gene restrictions and of antibody or complement. NK cells are thus enabled, along with macrophages and leukocytes, to act as a *first line of defense* playing a critical role in natural resistance against a variety of infectious diseases [289]. NK cells and CTLs are mutually self-regulated: NK-cell limitation of viral replication is higher in the first 3 days, contrary to CD8 lymphocytes developing from their precursors within 5–6 days. Accordingly, there is a complementary balance between innate and acquired immunity, since NK-cell cytotoxicity is temporally accomplished and replaced by that of CD8 T cells [273]. NK cells share with cytolytic cells of lower vertebrates and invertebrates both killing activity and lack of TcR and memory, thus suggesting that they are innate and primitive components of the vertebrate immune system [193]. Identified in humans, several CDs possess Fc receptors (FcR) that bind IgG (FcγR) and are activated by membrane receptors such as CD2R, CD16 (FcγRIII), CD39, CD69, and NKRP-1 (natural killer receptor = CD161) and CD94, a product of a gene in human chromosome *12p12–p13*, both members of C-type lectin superfamily [225, 320, 460, 470]. In addition to displaying cytotoxicity against autologous tumor cells, triggered by IFN-α, IL_2, IL_{12} and IL_{15}, NK cells release GM-CSF, M-CSF, IFN-γ, and TNF-α. Both activated IFN-γ and TNF-α are important for immune resistance against pathogens and regulation of hemopoiesis and immune responses, and IFN-γ also generated by other cells in response to microorganisms enhances NK cell cytolytic activity [25, 339, 460]. Increasing evidence shows that NK cells play a cardinal role in the control of microbial agents and with natural cytotoxicity of viral infections, also in absence of T and B cells, as in SCID mice [25, 130]. More precisely, the NK cell kills the abnormal target cell by inserting the pore-forming molecule perforin into the membrane of the target cell, and then injecting it with cytotoxic granzymes [115]. Furthermore, NK cells produce IL_2, necessary for their proliferation, IL_{12} [77], IFN-γ induced by IL_{15} generated by activated human monocytes [68], and VLA-4/VLA-5 (very late antigens 4 and 5) (CD49d/CD29 and CD49e/CD29) mediating NK-cell adhesion to fibronectin (FN) [64]. IL_{12} (NK cell stimulatory factor) primes in vitro Th1-specific immune responses and inhibits development of IL_4-producing Th cells [339]. IL_2 increases expression of adhesion molecules on their cell membranes [193]. Lastly, the MCP chemokines (monocyte chemotactic protein) are NK-cell major attractants, also inducing their chemotaxis [317].

One of the more intriguing aspects of NK-cell function is its possible recognition of foreign substances as non-self, allowing their recognition system to discriminate between self and non-self, to start cytotoxic activities and to produce ILs [289]. This theory is based on two models: an HLA-independent system of recognition triggered by IL_2 [289], or the *missing receptor* hypothesis focusing on immune surveillance with consequent elimination of cells failing to express HLA class I molecules [313]. The second theory has been confirmed by several experimental studies; however, at present how NK cells interact with target cells remains unanswered [667]. According to prevailing hypotheses, expression of HLA molecules could deal with a protective role from NK-mediated lysis [381]. In agreement with this model is the presence on NK cells of ≈20 receptors (NKR, natural killer receptor) specific for HLA class I antigens [4, 667]. NKRs are divided into NKAR (NK activating receptor) and NKIR (NK inhibitory receptor), among which are p50 1–3 (NKAR) and p58, p70, and p140 (NKIR), associated with IgSF, activators of HLA-C (p50 and p58), HLA-B, and HLA-A molecules, respectively [4, 381], and CD94 associated with proteins (94AP) phosphorylated by tyrosine, all implicated in HLA antigen recognition [427]. There are additional NKRs specific for HLA class I antigens, also IgSF membrane proteins and encoded by genes in human chromosome *19q13.4* [91], including the NKAT 1–4 (NK associated transcripts 1–4) family encoding transmembrane (TM) proteins with an extracellular region characterized by 2–3 IgSF domains and one cytoplasmic associated with ARAM (antigen recognition activation motif) [91].

HLA class I molecules may deliver negative signals protecting from lysis cells attacked by NK cells, and may resume cytotoxicity if target cells have reduced class I expression or abnormal peptide-HLA complexes impair recognition [320]. Thereby, NK cells are subjected to a delicate balance between activatory and inhibitory signals: only upon HLA molecule loss or reduction in number is inhibition dampened and killing enhanced [443]. A system of recognition that is characteristic of NK cells relies on the NKARs and NKIRs of these cells. The NKARs recognize a number of different molecules present on the surface of all nucleated cells, whereas the NKIRs recognize MHC class I molecules, which are also usually present on all nucleated cells. If the NKARs are engaged, a "kill" instruction is issued to the NK cell, but this signal is normally abrogated by an inhibitory signal sent by the NKIR on recognition of MHC class I molecules [287, 365]. Even if several issues remain to be adequately explained, for example, regarding specific functions of receptors so far identified and distribution of their activities, it is likely that different receptors may be used depending on the NK-cell activation state, thus releasing a negative signal that recognizes polymorphic HLA class I determinants on potential targets [667]. NK cells and CTLs may regulate functions of each other, in addition to the role of NK cells in CTL differentiation [273], but CTLs down-regulate NK-cell action expressing their inhibitor NKB1 [428], also complemented by TcR-αβ [273]. However, NK cells can express inhibitory receptors such as C-type lectins (CD94), while rodent NK cells may express those of IgSF [320].

The *LAK (lymphokine-activated killer)* cells are additional cells possibly with a cardinal role in discrimination between self and non-self [470]. LAKs display selective cytotoxicity for tumor cells not killed by NK cells with a broader spectrum, synergically expressed by IL_2 and IL_{12} and activated by IL_{15} [557, 693].

In the lytic process mediated by NK cells, we can distinguish four stages similar to those described for cytotoxic CD8 cells, the main difference regarding a shorter length of the whole procedure (4–6 h) compared to the longer one of antigen-specific CD8 lymphocytes. According to recent evidence, CTLs and NK cells not only deliver lytic messages to targets, but also bring about a substantial DNA fragmentation, a feature of CD8 cells via several secreted membrane molecules [190]. Recent reports of an adolescent and two children [43, 273] with life-threatening and relapsing infections, a quantitative and qualitative defect of NK cells [43] or no cells with NK-cell phenotype [273] and a reduced total number of CD8 T cells but with antibodies to several viruses [43], emphasize that NK cells *hold a key position in the response to infections* [460]. Dysfunctions of NK cells have been reported in Chédiak-Higashi syndrome with absence of cytolysis due to a secretory deficiency impairing granule secretion [21], in PID such as SCID, suggesting in this PID a combined deficiency of both NK and T cells, in X-linked lymphoproliferative syndrome (XLP), X-linked agammaglobulinemia (XLA), common variable ID (CVID), LAD (leukocyte adhesion deficiency), and in chronic fatigue syndrome.

K (killer) *cells,* morphologically and functionally similar to lymphocytes, are in practice null cells since they lack markers of both B and T lymphocytes. Not HLA-restricted, they have receptors for complement but not for surface Igs, and can recognize and kill target cells coated with specific antibodies by binding and being triggered via their FcRs: when target cells are killed but not phagocytosed, the process is called antibody-dependent cell-mediated cytotoxicity (ADCC). It appears that the NK-K cell system is actually one heterogeneous subpopulation also comprising LGLs, in which killing is alternatively mediated by a mechanism of NK or ADCC type [460].

A small subset of human γδ T cells fulfills in vitro either nonspecific killing or cytotoxic activities, possibly associated with CD1c molecules, with some similarity to HLA class I molecules [337]. Some activated γδ T cells can lyse infected phagocytes, being powerful K cells [110].

Lymphocyte Recirculation

T-cell recirculation illustrates the elegance of immune cell regulated migrations. Stem cells, after reaching the thymus or bone marrow via the bloodstream and maturing into B or T cells, enter the systemic circulation, peripheral lymphoid organs, and MALT, never traveling in opposite directions. Both phenotypes migrate electively between corresponding thymus-dependent and thymus-independent areas. Memory T cells leave the bloodstream via peripheral efferent vessels, especially to inflamed sites, and subsequently enter regional afferent lymphatic channels that eventually direct cells to a draining regional lymph node, circulating by lymphatics or via cortical venules into lymph node parenchyme (hence the high percentage of memory T cells) [634]. In contrast, naive cells move across afferent postcapillary HEVs into lymph nodes, directly through the HEV barrier. HEVs originate from pre-existing capillary venules (Fig. 1.3), differentiating under the influence of IFN-γ secreted by local Th1 T cells [226]. A particular feature of T lymphocytes is that they selectively bind to specific HEVs in lymphoid tissues and appear to completely ignore normal vascular endothelium, unlike in inflamed sites [226]. Moreover, between HEVs and distinct subsets of T cells there is a selective binding of finer specificity, further regulating lymphocyte homing into various lymphoid and nonlymphoid tissues [522]. In lymph nodes, encounters take place between novel antigens coming from afferent draining tissues and virgin cells. Lymphocyte traffic is not a random mixing of cells in varying tissues of the body. Yet this distinctive migration is directed by lymphocyte cell surface molecules that are receptors for ligands expressed on endothelial structures on HEV cell membranes (*homing receptors*) (Figs. 1.5, 1.11) [62]. As a result of these interactions, T lymphocytes transmigrate into mucosal tissues with immune memory of antigen sensitization, hence regulating local immunity [326]. Leaving secondary lymphoid organs and entering efferent lymphatics, lymphocytes of either phenotype recirculate via mesenteric lymph nodes and return to the blood via the thoracic duct, emptying into the superior vena cava, and crossing HEV endothelial vascular linings; they are eventually exported back to mucosal sites as memory T cells via the subclavian veins [591]. It is believed that lymphocytes migrate nonrandomly to their home: for example, naive T cells expressing CD62E that binds HEV can also migrate into skin T cells, as well as memory T cells, if they are equipped with CLA (cutaneous lymphocyte-associated antigen), which binds to CD62E on endothelium of skin venules [634]. The contribution of adhesion molecules should be pointed out: for example, $\alpha_E\beta_7$ integrin is equal to CD103 inducible by TGF-β1 (transforming growth factor β1), binding to E cadherin directs T lymphocytes to the IEL (intraepithelial lymphocytes) group, >95% of which expresses it, thus mediating lymphocyte adhesion to mucosal epithelial cells [76]. These meaningful data provide an immune basis to analyze reactions triggered in distant target organs, so that lymphoid cells stimulated, for instance in GALT, migrate into the bloodstream and then to the gut lamina propria: *this traffic is very important for maintaining the immune surveillance within the MALT system* [326]. This also elucidates why some T lymphocytes appear to

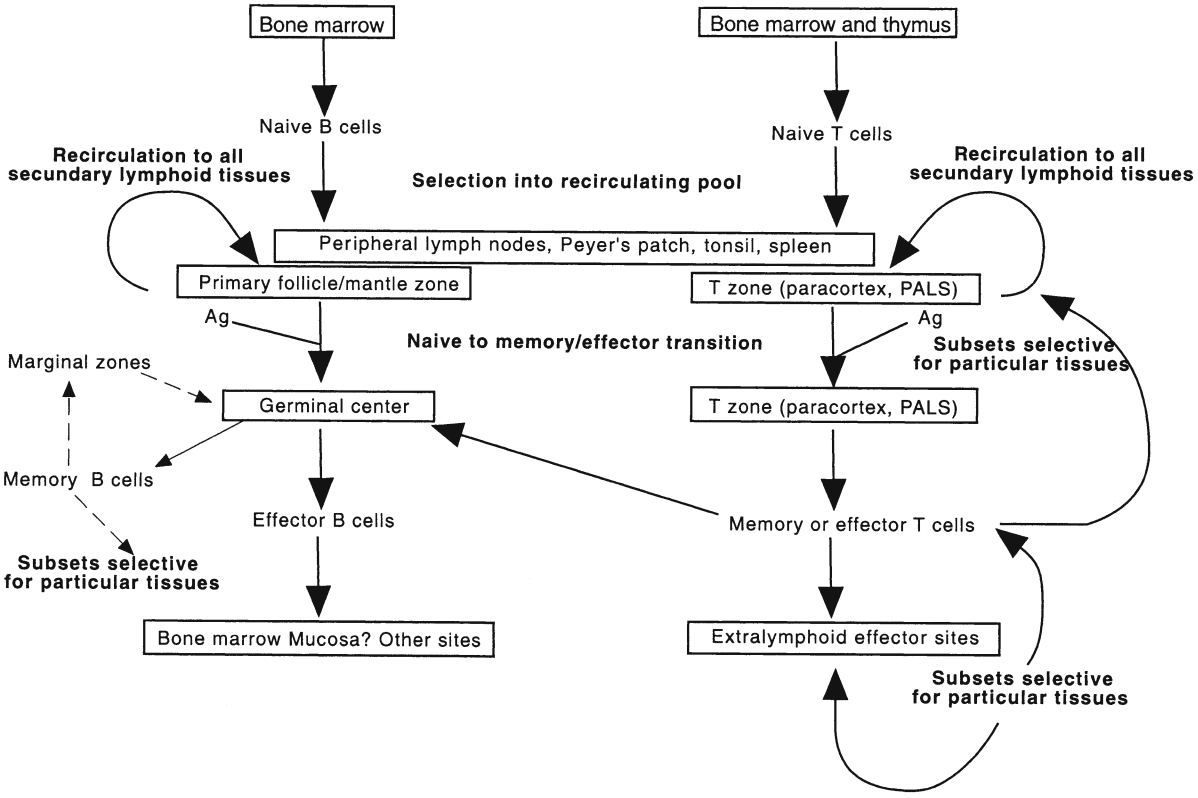

Fig. 1.11. Recirculation of lymphocytes: differential distribution of naive versus memory cells. Unlike naive cells, memory and effector T (and probably B) cells can efficiently extravasate in tertiary or extralymphoid tissues (see text). Antigen-activated B cells may home to specialized environments in the outer T zone during primary responses, or may colonize germinal center sites of hypermutation, affinity maturation, and memory cell differentiation. Less numerous, specialized lymphocyte subsets, such as γδ T cells or IELs, may be targeted from their origin in the thymus or bone marrow directly to reproductive, cutaneous, intestinal, or other tertiary sites. Extralymphoid tissue sites of selective homing include skin, lung, intestinal lamina propria, and synovial tissues. *Ag* antigen, *IEL* intraepithelial lymphocytes, *PALS* periarteriolar lymphoid sheath. (Modified from [62])

patrol throughout the body (*recirculation*) and their traffic is greatly enhanced if an inflammatory response develops. The toxic action carried out by viruses can alter both homing and recirculation of T cells until inactivation, notably of lymphocytes specific for that particular virus (Chap. 22). The immunocompetent memory cells recirculate uninterruptedly, since encounters with particular antigens and triggering of immune reactions are facilitated on the one hand, and on the other localization of specific cells in elective areas is supported [634]. While naive cells recirculate almost exclusively via lymph nodes and other secondary lymphoid tissues, where priming may take place, traffic of memory and effector lymphocytes is also directed to nonlymphoid tissues, including gut lamina propria, lung tissues, as well as inflamed skin, and joints (Fig. 1.11). More precisely, naive cells are excluded from effector mucosal sites because their HEVs lack MAdCAM-1, expressing inadequate levels of $\alpha_4\beta_7$ to bind it [62]. Sophisticated studies on animal models have observed that homing receptors direct traffic with a specific migratory behavior of the cells: those coming from GALT, for example, from PPs, have a preferential migration into the gut, mediated by β_7 integrins [615], and to a lower extent into other sites, and likewise for other preferential localizations (Fig. 1.12) [534]. Memory cells, once activated in specific tissues, depend on unending antigen stimulation and with remarkable selection home in to tissues related to initial exposure to foreign antigens [226]. The selective pattern of recirculation has a prerequisite of preventing inappropriate competitions between T and B cells and migrations into nonlymphoid organs [62]. Similar discrepancies involve specialized subsets making use of preferential routes, such as γδ and IEL cells, which can migrate into skin and/or gut [62]. Studies have hypothesized that an important role may be entrusted to gut-derived IELs homing preferentially to mucosal lung tissue, also effective in preventing airway infections [454]. Because of lymphocyte circulation, B_{IgA} cells of PPs following antigen sensitization home in to regional lymph nodes, where they differentiate, activate, and then return to colonize electively the lamina propria of various compartments [548], including mammary glands, where they transform into IgA-se-

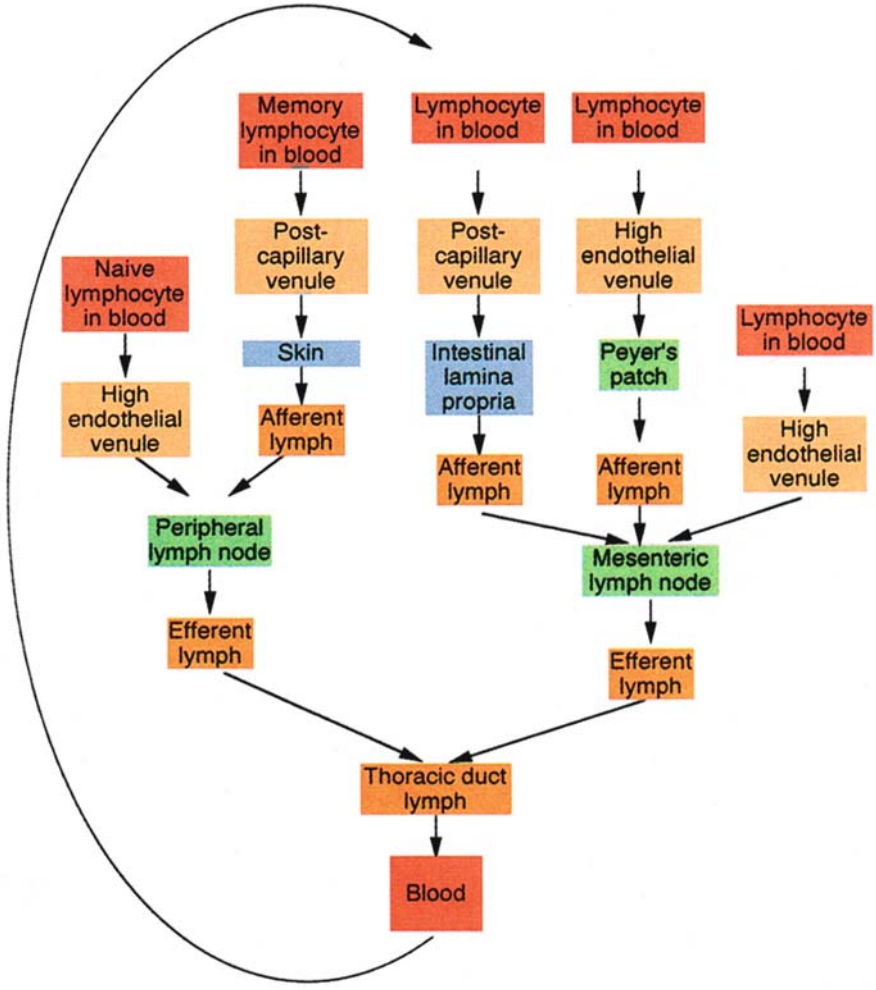

Fig. 1.12. Lymphocyte circulation routes. Patrolling the body in search of foreign antigens, lymphocytes follow circuits through both lymphoid and non-lymphoid tissues

creting plasma cells (*enteromammary axis;* Chap. 2). Analysis of B lymphocytes is limited: naive B cells are the great majority of cells recirculating between blood and lymphoid tissues [635]. As regards the volume of cell traffic, human circulating blood contains $\approx 10^{10}$ lymphocytes, with a blood transit time of 25±6 min, resulting in a 40-fold daily exchange ($\approx 5\times10^{11}$ lymphocytes) [635]. In the human thoracic duct, there is a recirculation of only $\approx 3\times10^{10}$ lymphocytes, that is about 6%–7% of the daily migration via peripheral lymphoid tissues: in rats the rate of naive and memory cells is nearly equivalent [636].

T and B Cell Receptors

T and B lymphocytes can recognize an extremely wide range of disparate foreign antigens because of the high variability of their membrane receptors, stemming from the ability of developing cells to arrange and modify genes encoding antigen receptors, even if single B cells express only one type of specificity, and the same is probably also true for T cells [225]. There are $\approx 10^{14}$ TcR and 10^{18} BcR [353] (Fig. 1.13) playing a central role in antigen recognition and activation, with structures complementary to those of specific antigens; epitope recognition by receptors is a critical event triggering immune responses. In contrast, the human genome contains 75,000–100,000 genes, most of which have no role in immune recognition [353]. Molecules coded for by HLA molecules regulate B- and T-cell differentiation, because they are involved in the host's ability to set humoral or CMI responses. More prominently, HLA molecules are necessary to signaling and their intercellular interactions contribute to distinguishing between self and non-self [470]. Specificity dominates in the molecules induced in every individual *in one or two versions,* dictated by maternal and paternal genes, whereas TcR and BcR are produced in *millions of copies* that, although adhering to a common structural plan, are different in V domains [115]. If each lymphocyte bears receptors with a unique specificity, coordinately expressed by progenitor stem cells via processes of genetic recombination, there must necessarily exist a great variety calling on the immune system to recognize an extensive spectrum of antigens. Doubtless, clonal selection interferes to naturally eliminate receptors destined to die via PCD [276, 510]. Both TcR and BcR are able to recognize a given antigen due to their unique molecular structures, which are spatially and chemically complemen-

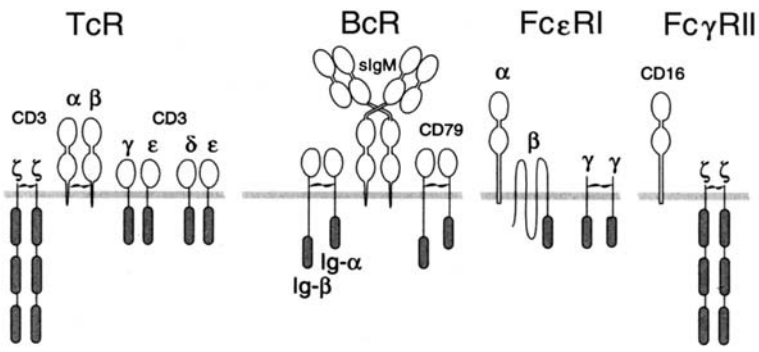

Fig. 1.13. Receptors of hemopoietic cells

tary to one another, fitting together in a "lock-and-key" relationship, thus giving the starting signal to cellular replication. The progeny of cells derived from any naive cell originate as a lymphocyte clone with cells morphologically identical to one another in nearly all respects, while each BcR or TcR expressed by cells of a given clone are also identical [185]. Lymphocytes, already triggered by binding to their specific antigens and activated, proliferate and deliver specific effector functions, thereby recognizing the intruder and successfully inactivating or eliminating it: evidence exists that cells with a specific receptor that fits better to binding sites may differentiate selectively, thereby predominating over other cells [47]. Receptor molecules mediating specific recognition have heterodimeric structures: L and H Ig polypeptides behave as BcR, while α and β chains are related to TcR. L, H, α and β chains possess V domains arranged in a specific spatial contour on available antigen surfaces and also C domains interacting with receptors on host tissues and transmitting signals to cell cytoplasm.

Therefore, BcR and TcR genes share many features and both undergo similar DNA rearrangements [18]. In addition, genes coding for BcR and TcR use a unique strategy to achieve the degree of diversity required. The set of human BcR and TcR genes is complete for all the seven *loci* – the three Ig *loci:* IgH (after the H chain), IgK (after the κ L chain) and IgL (after the λ L chain); and the four TcR *loci:* TcRα/δ on chromosome 14, TcRβ (on chromosome 7, and TcRγ on chromosome 7. The IgH cluster (431 human genes and 798 alleles) corresponds to 4 types of gene segments: V, D, J, and C. The Igκ and Igλ clusters lack D segments. All these segments contain multiple genes; in the IgH cluster, for example, there are ≈50 functional V segments. The *TcR genes* have a similar organization and in the 4 TcR *loci* there are 242 human genes and 443 allels [115, 183]. In contrast to the TcRβ and TcRδ *loci,* the TcRα and TcRγ *loci* do not contain D segments. And, as in the case of Ig genes, each TcR *locus* contains multiple V, D, and J genes; on TcRα, for example, there are 70 to 80 V genes and ≈60 J genes [115]. To such genes is committed a molecular control to increase variability via somatic and evolutive processes, but inheritable chromosomes, as discussed earlier, contain no Ig genes at all: otherwise there would be several million of these genes. For example, spermatozoon and ovum contain gene fragments that via subsequent phases of rearrangement, reorganize genome sequences so that *new genes can be created in immune cells* to continue the cycle [18]. The basic principles governing the genetic mechanism to create such a variety can be focused on DNA somatic rearrangement, versatile and casual, accompanied by deletion and an evolutionary mechanism with reference to active engagement and frequent combinations [185]. Antibodies and T-cell clones thus achieved are specific not only for antigens present now in the microenvironment, but are also able to develop different specificity to antigens not yet present, to be encountered in the future [326].

T-Cell Antigen Receptors

While nearly all developing TcRαβ thymocytes express a single TcRβ protein, many thymocytes rearrange and express two different TcRα chains and, thus, display two αβTcRs on the cell surface. The number of such dual TcR-expressing cells is surprisingly lower among the mature T cells [284]. The immature TcR consists of a β chain identical to that found in the mature TcR and a pre-T chain that contains only a C region. This segment is replaced by an α chain to form the mature TcR, and each chain consists of a V and a C region [115]. The PTK signaling and coreceptor involvement may be operating in normal thymocytes [284]. *Antigen-specific T cells have a TcR similar to membrane Igs (mIg) of B cells* and also contain V, D, J, and C segments. *CD3-TcR complex is the unity of mature T cells: TcR is able to recognize and discriminate among different foreign antigens, CD3 polypeptides have long intracytolastic tails necessary to TM transduction of activation signals* [222]. *Each TcR* molecule *is formed by two pairs of heterodimers, αβ and γδ,* each α, β, γ, and δ chain containing a V domain and a C domain, and a *CD3 complex by three distinct invariable chains known as γ, δ, ε correlated between them.* Antigen-specific T cells have a TcR similar to membrane Igs (mIg) of B cells. CD3-TcR complex is the unity of mature T cells: TcR is able to recognize and discriminate among different foreign antigens, CD3 polypeptides have long intracytoplasmic tails necessary to TM transduction of activation signals [225]. Each TcR molecule is

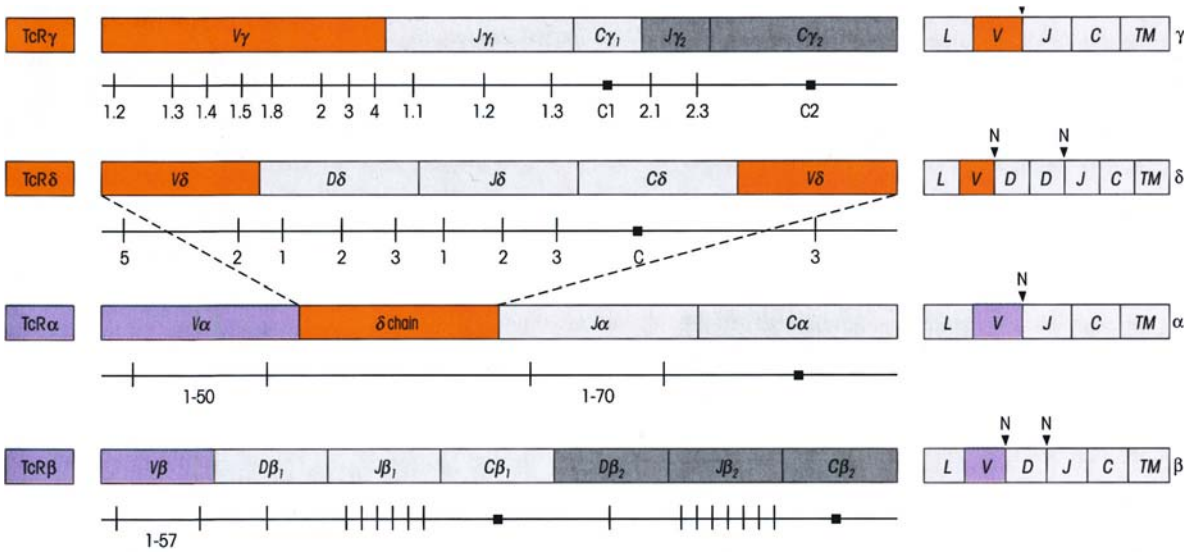

Fig. 1.14. Genes coding for TcR (for details see text)

formed by two pairs of heterodimers, αβ and γδ, each α, β, γ, and δ chain containing a V domain and a C domain. CD3 complex by three distinct invariable chains known as γ, δ, ε correlated between them. As in the antibody molecule, the V domains contain three CDRs, where the highest degree of amino acid variability is concentrated. The CDRs in the case of the αβ TcR recognize a complex formed by a peptide seated within the groove of an MHC molecule [171]. Each TcR has a single extracellular Ig-like C domain, a TM segment, a cytoplasmic tail (44–81 amino acids in length), and is completed by ζ and/or η chains. ζη chains also are invariable molecules, derived by conjunction of alternative transcripts of the same gene, and form homodimers linked by a -S-S (ζ-ζ and/or η-η) bond, or heterodimers (ζ-η), not covalently associated with five subunits (αβγδε) to form the heptameric complex. The human chain MWs are as follows: γ 25–28 kD, δ 21 kD, ε 20 kD, ζ 16 kD and η 22 kD [4].

Two T structures recognize antigen peptides bound to HLA molecules:

- In 90%–95% of T lymphocytes is found a TcR formed by two polypeptide chains α and β (αβ) (MW of 45 and 40 kD) expressed on the cell membrane in the form of 90-kD heterodimers and linked by -S-S bonds, associated on the cell surface with CD3, a clonally invariable protein, and encoded by gene segments organized in a discontinuous way on chromosomes (V, D, J and C); hence gene rearrangements are necessary. V regions are present in both chains; in addition there are J and C for α chain, and D, J and C for β chain. The α and β molecules, membrane gps belonging to IgSF (Table 1.4), are encoded by genes located on chromosome 14 (region *q11*) for α chains and on chromosome 7 (region *q32*) for β chains [337]. Use of Vα and Vβ regions of TcR from T lymphocytes is very stable, as TcR gene expression is controlled by DNA sequences, among others.
- In 5%–10% of TcRs a second heterodimeric receptor formed by a γ (45 kD) and a δ chain (40 kD) (γδ) linked by S-S bonds is expressed. The γ chain locus is on the short arm of chromosome 7 (region *p15*) and the δ chain on chromosome 14 is embedded within the α locus [222, 337] (Fig. 1.14) [470]. Human genes encoding γ chains contain exons for V, J and C regions, and gene exons for δ chain encode for V, D, J and C regions, similarly to α and β chains [18]. In humans, γ chains have two different Cγ2 exons, one encoding a cysteine residue. The γδ cells are about 80%–90% $CD8^+$ and the remaining cells $CD4^+$ [337]. In humans, both receptors are present in IELs, but αβ T cells prefer to differentiate mostly in normal epithelia homing lymphocytes [525].

The same basic principles of gene rearrangement described for Ig apply for TcRs. Also, genes encoding V and C regions of TcR chains are found on DNA varying segments, and therefore should be rearranged. However, repertoires of different TcR are believed to be at least as large as Ig molecule repertoires, also regarding antigen specificity. A remarkable degree of independence seems to dominate in the generation of αβ and γδ lineage cells from progenitor cells that, in theory, could simultaneously express a TCRγδ and a pre-TCR [180]. In peripheral lymphocytes, STAT5 is primarily required for the generation and/or maintenance of γδ T cells and TCRγδ(+) IEL [246]. Both γ and δ chains exhibit typical *fetal rearrangements* because there is essentially no N region diversity at VJ or VDJ junctions of rearranged γ and δ genes [525]. A remarkable difference between genes coding for αβ and γδ chains of TcR is a programmed regulation of their activation during ontogenesis [229], in that comprehensive rearrangements at γδ loci appear before those at αβ loci [525] in reciprocal independence [229]. *The γδ TcR is the first receptor expressed by thymocytes in utero* [279]: until day 17 of gestation, γδ cells are mainly TcR^+ subsets in murine

thymus [263]. Such TcRs appear to predominate compared to αβ TcRs in murine skin and gut epithelia [582], where γδ could play a leading role in *first-line* defense. The much earlier activation and conversion to memory of the γδ T cells is a significant differnce between the γδ and αβ T cell lineages, and illustrates the central role that γδ T cells have in adressing Ag challenge from birth onward [111], substituting for αβ cells that are scarce in mice [587], and protecting epithelia from damage caused by inflammations via selective suppression of IgE responses [279]. This effect is endorsed by normal levels of γδ cells [80]: reduction to only 500 cells [350] or suppression of γδ cells, as reported in atopic babies [495], could imply an increase in IgE levels [80, 350, 495]. As γδ TcRs develop normally in mice deficient in HLA class I and II molecules, these cells could be present in HLA defects. In addition, studies related to CDR3 of γ, δ, and α TcR chains and Ig H and L chains suggest that γδ cells may act as Igs in antigen recognition without a prior processing and presentation by professional APCs [466, 500].

In children with PIDs, studies reported CD3 γ, ε, or ζ deficiency, with TcR expression reduced on the cell membrane by about 50%–90% of T lymphocytes; ε defect is much more severe than γ defect as regards TcR expression or complete conformation, thus resulting in mature and immature T cells [263]. According to recent data, it does not seem necessary that parts of TcR αβ, γδε and ζ be present all grouped together in one complex to be expressed on the cell membrane as a functional unit: in the absence of functional γ chains, a healthy child shows that in vivo T cells may use fewer receptors than is expected (see "CD3γ Deficiency," Chap. 22). *ζ chain deficiency seems to be more severe* because of the high reduction of CD4, CD8 and TcR-αβ levels and absence of CD44 and CD25 [102].

The three CD3 chains, γ, δ, and ε, have homologous sequences of amino acids and their cytoplasmic domains comprise ITAM (immunoreceptor tyrosine-based activation motif) or ARAM, which contain tyrosine residues necessary to induce tyrosine phosphorylation in activated TcRs [3289]. TcR complex is not expressed by mature T cells and exists at their surface to carry out the whole set of T-cell functions, showing several similarities with Ig structures: it is formed by two instead of four polypeptide chains that are different from one another, linked by -S-S bonds, and consist of both V and C regions. The two polypeptide chains (similarly to Ig chains) are delineated by a C-terminal C region, the same for each TcR, and an N-terminal V region, different for each TcR. Such wide variability enables various TcR clones *to recognize a practically infinite number of invaders* [225]. On lymphocytes and in the bloodstream, there is a substantial number of TcR and BcR with different V regions; variability is acquired during somatic rearrangements between gene segments V, D, and J linked together in respective chromosomal regions. *Diversity* is generated by multiplicity of independently assorted components of V regions; however, TcRs have a greater tendency to use N-region diversity and frame shifts, whereas Igs prefer to use somatic hypermutation. TcR diversity is amplified by multiple V genes in germline, random combination, and junctional and insertional variability, thereby ensuring generation of a noteworthy structural diversity to deal with a practically unlimited universe of non-self antigens [36].

As a corollary of data discussed above, self/non-self discrimination by TcR is HLA-restricted, in that T cells and APCs must be complementary to HLA molecules: following this assumption, CTL $CD4^+$ recognize class II antigens as highly preponderant T $CD4^+$ cells, and CTL $CD8^+$ (the majority) recognize class I antigens. Therefore interactions between CD4 and CD8 and respective HLA class molecules increase efficiency of T-cell and APC interactions. CD4 and CD8, IgSF members, adhesion molecules, and signal transducers could act as receptors for nonpolymorphic HLA epitopes, contrary to TcR interacting with polymorphic epitopes [463].

B-Cell Antigen Receptors

The events following transduction of activation signals are better understood for T than for B cells. The immature pre-B cells (and pre-T cells) express preliminary versions of the antigen receptor. At this stage, the BcR comprises a pair of H chains, each with a V and a Cμ region identical to those found in the mature receptor, and a pair of surrogate L chains, termed Vpre-B and γ5. As the B cell develops, the surrogate L chains are replaced by conventional L chains, each with a V and a C region [115]. BcR consists of mIgs, more common proteins critical for antigen recognition, differing from antibodies only for an extra sequence of amino acids at C-terminal domains of H chains [214]. During embryonic and fetal life, mIgs of different isotypes alternate in B-cell populations; similarly, this occurs during clonal maturation in their adult life [3]. Igs of all classes can exist in either membrane-bound or secreted forms. Membrane forms combine with Ig L chains to make mIg; however, mIgs are retained in ER, unless associated with Igα and Igβ [414] . B cells comprise:

- *Specific mIgs:* IgM (5%–20%) and IgD (5%–10%) more frequently than IgG (1%–7%) and IgA (<5%) antibodies. These specific molecules facilitate B cell identification by immunofluorescence (IF) techniques, using antisera specific for each isotype.
- *Membrane receptors* for the Fc fragment of IgG (FcγR) [18], found also on non-B cells and monocytes (Table 1.3), possible false positivities due to IgG passive fixation on such receptors.
- *Receptors for complement* components C3d and C3b with rosette formation; receptors recognize complement when bound to either IgG or IgM antibodies (EAC rosettes).

- *CD21* is the receptor for C3d complement fragment and EBV (Epstein-Barr virus). This latter event allows microorganisms or their products to link to B cells, thus giving activating signals. The mature IgM molecule acts as the BcR for antigen, usually together with IgD BcR with the same antigen specificity. The V regions of the H and L chains each contain three CDRs. The CDRs make contact with the antigen [115]. When IgMs (with low affinity bond) play a BcR role, membrane signaling requires binding to CD45, equal to LCA (leukocyte common antigen), an important amplifier of BcR-mediated signals contained in intracytoplasmic tail domains with phosphatase activity (PTPase) [103], with several isoforms indifferently distributed between B and T cells [395].
- *Additional receptors* of mature B cells include IFN, IL_4 and IL_2. B cells present unrestricted surface antigens to cells of B lineage such as CD9, CD10 and CD23 (FcεRII).
- *B cells* have a high density of HLA class II molecules and express CD71 [96].

BcR consists of tetrameric H chains (IgH) with five isoforms: μ (73 kD), δ (67 kD), γ (50 kD), α (55 kD), and ε (70 kD), and L (IgL) with two isoforms: κ (26 kD) and λ (26 kD) [4]. mIgs of all types associate noncovalently with two heterodimers, each formed by a pair of polypeptidic chains, α and β, Igα (CD79a) and Igβ (CD79b), -S-S-linked to each other. In addition, two TM gps have an extracellular domain of Ig type (included in the IgSF), and an intracytoplasmic tail of 61 amino acids for α chains and of 48 for β chains in close contact with mIgM (mμ) [453]. Interestingly, a BcR without the T-cell CD3 complex has these proteins structurally resembling it [214]. More precisely, CD79a and CD79b cytoplasmic tails contain an amino acid motif with two tyrosine residues such as ITAM (see activation of lymphocytes), representing an important point of communication between BcRs and two types of PTKs: *src-family kinases and spleen tyrosine kinase syk* [453]. The nonreceptor PTK syk is widely expressed and has an important role in intracellular signal transduction in hemopoietic cells. It displays a leading role in BcR spectrum of activities, as demonstrated by BcR complete activation via PLCγ1 (phospholipase Cγ1) linking. In addition, syk controls signaling pathways between the two, whereas its deficiency blocks B-cell development at pre-B stages [446, 589]. A member of the src family is Bruton tyrosine kinase (btk) underlying XLA (Chap. 22). As an illustration of the SHP-1-dependent inhibition pathway, recruitment of SHP-1 to the B cell inhibitory receptor PIR-B attenuates BcR-triggered activation responses [446]. Extra BcR functional interactions are with B-cell-specific surface proteins CD19 and CD22 [453], two ligands, CD80 and CD86 (Table 1.2), also common to T cells, DCs, macrophages, etc. Their activation increases CD80 and CD86 levels [453]. CD80 expression peaks after several days, whereas CD86 expression peaks within 24 h of activation; thus higher levels are stimulated [242]. Two pairs of TM BcR-associated proteins, *BAP32/BAP37* and *BAP29/BAP31,* have been recently mapped, associated with IgM BcR and IgD BcR, respectively, in a class-specific fashion [453].

In conclusion, there are evident analogies in gene organization and structure of both receptors that suggest a common evolution from ancestral genes. All genes belong to IgSF (Table 1.4).

Immunogens, Antigens and Allergens

Definitions. Briefly, immunogens, antigens and allergens [1, 185, 428] can be defined as:

- *Immunogen:* any antigen that in a particular host can elicit immune responses and react with the relative products
- *Immunogenicity:* the capacity of provoking an immune response (B- or T-mediated)
- *Antigen:* anti(body) gen(erator), any substance recognized by TcRs or antibodies, that can trigger immune responses
- *Antibody:* selected Ig molecule containing a specific sequence of amino acids and binding specifically to antigens, inducing its synthesis
- *Antigenicity:* an epitope capacity to be recognized by specific receptors of the immune system
- *Allergen:* aller(gy) gen(erator), any foreign substance able to activate IgE synthesis
- *Allergenicity:* the ability of an allergen to elicit an IgE-mediated reaction in sensitized patients
- *Sensitization:* natural or artificial induction of an immune response, notably when it causes allergy in the host. In subsequent contacts with the same immunogen there is a quicker onset and a more severe immune response [185]
- *Panallergen:* molecule with properties shared by different species, for example, a protein with a conserved IgE-binding epitopes across species that cross-react with foods, plants, and pollen
- *Epitope:* antigenic determinant; an *allergenic epitope* marks a specific peptide domain associated with allergenic potential
- *Paratope:* antibody-combining site for epitope

Strictly speaking, all immunogens are also antigens, but not all antigens are naturally immunogens: the immune system may recognize an antigen, although it does not respond to an antigen unless it is also an immunogen. However, the terms "antigen" and "immunogen" are often employed interchangeably [185].

Immunogenicity *of a given protein* depends on epitopes present on its molecule triggering sIgE synthesis (specific IgE antibodies), thus in turn triggering allergic reactions. It also relies on the existence on the protein surface of hydrophil amino acids such as lysine, arginine, and aspartic and glutamic acids. That a non-immunogen molecule could become the target of immune responses if attached to an immunogen protein is evident with compounds with low MW, called *haptens*

(from the Greek "απτειν," to fasten) or ligands, small molecules with a restricted number of identical epitopes. Haptens are therefore antigenic but not immunogenic, and can combine with only one type of antibody, but are unable by themselves to elicit immune responses, owing to their low MW. To become an immunogen, the free hapten must bind a *carrier,* either serum proteins or epidermal proteins: for a single hapten more than one carrier may exist [185]. Anti-hapten antibody responses require cooperation between subsets of B and T cells first recognizing the hapten and second the carrier. Current examples are drugs, metal contaminants such as Ni, Cr, Cu and β-lactamines, natural constituents of vegetable origin, including balsams, fucomarins, lactones and terpenes, to be found in fruits, vegetables and aromatic plants [18].

Antigens are soluble or corpuscular substances, mostly made up of proteins, each formed by one, two or more chains composed of different combinations of about 20 amino acids linked to one another. Every chain is rolled and folded; hence when it is extended, parts distant from each other come into contact when protein structures fold [12]. The term "antigen specificity" refers to antigen binding only to antibodies thereof activated. This specificity has a crucial value in the immune system: notwithstanding complexity of molecular structure, any given antibody including IgE will recognize and bind not to the whole molecule, but to the epitope, a limited portion of such a molecule formed by a few amino acids arranged in sequence or close by because of chain folding. Antigen–antibody reactions always denote a primary, dynamic fixation, based on noncovalent forces; hence they are relatively low and dependent on steric complementarity between epitopes and antibody. Epitopes often behave as haptens [18].

Epitopes and Paratopes

The *epitope* is a molecular structure with a diameter of 2–3 nm representing *the antigen part electively recognized by* a given antibody (that is *the paratope*) or TcR, thereby determining immune reaction specificity. Chemically, it is composed of five to seven amino acids active in molecules of globular proteins and glucide units of lateral chains of polysaccharides (PS). A part of the epitope reacts with Fab of L chain, the other with antibody H chain, being the fundamental part of a protein molecule recognized by binding either to T cells or Fab fragments [1]. Another molecule, the *agretope,* also formed by amino acid residues interspersed in primary sequences, binds to both TcR and paratope [11] and to a HLA-DR molecule of new synthesis localized in a hypervariable β1 region, the *desetope* (Fig. 1.15) [577]. Each TcR chain supplies three CDRs [in particular CDR3 with (D) J sequences as Igs interact with epitopes] contributing to the antibody combining site, the paratope, three-dimensional space defined by the folding of new

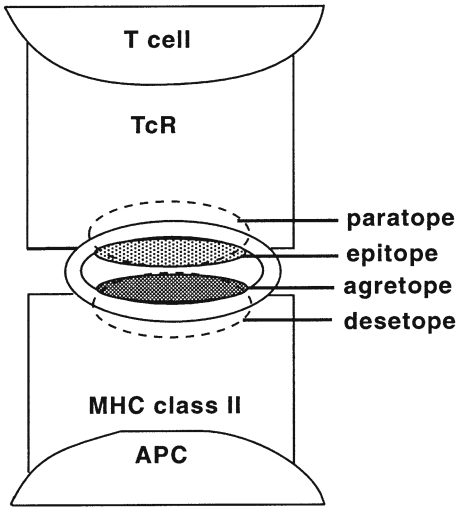

Fig. 1.15. Interactions between T cell, TcR and APC before antibody production. The epitope of the immunogenic peptide binds to TcR (and the paratope region), while the agretope binds to the Ia antigens of APC. The desetope is the part of HLA molecule to which the agretope binds. *APC* antigen-presenting cell, *TcR* T cell receptor

polypeptide chains. H chain regions corresponding with V_H and C_H1 domains and whole L chains forming Fab (Fig. 1.6) are closely located to form paratope walls. In conclusion, one H and one L chain together form a paratope, therefore a single four-chain unit is bivalent, since it contains two combining sites [469]. The paratope is positioned in the NH_2-terminal Fab region, whose shape changes to recognize and ensure a close fit between antibodies and complementary epitopes [459]. A *paratope* is a molecule portion determining antibody specificity, making contact with an antigen-related part, a binding pocket allowing peptides to be accommodated, thus suggesting the picture of a *key in a lock* [1, 470] (Fig. 1.16). Paratope specificity depends on amino acid sequences of hypervariable loops, an effect of minute variations of genes encoding for this antibody portion. Analyses of antibody terminal parts have demonstrated a three-dimensional flexibility of the paratope calling antigens for binding, with spatial conformational changes made on peptide binding, absent in unliganded Fabs. As Fig.1.17 illustrates, in liganded Fabs a prominent groove connected to a deep pocket is formed to fit peptides, adding a prominent channel to encompass extended portions of bound peptides [459]. Affinity between these two structures depends on the strength of attraction and repulsion existing between them. Mutation of an amino acid residue forming part of an epitope or paratope can greatly increase or weaken such affinity [459]. Structurally, there is also flexibility in epitopes, permitting antigens to interact with antibodies, thus widening the likelihood of antigen–antibody encounters of sufficient affinity to generate immune responses [459]. The immune system utilizes such properties to

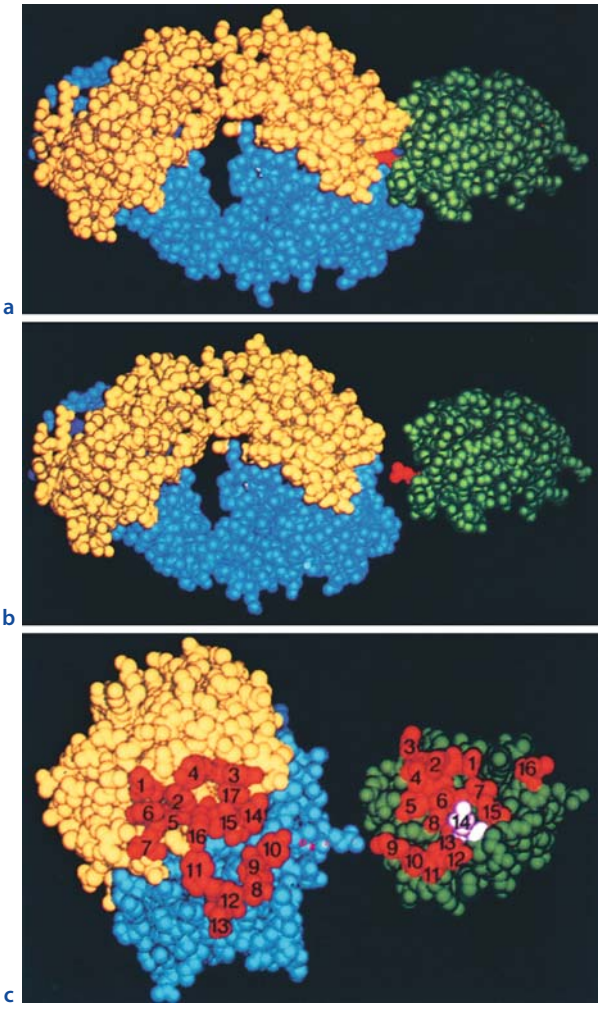

Fig. 1.16 a–c. Structure of the antigen-antibody interface. **a** Space-filling model showing Fab and lysozyme molecules fitting closely together. Their interactions form an antigen–antibody complex. The antibody H chain is shown in *blue*, the L chain in *yellow*, lysozyme in *green*, and glutamine 121 in *red*. **b** The Fab and lysozyme models have been pulled apart to show that protuberances and depressions of each are complementary to each other. **c** End-on views of the paratope (*left*) and lysozyme epitope recognized by antibody (*right*), formed from **b**, by rotating each molecule approximately 90° around a vertical axis. Contact residues on both antigen and antibody are shown in *red*, except for glutamine 121 in *light purple*

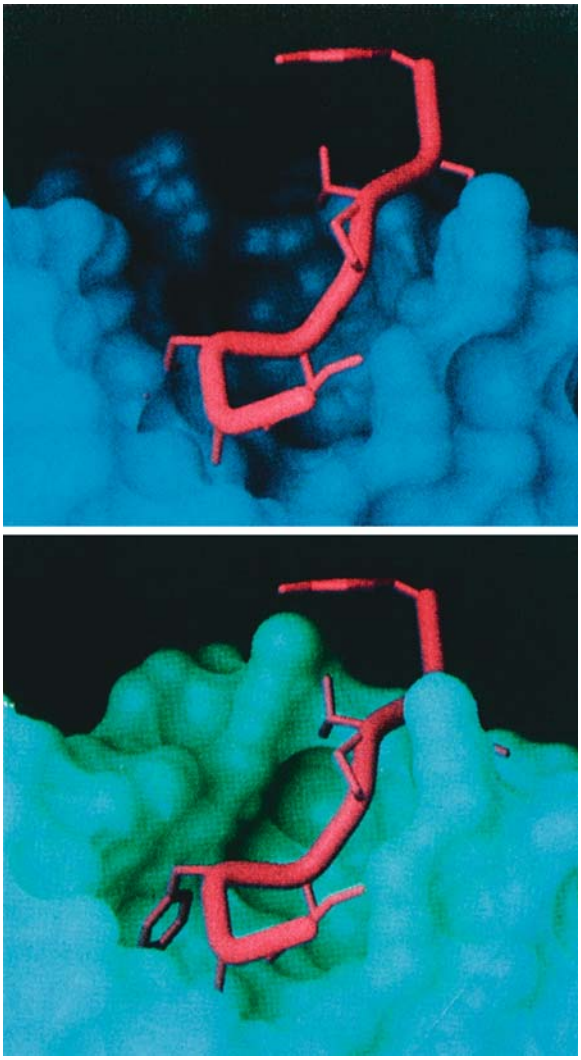

Fig. 1.17. Shape of the binding pockets of the unliganded (*above*) and liganded Fab (*below*). The unliganded Fab appears as an open, basin-shaped pocket, and in the liganded Fab a prominent groove connected to a deep pocket is formed to fit the peptide antigen

amplify antibody affinity during immune responses (affinity maturation and antigen selection). However, microorganisms may use such changes to evade host immune recognition by a variety of strategies, including shifts in critical surface antigens, as is the case of HIV, of influenza virus, etc. [337].

Epitopes are classified into *B- or T-reactive epitopes*. *B-epitopes* are recognized by B cells and binding sites of specific antibodies, whereas T-epitopes correspond to small peptide fragments (8–12 amino acids) recognized by TcR in the context of HLA molecules on antigen linear surfaces [368]. Several B- and T-epitopes have been characterized, but antigen-specific T cells appear to be distinct from those individuated by IgE antibodies [672]. The total number of separate B or T epitopes on antigen molecules, identical or different, is called *valence*, overall proportional to foreignness, molecular size and chemical complexity, which represent the factors influencing immunogenicity of a given antigen [185]. We shall see that an immune response also depends on the dose and mode by which foreign invaders enter the body. As a rule, macromolecules are the strongest immunogens, usually having more epitopes; however, in a given subject and under the influx of particular circumstances, only one or a few are recognized by BcRs and/or TcRs, since they are targets of immune responses. Macromolecules with one type of epitope are

named monospecific, but their greatest part has many independent epitopes with different specificities. Some large proteins have been found to contain as many as 50 separate T-cell epitopes. However, even small molecules can have bivalent structures: for example, the human hormone glucagon, which is only 29 amino acids long, contains separate B- and T-cell epitopes [185]. In addition to the events described, T-cell epitopes show the exquisite specificity required to activate CD4 T cells, which in turn are needed for B-cell responses against nearly all antigens. The first requirement for a molecule to be an immunogen is to contain at least one T-cell epitope: consequently, molecules comprising only B-cell epitopes (such as haptens or amino-terminal parts of glucagon) may serve as targets for antibody responses, being unable to elicit such responses autonomously [185]. Even if, in theory, T-cell epitopes do not bind to IgE antibodies, small peptides may do so and subsequently block (as monovalent haptens) or stimulate basophils [496]. These observations are of substantial importance, since identification of IgE-binding B-cell epitopes may:

1. Increase both specificity and sensitivity of diagnostic tests by including molecules with epitopes of this type
2. Distinguish B-cell from T-cell epitopes
3. Elucidate trigger mechanisms of IgE-sensitized metachromatic cells [496]

The epitopes of a protein are of two types [12, 185]:

- *Sequential,* or linear, or segmental epitopes (usually T-cell epitopes), determined by primary structures, wholly positioned sequentially in linear sequences of a protein or PS antigen, a segment of amino acid sequences: immunogenicity is the result of covalent linkage of these residues to one another, which cannot move significantly apart. By definition, such epitopes are more resistant and generally remain unchanged following heat or enzyme denaturation and may be left untouched by enzymes not specific for amino acid bonds present within epitopes.
- *Conformational,* or discontinuous epitopes (usually B-cell epitopes), are far apart in primary sequences and critical residues are brought close together via folding of antigen chains in normal three-dimensional steric configurations, so that they may encompass residues widely distant from one another along protein sequences, positioned also nearby, but juxtaposed in tertiary structures. Immunogenicity is due to molecular configuration. Normally, such epitopes are scarcely resistant; hence they are lost when antigens are denatured and fail to refold appropriately [13, 414] (Fig. 1.18).

Consequently, since B epitopes are mostly conformational, they can be more easily eliminated, while sequential T epitopes are more resistant. Epitopes of this type have acquired relevance for their use in specific immunotherapy (SIT) and preparation of protein hydrolysates. *Spatial conformation* plays a key role, since *accessibility* of epitopes is a prerequisite for binding to immunocompetent cells and for immunogenicity. In the case of atopy, IgE antibodies recognize one specific B-cell epitope in peptide tertiary structures, whose three-dimensional conformation can mask additional epitopes that will not bind to antibodies. On the contrary, T lymphocytes recognize sequential epitopes with a few amino acids located on antigen linear sequences [368]. T- and B-cell epitopes are distinct by their topographical position being located at different points, with T-cell epitopes positioned in primary structures, whereas B-cell epitopes lie in secondary and tertiary structures. Due to such differences, following heat denaturation, conformational shifts may eliminate certain epitopes on a protein, not affecting the integrity of sequential ones, and enzyme hydrolysis may alter both types. Physicochemical manipulations therefore do not alter all conformational epitopes, yet they may unmask epitopes hidden within a native protein three-dimensional structure, which may become immunogenic and accessible to IgE antibodies for binding while causing new ones to form [1, 12]. Actually, polypeptides without flanking amino acids can originate from hydrolysis, apt to combine with antibodies [591]. Instead, hydrolytic reduction of -S-S bonds of β-lactoglobulin (βLG) does not influence reactivity with IgE antibodies of native molecules or of fragments of tryptic hydrolysis, but reduces IgG reactivity [351]. These studies have revealed the structural bases of βLG antigenicity and immunogenicity: βLG immunogen epitopes are comprised in a relatively restricted part of the molecule, while those reactive with IgG appear to be correlated with conformational sites [351]. However, the distinction between immunogen and antigen epitopes is as yet scarcely known [402]. Individual residues within single epitopes, due to characteristics of either antigens or those specific to patients, are called *immunodominant,* thus are recognized

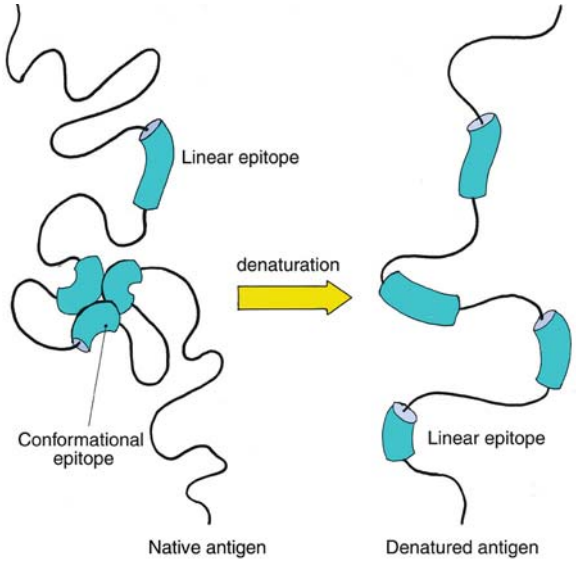

Fig. 1.18. Conformational and linear epitopes

Table 1.13. Main properties of human immunoglobulins (*Ig*)

Ig class	Heavy chains	Light chains	MW (kD)	Serum level (mg/dl)	Presence in secretions	Serum half-life (days)
IgA	α	κ/λ	160 (sIgA 390)	200±50	+	6
IgD	δ	κ/λ	175	3–4	–	3
IgE	ε	κ/λ	190	0.03	±	2
IgG	γ	κ/λ	150	1,250±300	–	23
IgM	μ	κ/λ	900	150±50	±	5

by most T or B lymphocytes induced by whole proteins. However, certain immunodominant, linear epitopes are represented by peptides with four to nine amino acids [511]. A single antibody may also react with an antigen other than the one causing its formation, as well with *different epitopes on the same molecule or carried by different molecules*: this is called cross-reactivity. Consequently, *allergenicity does not depend on the size of a given protein, but on the number of immunoreactive epitopes, similar or not* [185]. In practice, the same molecule can bind several different epitopes, either two combining with and cross-linking the same IgE molecule, or six, eight, or even ten nonidentical epitopes; whereas sIgE can bind more strongly to an allergen different from the one that stimulated its synthesis, but with characteristics similar to the first one [1].

In this context, children sensitive to Der p (*Dermatophagoides pteronyssinus*), for example, may produce sIgE binding to allergens of a species they have never met in the environment. Accordingly, following exposure to only one species of mites, children recognizing these common epitopes may produce antibodies that will recognize and respond to other species with this epitope, even if such species are absent in the environment where children live [671]. Additional studies support that different proteins may have common epitopes, thereby explaining cross-reactivities between different proteins within a given food as well as between different related foods, or between pollens, vegetables and fruits [1] (see p. 164). Likewise, if there are epitopes common to different substances with the same amino group in *p* (para) position on the benzene ring, patients sensitive to a drug with such a group should prudentially avoid other substances within the same chemical group. In conclusion, *epitopes identical or nearly identical can be found on antigen molecules of different origin or species*: an epitope common to two or more allergens triggers cross-reactions between substances with a similar structure, or between metabolites alike from an immunochemical point of view. As a consequence all molecules containing an epitope provoke allergic reactions in patients sensitive to another, even in the absence of a previous exposure and/or sensitization.

Antibodies

Immune responses are characterized by Ig production (Fig. 1.6): there are nine different isotypes correlated with nine C_H genes and two C_L genes: IgA_1, IgA_2, IgD, IgE, IgG_1, IgG_2, IgG_3, IgG_4, IgM, belonging to five major classes [3]. All Igs are glycoproteins and contain 3% to 13% of carbohydrates, depending on the class of antibody. The carbohydrate is essential in maintaining the Ig structure [115]. Tables 1.13 and 1.14 [544] summarize their main characteristics, including MW and half-life, and Table 1.15 [545] presents Ig levels at various ages compared with adult values; other authors prefer geometric means (GM). Isotype switching has an indubitable final significance, with every isotype having specialized biological properties, as follows:

- *IgG* comprise 75%–80% of serum Igs, being the only class crossing the placenta from mother to fetus, where it is found and is responsible for neonate protection during the first months of life. The levels decrease progressively, leading to a transient hypogammaglobulinemia at approximately 4–6 months of age, while normal adult values are attained only at about 4–6 years. Molecules are further divided into four subclasses: IgG_1 (70%), IgG_2 (20%), IgG_3 (8%), IgG_4 (5% of total). Besides the Hγ chain, subclasses have different properties, regarding for example, binding to serum complement and activating its alternative pathway, and adhesion to macrophages. IgG_2 has a lower placental passage, and IgG_4 is the only IgG unable to fix complement by the classic pathway, in addition to having a poor affinity for phagocytes. Abnormal levels of one or more IgG subclasses have been reported in children with severe chronic asthma, or recurrent respiratory infections (RRI) whether associated with asthma or not, of allergic type or not, with selective IgA deficiency (IgASD) or other PIDs, but not in otherwise healthy subjects (Chap. 22). Therefore, IgG antibodies represent the more differentiated phase of antibody responses with variations of subclasses according to encountered pathogens (or persistence of antigen stimuli). IgG is also an opsonizing antibody, although with lesser potency than IgM, reacting with epitopes on microorganisms via its Fab portions. However, the Fc portion for which many phagocytes bear

Levels of total serum IgE are in given in Chap. 6.
Modified from [545].

receptors delivers opsonizing properties; similarly it plays a critical role in ADCC, focusing NK cells on their targets [36]. To sIgGs (specific IgGs) and STS-IgGs (short-term sensitizing IgGs) has been credited a sensitizing activity mostly belonging to IgG_4, that turned out to mediate *similar-reaginic reactions but not of the IgE*

type, competing with IgE antibodies to bind to allergens [514]. In allergen molecules, IgE antibody binds to sIgE epitopes, while IgG antibody can bind to IgG-specific epitopes localized in the same point of the molecule or elsewhere: namely, IgG may react with the same epitope as IgE antibodies or the two Igs may react with two quite different epitopes on the same molecule [401]. IgGs are erroneously called *blocking antibodies* since they inhibit effects of IgE antibodies in the Prausnitz-Küstner test [1]: IgGs probably act as such, without interfering with sIgE epitopes to provoke an in vivo synthesis of IgE antibodies to a given allergen. However, not being reagins, IgG antibodies cause diagnostic perplexities due either to negativity of allergic tests in individuals with typical symptoms of immediate hypersensitivity or to a paradoxical situation of the same antibody acting in pathogenic and protective ways [1], an issue to be dismissed among the hypotheses put forward [13]. In summary, no direct challenge can reproduce clinical disease or tissue reactivity ascribed solely to specific IgG_4 antibodies to challenged allergens [13]. From a clinical point of view, in FA diagnosis measurement of IgG antibodies is superfluous because healthy subjects following a prolonged allergen exposure also have frequent elevations of serum IgG antibodies [13], while in respiratory allergy such levels are identical in patients whether they be atopic or not (Chap. 11). Characteristically, IgGs increase during SIT, although correlations between their rise and clinical results are unstable (Chap. 13). A high amount of IgG_4 was found in complexed IgG anti-IgE antibodies, recognizing at least two epitopes located within Cε2-Cε3 and Cε4 domains. IgG antibodies binding FcεRI located within interdomain regions might potentially cross-link IgE bound to FcεRI and blocking it, since only one of two ε sequences binds to FcεRI [514]. That an effector function of such weight is recognized by anti-IgE allows us to conclude with good reliability that anti-IgE antibodies play a modulator role, so essential during activation of metachromatic cells as to stimulate basophils to release histamine, a fact related not to IgG antibody levels or to subclasses, but to epitope specificity [513]. Administered intravenously (IV), Ig are highly beneficial to children with PIDs and several other affections.

- *IgA* antibodies prominent in the MALT are the sole antibodies in secretions (aside from a small percentage of IgM), hence it is called sIgA. IgA occurs as monomers, dimers, trimers and polymers. IgA monomers have no agglutinating properties (unlike sIgA) but can bind to antigens, predominant in serum, while dimeric IgA is quantitatively the most abundant in secretions. Two dimers are held together by the same J chain and associated with a polypeptide, called *secretory component* (SC), localized on the long arm of chromosome 1. SC is a fragment of epithelial cell poly Ig receptors and a component of high significance because it protects mucosal sIgA from proteolytic degradation, literally wrapping round $C_\alpha 2$ domains of both sIgA subunities, even if -S-S bonds are for only one subunit [186]. The two subclasses, IgA_1 and IgA_2, represent 12% and 3% of total serum Igs, respectively. sIgA is actively transported across epithelial cells, *covering as a film* and protecting mucosal surfaces from microorganisms, preventing organism attachment to cells and clearing them off by phagocytosis. IgA can activate complement via the alternative pathway, not inducing bacterial lysis mediated by the classic pathway, and possess bactericidal activity against Gram– organisms, but only when lysozyme is present, interestingly, in the same secretions containing sIgA [36]. Table 1.15 shows IgA levels slowly ascending, and sIgA levels quickly produced. IgA antibodies present in colostrum and breast milk protect at-risk infants (Chaps. 2 and 24). IgASD is the most frequent PID.
- *IgE* (in which the E is erythema), also termed reagins with a half-life of 2–4 weeks on metachromatic cell membranes, are normally present in serum at the lowest concentration, <0.001%, of total circulating Igs. For this reason, IgE concentration is expressed in international units (IU), one IU being equal to 2.4 ng/ml. IgE levels increase considerably in atopic diseases, hyper-IgE syndrome (HIgES), infections with parasites [471], pediatric AIDS, and other diseases. High levels saturate mast cell receptors and pass into the circulation, where detectable levels are extremely elevated compared to normal subjects [471]. IgE antibodies come from plasma cells distributed primarily in lymphoid tissues of respiratory and gastrointestinal tracts, derived from pre-B cells from a differential lineage originating from IgM B lymphocytes and via the following passages: $B_{IgM-IgD}$ – $B_{IgM-IgD-IgE}$ become IgE B lymphocytes. Like other Igs, IgE has four polypeptidic chains, but two chief immunobiological characteristics: an ε chain 11 kD greater than homologous chains, with five domains, one V and four C, one more than other Igs, and is cytophilic, having a propensity to bind to metachromatic cells with Fc fragment, of which FcεRI is a receptor (Table 1.3). FcεRI extends from the C-terminal part of Cε2 to the N-terminal sequence of Cε3 domains, while the FcεRII binding site, the second receptor, is localized in the N-terminal part of the Cε3 domain close to FcεRI [553]. Since IgE molecules have a bent form, their convex surface nearest the membrane (Cε3) binds to FcεRI, thereby *making remote a binding site for another receptor* (Fig. 1.19, showing also FcεRII). This explains why FcεRI has only an α chain, its affinity for only an ε chain, and why there is only one receptor [553]. IgE molecules have no subclasses, similarly to IgM and IgD molecules [186].
- *IgM* is present early in primary immune responses to most antigens. Small IgM amounts in secretions (sIgM) also contain SCs. Being a pentamer, covalently linked by -S-S bonds with J chain, it *does not pass through the placenta*. Moreover, the IgM molecule is the most efficient agglutinating and complement-fixing Ig (by classic pathway). Because of their pentameric form, IgM antibodies can form macromolecular bridges between epitopes that may be too distant from each other to be

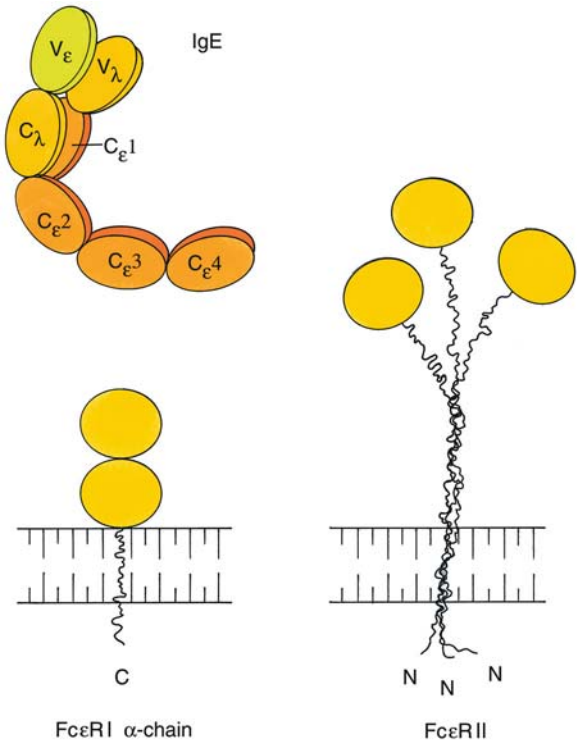

Fig. 1.19. IgE and its receptors. FcεRI α-chain. Schematic representation of IgE and its receptors FcεRI and FcεRII drawn to the same scale. IgE is illustrated as a drawn molecule, whereas the FcεRI α-chain is drawn erect. The other chains have been omitted to simplify the diagram

bridged by monomeric IgA antibodies. Also, because of their multiple valences, they are best suited to combine with antigens containing more epitopes, as related to PS or cellular antigens [36]. Together with IgD, IgM is the most common Ig expressed on B cell surfaces (and virgin B cells). IgM is the first Ig class synthesized by both the fetus and newborn: high fetal IgM levels are indicative of congenital or perinatal infections [186]. IgM is the isotype synthesized in noticeable amounts by children and adults as a primary antibody response after immunization or exposure to T-dependent and T-independent antigens; therefore a role of IgM as regulator of immune responses via a specific receptor of Th lymphocytes has been postulated. IgM antibodies are significantly increased in IgASD and particularly in HIgMS.

- *IgD* is present in serum in very small amounts. Its presence on B-cell membranes during certain stages of development may suggest either an involvement in B cell maturation or a prominent role in immune tolerance. However, IgD functions are mainly unknown 186].

Idiotypes and Anti-idiotypes

V regions of antibodies may have two different functions:

- *Recognizing, with the paratope,* one or more epitopes present on an antigen or on different antigens
- *Acting as an antigen* with an idiotype leading to anti-idiotype antibodies [18]

Such antigen functions are committed to idiotypes, present in V_H and V_L regions of antibody molecules.

Definitions

- *Public or cross-reacting idiotypes,* expressed by antibodies produced by all individuals of the same race, are directed against a single epitope or against nonidentical antigens. V gene mutations altering paratopes without modifying idiotypes determine the sharing of a public idiotype from antibodies with different specificity.
- *Private or individual idiotypes,* present in a single clone, expressed irregularly by subjects of the same species, therefore exclusive of a given individual, directed against a single epitope.
- *Anti-idiotypic antibodies* are complementary antibodies, directed against the structure of an antigen-recognizing antibody, which can prospectively trigger production of a network of anti-anti-idiotypic antibodies and so on.
- The *internal image of the epitope* is a structurally identical idiotype cross-reactive with epitopes of foreign antigens.
- *Regulatory idiotype,* present on a relatively high number of Ig molecules and/or T lymphocytes, where it can function as a base of a regulatory receptor-specific system.

In other words, a V region of an antibody contributing to paratope expression and antigen recognition has idiotypes against which the organism reacts, instinctively inducing anti-idiotype antibodies against sIgE; anti-idiotype antibodies are normally formed during immune responses. In some instances, a fraction of an anti-idiotype may exemplify a facsimile (or an internal image) of the nominal epitope that triggered the original reaction [47]. Figure 1.20 summarizes a wide panorama of idiotype activities.

In Network Theory, the Nobel laureate Niels Jerne [238] proposed a network of idiotype–anti-idiotype interactions as a regulatory mechanism of immune responses, the expression of each idiotype being suppressed by complementary anti-idiotypes. The foreign antigen approach, disturbing pre-existing homeostasis sustained by an equilibrium between idiotype and anti-idiotype, generates an immune response by T and B cells, activating *anti-idiotype responses* [238], either humoral (antibodies against idiotypes of soluble Igs) or CMI (T cells with TcR specific for hypervariable regions of both TcR and BcR) [474] (Fig. 1.20). Some anti-idiotype antibodies may competitively block binding to paratopes of corresponding antigens, interacting with epitopes or directly with paratopes (*associated idiotypes*), thus eliciting an antigen–antibody reaction wholly similar to classic reactions induced by antigens [454]. Other anti-idiotypes, without such selective inhibition,

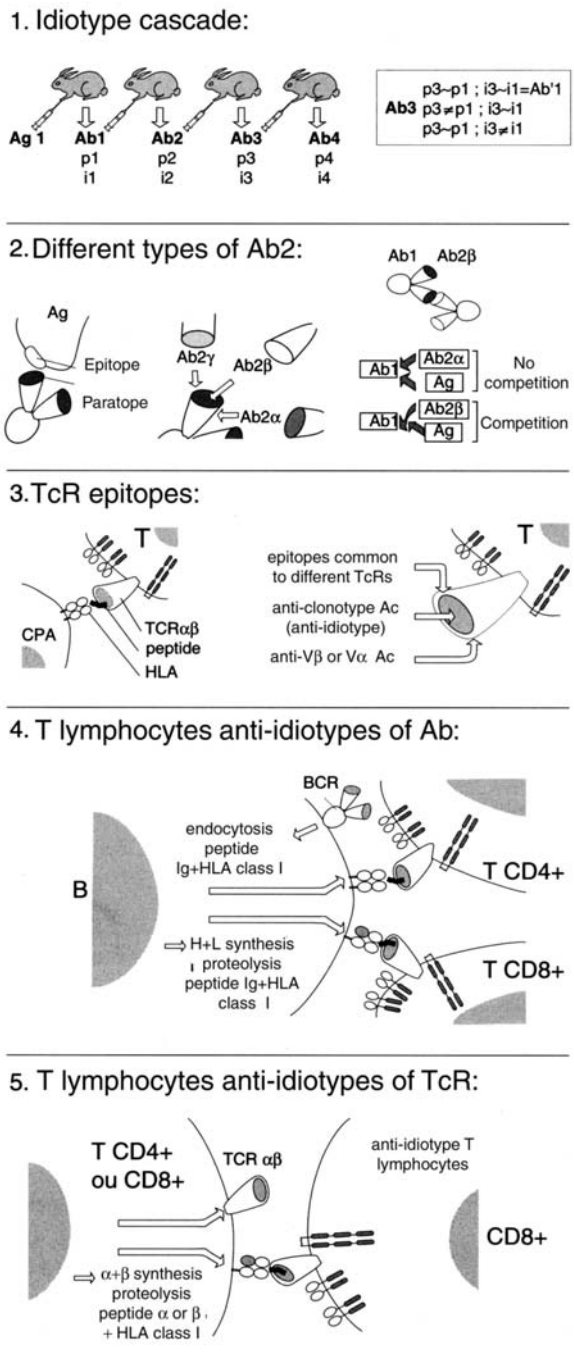

Fig. 1.20. *1*: Idiotype cascade. It was observed that antibodies with different specificities can share the same idiotypes. *Ag* antigen, *Ab* antibody. *2*: Different types of Ab2α. Ab2βs, internal images of Ag, bind to Ab1 at a site corresponding to the paratope, thus inhibiting Ab1-Ag binding. *3*: TcR epitopes. The anti-clonotype Abs are directed against the hypervariable regions of Vα and Vβ domains forming the TcR binding-site: anti-Vα or Vβ Abs recognize epitopes defined by sequences common to members of the same family, while other Abs recognize epitopes common to TcRs with different specificity. *4*: T lymphocytes anti-idiotypes of Ab. *5*: T lymphocytes anti-idiotypes of TcR

may instead bind to amino acid sequences of the paratope FR region, which do not contribute to antigen binding (*not associated idiotypes*) [454]. As it was demonstrated, anti-idiotype antibodies can bind directly to Ig idiotype determinants, regulating their expression [58]. Also for T cells there is evidence of T-cell idiotypes (clonotype markers) and of interactions between B-cell and T-cell idiotypes [58]. In addition, anti-idiotype antibodies specific for TcR clonotype markers have been observed, in turn interrupting the network of anti-idiotype antibodies produced in certain diseases during a normal immune response: since T cells can have varying phenotypes, a potential exists for augmenting or suppressing immune responses via idiotype networks involving T cells [58]. For example, T-cell idiotypes may be recognized by B cells (antibodies) or by peptides associated with T cells (TcR) presented by HLA class I or II molecules. Similarly, T cells can recognize B idiotypes presented as HLA-associated peptides [236] (Fig. 1.20). Additionally, although antibody responses to target antigens are characterized by formation of several hundred different antigen–antibody molecules, idiotype–anti-idiotype reactions are much more restricted depending on common amino acid sequences, in close contact with paratopes of different antibodies. According to these studies, cross-reactivity is frequently observed among various antibodies in anti-idiotype responses to target antigens. In other words, if paratopes able to recognize a given idiotype exist, classic epitopes should present it together with idiotypes already existing in the molecule [236].

Anti-idiotypes can regulate sIgE responses but cannot cause antibody responses; however, miming functionally original epitopes, the so-called idiotypes *internal image* of antigen *or network antigens* (in the sense given by Kohler) [268] can behave as *surrogate* antigens, or as epitopes in terms of structural affinity, like antigen molecules, thus increasing antibody responses. Figure 1.21 [58] shows another of Jerne's theories, in which idiotypes can mimic structures of apparently unrelated antigen molecules, binding to receptors specific for that antigen and inhibiting immune responses or, on the contrary, up-regulating them by replacing some antigen functions. The paratope of antibody 1 is complementary to a structure on the immunizing antigen; in turn the paratope of antibody 2 is complementary to that of antibody 1, and thus antibody 2 can resemble a structure on the immunizing antigen. In the case of insulin and of anti-insulin antibodies (Fig. 1.21), the paratope of antibody 1 is complementary to the epitope, antibody 2 is an anti-idiotype vs anti-insulin antibodies (antibody 1), and can bind to the insulin receptor and even stimulate glycolysis [58].

The circuit thus far described may have envisioned an idiotype network. Examining part A1 of the figure, we consider two B cells, B1 and B2, whose complementary surface Igs form an idiotype–anti-idiotype pair. Thereby, B1 cell binds to an Ig V region on the B2 cell surface,

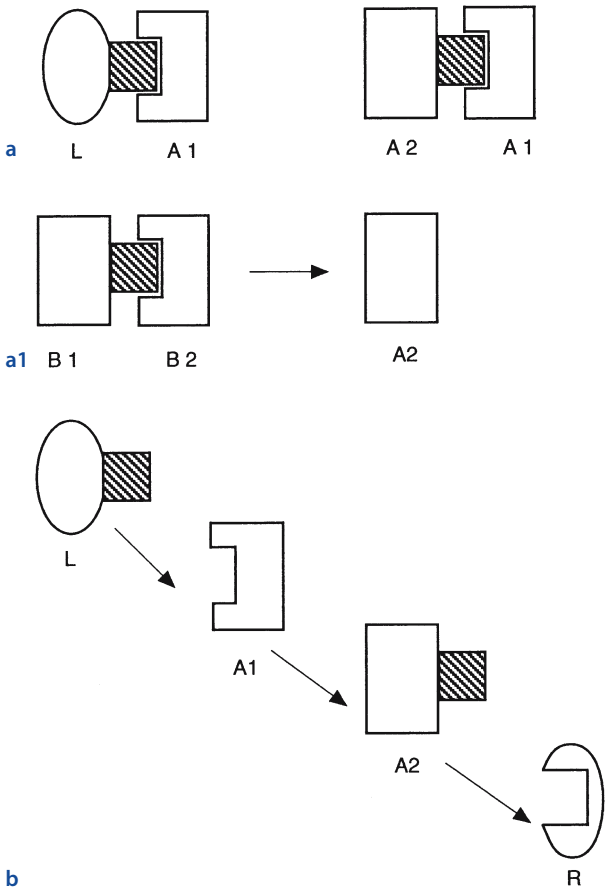

Fig. 1.21. **a** Diagram of the complementary relation between antibody 1 (*A1*, idiotype) and antibody 2 (anti-idiotype). **b** Because of the complementarity with the ligand (*L*), *A2* can bind to the receptor (*R*) for L. (Modified from [58])

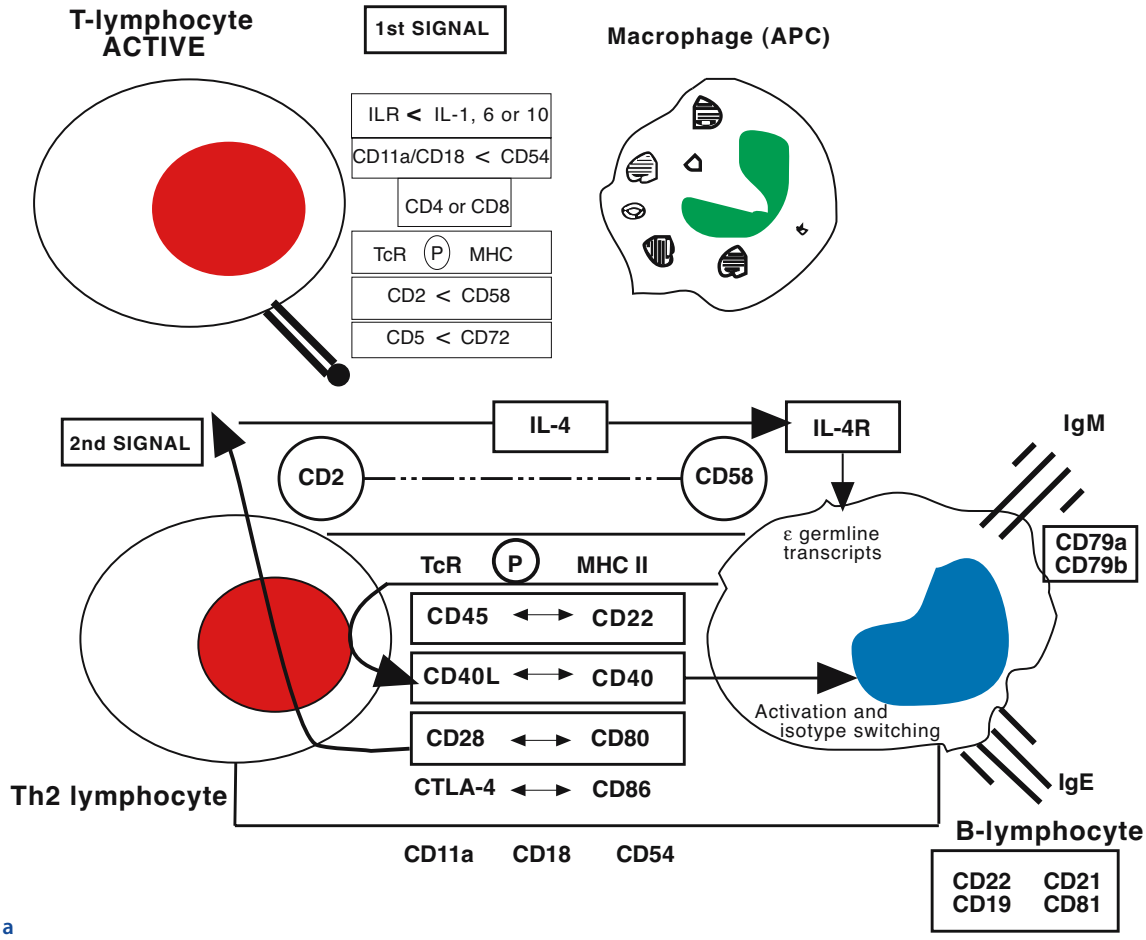
stimulating the cell to secrete antibody 2: in this way an idiotype secreted during immune response to a given antigen can yield a corresponding anti-idiotype. In several idiotype–anti-idiotype systems, anti-idiotypes can act as anti-receptor antibodies. Among hormones, besides insulin, we find thyroid-stimulating hormone, prolactin, glucagon, etc.; among neurotransmitters are found acetylcholine, catecholamines, endorphins, reovirus, etc. In all these instances, the V region of antibody 2 represents the internal image of the external antigen. It may seem odd that an antibody is disguised as an antigen, but among 10^8 three-dimensional V regions there must be a kind of mimicry of other molecules [58].

Interesting applications of these studies are observed in laboratory animals: the basic principle is that in different species immune responses elicit formation of antibodies expressing a common idiotype. For example, oral immunization with heterologous antibodies modulates both systemic and mucosal anti-Ig responses: after administering murine IgA antibodies to rabbit females, murine anti-idiotype anti-antibodies are found in the serum and colostrum [683]. It is striking that murine monoclonal anti-idiotype antibodies, specific for the rye grass pollen allergen *Lol p 4*, are able to inhibit binding of murine, rabbit, and even human antiserum. Since *anti-Lol p* antiserum can inhibit idiotype–anti-idiotype interactions, accordingly the monoclonal antibody in question has been characterized as an internal image anti-idiotype of the antigen [683]. Further experiments have demonstrated that immunizing adult mice with anti-idiotype antibodies against poliovirus are activated antibodies that effectively neutralize upcoming viruses. An interesting study (Chap. 2) following this line of research has revealed that the CB of offspring of agammaglobulinemic mothers or with IgASD was able to inhibit binding of poliovirus antigens to anti-poliovirus antibodies: a suggested rationale is a probable reactivity against CB anti-idiotype anti-antigen antibodies.

Current acquisitions on immune system regulations are still a matter of debate. At least two control systems are concerned, one provided by the suppressor cell network and the other by the idiotype cell network. The first network can be activated by original immune stimuli that regulated the system. CD8 T cells may be specific for a given clone or may down-regulate T-cell responses in a nonspecific way. Consequently, the same complex molecule can trigger helper T cells, effector T cells, and specific or nonspecific suppressor T-cell responses. Several ILs can also contribute to these results, modulating CD4 or CD8 T cells [469]. Idiotype regulation depends on recognition by the immune system that an immune reaction took place. In this event, antibody production in response to an antigen stimulus and pertinent antigen–antibody interactions trigger a response by a second series of IgE-producing B cells. The second-generation antibodies react with idiotypes on the original paratope producing the first-generation antibody and block its production. Anti-TcR antibodies are also formed and down-regulate T-cell responses in a similar way, while CD8 T cells can operate against idiotypes. Such intervention of cells and responses is essential to avoid that *a failure, even partial, of any regulatory systems may result in active immune responses* [469].

Apoptosis or PCD

If a thymocyte fails to produce any functional α chain, it cannot be selected and eventually dies of apoptosis; if a T-cell cannot be activated because the second signal is absent, it may be a target of a distinctive event known as *clonal anergy* (Fig. 1.22a) [138, 160, 177, 457]. Consequently, mature lymphocytes are rendered functionally unresponsive, resulting in *tolerance,* for example because CD28/CD80–CD86 [446] or CD40–CD154 (CD40L) costimulatory signals are lacking, which instead amplify such signals [37, 160]. Signaling via the CD122 γ chain can prevent induction of T-cell anergy



a

Fig. 1.22. **a** Schematic representation of the interactions arising during antigen presentation and the effects of T and B cells in the lymph node cortex (T zone) (see text). *CTLA-4* CD152, *CD40L* = CD154. (Modified from [138, 160, 177, 436]). (Fig. 1.22 b, c see next page)

[4]. *Clonal deletion* applies to particular clones of autoreactive, immature T cells that are physically destroyed during ontogeny to maintain self-tolerance [30]. Figure 1.22b shows that a CD4 T-cell associated with a HLA molecule recognizes a self-antigen and is eliminated instead of being activated (PCD) [138, 185]. Costimulatory signals are crucial also for T naive cells: when such signals are absent, the first stimulation by TcR renders them ignorant, refractory to further stimuli, and following a likely second stimulation, they are exposed to an inappropriate activation; therefore they may remain functionally inactive (anergy) or die (PCD) (Fig. 1.22c). Clonal deletion and negative selection also take place in immature B lymphocytes. For example, *limitin* (IFN-ω) (Table 1.5) produced by mature T lymphocytes in spleen and thymus as well as by bronchial epithelial and salivary duct cells suppresses the proliferation of pre-B cells [402]. Figure 1.23 shows positive and negative selections developing in GCs [309]. PCD occurs during embryogenesis, in the thymus during cell immune maturation, and at the end stage of immune responses [115, 276, 510]. It was also shown that PCD is an active form of genetically programmed cell suicide, not provoking inflammatory reactions [192]. More precisely, PCD is a physiological apparatus essential for normal development and homeostasis of multicellular organisms, a sophisticated defense mechanism to remove potentially dangerous cells, including self-reactive cells, virus-infected cells, and tumor cells, aiming at restoring a previous equilibrium [542]. CD4 and CD8 T cells, after their maturation into effector cells, die in 95% of cases, not only for precise regulation of cell numbers, or to maintain cellular homeostasis, but to protect T cells from continued secretion of potentially harmful amounts of ILs [400] and to leave a stable pool of long-lived memory cells [7]. Apoptosis occurs by *ex novo* activation of specific genes acting as PCD inducers/activators, or whose expression coincides with cell entry into apoptotic pathways (Tables 1.16, 1.17) [192, 400]. Here Fas/Apo 1 (CD95)-induced apoptosis is an important

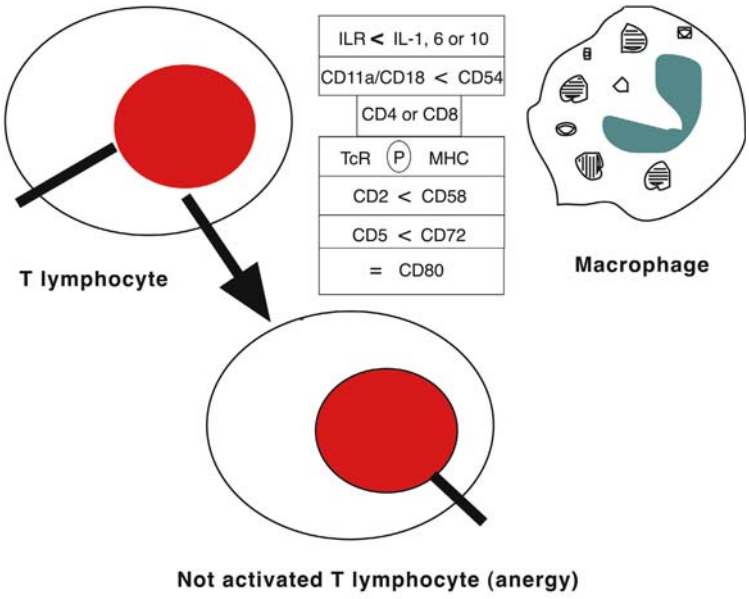


Fig. 1.22. b *Upper part*: Clonal anergy. CD4 T cell recognizes the antigen presented by APC; however, there is no CD80–CD28 interaction and it remains inactivated. *Lower part*: Clonal deletion. CD4 T cell recognizes a self-antigen; however, instead of being activated it is eliminated (apoptosis). **c** Effect of the intervention or not of costimulatory signals: on the *left* there is normal binding between peptide-HLA-TcR associated with the binding of a costimulatory ligand (*CL*) to a costimulatory receptor (*CR*), on the *right*, ignorance, anergy and apoptosis result because of the lack of costimulation. (Modified from [138, 160, 177, 457])

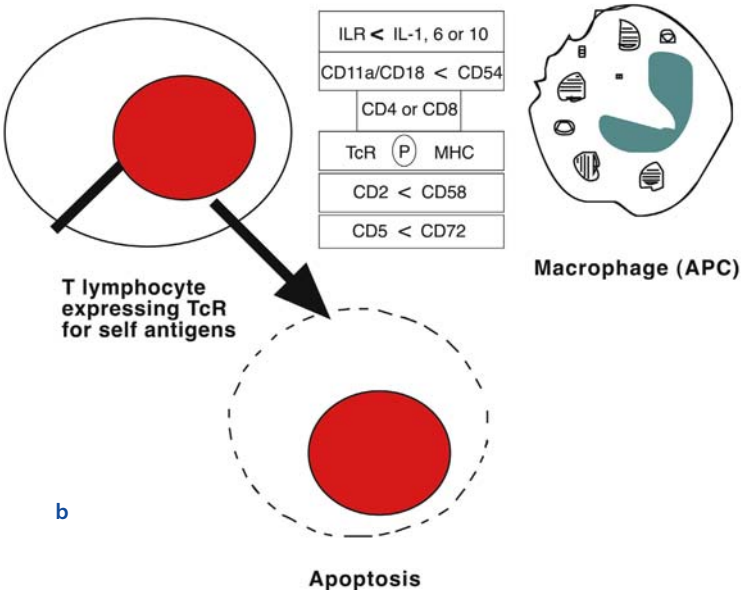

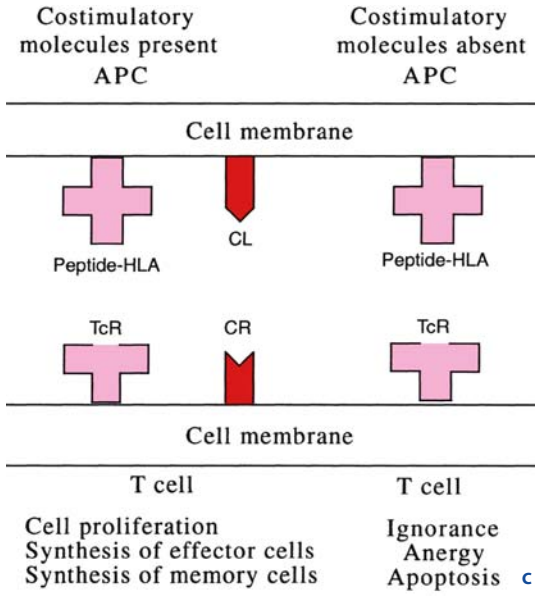

Table 1.16. Genes of the apoptotic pathway, either induced or expressed during apoptosis

Gene	Gene products	Probable function
c-*fos*	Transcriptional factor	Induces apoptosis when continuously expressed
c-*myc*	Transcriptional factor	Activates an apoptotic program
Fas/APO-1	Membrane receptor	Ligand binding induces apoptosis
Grb-3	Transduction factor	Expressed in some tissues during apoptosis
ICE/pr ICE	Cysteine protease	Initiates the active phases of apoptosis
nur 77	Nuclear receptor	Expression during apoptosis starts gene transcription
p-53	Transcriptional factor	Induces apoptosis upon DNA damage or loss of Rb function
RP2	Membrane receptor	Expressed during early stages of apoptosis
TG	Transglutaminase	Accumulates in apoptotic cells
TRP M2	Clusterin, SGP-2	Expressed in some tissues during apoptosis

Modified from [192].

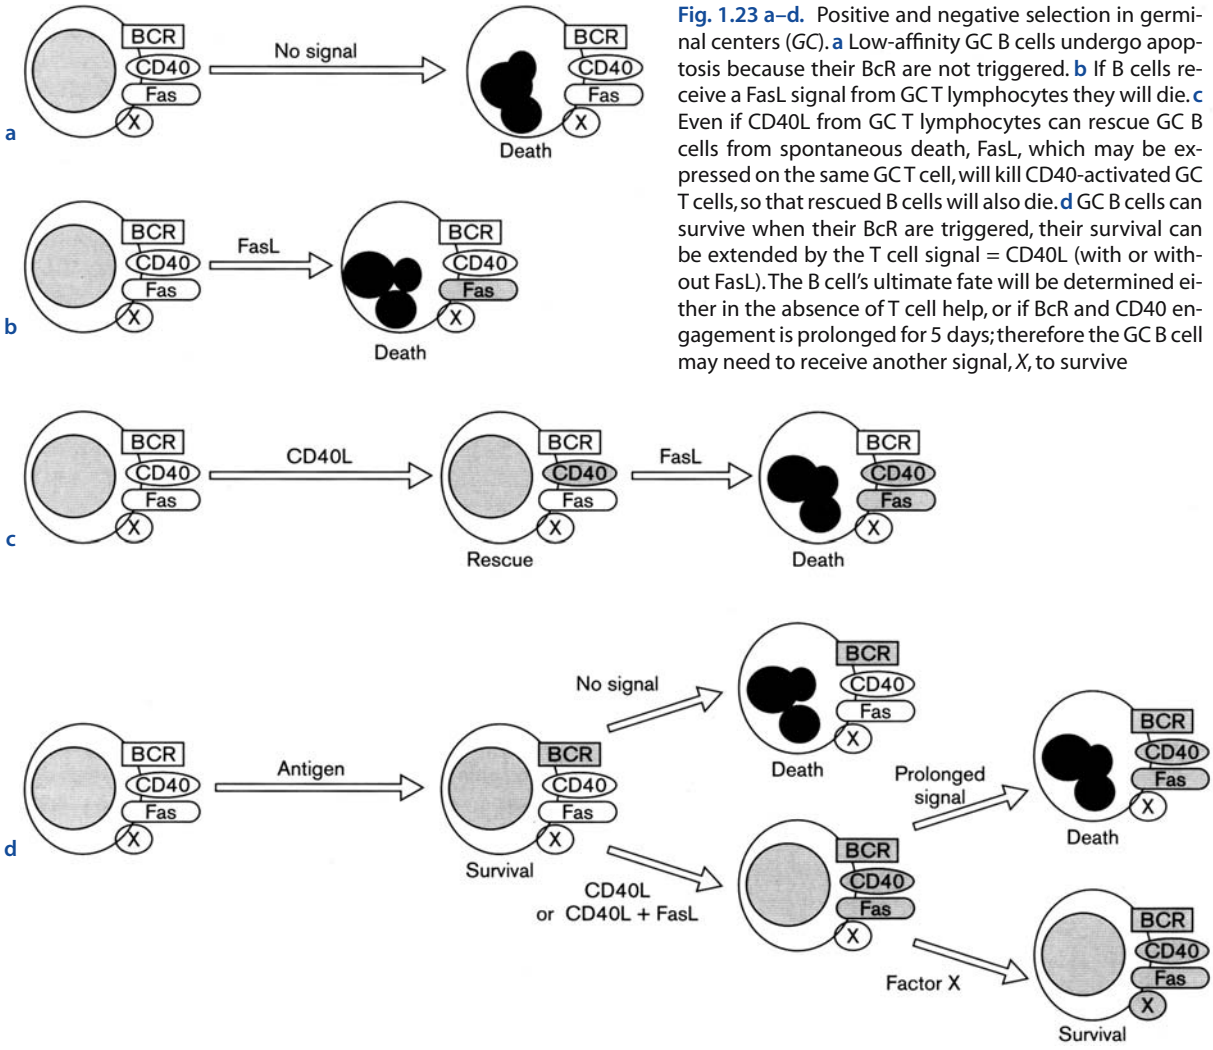

Fig. 1.23 a–d. Positive and negative selection in germinal centers (*GC*). **a** Low-affinity GC B cells undergo apoptosis because their BcR are not triggered. **b** If B cells receive a FasL signal from GC T lymphocytes they will die. **c** Even if CD40L from GC T lymphocytes can rescue GC B cells from spontaneous death, FasL, which may be expressed on the same GC T cell, will kill CD40-activated GC T cells, so that rescued B cells will also die. **d** GC B cells can survive when their BcR are triggered, their survival can be extended by the T cell signal = CD40L (with or without FasL). The B cell's ultimate fate will be determined either in the absence of T cell help, or if BcR and CD40 engagement is prolonged for 5 days; therefore the GC B cell may need to receive another signal, *X*, to survive

regulatory mechanism in T cells. CD95 is in the first place as well as additionally involved proteins, including ICE ($IL_1\beta$-converting enzyme), and other proteases of the family, which may be common effectors of cell death [400]. Other genes code for products preventing cell entry into PCD pathways or regulate cell survival (Table 1.18) [192]. A third option is the inhibition or induction mediated by viral genes (Table 1.19) [192], clearly a strategy to ensure virus survival until the genome has replicated to establish a successful infection. More recently, the protein kinase RIP (receptor-interacting protein) has been included. Although the best role of RIP is in TNF signaling and NF-κB activation, it contains a death domain and it is capable of causing apoptosis upon cleavage [26]. From the picture shown by the tables, this multiform apoptosis pattern is unfolded: at variance with necrosis, cells shrink, both nucleus and cytoplasm condense, dying cells often release intercellular elements bound to membrane fragments, rapidly phagocytosed and engulfed by neighboring cells to remove possible noxious contents, and activated nucleases extensively degrade chromosomal DNA into small oligonucleotide fragments [542].

Studying cell-death defective (ced) species, three genes were shown to play a central part in PCD: *ced-3, ced-4 and ced-9*. The first two promote cell suicide; instead, ced-9 prevents the process started by ced-3 and ced-4, thus inhibiting apoptosis [542]. The mammalian counterpart of ced-3 is ICE, and that of ced-9 is proto-oncogene *bcl-2* (B cell lymphoma-2), mainly located within outer mitochondrial membranes, the ER, and nuclear membranes [267]. *The bcl-2/ced-9 gene prevents*

1.18. Genes of the apoptotic pathway: inhibitors and survival regulators

Genes	Gene products	Probable function
bcl-2 (ced 9)	Radical trap (?)	Inhibits apoptotic program(s)
Regulators of bcl-2 (with structural homology with bcl-2)

C cytochrome mitochondrial release, necessary to start apoptosis, and interacts with ced-4 inhibiting its function [661]. Expression of gene product par-4 correlates with severe impairment of cell proliferation and apoptosis via inhibition of PKCζ (protein kinase Cζ) enzymatic activity more probably of atypical PKC isoforms, also impairing MAP kinase (mitogen-activated protein) activation [655], whereas PI3K (PI-3-kinase) *generates survival signals* [412, 684]. The PKC family consists of serine/threonine-specific protein kinases that transduce a cascade of signals especially derived from the hydrolysis of PIP2 (phosphatidylinositol-bisphosphate). The classical PKC (cPKC) α, βI, βII and γ isoforms require diacylglycerol (DAG) and Ca^{++} for activation, whereas PKC δ ε γ and η isoforms, along with the related protein PKCμ, need DAG but do not require Ca^{++} [114]. In a recent study, CD43 ligation led to membrane translocation and boosted the levels of membrane-bound PKC isoenzymes, mainly of the PKCζ, PKCα/β, PKCε and θ, and PKCμ isoforms. Following CD43 ligation PKCθ activation induced CD69 up-regulation via an ERK (extracellular signal-regulated kinase)-dependent kinase pathway, promoted the AP-1, NF-κB activation and an ERK independent pathway promoting NFAT (nuclear factor of activated T cells) activation. Consequently, PKCθ was found to play a key role in the co-stimulatory functions of CD43 in human T cells [114]. bcl-2 was identified as a mammalian homolog to the antiapoptotic ced-9 in *Caenorhabditis elegans,* but mutations in the bcl-2-like gene ced-9 as well as DRP-1 (dynamin-related protein-1) and BH3-only protein EGL-1 may block its mitochondrial fragmentation [235]. Studies on this nematode by the 2002 Nobel laureates have shown that it has a fixed number of cells, 959, and if the number is altered, it is because too many cells die or, conversely, too many proliferate. In humans, AIDS could be provoked by excess PCD and autoimmune disease by insufficient PCD. At least 19 bcl-2 family members have been identified in mammalian cells, which possess at least one of *four conserved motifs* (BH1–BH4) [684]. The bcl-2 family members can be subdivided into three categories according to their function and structure: *antiapoptotic members,* such as bcl-2, bcl-XL, bcl-w, Mc1–1, and A1 (Bf1–1); *proapoptotic molecules,* such as Bax, Bak, and Bok (Mtd); and the BH3-only proteins, Bid, Bad, and Bim, which are called BH3-only proteins because of 4 bcl-2 homology regions, and share only the third [684]. *Galectin-1* (Gal-1) and *galectin-3* (Gal-3) are

β-galactoside-binding proteins with pro- and anti-apoptotic properties, respectively (Chap. 18). Some CTLs play a role of effector cells during apoptosis, as we have seen: this is the result of perforin action [69] or of activation and concurrent transcription of Fas and its counterreceptor CD178 or Fas ligand [388]. In humans, Fas gene is located on the long arm of chromosome 10, spans 12 kb, comprises nine exons, and in mice is expressed in tissues enriched by mature lymphocytes, except for DN [388]. A further study documented a TNF role in the apoptosis of activated CD8s [681], thereby confirming the higher inclination of Th1 T cells to effectively modulate killing by Fas binding [69]. A main pathway involves the signaling pathway of TNFR/CD95 activating both PCD and TF nuclear factor κB (NF-κB) (also activated by IL_1), the two events occurring independently [599], via recruitment of multifunctional FADD (Fas-associated death domain) and TRADD (TNFR-1-associated death domain) molecules [82]. PCD provides death receptor 3 (DR3) that most likely participates in lymphocyte homeostasis [82]. Activation of NF-κB is also regulated by the NF-κB phosphorylation via the IKK complex. The IKK complex, consisting of two kinases, IKK1/α and IKK2/β, and the NF-κB essential modulator (NEMO)/IKKγ regulatory subunit, mediates NF-κB activation by most known stimuli [503]. Another essential component of NF-κB activation is NIK (NF-κB-inducing kinase) whose interacting protein, TNAP (TRAF or TNFR-associated factor and NIK-associated protein) specifically inhibits NF-κB activation induced by TNF-α, TNFR1, TRADD, RIP, TRAF2, and NIK but does not affect IKK1- and IKK2-mediated NF-κB activation [217]. Overexpression of a new molecule, NIBP (NIK and IKKβ-binding protein), potentiates TNF-α-induced NF-κB activation [218]. TRAF6 interacts with TIR domain-containing adaptor inducing IFN-β (TRIF) through the TRAF domain of TRAF6. However, disruption of TRAF6-binding motifs of TRIF impaired its association with TRAF6, thus resulting in a reduction in the TRIF-induced activation of NF-κB [491]. TRAFs as components of the IL_1 signaling pathway mediate signaling by interacting with TNFR, rather than with TLR, thus playing a role in cellular processes such as apoptosis [327]. The scenario is not complete, since TRAF2 and TRAF3 have been shown to play opposing roles: a positive one in the standard pathway that activates NF-κB through IKKβ, but a negative role in the uneven pathway that activates NF-κB via IKKα, roles of TRAF proteins possibly linked to their ability to synthesize different forms of polyubiquitin chains [656]. The apoptosis–associated induction of the ubiquitin–proteasome pathway components and the proteasome activity shows that the proteasome plays an important role in the successful execution of apoptosis. Inhibiting either the proteasome activity or the increase in proteasome 26S gene expression or its upstream PI3 kinase activity results in an inhibition of NF-κB translocation thereby suppressing apoptosis [527]. There are many Fas variants: soluble Fas (sFas) can block apoptosis induction [600] as well as crmA – inhibiting ICE/ced-3 (Table 1.19). A second pathway depends on mitochondrial participation by releasing apoptogenic factors: cytochrome c catalyzes the oligomerization of APAF-1 (apoptotic protease activating factor 1), which recruits and promotes the activation of apoptosis proteins (IAPs) such as procaspase-9. These proteins interact via CARD-CARD (caspase recruitment domain interactions) [599]. Procaspase-9, in turn, activates procaspase-3, leading to apoptosis, but is prevented by members of the bcl-2 family, but cells also contain natural IAP inhibitors, the caspases (aspartate-specific cysteine protease), a family of cysteine proteases, which were found both in baculovirus and in human cells (XIAP, c-IAP1, and c-IAP2). IAPs can act as direct inhibitors of the two death effectors, caspase-3 and caspase-7, and are able to suppress the activation of two initiator caspases, caspase-8 and caspase-9 [418, 599]. Studies performed on the activity of effector caspase 3 and on the initiator caspases 2, 8, and 9 revealed that, in the absence of RIP, the activity of these caspases decreases, indicating that RIP-associated apoptosis is caspase-dependent [26]. Thus, Fas, TNF-related apoptosis-inducing ligand (TRAIL) and TNFRs can initiate cell death by two alternative pathways, one based on caspase-8 and the other dependent on the RIP kinase [211]. NF-κB is an essential regulator of immune cell survival, critical for the activation of T and B lymphocytes, and is a central coordinator of innate and adaptive immunity [470].

The apoptosis machinery in B lymphocytes may be different, generally immature cells with IgMs or IgDs or cells that have formed an extra paratope [37]. Also, B cells with poor affinity for antigens, or autoreactive, are destined to a rapid apoptosis and are phagocytosed by macrophages leaving nuclear residues forming tingible bodies [254]. The *bcl-2/ced-9 gene blocks PCD* in B cells and *cells provided with bcl-2* [400]. CD23 may prevent apoptosis of GC B cells [4]. Mounting evidence suggests that autoimmune diseases and viral infections, for example, may be associated with failure to undergo PCD, as well as others characterized by inappropriate cell destruction, AIDS as a first example [542].

The HLA System

The HLA system is the human version of the MHC called H2 in mice. HLA, first discovered in the 1950s, was recognized by its major influence in transplant rejection. Subsequent studies have revealed that HLA is in mammals a single gene region with a pivotal role in antigen recognition and control of immune response (Ir); some Ir genes are also mapped within its structure [329]. The chromosome region containing genes coding for self/non-self discrimination is a highly polymorphic complex region of about 4,000 kb located on *chromosome 6 short arm* (6 in region *p21.3*) (Fig. 1.24). HLA is

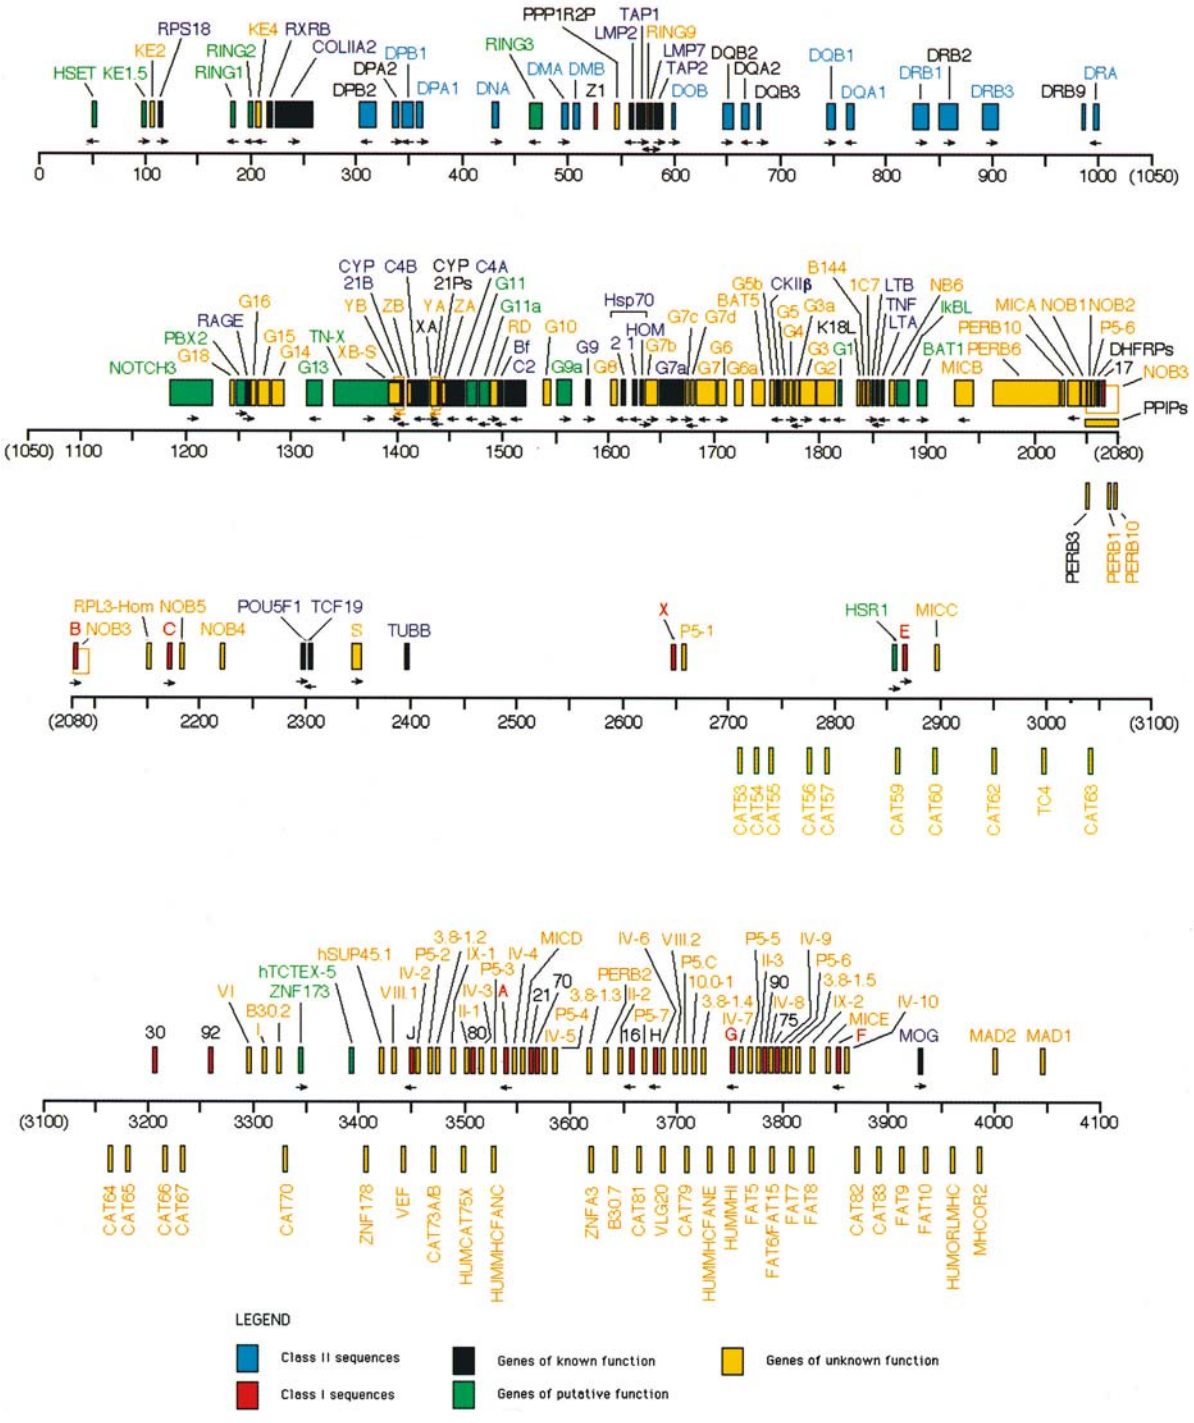

Fig. 1.24. Scheme of human HLA

referred to as complex because its genes are located on a single chromosome, and all genes can therefore be transmitted to children as one unit [18]. In humans this is the best known histocompatibility system as defined at the genetic level, comprising hundreds of genes connected together (>40% of which encode leukocyte antigens) and characterized by structural and functional diversions [264]. *Histocompatibility* is the property of accepting cells or tissue grafts between individuals [329]. Because of their close linkage, the combination of alleles at each locus on a single chromosome is usually inherited as a unit, except for infrequent cases of recombination, and is referred to as the *haplotype*. Although during evolution there may have been variations, the haplotypes of various mammals and birds hitherto studied are fundamentally similar. A key task

carried on by these molecules is to present antigens or peptides deriving from enzyme cleavage to TcRs. That peptides associate with HLA molecules and are recognized as a single entity demonstrates either the phenomenon of restriction [688] or the genetic control mediated by products of HLA genes present on all nucleated cells. HLA class II genes, expressed in a constitutive way in some cells, including B and T cells, macrophages, and DCs, stimulated by specific activators such as IFN-γ in endothelial and epithelial cells, form a trait with high genetic variability, so that proteins encoded by the above-mentioned genes usually differ from one individual to another [329].

In mice, chromosomal segments controlling immune phenomena are divided into five regions: K and D regions encode serologically defined (SD) antigens, found in all nucleated cells and called *HLA class I molecules.* Ir genes (in mice antigen-associated with the I region of the H2 complex and in man DR- and D-related) are present on APCs, more restricted as regards their distribution and defined as *HLA class II molecules;* the S region controls synthesis of complement components. K and D regions are recognized by CD8 T cells during transplant rejection. It was also shown that following a viral infection, murine CD8 cells will lyse only infected target cells derived from a line that is genetically identical with the same K- and D-region molecules as the original stimulating cells [33].

HLA includes *loci* A, B, C (class I region) and D (class II region); lymphocyte-defined (LD) antigens are called HLA-DR, -DP and -DQ. Each *locus* is composed by a series of alleles determining the corresponding gene products (HLA antigens) on cell membranes. According to recent nomenclature, alleles with confirmed sequences of amino acids or nucleotides have a specific designation, including the name of *locus* and four arabic numbers: the first two designate more closely related specificity and the last two the allele number (Appendix 1.1) [640]. The number is preceded by an asterisk: e.g., HLA-DRB*0401 stands for allelic variant of 0401 of gene 1 [264]. The nomenclature of different HLA specificities has grown very large, including more or less completely defined *locus* numbers of alleles: 287 HLA-A, 527 HLA-B, 147 HLA-C, 6 HLA-E, 1 HLA-E, and 15 HLA-G, making a total of 980 class I alleles, 454 HLA-DR, 79 HLA-DQ, 128 HLA-DP, 10 HLA-DM, 16 HLA-DO, for a total of 649 class II alleles [640]. Some genes HLA-C, HLA-D, HLA-E, HLA-F, HLA-G are less characterized [640]. There are 54 class I genes and MICA pseudogenes; TAP 1 and 2 (transporter associated with antigen presentation 1 and 2) are 10 in number [640], while MICB, MICC, MICD and MICE do not yet have a fixed function [469]. MICA and MICB are ligands for the activating CD94: CD94R may inhibit class I molecules [329]. As Appendix 1.1 shows, not all alleles have serologically defined specificities. Inclusion of different designations of HLA alleles and specificities comes from using serologic methods instead of molecular reactions recently employed for typing such as *in situ* hybridization, PCR (polymerase chain reaction), RFLP (restriction fragment length polymorphism), etc. For example, HLA-B27 was associated 30 years ago with several autoimmune disorders [329], now encompasses several subtypes, from B*2701 to B*2709 [640].

HLA and encoding genes form three categories, classes I, II and III, membrane gps expressed on all nucleated cells. Class I and II molecules are members of IgSF (Figs. 1.25–1.27) [454]. Class I and II molecules can be differentiated according to their structure, tissue distribution, and function [329]:

- *Class I genes,* located in the more distal region from centromere, encoded by main HLA-A, HLA-B and HLA-C *loci,* include a polymorphic H chain, a 45-kD α chain, in close, noncovalent association on the membrane with a nonpolymorphic 12-kD L chain, a β_2-m encoded by a single gene located on chromosome 15. A molecular three-dimensional structure shows H chains divided into six regions: three extracellular globular domains, α1, α2, an Ig-like domain, α3, a short extracellular connecting peptide N-terminal, a hydrophobic TM region (25 amino acids), and a hydrophilic intracytoplasmic C-terminal tail (30 amino acids), while L chain forms only an extracytoplasmic Ig-like domain. A molecular part furthest from the membrane embraces a deep groove or cleft, *the peptide-binding site,* made up of segments of α1 and α2 domains with α-helical sides and an irregular β-sheet base. A single α3 domain has sequences interacting with CD8 cells.
- *Class II genes,* positioned in a more proximal region to the centromere, controlled by at least three HLA-DR, HLA-DP, HLA-DQ subloci, consist of two polypeptide domains, a 33-kD α and 28-kD β, noncovalently linked. This pattern resembles that of class I, but with five domains, since each chain contains two extracellular globular regions (α1 and α2, or β1 and β2), not covalently linked. The peptide binding groove has a structure similar to that of class I molecules. Also in this case the cleft chemical surface, distinct from class II molecule GPM, determines specificity of antigen binding. Class II is restricted to immunocompetent cells presenting processed antigens to CD4 cells and is necessary for interactions between immunocompetent cells. Additional class II-related molecules are eight HLA-DOA alleles [469]. The designation of class II *loci* on chromosome 6 consists of three letters: the first (D) indicates the class, the second (M, O, P, Q, or R) the family and the third (A or B) the chain (α or β, respectively).
- *Class III genes,* placed between classes I and II loci, encompass a heterogeneous mixture of genes, including classic pathway complement components (C2, C4a, C4b), properdin factor P of the alternate pathway, enzyme β-21 hydroxylase, molecules of the heat shock protein family (HSP70-1 and -2), and TNF-α and TNF-β. Many class III genes are involved neither as transplant antigens nor in antigen presentation [329, 337].

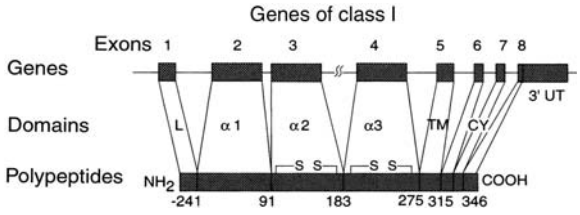

Fig. 1.25. Diagrammatic representation of HLA class I genes and molecules

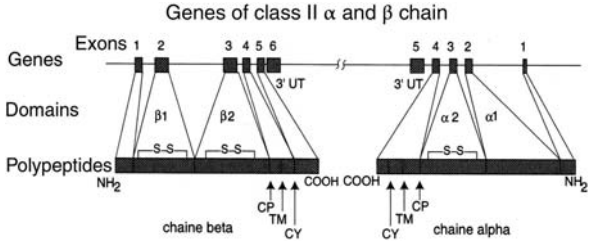

Fig. 1.26. Diagrammatic representation of the genes of α and β chain of HLA class II molecules

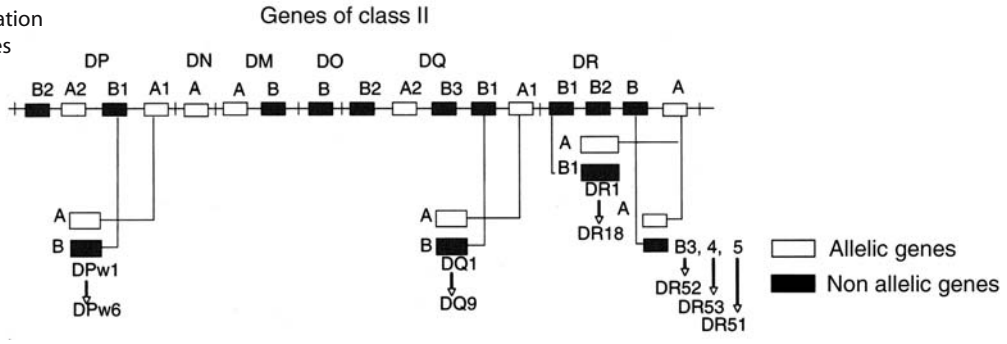
Fig. 1.27. Organization of HLA class II genes



Other genes encoding proteins involved in antigen processing machinery have been identified interspersed among class II genes, between HLA-DQ and HLA-DP, such as six TAP-1 and four TAP-2 alleles (Appendix 1.1), and two LMP2 and LMP7 genes (low-MW polypeptides 2 and 7) [329].

The Ir genes, mostly mapped to HLA antigens, encode a synthesis of class II molecules, that is HLA-restricting elements recognized by CD4 cells. Owing to allelism of the above-mentioned molecules, different individuals respond differently to the same antigen when responses are HLA-restricted, that is, only when antigen presentation is in the context of class II specific molecules. In the absence of Ir alleles, there is no production of antibodies against specific antigens; hence individuals have inherited HLA antigens that in peptide presentation to TcR are markedly effective in eliciting synthesis of antibodies different from IgE antibodies. It was speculated that Ir genes are expressed on macrophages and not on T cells. Actually, the genetic control related to interactions between T cells and macrophages is localized in HLA I regions and products encoded by genes of such regions are defined as HLA-DR [198]. Only 10%–50% of macrophages isolated from peritoneum and spleen are provided with these antigens, and it seems that only HLA^+ cells look after antigen exposure [12]. To better define *genetic restriction,* it refers to different specificity for different HLA molecules, since not all T-cell subsets use the same HLA molecules, each having a capacity of response limited to some HLA components, since both class I and II contain recognition sites for CD8 and CD4 coreceptors on T cells [463].

According to the restriction concept, the HLA molecule has a key role in binding to immunogenic peptides deriving from processing foreign proteins: bimolecular HLA–peptide complexes expressed on APC membranes are the ligand recognized by T cells. CD4 cells recognize only peptides expressed on membranes of actively phagocytic APCs (10^5 molecules/cell) [337] associated with HLA class II antigens. Suppressor-CTLs are restricted to associating with HLA class I molecules, expressed by most nucleated cells of the body (between 10^4 and 5×10^5 molecules/cell), while the HLA C region contacts CD8 coreceptor [463]. HLA class II antigens bind to peptides with sufficient affinity by means of amino acid sequences of their hypervariable parts situated in α-1 and β-1 domains; similarly, TcRs recognize HLA–peptide complexes. Instead, T cells, with a γδ TcR that is often DN, represent an exception to restriction in that, in addition to class II antigens on DCs [558], they recognize bacterial proteins as well as heat shock proteins (HSP) in an HLA-independent way [279]. Centrality of HLA molecules in tripartite interactions with processed antigens and TcRs is exemplified by the repertoire of antigen specificities recognized by T lymphocytes.

Main features distinguishing class I and II molecules are GPM, association and codominance [18, 329]:

- *The major part* of HLA genes is characterized by an almost unique GPM, which has been shown to be even more extensive by rDNA technology. Each gene has multiple alleles, leading to a great number of likely combinations on each chromosome (haplotype): the number of genotype combinations is $>10^{10}$. Besides these alleles, there are many variants in the general population, so

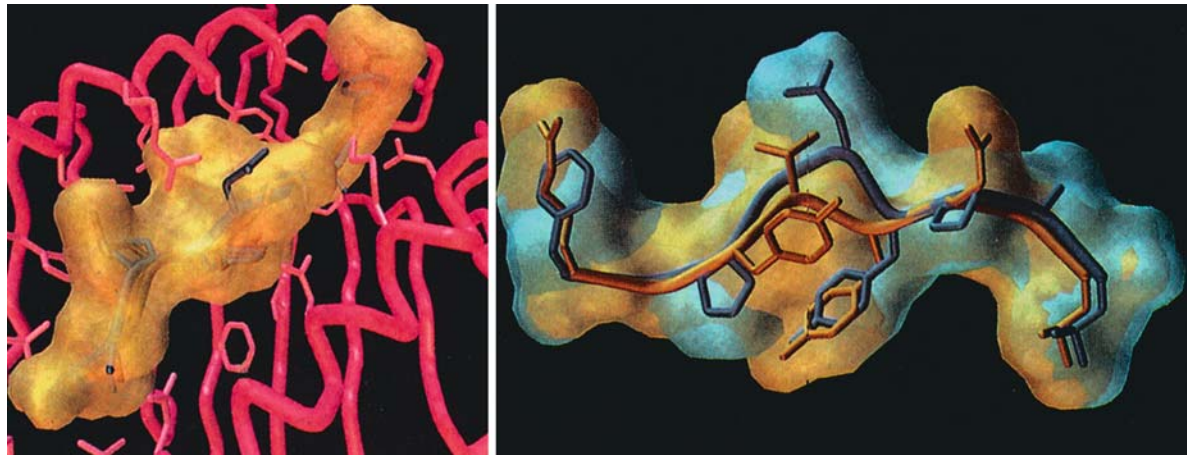


Fig. 1.28 a,b. A viral peptide buried in a HLA class I molecule (**a**), and together with another peptide (**b**) in the extended configuration they assume when complexed with HLA class I molecule [161]

that the majority of subjects are heterozygous (HZ) for different *loci*. Therefore, an extensive GPM makes wholly different HLA molecules expressed by genetically distinct individuals, that is each one has his own genetic set of HLA molecules, shared only by a few individuals of the same population. GPM is also the basis for rapid graft rejection between genetically different individuals.

- *Association* means that all genes are transmitted en bloc by HZ parents to their children. When paternal haplotypes are a and b and maternal ones c and d, each child inherits from both haplotypes, that is ab, ac, bc and bd; thus the chances of a child having the same two haplotypes are = 25 %. A recombination between two haplotypes (cross-over) can be in germ cells, paternal or maternal, creating a new haplotype. The recombination rate is 1 % in HLA-A and -B and between -B and -D.
- *Codominance* means that each cell expresses HLA proteins transcribed from paternal and maternal chromosomes. One point worth noting is that only one chromosome is used to form Ig and TcR molecules, the unique occurrence of allelic exclusion. Each individual is commonly HZ for each *locus* and her/his HLA group is composed by several letters as described above, plus two numbers corresponding schematically to the alleles transmitted by both parents.
- Moreover, *some gene combinations* can have an unexpected frequency, because individuals of a heterogeneous population can have two genes segregating together, with a frequency markedly different (higher or lower) than the predicted frequency. *Linkage disequilibrium* is a phenomenon common to almost all complex genetic systems, the tendency of specific alleles of linked genetic *loci* to be inherited together (as a unit or haplotype) on the same chromosomal region far exceeding that expected by chance association, functionally interacting between themselves.
- *GPM* is a strategy for generating diversity of HLA molecules; hence it contrasts with the unique strategy of gene rearrangement of TcR and BcR. Accordingly, each lymphocyte expresses only slightly different receptors, whereas every cell of an individual expresses the same HLA molecules, but different from HLA molecules expressed by genetically unmatched subjects. GPM also contrasts with principles of allelic exclusion and thus with the genetic principles governing receptors: class I and II molecules are codominant, that is, each cell expresses HLA proteins transcribed from both maternal and paternal chromosomes, consequently confirming GPM [36].
- As regards the respective functions and properties, class I and II molecules have a similar general structure, although not identical: both seem to have a wide GPM and bind to peptide fragments subsequently recognized by TcRs. Perhaps due to different types of processing, class II molecules appear to present a heterogeneous group of peptides for a given epitope, instead of only one well-defined epitope as is normal for class I molecules.
- GPM of HLA *loci* and some alleles of different *loci* tend to associate between themselves; this inclination has been understood as necessary for human immune system diversity or functioning [463].

Several ILs can stimulate HLA molecules: IFN-γ is one of their most potent activators, whereas TNF-α, TGF-β and IFN-α and -β functions remain obscure [579]. IFN-γ induces activatory signals for CIITA (class II transactivator) expression [539], which is more of an essential regulator for expression of HLA class II genes than their direct modulator: CIITA is defective in a form of primary HLA deficiency [539].

Many peptides bound to HLA molecules may not be invariably presented to TcRs, in part because cells expressing TcRs reacting with peptides derived from a given individual are often removed during T-cell development in the thymus, either clonally deleted, or dying by apoptosis as formerly alluded to [579]. The set of HLA alleles inherited by an individual is exceedingly tiny compared to diverse TcR repertoires. In theory, TcRs are

restricted to recognize a very limited subset, while HLA molecules can bind to a large collection of foreign and self-derived peptides: this issue appears to be paradoxical since HLA molecules can bind a multitude of peptide fragments in a very restricted way, with an affinity at least 1,000-fold higher than that of TcR. Of course, each HLA molecule could bind this large group of peptides, but what governs the ability of a peptide to bind one HLA haplotype rather than another? [18]. It might also be that a very small number of HLA–peptide complexes are required at the APC surface to generate immune responses [36]. As we see from Fig.1.28 [161], class I molecules in concomitance with the encounter with molecules to be scrutinized present, as previously described, the special conformation with binding grooves destined to reception of already processed peptide fragments [161]. In particular, as evidenced by crystallographic studies, conserved pockets at both ends of the peptide-binding groove accommodate their N-terminals via extensive H_2 binding, thus warranting a correct orientation of peptide-binding and its closed nature at both ends [264]. In the middle of the groove there is a deep pocket providing structural complementarity (like a gem in a ring) for one of the peptide amino acids called the *anchor* (the amino acid residue recurring more frequently). The peptide antigen appears to be anchored by residues either at or near the end of the peptide, thus enhancing the specificity of HLA–peptide binding [344]. The single substitution of an amino acid of an exposed peptide residue, although changes do not seem to be critical for the above binding, is sufficient to abrogate TcR recognition. Since HLA molecules are very unstable, only peptides with an allele-specific anchor residue may provide sufficient stability, while a small decrease in affinity has the wide biological effect of increasing the dissociation rate of bound peptides, hence preventing adequate time for presentation to T cells [161]. The pocket of class II molecules is open-ended, allowing larger peptides to bind [264].

Initial Phase of the Immune Response

Functions of HLA Molecules and Antigen Processing

Antigen presentation is defined as processing or cleavage of foreign antigens consisting in transformation from a native form to a nonnative form to yield peptides complexing with HLA molecules, thereby associating HLA products only with fragments of presenting antigens, and not with intact antigens themselves, drawing attention to the analysis of proteolytic events lying upstream of presentation events.

A remarkable contribution to understanding this step of immune responses comes from studies on related viral attitudes. As discussed in the preceding section, HLA class II molecules interact with CD4 cells, class I molecules with cytotoxic CD8 cells (Fig. 1.29) [591]. These mechanisms entail recognition of peptide fragments deriving from intracellular microbial antigens, which sometimes expose native proteins to the host surface, and thus to a cytolytic attack [591]. Some viruses in particular can infect every type of human cell, so that to respond to aggressions T cells must recognize viral peptides associated with class I molecules. When other pathogens degraded via phagocytosis are active, this process implies T cells being reactive with exogenous peptides associated with class II molecules [337]. Such programming has a remote ontogenetic origin, since TcRs were planned by the immune system to recognize even small fragments of viral antigens, sometimes of only eight to ten amino acids, hence virtually indistinguishable from the related peptides of human cells. Consequently TcR was diversified to react with such fragments only if associated with HLA products [457]. Prerequisites are therefore processing outside peptides and assembling molecules for one or more HLA alleles. To degrade a protein into small fragments, both endogenous and exogenous antigens should be first broken down into vesicles with acid pH, to be associated with HLA alleles on the cell surface. Processing clarifies why T cells, unlike B cells, fail to recognize protein conformational epitopes, but only linear ones, and why they cannot distinguish between native and denatured proteins of the same antigen [474].

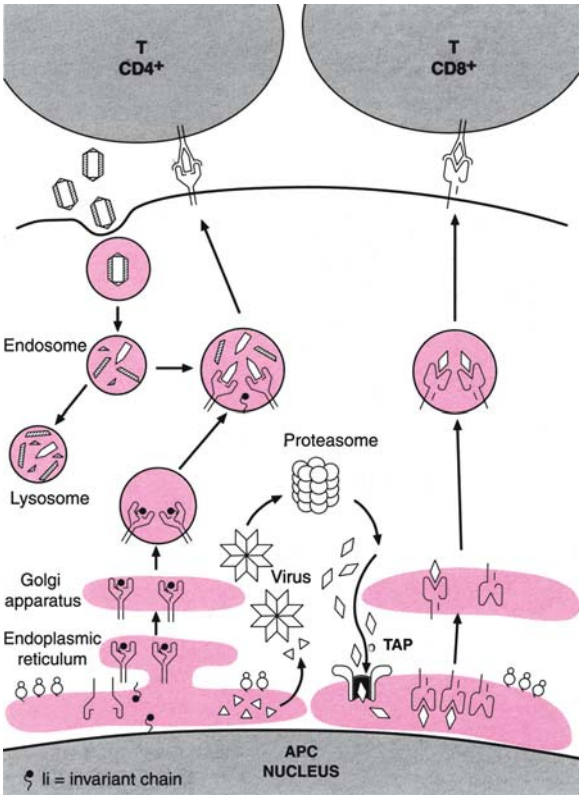

Fig. 1.29. Antigen processing and presentation to T lymphocytes

Various methods are employed by cells for antigen processing as follows:

- *Phagocytosis* delineates the most prominent function of mononuclear phagocytes at the point of assuming such denomination, and antigen processing has a pivotal role in inducing immune responses: during the different steps, among fragments subjected to processing, those cleaving in the endosomes and with affinity for HLA molecules escape a complete denaturation, bind to HLA alleles, and are then transported to macrophage surfaces [540]. On the contrary, after an exhaustive proteolytic cleavage in *lysosomes,* peptides with no HLA association are excreted outside the cell surface through a process of exocytosis.
- *DCs and B lymphocytes* cannot use phagocytosis, but a more common process called pinocytosis, by which fluids or very small particles (diameter <10 nm = 100 Å) are taken into the cell.
- *B cells* can employ antigen-specific Igs (IgMs or IgDs), a much more effective procedure because the antigen concentration necessary is 1,000-fold less than that required by pinocytosis. However, despite the advantage of close linking with B lymphocytes, this process is really restricted to a comparatively limited number of these cells [384].

Exogenous peptides generated in acid vesicles bind to class II restricted T cells [391], whereas endogenous peptides synthesized by cytosol and ER are recognized by class I restricted T cells [372]. When processing of a non-virus-infected cell (modified, for example, in a vaccine) takes place in acid vesicles, the resulting peptides are presented to CD4 lymphocytes associated with class II molecule. However, if the same antigen infects the cell, processing moves over the cell cytosol/ER, then antigens are presented in association with CD8 lymphocytes and HLA class I molecules. Following these two different procedures, CD4 and CD8 lymphocytes of an individual can recognize different epitopes of a given antigen [47]. Moreover, as a number of experiments have demonstrated, the structural characteristics of peptides do not determine the binding to one or to another HLA class, but it can be hypothesized that distinctions arise from two different ways of processing and presentation [369, 391].

Now the way by which HLA molecules acquire peptides is the center of attention, rather than the origin of peptides presented by HLA products. As regards class I molecules, before entering an exocytic system, processing of antigen material in the cytosol is usually attributed to *proteasomes,* an ATP-dependent complex of peptidases, proteolytic enzymes encoded by LMP2 and LMP7, a pathway probably operative in converting native antigens into peptide fragments then translocated into the ER to associate with class I molecules [377]. Unfolded or worn-out polypeptides in the ER are retrotranslocated into the cytosol where the SC factor (SCF) (Fbs1, 2) proteins distinguish native from unfolded glycoproteins and ubiquitin targets the worn-out proteins for dumping [648]. These proteins unfold with the help of other specialized molecules, the chaperones, and the polypeptide chains are then fed into the proteasomes, where unassembled or defective proteins in the cytosol are degraded into peptides [264]. The ubiquitin-proteasome system is a fundamental machinery in the cell [520] and has been shown to be involved in the virion budding process of several viruses, particularly of rhabdoviruses [198]. In the presence of the proteasome inhibitor MG132, the entering viruses accumulated in both the endosome and denser lysosome, suggesting that the ubiquitin-proteasome system is involved in the virus transfer from the endosome to cytoplasm during the virus entry step. Understanding the sensitivity to the ubiquitin-proteasome inhibitors may be used to distinguish the early steps of viral entry [656]. Studies of *Thermoplasma acidophilum* [316] have shown that proteasomes, with a barrel-shaped structure, consist of two inner rings, each consisting of seven β subunits, and two outer rings, each made up of seven α subunits, all different [316]. Proteasomes interact with either ER membranes or TAP-1 and TAP-2 [293] encoded by polymorphic genes of class II and associated with H chain α1 and α2 domains [443] (Fig. 1.30). TAP-1 and TAP-2, closely located to genes encoding LMP2 and LMP7 inducible by IFN-γ [293], import into the ER *lumen* selected peptides, which may attach to a newly synthesized β chain of the class I molecule encoded by the β_2-m gene [263]. Possibly the peptide NH_2 terminus is also trimmed [361]. The peptides are necessary for a correct assembly of HLA class I molecules. Class I molecules first assume a peptide-receptive conformation, then release peptides to be delivered to the cell surface for antigen presentation to CTLs with CD8 markers [337]. However, subsequent analyses have shown the polymorphism of TAP and LMP genes that map between DPB1 and DQB1 within class II genes [372]. So it seems reasonable to imagine that different epitopes of the same antigen are presented to T cells of different subjects. Support for this hypothesis will lead to evident implications, such as individual differences in immune responses to specific antigens [28], in addition to differences in tolerance induction, predisposition to autoimmunity, and disorders associated with HLA molecules [28]. HLA class I molecules could also bind to exogenous antigens loaded by macrophages and DCs [39]. The principal routes are as follows: release of antigens acquired from endocytic or phagocytic vesicles returning immediately to normal pathways, or antigen digestion in a vesicle by using normal class I mechanisms; pertinent examples in support of both hypotheses derive from inhibitors of processing pathways such as brefeldin A and chloroquine [39]. When TAP-2 is deficient, assembly of class I molecules cannot be completed.

As reported by studies on the routes of class II molecule intracellular traffic, newly synthesized HLA products are collected in the ER where they are delayed for

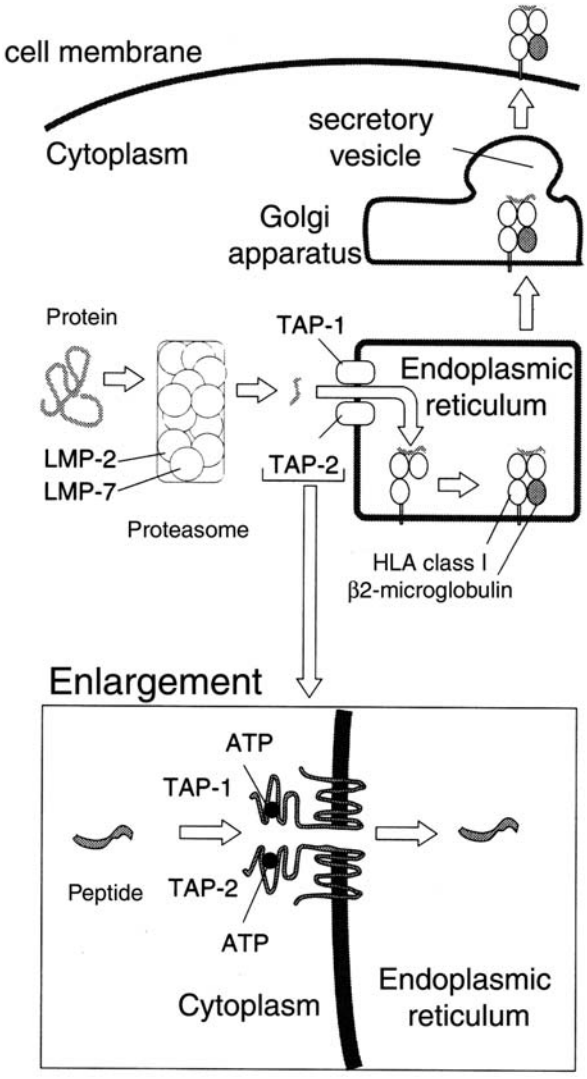

Fig. 1.30. Biosynthesis of HLA class I molecules

1–3 h, apparently not for recycling back to the cell surface, but for peptide loading to take place. Molecules leave it only when linked with three pairs of αβ heterodimers of the same ER, transiently aggregated to three copies of the TM invariant chain (li=CD74) [61]. The agglomeration of nine chains (nonamer) without contacting peptides in the ER is transported across trans-Golgi and post-Golgi networks to an endocytic compartment, MIIC (MHC class II-loading compartment) [443]. The li chain appears to protect class II dimers from binding cytosolic peptides imported into the ER for class I binding [61]. The li region, important in binding class II molecules and in preventing premature peptide binding, corresponds to CLIP (class II associated invariant chain peptide), which binds HLA-DR3 in sites normally occupied by peptide antigens [61]. In *Golgi networks,* after glycosylation peptides are internalized into the cell by endocytosis, an APC encounter with foreign peptides occurs in endosomal or prelysosomal compartments where peptides are internalized, then extruded in intra- and extracellular compartments [378]. HLA class II peptide presentation can be inhibited by lysosomotropic agents such as chloroquine and NH_4Cl, which raise the pH, and by inhibitors of endosomal proteases, with no effect on class I endogenous peptides [378]. While in transit to endocytic routes, the li chain subjected to the compartment acid pH is degraded by endosomal proteases and CLIP is removed from DR3 by HLA-DM [182]. As the intact li chain, CLIP inactivates the groove by binding directly to it [61]. Consequently, HLA molecules can bind processed antigen peptides, and peptide–class II-αβ complexes can be transported to cell surfaces: HLA molecule antigen binding assures sufficient stability, allowing it to reach cell membranes to activate the correct T cells [372].

In conclusion, the intracellular routes followed by HLA class I molecules and respective antigens traverse structures different from those crossed by both antigens and HLA class II products, thus avoiding their reciprocal encounter.

Antigens presented in association with class I molecules bind preferentially to peptides usually 8–11 residues long (their grooves are restricted in length and are closed at both ends) [337], whereas class II molecules can accommodate much longer peptides, with 11–17, and up to 25 amino acids [337]; therefore both ends of a class II molecule-bound peptide have been assumed *to protrude out of the groove* [482], thus showing a higher heterogeneity at NH_2 and COOH termini [337]. Accordingly, peptides with 13–17 amino acids associated with class II molecules can stimulate T-specific clones [482], considering that the theoretical number of different peptides formed by nine amino acids is 5.1×10^{11} [337]. Selectivity of HLA molecules implies that only some of them have grooves with sufficient length to hold processed peptides [482]. It is critical that a different structure is appointed for trimming of longer peptides, which could be:

- In *ER precursors,* associated with class I molecules [144]
- In accordance with *binding sites,* or the same peptide, not associated with class I molecules [482]
- *Within the cytosol,* where peptides may be immediately re-exported [361], or where there may be envisaged a proteolytic structure specialized in reducing peptides to fitting size for HLA before transport in the ER
- *Stress protein gp96* may function as a chaperone for peptides not fitting HLA molecules [286]

On the contrary, class I molecules need no trimming, being unable to hold longer peptides.

Antigen processing also has particular features: if amino acid chains or peptides are rolled up and folded, when the chain is extended, distant parts can be brought together via folding of protein structures, leading to conformational epitopes. Furthermore, unlike B cells directly interacting with antigens, being able to recog-

nize epitopes contained in intact and normally folded protein molecules, T cells recognize only epitopes present in denatured and linear molecules. Besides splitting, in macrophage intracellular vacuoles an unfolding takes place, which makes accessible previously hidden, totally or partially, immunogen peptide parts [443]. Small amino acid sequences equipped with the structural characteristics essential for complex formation with HLA molecules are often found inside of rising protein molecules and become available for binding to HLA products only after *unfolding of protein structures* is accomplished: fragments containing the critical amino acid sequences are transferred into the macrophage membrane surface, ready for subsequent antigen presentation [12].

Therefore, if antigen processing consists in the *conversion of an antigen from the native to a non-native form*, a process carried out by APCs expressing HLA antigens, peptides must make contact with TcR as well as bind to an HLA molecule. A most likely hypothesis is that processing involves changes into antigens provided with a conformational freedom to form a secondary structure permitting both epitope and agretope to form. Both are composed of small amino acid sequences, at least *two or three residues* interspersed into the primary sequence of native proteins: *recognition is facilitated* by an α-helical conformation of peptide chains, in other words the helicoidal spatial arrangement. Residues making contact with T cells and HLA molecules, respectively, during enzyme splitting segregate to opposite sites of the α-helix one group forming the epitope and the other the agretope. However, although in many instances the whole amino acid sequence of several allergens was successfully disclosed, it is poorly understood which sequences are responsible for IgE binding, probably because IgE antibodies have different requirements as regards the conformation of the peptides to bind [12].

Subsequent studies have proposed a new type of antigen processing, a noncytosolic pathway, typical of class I molecules, also suggesting that peptides internalized into phagosomes are hydrolyzed by proteinases in endocytic compartments, but it is uncertain how these peptides bind to class I molecules, thus more mechanisms may be operative [467]:

- In the first type, HLA class I molecules from plasma membranes or newly synthesized may enter the phagosome, bind peptides and transport them to the cell.
- In the second type, class I molecules in macrophages may recycle between the cell surface and endocytic compartments.
- In the third type, the li, although commonly used in class II transport, can associate with newly synthesized class I molecules and direct their transport into endocytic vesicles [467].

The role of this exogenous pathway may be in innate immunity, again with three different types:

- In the first type, the immune system may have the privilege to detect and monitor pathogens surviving in phagosomes, not eliminated by CD4, permitting CTLs to destroy infected cells, in turn CTLs can secrete IFN-γ, which would stimulate macrophages to kill the microbes.
- In the second type, antigens are imported from somatic cells, poor stimulants of naive T cells lacking CD80, CD86 and CD54, into professional APCs; such exogenous pathway APCs can trigger primary T-cell responses since they express high levels of HLA class I and II molecules, in addition to costimulatory and adhesion ligands, and trafficking into lymphoid organs at that time.
- In the third type, the exogenous pathway potentially stimulates CTL immunity using protein-based vaccines: as a rule antigens in extracellular fluids are not presented in association with class I molecules on mast cells [467].

Cells of the Immune System Participating in Immune Responses

Phagocytes, so called for their ability to ingest and digest living or inert particles, have a common origin in the bone marrow, from progenitor cells, or colony-forming unit-spleen (CFU-S), or -thymus (CFU-T). CFU-S can generate myeloid, lymphoid and erythroid cells (Fig. 1.31) and, in the presence of stimulating factors (M-CSF, GM-CSF) (Table 1.5), mixed colonies of polymorphonuclear leukocytes or PMNs and macrophages. Mononucleated phagocytes, having achieved their maturation in the bone marrow, pass into the bloodstream for a short period of time, which leave to enter the tissues through capillary walls by diapedesis in response to chemotactic factors released in inflammatory processes (see "Innate Immunity", p. 152). Strictly speaking, phagocytes are granulocytes and monocyte macrophages with the particular uptake of vital strains, as numerous other cells are widely distributed throughout the body (macrophages of alveoli, spleen, lymphoid tissue, and histiocytes, Kupffer cells, osteoclasts, chondroclasts, mesangial cells of the kidney and microglial cells of the brain), and constitute the reticuloendothelial system (RES), comprising other phagocytes in a broad sense (Fig. 1.32) [470].

Monocytes (Fig. 1.32, a–c) derive from bone marrow promonocytes under the action of specific mediators (CSF). They have a diameter of 9–15 µm, and a round, oval or indented nucleus in an eccentric position with one or two prominent nucleoli [609]. The first cells to circulate in blood, but only for about 1–2 days, they migrate via blood-vessel walls, then are discharged into various tissues where, because of the stimuli of differentiation signals typical of each tissue, differentiate into resident macrophages. In certain tissues they become fixed or may enter internal cavities. During this period, the resting cells are activated by IFN-γ, a process also increasing the transcription of new genes [474]. Moreover,

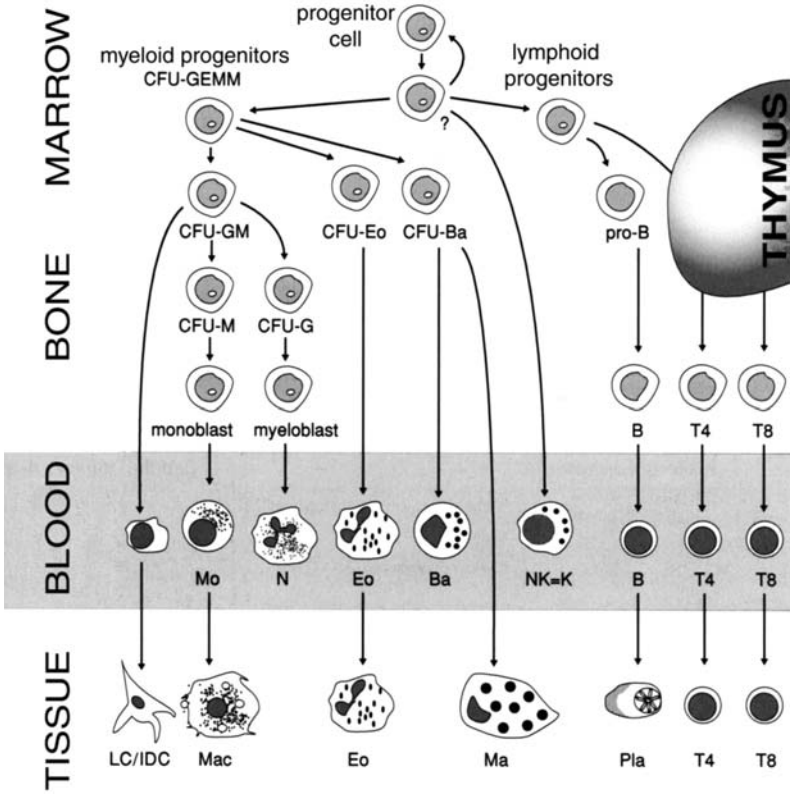

Fig. 1.31. Hemopoiesis: myeloid and lymphoid differentiation and the tissue compartment in which they occur. *Ba* Basophils, *IDC* interdigitating dendritic cells, *LC* Langerhans' cells, *CFU* colony forming unit, *Eo* eosinophils, *CFU-GM* colony forming unit-granulocyte-macrophage, *Mac* macrophages, *Mo* monocytes, *N* neutrophils, *Pla* plasma cells, *T4* CD4, *T8* CD8

IFN-γ-primed monocytes exposed to LPS showed enhanced phosphorylation of IRAK (IL_1R-associated kinase) and increased NF-κB DNA binding activity [49]. Mature cells, before differentiating lose CD34, an early marker of hematopoietic progenitor cells and of other immune cells, and CD62L ligand, whose delayed maturation could be, for example, an SCID marker. Monocytes express normal levels of CD13 and CD33, and high levels of $CD14^+/CD11c^+$ useful for their identification, in addition to a greater number of membrane receptors for IgG Fc fragments. CD14 engagement on monocytes could also inhibit human Ig synthesis, including IgE antibodies [608]. The phenotype and function of monocytes are modulated by several ILs and include IL_1RA, IL_2, IL_3, IL_4, IL_7, IL_8, IL_{10}, IL_{12}, IL_{13}, IL_{15}, IL_{16}, IL_{18}, IL_{19}, GM-CSF, TNF-α and -β, IFN-γ [73, 609]. The TNF and IL_{12} induction was dramatically increased in IFN-γ-primed monocytes [49]. The release of these ILs by monocytes can be modulated by different infectious and noninfectious stimuli. Monocytes also yield MCP 1–3 (see later) several ILs, such as IL_1RA, IL_8, TNF-α and -β [73], and MIF (monocyte migration inhibiting factor) [73, 609]. As IgE antibodies bind to their receptors, they acquire bactericidal and cytotoxic properties producing $O_2^{\bullet -}$ (superoxide), apparently due to activation of NADPH (reduced nicotinamide-adenine dinucleotide phosphate)-oxidase [115]. They are endowed with CD23 [115] and FcεRI, with a stronger binding to IgE [347], also becoming capable of engulfing complexed IgE-peptides subsequently presented to T lymphocytes [347]. In atopic patients they provide the RNA with IL_{13} transcripts [219].

Macrophages [540, 593] (Fig. 1.32, d, e) have variable dimensions (15–50 μm) and probably a structural and functional heterogeneity like mast cells. They are particularly active, together with PMNs, in defense against infections, playing a pivotal role in immune responses via a wide range of functions performed (Table 1.20) [68, 540, 609]. Although referred to by a variety of names depending on the location, they have mostly common features: in addition to being APCs, they are avid phagocytes engulfing any bacteria, cellular debris, or foreign particulate materials in the area. Stimulated by the ILs produced during the recognition phase, they are attracted into a site of injury and acquire the phagocyte's typical aspect. Macrophages undergo several morphological, functional and metabolic changes, with a parallel increase in size, adhesion, endocytosis (both pinocytosis and phagocytosis), lysosomal enzymes and chemotaxis, as well biochemical-metabolic activities, enhancing their equipment of enzymes of the respiratory chain, the Emden-Meyerhof way, and hexose-monophosphate shunt [540]. Thus positioned along capillaries, macrophages readily make contact with and engulf invading antigens and pathogens, which are broken down with the aid of the cited enzymes into simple amino acids, glucides and other substances, for a subsequent excretion or recycling, and eventually remove them from circulation [47]. These cells also express HLA class I and II molecules for CD4 and CD8. Due to receptors for IgG

- *Complement* (C3b, C5a).
- *Hematopoietic growth factors* (M-CSF, GM-CSF), lipoproteins, peptides and PS.
- *Membrane receptors* the best characterized of which are FcεRII (bind to IgH chains) and CR3/CD11b (fix iC3b) [445].

Macrophages are versatile secretory cells: they have ≈ 100 receptors on their surface, including complement proteins, active O_2 radicals, bioactive lipids such as PGE_2, PAF (platelet-activating factor), nucleotides and arachidonate metabolites and several enzymes including lysozyme, acid hydrolases, neutral proteases, and enzyme inhibitors (Table 1.20). Macrophages generate CCL chemokines, including MIP-1α and -1β (macrophage inflammatory protein-1α and -1β) and MCP-1 [540, 609]. Like monocytes, they are activated by IFN-γ and MIF, in certain conditions acquiring cytotoxic or suppressive properties, in addition to contributing to lymphocyte responses as accessory cells, releasing ILs such as TNF, IL_6, IFN-γ via IL_1 and IL_{12}, as well as IFN-α and TGF-β [488]. Macrophages synthesize IL_{18} as an IFN-γ induction factor [669]. In turn, IFN-γ induces in macrophages IL_{12} and $IL_{12}R$, whose activity depends on Th1 T-cell activation [124]. IL_{15} can also be a macrophage endogenous product [67]. Four ILs instead deactivate these cells: IL_4, IL_{10}, IL_{13} and TGF-β [124]. Correspondingly, macrophages are pluripotent cells supporting opposite actions depending on their local microenvironment: for example, the response to IL_2 can activate T-cell proliferation or suppression and CMI [124]. Probably, CD28 expression by IL_{12}-producing macrophages can lead to generation of Th1 T-cell responses [387], anticipating that CD28 binding to CD80 represents a costimulatory signal for T lymphocytes. Because the number of monocytes and macrophages can increase 3- to 100-fold at a site of inflammation, the regulatory and effector roles of these cells become even more prominent after an inflammatory response has begun. Also prominent is the portfolio of chemokines that attract these cells to a site of inflammation, which include CCL2, CCL3, CCL5, CCL7, CCL8, CCL13, CCL17, and CCL22 [87].

Granulocytes live only a few days; have the main function of ingesting and kill any non-self substance. C/EBPα is essential for their development [678]. Cells of granulocyte lineage, PMNs, eosinophils, and basophils are distinct according to cytoplasmic granule staining. Granulocyte surface markers are shown in Table 1.21 [470] and compared with metachromatic cells.

Neutrophils (Fig. 1.32, d, f, g, h) are the most numerous leukocytes in the bloodstream (half-life, 4–10 h), with a normal adult having >100 billion PMNs present daily, a number that can increase to almost 1 trillion when the host is stressed by infections. PMNs carry on

Table 1.21. Surface markers of neutrophils or PMN and eosinophils compared with metachromatic cells

the following activities: chemotaxis, phagocytosis, degranulation, and opsonization [360]. PMNs are involved in the immune inflammation in concert with eosinophils and platelets, also determining within such processes the delayed phase of allergic reactions. Prolonged ADAM17 (a disintegrin and a metalloproteinase 17) expression during neutrophil effector functions and apoptosis may play a role in both the induction and downregulation of neutrophil activity [617]. Primed PMNs in the presence of tissue injury due to microbial agents produce factor(s) which inhibit some of the cell's antimicrobial functions contributing to immune dysfunction, while the factor(s) produced by unprimed PMNs facilitate antimicrobial countermeasures [407]. High mobility group box 1 (HMGB1) protein increases the nuclear translocation of NF-κB and enhances the expression of proinflammatory ILs in human PMNs. These effects appear to involve the p38 MAPK, PI3K (phosphatidylinositol 3-kinase), and ERK1/2 pathways. However, the mechanisms of HMGB1-induced neutrophil activation are distinct from endotoxin-induced signals [407]. They have receptors for:

- *Igs:* IgG=FcγRII and FcγRIII (CD16) and IgA=FcαR (CD89), while PMNs appear to lack IgE receptors.
- *Complement:* C3b, C3a, C5a; C5a is different in structure and affinity from that of eosinophils.
- *LTB_4* (LTB_4), GM-CSF, and G-CSF.

As APCs, PMNs have only limited potential as they synthesize only HLA class I molecules. PMNs have a rich equipment of proteins and mediators, and release several immunoregulatory ILs, modulating both cellular or humoral immunity (Table 1.22) [73, 315]. During acute inflammations, IL_1 enhances T-cell activation, also inducing IL_6, IL_8 and GM-CSF. Recruited early to injured sites, PMNs release M-CSF, hence activating the more slowly invading monocytes [315].

PMNs are activated by NAP (neutrophil activating factor)/IL_8 released by PBMCs (peripheral blood mononuclear cells) and then recruited to inflamed sites by NCF (neutrophil chemotactic factor) and LTB_4, utilizing CD11/CD18 integrin ligands of CD54 (ICAM-1) and CD102 (ICAM-2, intercellular adhesion molecule 1,2) to adhere to vascular endothelium (margination) [23]. PMNs infiltrate injured sites ingesting whatever foreign protein or cellular debris they encounter, including bacteria and CIC (circulating immune complexes)-IgG by virtue of specific receptors, releasing enzymes with lytic action responsible for the maintenance of immune inflammation [135]. When activated, the enzyme NADPH oxidase attached to the cytoplasmic membrane produces monovalent hydroxyl radicals with oxidant properties and oxidized metabolites [663]. During phagocytosis and especially when antigens adhere to the PMN surface and are therefore not phagocytosed, PMNs undergo a respiratory burst, degranulate and fully mobilize their secretory vesicles. Their cytoplasmic membrane fuses with the intracellular granules, finally emptying their enzyme content into the cell lumen

[135]. The secondary granule proteins (SGP) are secreted in a hierarchical manner: first gelatinase-containing granules, then specific granules, and last azurophilic ones [135] (Table 1.23 [315], Fig. 1.32 g). In the later stages of myeloid development, the SGP genes are coordinately upregulated, and members of the C/EBP family of TFs, in particular C/EBPα and C/EBPη, play specific and unique roles in upregulating their expression [257]. Among the many granule enzymes (>20), MPO (myeloperoxidase), elastase, collagenase and gelatinase play a prominent role in cytotoxicity, also attacking and degrading above all connective tissues [630]. The mature granules also contain Igs, complement proteins, clotting factors, cationic proteins and defensins (see "Innate Immunity" p. 152). The CCAAT-enhancer binding protein (C/EBP) family of nuclear TFs is implicated in the regulation of terminal myeloid differentation. In particular, C/EBPα and C/EBPη play specific and unique roles in upregulating SGP expression [257, 646]. The abnormal PMN accumulation in states of acute inflammation consists of several processes taking shape in sequence:

endothelium and PMN activation, adhesion, diapedesis and phagocytosis [315]. Besides their essential defensive functions, PMNs are coming under scrutiny whereby they may cause excessive injury to host cells, since a potent cytotoxicity in acute inflammation is potentially damaging. PMN persistent accumulation involves an excessive secretion of O_2 toxic radicals and proteases, with amplification of tissue injury following LTB_4, LTC_4 (leukotriene C_4) and TXA_2 (thromboxane A_2) synthesis [630]. It has been suggested that such negative regulation is favored by the density reduction observed in allergic subjects [364]. Aged neutrophils undergo *apoptosis* [276]: endogenous activations of endonucleases allow PMNs to be recognized and engulfed intact by macrophages to avoid dispersion of cytotoxic products [510] (Fig. 1.34). Early neutrophil influx into the airways after allergen challenge is mediated by IL_1, IL_{18} and p38 MAPK and can be reduced by inhibiting either IL or p38 MAPK. However, both the neutralization of these ILs and reduction of PMN number do not modify the later development of eosinophilic airway inflammation or the BHR (bronchial hyperreactivity) insurgence, thus suggesting that the early and transient neutrophil response fails to play a direct role in the development of allergen-induced BHR. The effects of inhibiting p38 MAPK in decreasing BHR indicate activities independent of its prevention of PMN accumulation [569].

Eosinophils (Fig. 1.32f, 1.35a) [680], present in peripheral blood at a mean concentration of 300–400 cells/m^2 from 0 to 2 years and of 200–250 cells/m^2 from 4 to 21 years, survive longer than other granulocytes (half-life, 6–12 h). Eosinophils migrate into the thymus during the neonatal period, localize to the corticomedullary region and attain maximum levels by 2 weeks of age. A second influx of eosinophils to the medullary region is observed at 16 weeks of age, when the thymus begins to involute [477]. Even after leaving the bone marrow together with CD34, they continue the synthesis process and can return into the bloodstream from tissues; however, compared to PMNs, they are inconclusive as phagocytes and less efficient at intracellular killing [631]. Eosinophils are present in allergic, immunological, parasitic disorders and hypereosinophilic syndromes. They can be activated either *in vivo* or *in vitro* gy diverse agonists, such as Igs, lipid mediators, and ILs [371] and from CD69, CD44, and CD54 [670]. On activation, they probably kill parasites mainly by releasing cationic proteins and reactive O_2 metabolites into the extracellular fluid [623]. Eotaxin induces a rapid concentration-dependent activation of ERK2 and p38 in eosinophils, and the activation of these kinases is required for eotaxin-induced eosinophil chemotaxis, actin polymerization, and degranulation. It is therefore proved that eotaxin plays an integral role in the development of eosinophilic inflammation in asthma and allergic inflammatory diseases [247]. Key eosinophil regulatory ILs such as IL_5 and the eotaxin subfamily of chemokines regulate eosinophil production and localization at baseline and during inflammatory responses

[477]. *In vitro* studies and those on BALF (bronchoalveolar lavage fluid) show that the regulation of eosinophil production is highly dependent on GM-CSF, IL_3 and IL_5 [550]. Such ILs play a pivotal role in promoting eosinophil maturation, remarkably influencing both differentiation in the bone marrow and activation in the tissues [61]. GM-CSF and IL_3 particularly increase the number of precursor cells prolonging their survival, IL_5 acting primarily as a selective chemotactic factor mediates their maturation and triggers degranulation and adhesion [34]. GM-CSF and IL_5 further activate eosinophil cytotoxicity and oxidative metabolism and, added to culture with CD34, increment notably their number, making the cells functionally mature on the 21st day [515]. Since during intense responses eosinophils can undergo cytolysis, the detection of cationic proteins is a useful marker of their involvement (Chap. 7). Eosinophils can be engaged to express HLA class II molecules and act as APCs [632]. Eosinophils also express CD48, CD58, CD84, CD244/2B4, but not CD [371] on their surface. Table 1.24 [197] summarizes the most significant data on surface molecules and Tables 1.5–1.8 detail IL effects on eosinophils playing a vital part in inflamed lesions of allergic disorders. Accordingly, eosinophils yield [631]:

- Fc receptors for Igs: both IgE receptors, FcεRI and FcεRIIb, present chiefly on the hypodense phenotype, with an affinity comparable to that of FcγRII (CD32) for IgG antibodies and FcαR; IL_4 and other unidentified factors amplify FcεRI α chain expression on eosinophils [573], making them capable of diffusing their cationic proteins.

- Receptors for complement components: C1q, C3a, C3b/C4b (CR1=CD35), iC3b (CR1, CR3) and C5 are different from neutrophil receptors. C3a, C4a and C5a are called *anaphylatoxins,* a term derived from anaphylaxis-like responses produced when such peptides were injected in experimental animals [159].
- Receptors for GM-CSF, IL_3, IL_5 and IL_8 are further potential sources of IL_1, IL_4, IL_6, TGF-α, TNF-α and MIP-1α [46, 477]. Signal-transduction molecules implicated in these IL-mediated priming responses include Lyn, JAK2, PTK, and p21 [46].
- A functional CD244R cross-linking on the surface of eosinophils which elicits ERK, activates NK cells, and causes eosinophils to release EPO, IL_4 and IFN-ɣ can contribute to eosinophil effector functions in both Th1- and Th2-like responses, thus indicating a broader role for eosinophils in health and disease [255].
- Receptors for chemokines, including eotaxin, MCP1–4, MIP-1α and β (now called CCL3, CCL4), and RANTES (regulated on activation normal T expressed and secreted), now called CCL5 [687].

Whether eosinophils generate additional ILs is unclear, since circulating cells, unlike BALF cells, fail to express ILs [550]; however, they can secrete, as no other cell does, the *CD40–CD154 couple* [175], with substantial repercussions on B cell isotype switching to IgE phenotype, in addition to synthesizing IL_4, especially in the airways [397].

Eosinophils contain substantial intracellular quantities of several granule- and vesicle-associated IL receptors, including IL_4R, IL_6R, and $IL_{13}R$ as well as CCR3. A temporal coincidence of $IL_4Rα$ and IL_4 mobilization from granules into the vesicles was combined with a clear association of IL_4 with secretory vesicle membranes, thus suggesting that eotaxin-mobilized $IL_4Rα$ functions as a transporter for IL_4 via the secretory pathway. The intracellular ILRs localization possiby extended to granules of innate immune system cells. Mast cells and neutrophils may play a role in the secretion of granule-derived ILs from both these cells comparable with the ILs recognized in eosinophils. This suggests that several additional ligand-binding receptor chains such as an ILR chain specific for eosinophil-derived ILs and chemokine secretion may provide a crucial component of the regulatory mechanisms governing specificity of rapid, stimulus-induced release of preformed immunomodulatory ILs from human eosinophils, as well as other innate immune cells containing granule stores of preformed ILs and chemokines [532].

Eosinophils also express:

- $β_2$ integrins facilitating their migration from blood into normal and inflamed tissues such as CD11c (p 150,95), the adhesion molecules CD54, its receptor CD11a/CD18 and VCAM-1 (vascular cell adhesion molecule), CD106, and IL-induced endothelial protein (appears 6–12 h after stimulation), playing a critical role in eosinophil adhesion to activated vascular endothelium and epithelium, their extravasation, tissue localization and interplay with other cells [197].
- The surface molecule CD4 identified on T4 lymphocytes binding to HIV-1 glycoprotein 120 (HIV-1 gp120). So far the role of CD4 is less clear; however, it might act as a signal transducer, as demonstrated by the capacity of its three ligands (HIV-1 gp120, bivalent monoclonal anti-CD4 antibody and chemotactic factor of leukocytes) to trigger eosinophil migration but neither their degranulation nor their superoxide formation [593].
- GM-CSF, IL_3, IL_5, TNF-α, and RANTES positively regulating the last two properties [210].
- HLA-DR class II synthesized by mature cells stimulated by GM-CSF, IL_3, IL_4, IFN-ɣ [594], thereby mediating interactions of other APCs with $CD4^+$.
- Eicosanoids, released in particular conditions from membrane phospholipids, including LTB_4, LTC_4 prostaglandins (PG) such as PGE_2, and PAF, substances with a well-known bronchoconstrictor action, bradykinin, H_2O_2, $O_2^{\bullet -}$ and several enzymes. They include peroxidase and additional enzymes with oxidoreductive power, among which histaminase (inactivating histamine) is the best known, digestive enzymes (proteases, nucleases, other hydrolases such as kininase), anti-inflammatory enzymes, aryl sulfatase B specifically inactivating LTs, one of the main mediators of bronchospasm and immune inflammation, phospholipase D (PLD) inactivating PAF, catalase, collagenase, β-glucuronidase, and non-enzymatic molecules of which plasminogen is the most notable [470].

Eosinophils are also active in immune reactions with a *destructive armamentarium at the tissue level,* initiating highly damaging actions committed to cationic proteins and O_2 radicals. Histamine released by skin mast cells and other chemotactic factors, PAF in the first line, C5a, IL_{16} and various chemokines such as eotaxins 1, 2, 3 [435] selectively recruit eosinophils to the site of inflammation where they release cationic proteins and other mediators [581]. Whether cells are activated during their migration is not clear, but certainly the involvement of chemotactic factors and interplay with the extracellular matrix (ECM) expedite their progression, including signals transmitted from adhesion molecule receptors, which, all findings considered, involve cell activation and mediator release [625].

Diversely from other granulocytes, eosinophils have typical secondary granules, containing four distinctive cationic proteins. All of them yield toxic actions at the cell level, *directly damaging host cells and tissues.* MBP (MBP-1 and MBP-2; major basic protein) of 14 kD, elaborated also by basophils and rich in reactive sulfydryl groups, has no inflammatory property, but via a direct cytotoxic mechanism, has adverse effects extended to mono- and multicellular parasites and to human cells, including bronchial epithelium. MBP produces pomphoid reactions, *induces ciliostasis,* activates neutrophils and platelets and neutralizes heparin, pro-

vokes degranulation of metachromatic cells and histamine release, making a relevant contribution to the perpetuation of inflammation. A likely cause of its accumulation in AD lesions is the IgE-mediated delayed reaction [593]. In asthmatic patients, it provokes *BHR*, inhibited in vivo in animal studies by a specific antiserum [294]. MBP is the crystalloid core of secondary granules, while the matrix surrounding it contains other cytotoxic proteins: all are among the more destructive mediators, not released by extrusion from the entire granule (as in the case of mast cell reaction), but following a process of granule exocytosis, unlike PMNs, to kill foreign substances internally [337]. About 90% of granule proteins are represented by EDN (eosinophil-derived neurotoxin), or EPX, of 18.6 kD, cytotoxic and neurotoxic, interfering with CMI. EPO (eosinophil peroxidase), consisting of two 15- to 55-kD polypeptides, carries on the same routine as EDN, interferes with coagulation and fibrinolysis, degranulates metachromatic cells and has ribonuclease properties. ECP (eosinophil cationic protein), 18–21 kD, more cytotoxic than EDN and up to tenfold more potent than MBP, degranulates mast cells and has a peroxidase activity [631]. Release of such proteins is selective, because EPO release takes place subsequently to the others, perhaps in different stages of activation. The remaining 10% of proteins are formed by hexagonal and bipyramidal Charcot-Leyden crystals (CLC), present also in basophils. CLCs, first observed in 1872, belong to the type-S lectin superfamily; they can neutralize natural lung surfactants, causing atelectasis [631]. Both eosinophil activation and release of cationic proteins are IgA-mediated [581], via production of IgA antibodies endorsed by IL_5, SC binding, and consequent IgA-mediated eosinophil degranulation [572]. If ECP reduces IgA production and alters oral tolerance this could confirm that eosinophil detrimental activity is a prominent pathological feature at the expense of mucosal surfaces. Evidence suggests that eosinophil damaging activity is also committed to their oxidative products, such as reactive O_2 radicals, triggered by PAF and to a higher extent by C5a, while EPO will oxidize a variety of substrates in the presence of H_2O_2 (Fig. 1.35b) [680], with resulting production of other potent O_2 radicals, among which is singlet O_2 ($^1O_2$) [680]. PAF deriving from T lymphocytes is also active on mature cells and on the most potent chemotactic factor for eosinophils also due to O_2 uptake, $O_2^{\cdot -}$ release and iC3b increase in binding capacities [673].

Recent studies have critically revisited eosinophil phenotypic changes, showing that peripheral cells may be distinguished on the basis of their *hypodensity* (of sedimentation), chiefly under GM-CSF, IL_3, IL_5 [631], C5a and PAF effects [680] (Fig. 1.35c), but such cells are also found in normal nonatopic subjects [649]. Furthermore, in addition to speed cell survival, the hypodense phenotype can more easily bind to IgE antibodies, thereby appearing more metabolically active with IL_3 intervention and above all with IL_5 [367]. Certainly such change is not synonymous with activation [680], of which a more sensible parameter is LTC_4 synthesis under GM-CSF, IL_3 and IL_5 stimulation [631]. Eosino-

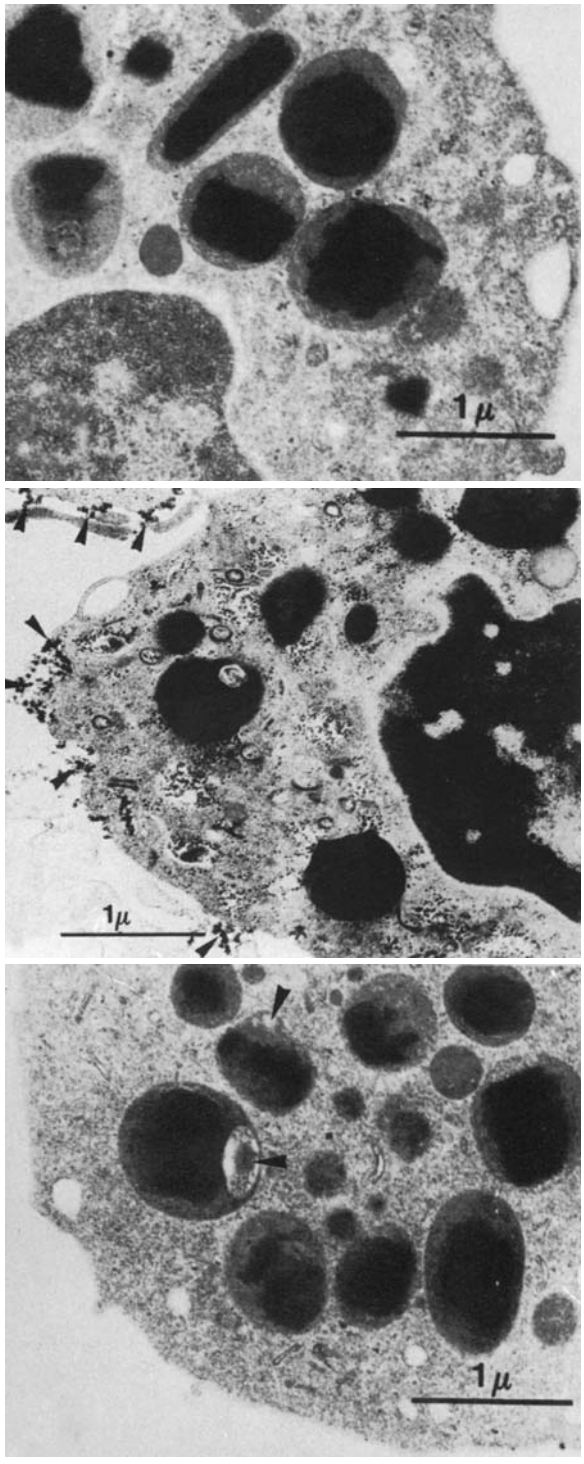

Fig. 1.35 a–c. Ultrastructural aspects of eosinophil activation (electron microscopy, EM). **a** Unstimulated eosinophils. **b** Eosinophils stimulated with PAF: *arrowheads* indicate production of H_2O_2. **c** Eosinophils stimulated with PAF and C5a: *arrowheads* indicate *hypodense cells*

phil exposure to activating ILs leads to the development of these hypodense eosinophils, with a specific gravity of <1.085 g/ml. Increased numbers of hypodense eosinophils are found in many allergic disorders, including AR and asthma [46]. In children these hypodense cells may be *truly immature* (Chap. 11): these findings could explain why ECP levels, activation markers, are not augmented in children compared to adults [367]. Studies have given rise to the hypothesis that hypodense cells are of two types, one with features similar to normodense cells [631].

Mast cells and basophils (*metachromatic cells*), cells prominently involved in immediate and late reactions, have in common cytoplasm granules containing histamine, heparin, serotonin or 5-hydroxytryptamine (5-HT) and kinins. Immature progenitors of human mast cells (SCF=c-kit=CD117) are present in fetal liver cells, bone marrow and CB, enter a peripheral tissue still without secretary granules and cell surface FcεR1, and then complete their differentiation probably with multipotential capabilities in connective tissues and mature beneath epithelial tissues and in areas adjacent to blood and lymph vessels, and near or within nerves [168, 509]. Basophils differentiate and mature in the bone marrow and circulate in the bloodstream (CDw17), but only rarely in connective tissues [341]. Basophils develop largely under the influence of IL_3, a process that is increased by TGF-α [509]. IL_3 present in cultures with CD34 promotes basophil and mast cell development up to 16%–28.5%; however, addition to the medium of GM-CSF and IL_5 reduces the rate to 3%–15% in favor of eosinophils [515]. Mast cells, which Ehrlich called "overfed cells" because their cytoplasm is filled with granules [136], abound in lymphoid organs, connective tissues of most organs, in particular on the epithelium and airway lumen, sensitive to IgE-dependent stimuli, while in blood and lymph there are instead basophils [593]. Mast cells and basophils migrate toward the chemokine gradient at a site of inflammation but stop and accumulate at the site where allergen concentration is high [580]. Both cell types, real biochemical "powder-kegs," interact with allergens, degranulate and release mediators with different pharmacological actions, and provoke clinical manifestations of immediate hypersensitivity, such as vascular permeability increase, smooth muscle contraction, epithelial mucus secretion, chemotactic action on eosinophils, and platelet aggregation. Costimulation via FcεRI engagement with IgE/antigen and CCR1 engagement with human rCCL3 synergistically enhance the degranulation of metachromatic cells at the site where the cells accumulate, thus playing important roles in the orchestration and focusing of the allergic response. The progression toward chemoattractants requires actin cytoskelton rearrangement and polarization such as formation of leading edge and membrane ruffles [127]. However, FcεRI engagement affects CCL3-mediated actin reorganization and chemotaxis of CCR1 cells [580]. Moreover, Rac signaling and/or phosphatidylinositol (PI)4,5-bisphosphate synthesis by PI 4-phosphate 5-kinase I was required for membrane ruffling [127]. Only inflammatory cells provided with cytoplasm granules containing histamine and FcεRI [358], together with other cells, also express FcεRII a and b and can up-regulate and aggravate tissue inflammation [509]. Both cells are important sources of CD16 (FcγRIII), C5aR and CD35 [470]. In concert with adhesion molecules and receptors, they mediate the binding to other cells and to ECM gps, including CD49d and 49e/CD29 (β1 integrins), basophils add CD11a, CD11b, CD11c/CD18 (β2), and mast cells CD51/61 (β3) [196]. Metachromatic cells possess high-affinity receptors for IgE (FcεRI) and thereby become coated with IgE antiboidies [175]. *Activated metachromatic cells produce IL_4 and express CD154, with the immediate consequence that IgE antibody synthesis may also occur in peripheral tissues* [174], even independently of T cells. Therefore these cells are important in AD, asthma, and AR in which allergen binding to the IgE cross-links the FcεRI [347]. Several differences call for distinguishing these cells from functional, ontogenetic, histochemical points of view, and the quantity and quality of released mediators: Table 1.25 [166, 168, 340, 567] shows that differences prevail over analogies also regarding the immune stimuli activating them (Table 1.26) [340].

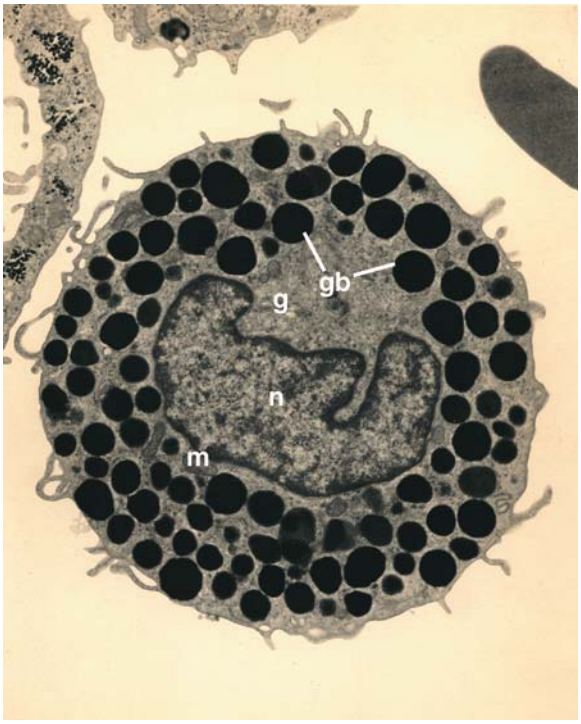

Fig. 1.36. Basophil, EM (×18,500). *n* Multilobed nucleus, *m* mitochondrion, *gb* basophil granules, *g* Golgi apparatus

Circulating *basophils* (Fig. 1.32 i, 1.36) have concentrations of 20–45 cells/mm^3, = 0.3%–0.6% of leukocytes, 6–60×10^5 FcεRI/cell (twice as much as mast cells), 0.04 pg/cell of tryptase [166, 168] (250- to 875-fold less

Table 1.25. Differences among mast cells and basophils

Characteristics	Mast cells	Basophils
Origin of precursors	Bone marrow	Bone marrow
Site of maturation	Connective tissue	Bone marrow
Mature cells in the circulation	No	Yes (<1 % of blood leukocytes)
Mature cells recruited from the circulation	No	Yes (immune inflammation)
Mature cells normally residing in connective tissues	Yes	No
Form	Round	Irregular
Cell diameter	10–15 μm	5–7 μm
Nucleus	Round or oval; eccentric	Bilobed or multilobed
Granulations	0.1–0.5 μm	10–15 μm
Cytoplasmic membrane	Less regular	More regular
Cell surface	Cytoplasmic protrusions	Smooth
Life span	Weeks or months	Days
Preliminaries to degranulation	The granules fuse intracellularly	Fusion of individual granules
Degranulation procedure	Chains of connected granules are released via newly formed channels to cell membrane	Fusion to cell membrane with extrusion of the granule
Cytoplasmic granules	Numerous and relatively small granules	Relatively few and large granules
Major granule contents	Histamine, chondroitin sulfate, neutral acid hydrolases, heparin, MBP	Histamine, chondroitin sulfate, proteases, neutral proteases, MBP and CLC
Mediators and other molecules	PGD_2, TNF-α, thromboxane A_2 (TXA_2), LTB_4, LTC_4, 5-HETE, PAF, NCF, ECF	PGD_2, LTC_4, LTC_4, TXA_2
LTC_4	60 ng/10^6 cells	60 ng/10^6 cells
PGD_2	60 ng/10^6 cells	0.006 ng/10^6 cells

than TC and T mast cells) and ≈1 pg/cell of histamine, 25% of mast cells [341]. Although basophils account for only 0.5% to 1% of peripheral leukocytes their participation is emphasized in all allergic diseases, and the presence in tissues is correlated with affection severity. Despite their short life span and their reduced percentage, they characteristically increase in number in delayed-type responses, matching the rise of histaminemia [46, 332]. Circulating human basophils co-operate with eosinophils by playing a significant role in promoting allergic inflammation through the release of pro-inflammatory mediators [including ECP, MBP, histamine-releasing factor (HRF), IFN-γ, IL_4, and IL_{13}], capable of potentiating or priming histamine and LTC_4 release [46], as well as CD203c on blood cells exposed to recombinant allergens (RAs) [200] and represents a basis for a sensitive novel allergy test (Chap. 6). Basophils have several receptors (Tables 1.25, 1.26), and ILs as well as adhesion molecules regulate their chemotaxis [567]. Several chemokines induced chemotaxis at different potencies: eotaxin > SDF-1 > RANTES MCP-1 >> MIP-1 [239]. Their passage from blood vessels to inflamed tissues is correlated with the availability of specialized chemotactic factors, among which are factors of leukocyte derivation, kallikrein, C5a, specific antigens [528] and CD62L [625]. CD44 and CD54 are constitutively expressed on basophils, CD69 expression is preferentially and strongly upregulated by IL_3 [670]. Exposure of basophils to priming stimuli increases their sensitivity to FcεRI mediated-activation [46]. Basophil recruitment and activation may be facilitated by the CXCR4-SDR-1 receptor ligand pair [239]. The action of

anti-IgE, and in sequence by growth factors including GM-CSF, IL_3, IL_5, NGF, IL_8, IL_{18}, IFN, PAF and C3a, drive basophils to release histamine [46, 567, 669]. IL_{18} also stimulates IL_4 by basophils [669]. Histamine release was induced by MCP-1 SDF-1 > eotaxin > RANTES > MIP-1 [239]. In this process, the PAF role is Ca^{++}-dependent and -independent of GM-CSF and IL_3, which up-regulate PAF activity [92]. IL_3 increases adhesion to endothelium and induces basophils either to produce IL_4 priming these cells at the level of membrane IgE [55], even if there are measurable IL_4 levels in cells devoid of IL_3, although tenfold less [506], or activating MCP-1 triggering their degranulation with dose-dependent histamine release [22], an effect inhibited by several CXCL and CCL chemokines [281]. The tendency to release histamine is genetically controlled, but in a way different from IgE production: it may be particular of allergic subjects, in whom it should be considered as a biological feature favoring the progression to chronic inflammation [331]. Several disease states also result in a concordant relationship between serum IgE and basophil FcεRI expression [485]. Studies have focused on new aspects of releasability (Chap. 11), a parameter not yet defined from a biochemical point of view, although it regulates proinflammatory mediator release and IL release from effector cells, including mast cells and eosinophils [332]. *Basophils represent a prominent source of IL_4, above all considering that IL_4 stimulates peripheral monocytes to synthesize IgE antibodies* and maybe also additional ILs regulating immune responses of other cells, thus amplifying inflammation. The role of IL_4 produced by basophils is also reflected at the Th2 T-cell level [507]. IL_4 present on endothelial surfaces participates in regulating eosinophil adhesion and selective transmigration as well; therefore eosinophil accumulation in inflammatory sites can be propitiated by activated basophils [506]. A recent study shows that the ability of TLR2 ligands to target basophils not only for IL_4 but also for IL_{13} secretion could have relevance to *in vivo* findings [41], *yet IL_{13} early in ontogeny* [182] so that they could play an important role in promoting and amplifying the Th2-dependent responses manifest in allergic disease [506]. The best characterized TRL2 ligand, peptidoglycan, directly activated basophils for IL_4 and IL_{13} secretion and greatly increased IL and mediator release in response to IgE-dependent activation [41]. Increased spontaneous basophil histamine release improves with food avoidance in children with FA (Chap. 10).

Each mast cell (Figs. 1.32 j, k, 1.37) bears on its surfaces $10–30\times10^5$ FcεRI receptors able to bind to Fc fragments, leaving free the Fab one, which is provided with the binding site for antigens, probably within the Cε3 domain [168]. An IgE molecule binds to one FcεRI receptor and vice versa: as a result, parallel to a high number of receptors, *only one or a few ng of IgE are enough to start mast cell activation.* Mast cells are also capable

of presenting antigens to T cells, resulting in their activation, in either an HLA class I or class II-restricted and polarizing T cells toward the Th2 phenotype via the effects of IL_4 and IL_{13} [347]. Mast cell precursors arise from pluripotent bone marrow-derived stem cells, circulate in the blood and lymphatics, and migrate into tissues, in which they reach phenotypic maturation [347]. Mast cells are stategically located at perivascular sites to trigger inflammatory responses [343]. Increased vascular permeability induced by mast cell-derived tryptase and chymase, and degradation of ECM components by enzymes such as matrix metalloproteinase 9 (MMP-9) which has been shown to be released from mast cells on activation by T cells also following a possible autocrine regulation by mast cell TNF-α, may further expedite cell migration through barriers including the vascular wall and the blood–brain barrier [347]. These cells, usually absent from blood, are scattered in connective tissue sites throughout the body, and especially around blood vessels and nerve endings in a variable number, between 7,000 and 20,000 cells/mm^3 of tissue [168]. Molecules such as HLA class I and II, CD28, CD54 (ICAM-1), CD154, β_2-integrins, and TLRs (TLR1 to TLR4, TLR6 and TLR9 [333]) allow mast cells to interact with other inflammatory cells, thus orchestrating an immune response [347]. MIP-1α may be a costimulatory signal operating via CCR1 for mast cell-mediated immediate hypersensitivity reactions [357]. A unique role for mast cells is to produce and release a vast array of mediators such as vasoactive amines, products of arachidonic acid (AA) metabolism, and several proinflammatory, chemoattractive, and immunomodulatory ILs that may contribute to immune reactions by affecting cell growth, recruitment, and function [476] (see also Innate Immunity). By using complementary DNA microarrays 1–2 hours after cross-linking with FcεRI, 2,530 genes exhibited 2–200-fold changes in expression and mast cells were shown to produce 18 ILs, including 130–529 pg of $IL_{11}/10^6$ cells and TNF-α, 13 chemokines, including two CXCL (IL_8, Gro2) and lymphotactin), ten CCL chemokines and several adhesion molecules [494]. Every human cell isolated from nose, lung, skin and intestine contains on average 2, 2.5–10, 4.6 and 1–2 pg of histamine, respectively [402]. Mast cells have been identified as a potential source of MBP [376]. Moreover, IL_{11} mRNA was co-localized with MBP in inflammatory cells in the subepithelial layer of the airway in subjects with severe asthma [354]. This raises the possibility that both mast cells and eosinophils represent sources of IL_{11} in asthma [354, 494]. Studies in rodents have revealed two mast cell phenotypes, called T or TC, being associated either with mucosal and connective tissue or with both tryptase and chymase (35 and 4 pg/cell) or, respectively, only tryptase (10 pg/cell) [168]. Apparently, T mast cell maturation, but not the TC phenotype, requires the help of IL_3 and IL_4 generated by T lymphocytes. Mast cells produce several ILs in response to cross-linking with FcεRI (Tables 1.25, 1.26), including TNF-α and IL_4 [509] and in vitro IL_1, IL_3-IL_6, GM-CSF, IFN-ɣ, which do not elicit histamine release as for basophils, as well as chemokines such as MIP-1α and -1β [168]. IL_1, IL_3, GM-CSF, MCAF (monocyte chemotactic and activating factor), = MCP-1 and RANTES; IL_4 and TNF-α induce adhesion molecules on vascular endothelium in injured sites, a first step for inflammatory cell migration such as lymphocytes and granulocytes [420]. Also, the expression on the mast cell surface of integrins linked to the FN receptor causes their activation [420]: FN binds to β1 integrins including CD49a, CD49c, CD49d, CD49e, and CD49f/CD29, playing a fundamental role when both IgE and antigen levels are low in local microenvironments [420], whereas FcεRI aggregation to cells adherent to FN specifically amplifies the phosphorylation of such proteins [195]. Signal transduction obtained in such a way by FcεRI looks like that of TcR/CD3 in T cells. We mention that antigen binding to FcεRI-IgE brings about the degranulation of metachromatic cells, thus initiating reactions of immediate hypersensitivity; however, mast cells can undergo forms of non-IgE-mediated signals from their environment (Chap. 10).

Modified from [227].

Table 1.27 [227] summarizes several differences between T and TC mast cells on the basis of tissue prevalence. In humans, somewhat different phenotypes have been recognized; in addition, mast cells residing in the airways contain mostly tryptase, and those of other locations both proteases [227]. Their predilection to occupy tissues that interface the external environment makes them well represented in inflamed tissues under T-cell functional control through IL_3 (proliferation) and IL_4 (maturation) [593]. Under the influence of IL_3, IL_4 and NGF, T mast cells may assume characteristics of the TC phenotype; therefore, one may consider the distinction into two types nearly obsolete, with both phenotypes potentially coexisting in the same site, although in different proportions. Furthermore, it has been suggested that mast cells in unrelated locations respond to allergens with the same pattern of mediators [227]. As a consequence, mast cells are strategically positioned to

detect rapidly inhaled or ingested allergens, expressing a chronic array of proinflammatory mediators, without neglecting PAF and chemotactic factors such as LTB_4, NCF, and ECF (eosinophil chemotactic factor).

Appendix 1.2 summarizes receptors and surface molecules expressed from eosinophils, basophils and mast cells [593].

Platelets too have a virtual role in the pathogenesis of allergic disease [405], in addition to a typical role in coagulation processes. Classically thought to originate in the bone marrow from cytoplasm of megakaryocytes, it has recently been suggested that actually megakaryocytes travel to lung vessels, where they are physically fragmented into small clumps of granules, each of which is a platelet. These are the smallest blood cells, anucleated (2 µm in diameter), with a half-life of about 10 days. Platelets have been shown to express HLA class I molecules on their surface, IgG receptors (CD32), IgE (CD23), vitronectin (CD51), CD9, CD17, CD31 (GPIIa), CD36 (GPIIIb), CD41a (GPIIb/IIIa), CD42a–d (platelet antigens), CD49f, CD60, CD61 and CD63 (Table 1.2). Human platelet antigens (HPA) are at least 15: PHA 1–15 [298]. When activated, together with aggregation they undergo morphological modifications, secrete PAF, cytotoxic cationic proteins and free radicals. Moreover, platelets release 5-HT from dense bodies, which like histamine produce contraction of smooth muscles, increase vascular permeability and produce proteolytic enzymes and cationic substances from α granules with equal effects on blood vessels, in addition to chemotactic factors including PF4 (platelet factor 4), PDGF, 12-HETE, NO (nitric oxide), TGF-α and -β, albumin, β-thromboglobulin, eicosanoids (PGG_2, PGH_2, TXA_2, and CD62P), allowing binding to fibrinogen, FN and CD51. Consequently, platelets, although confined in the vascular compartment, also acting by diapedesis, can release mediators active in inflammatory extravascular foci. However, their specific role in inflammatory reactions is not well defined as it is for other cells: if activated, they also have chemotactic and phagocytic properties and contribute to immune reactions, releasing growth and coagulation factors, vasoactive amines and lipids as well as acid and neutral hydrolases. Following platelet aggregation, abnormal agglomerates develop and recruiting and entrapping leukocytes may contribute to the start of an endovascular occlusion. The human PMN adhesion to vascular endothelial cells was increased by the platelet presence. This effect was endothelial cell dependent and involved platelet activation. Thus platelet participation in cell recruitment occurs at the circulation level and might involve leukocyte priming for subsequent adhesion and transmigration into tissues [430]. Platelets produce enzymes cleaving C5, thus resulting in C5a, with a marked chemotactic activity for neutrophils: this is most likely the establishment of an active form of cooperation for the production of new mediators. C5a can prime mast cell degradation, while C5b-9 participate in the non-lytic platelet activation [680]. Platelets interact with the immune system via FcεRII (in 10%–30% of healthy and in 50%–60% of atopic subjects), FcγRII (CD32), the VLA-2, -5 and -6 integrins, ensuring adhesion mechanisms among immunocompetent cells and CD62P [65]. Activation of FcεRII elicits PAF production and an IgE-dependent platelet activation, which is not expressed as the classic aggregation, but by secretion of O_2 toxic radicals, triggered by SP, CRP (C-reactive protein), IFN-γ and TNF. Also prominent is the portfolio of chemokines that attract these cells to a site of inflammation, such as α-chemokines (CXCL), β-family (CCL), including eotaxin, Gro-α, RANTES, TARC, macrophage-derived chemokine (MDC), and SC-derived factor 1 (SCDF1), and chemokine receptors, such as CCL2, CCL3, CCL5, CCL7, CCL8, CCL13, CCL17, and CCL22, activate platelets to give Ca(++) signals, aggregation, and release of granule content [87]. The inappropriate platelet activation materializes with eosinophil recruitment on the sites of immune inflammation, TGF-β secretion with mitogen activity towards bronchial smooth muscles, PF4 released during asthmatic attacks and PDGF triggering fibroblast proliferation. So platelets can be involved in the onset and perpetuation of structural alterations underlying subepithelial fibrosis, which contribute to emphasize BHR. Two series of experiments account for what we discussed earlier: platelets from patients with asthma from ASA (acetylsalicylic acid) or NSAIDs (nonsteroidal anti-inflammatory drugs) incubated with SP, PCR, IFN-γ and TNF start the release of O_2 radicals. Thrombocytopenia is congenital in Wiskott-Aldrich syndrome (Chap. 22) [405].

Additional Cells

The principal *APCs* expressing class II determinants [541] are DCs (in the skin LCs), macrophages, Kupffer cells, endothelial cell, enterocytes, monocytes with FcεRI [384], and B cells. All these cells, provided with HLA class II molecules, constitutive or inducible by bacteria and macrophage IFN-γ, collaborate with T lymphocytes (as well as among themselves), in different procedures according to the microenvironment and antigen type. DCs present antigens and virus in extralymphoid tissues and B cell toxins, virus, and bacteria in the spleen, while macrophages focus their attention on intracellular pathogens [49]. A differential type I IFN gene transcription was induced in monocyte-derived DCs and PDCs stimulated by specific TLR agonists. TLR-9 stimulation by CpG DNA induced the expression of all IFN-α, -β, -ω and -λ subtypes in PDCs [88]. Activated TcR-γδ can secrete ILs efficient in the activation of several cell families, also inducing a functional maturation of professional APCs with the accessory aid of several molecules, among which is CD154, hence facilitating the recruitment of antigen-specific TcR-αβ [110].

Dendritic Cells

Myeloid DCs are crucial APCs for primary T-cell responses: tissue-resident immature DCs are excellent at internalizing and processing antigen, but they exhibit a low ability to stimulate naive T cells [88]. DCs encompass a heterogeneous group of cells present either in lymphoid tissues such as thymic DCs and FDCs or in parenchymal organs such as IDCs, circulating and/or cutaneous LCs. Moreover, several chemokine receptors in $CD4^+$ lymphocytes are primed by DCs (see Chemokines) [88]. LCs arise from bone marrow precursors that colonize peripheral tissues through the blood or lymph, according to recent data, a line common to macrophages [424], which modulated by GM-CSF and TNF-α [221, 546] leads to two precursors identified by CD1a and CD14, both maturating into LCs and, respectively, DCs or macrophages depending on IL influence [74]. Activation causes DCs to up-regulate the CSMs expression (CD80 and CD86) on their surface. CSMs provide the signals necessary for lymphocyte activation in addition to those provided through the antigen receptor [115]. Circulating conventinal DCs coexpress and IFN-γ most potently favors activating CD32a, whereas soluble anti-inflammatory concentrations of monomeric IgG express inhibitory CD32b, both isoforms of IgG FcγR II (CD32). Ligating complexed human IgG to CD32a *matures and activates DCs* in proportion to the frequency of CD32a expression. However, coligation of CD32b significantly abrogates all of these immunogenic functions. These findings have important implications for understanding the pathophysiology of CIC disease and for optimizing the efficacy of therapeutic mAbs [48]. DCs produce a wealth of ILs: immature DCs exhibited higher amounts of IL_1, TNF, TGF-1, and MIF mRNA/protein than mature DCs. After differentiation, DCs up-regulated the levels of IL_6 and IL_{15} mRNA/protein and synthesized *de novo* mRNA/protein for IL_{12} p_{30} and p_{40} and IL_{18}. CD1a precursors generate cells expressing Birbeck granules and E cadherin characteristic of LCs, while CD14 progenitors mature into CD2, CD9, CD14, CD68 and factor XIIIa, specific of dermal DCs [74]. DCs, described as localized in the suprabasal layer of epidermis, represent in the adult only 2%–8% of epidermal cells, sharing with dendritic lymph nodes several phenotypic and functional features [454]. Although immature bone-marrow-derived DCs did not stimulate naive allogenic T cells, mature DCs elicited a mixed population of Th1 (mainly) and Th2 cells. The DC subset may contribute significant polarizing influence on Th differentiation and the CD subset 1 may exert Th1 polarization by IL_{12} production and STAT4 activation [366]. Growth and differentiation of LCs and their migration delineate a crucial step in the immune surveillance of foreign antigens invading the host [221, 546]. LCs via afferent lymphatics reach the paracortical areas of regional lymph nodes as FDC with APC function; thereby they are the first cells to trap antigens, which are

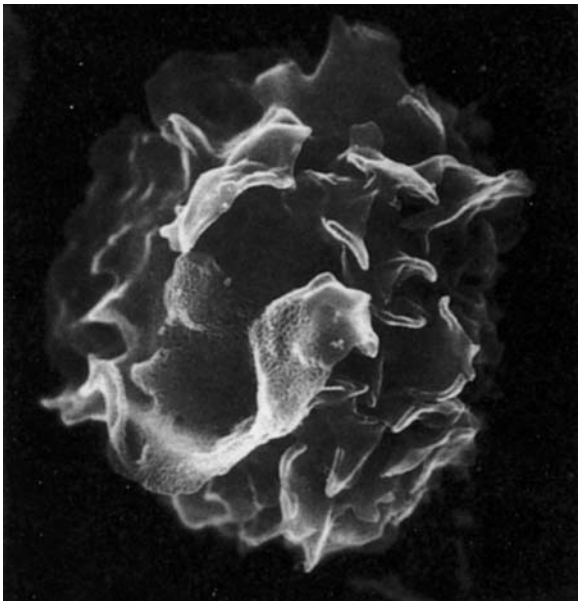

Fig. 1.38. Langerhans' cells appearing as veiled cells

then internalized and processed at the level of target cells [541], then presented in draining lymph nodes to upcoming T cells stimulated by the same DCs [546]. In comparison, DCs are strategically located below the M cells of PPs, thus sampling antigens in vivo and migrating to T-cell areas of the same PP or mesenteric lymph nodes, where they present antigen to naive T lymphocytes [253]. LCs migrate quite rapidly after having taken up a peptide, present a rounded phenotype with long cytoplasmic protrusions rhythmically moved, hence assuming the aspect of *veiled cells* [541] (Fig. 1.38). FDCs returned in paracortical areas as APCs, having a poor expression of HLA class II molecules, present the same peptide processed over several days [541] or months [37], also contributing to long-term maintenance of memory B cells [37]. FDC maturation due to an increased presence of CD80 or CD86, and enhanced by CD40, is stimulated until FDCs encounter T cells [424]. To understand the role of DCs in antigen presentation and processing, we mention that DCs select potential antigens taking up microbial glycoconjugates by means of specialized receptors. An in vitro model has demonstrated that PBMCs, in GM-CSF and IL_4-dependent cultures, develop into DCs that are extremely efficient as APCs, a property lost when treated with TNF-α [487]. LCs are thought to play a key role in enhancing immunogenicity since their first identification, because they *express FcεRI binding to IgE,* and pick up antigens in vivo even before presentation, and like they other APCs process antigens, degrading them into peptides that become approximately six to eight amino acids in size with a low MW [384]. The evidence that *LCs also possess FcεRII* [40] implies a major role in view of their significant activity shown in atopic diseases [546]. Table 1.28 [208, 424] summarizes their markers, denot-

ing the skin LCs [424]. The LC ability to stimulate primary responses is up-regulated in the epidermis where they migrate in association with CD15s and CD62E and express *in loco* the E cadherin to bind to keratinocytes [566]. Cells very sensitive to UV action lose the capacity of presenting antigens to T cells after irradiation, an effect modulated by IL_{10} secreted by keratinocytes [461].

Afferent Phase of Immune Response

Antigen Processing and Presentation

Antigen processing and presentation are among the key events between a foreign protein penetration into the host via mucosal, skin or blood routes and its recognition by immunocompetent cells. The immune response results from a complex network of subpopulations of different cells interacting via soluble proteins, the ILs, most of which are involved in either inactivating or activating the expression of immune effector functions (cytokine cascade) [34]. This picture is integrated by a variety of actively trafficking cells such as lymphocytes, APCs, adhesion molecules, etc. [28]. T lymphocytes cooperate in the induction of immune responses influencing the up-regulation of B cell progenitors of IgE-secreting cells (Fig. 1.39). Antigen recognition and activation are neither consequent processes nor are they homologous: antigens can be recognized by the immune system without inducing mandatory immune responses, as in nonatopic subjects who instead yield Th1-cell clones [601, 606].

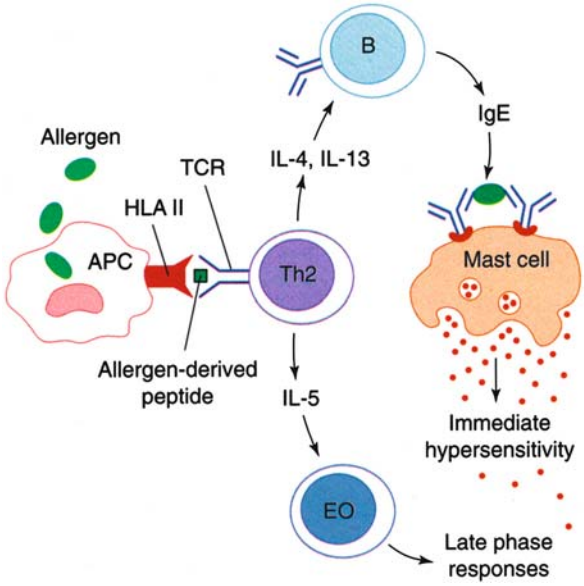

Fig. 1.39. Role of CD4+ cells in the immune response. Upon entry in the body, allergens are taken up and processed by APC, after presentation, HLA class Ii restriction and TcR usage of allergen-specific Th2-like cells, B cell progenitors of IgE-secreting cells are up-regulated. If IgE are produced, an immediate Th1-type response may ensue, but Th2-like cells may activate eosinophils, thus resulting in a late-phase response. *APC* antigen presenting cell, *B* B cell, *EO* eosinophil, *Th2* Th2 T cell, *TcR* T-cell receptor

CD4 cells do not recognize intact antigens, but interact only with previously processed native, exogenous antigens associated with class II HLA molecules, unlike CD8 and B cells recognizing endogenous peptides associated with class I molecules [12, 372]. γδ T cells recognize antigens differently, especially small molecules, but the functional consequences remain to be elucidated [109]. CD1 comprising five different proteins (Table 1.2) present lipids or glycolipids of microbial origin to T lymphocytes. However, their role in vivo is not yet clear [115]. HLA-E, HLA-F, HLA-G, HLA class I-like, representing differentiation antigens, have a limited tissue

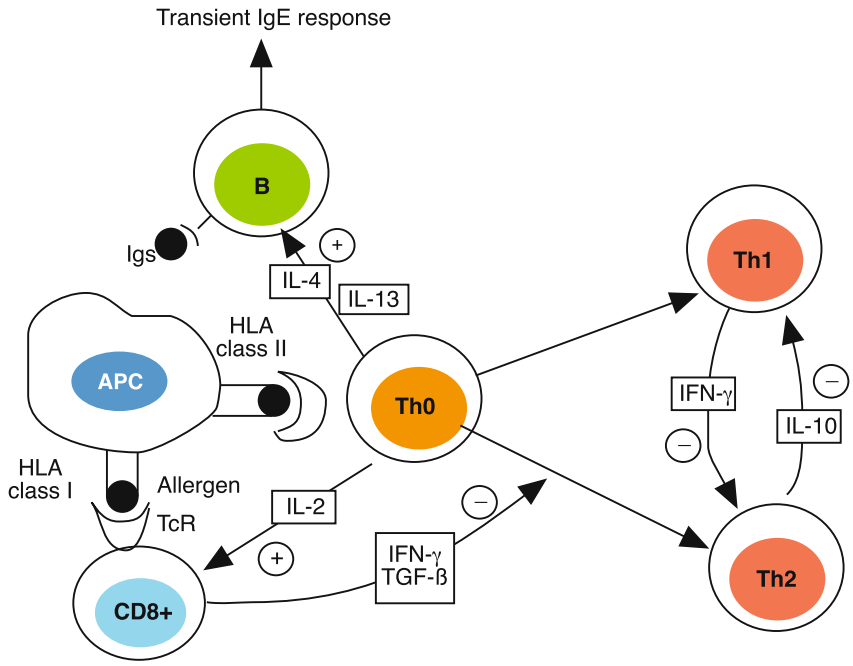

Fig. 1.40. Selection of Th1-mediated protective immunity toward allergens during primary immune response via class I $CD8^+$ HLA-restricted immunodeviation. distribution and polymorphism [47]. HLA-G has been recently characterized as TAP-associated, which directs its expression and binding to nonameric peptides [293]; HLA-G expression on target cells protects from NK-mediated lysis interacting with NKR [419], of special significance pertaining to maternofetal tolerance.

Classic studies have shown that immune responses consist in the production of antibodies, up-regulated stimulating CD4 lymphocyte activation, but may be down-regulated when CD8 cells predominate. Non-self substances that have gained access to sites patrolled by the immune system enter automatically in contact with it, thus activating a complex mechanism of cellular activity aimed at its destruction and at restoration of preexistent homeostasis. Therefore, immunogen peptides encountering lymphocytes of an atopic individual for the first time trigger a multiple pathway of cell interactions ensuring that B lymphocytes differentiate into antibody-secreting cells [601]. As soon as an invader is identified by two different immune effector mechanisms, antibodies (humoral effector limb) and TcR (cell-mediated effector limb), the foreign antigen is captured by APCs, the peptide-HLA complex is recognized by TcR, then internalized and processed in fragments subsequently exposed on the cell surface in association with class II HLA molecules. Thus the interaction between antigen-specific T and B cells (cognate interaction) and consequent IL release result in the activation of lymphocytes [290]. A theory of two signals is suggested also for the T cells: accordingly, Th0 T cells receive the first signal from the TcR triggered by pathogen-derived antigenic peptides bound to HLA class II molecules on APCs, which indicates the peptide molecular identity. Signal 2 delivered from costimulatory molecules (CSM) comprises contact-dependent and humoral signals and transmits the information about the DC-activating property of invading pathogens, reflecting its pathogenic potential. The combination of signal 1 and signal 2 results in Ag-specific activation of naive Th cells and their development into effector/memory cells [290]. A Th0 signal might provide a further refining cadence, whereby the IL milieu produced by DCs provides naive T helper cells with a Th1- or Th2-polarizing signal at the time of priming [212]. Activated T cells differentiate into Th2 T-cell clones, which secrete low amounts of IL_4, thought to play a crucial role in IgE isotype switching. The resulting IgE low levels can be captured by high-affinity receptors on the mast cell surface [290]. Thereby the first exposure to an immunogen leads to the production of antigen-specific IgE and priming of the immune system (*primary immune response*), an event preventing a second encounter via the $CD8^+$ class I HLA-restricted immune deviation (Fig. 1.40) [212]. In immunologically healthy neonates and infants, such initial responses, an integral part of normal immune responses, are self-limited and gradually resolve, after weeks or months, despite continuous allergen exposures, due to the development of tolerance [250]. In healthy, uncommitted subjects, membrane-bound IgG forms immune complexes with allergens. IgG is tethered to the membrane by binding the Fc fragment of FcεRIIb. When an allergen binds both IgE and IgG, the activating FcεRI is brought together with the inhibitory FcεRIIb, thereby silencing the FcεRI-mediated activation pathway [259]. According to this model, following subsequent exposures, CD4 clones from nonatopic individuals have a Th1 profile, whereas in atopic patients they can lead to an immediate hypersensitivity reaction (*secondary immune response*). Antigen persistence or reexposure leads to ongoing antibody production, which is outstanding, rapid, more specific

and enduring with different functional features, dominated by Th2 T cells and IgE, an expression of immune memory [212]. When receptor-bound IgE is cross-linked, release of potent biochemical mediators and further IL_4 production induce uncommitted T cells recruited at a site of allergen re-entry to differentiate into a Th2 phenotype, hence amplifying immune reactions [250]. Th2 T cells, IL_4-derived IgE production and IL_5-triggered serum and tissue eosinophilia result in *a vigorous IgE response* and a severe clinical response [212]. T cells, eosinophils, metachromatic cells provided with IL_4 and CD40L, ILs and adhesion molecules and their interactions are the major players around which atopic diseases evolve [177].

Antigen Capture and Processing

Antigen capture by APCs can occur via three distinct mechanisms [488]. The first is macropinocytosis [555], a type of fluid phase endocytosis, uptake of large vesicles (1–3 μm) mediated by membrane ruffling driven by actin cytoskeleton [488]. In DCs this constitutive mechanism calls for a continuous internalization of large volumes of fluid (1,000–1,500 μm^3, a volume close to one cell/h), whereas macrophages and epithelial cells need to be stimulated by growth factors [555]. The second mechanism is mediated via the mannose receptor (MR), a 175-kD C-type lectin, which on human cultured DCs modulates endocytosis of $>10^5$ molecules of mannosylated proteins per cell/h [488]. Furthermore, a membrane protein of murine DCs, structurally homologous to macrophage MR, internalizes peptides, delivering them to a multivesicular endosomal compartment provided with HLA class II molecules, of which DCs synthesize elevated levels: in this model, the signaling process initiated by T cells is up to 100-fold more efficient [488]. The third mechanism is mediated by FcγRII, also expressed by DCs [290]. B cell clones bear high-affinity mIgM and mIgD on their membranes ready for antigen epitopes and antibodies and their BcRs fulfill two functions: signal release leading to B cell activation and antigen uptake and delivery to processing compartments [290]. In addition, nonprofessional receptors are surface molecules able to occasionally capture antigens and effectively present viral proteins bound to surface receptors [396].

Presentation and Recognition

Antigen recognition from T cells with a TcR complementary to peptide-HLA association triggers the first phase of *T-cell activation and consequently the immune response* [28]. For this purpose, both the epitope and agretope that bind to an HLA molecule are critical (Fig. 1.15). The peptide–HLA complex exposed to the CD3–TcR complex of antigen-specific T cells is expressed on the cell membrane in the *fitting pocket* of HLA class II molecules (a *genetic restriction* mechanism) (Fig. 1.22). Such complexes are as firm and as high as the peptide affinity for the hypervariable part of HLA molecules; such adhesion is mediated by CD2, CD11a/CD18, CD54, CD58, and other integrins and selectins [534]. The cells expose peptide fragments assembled with HLA class I or II molecules, so that they are examined by circulating T cells, which, although relatively few in view of the great number of potential antigens, and of their great diversity, are conditioned to recognize those they encounter [34]. The affinity for peptides depends on the amino acid sequence of hypervariable regions and consequently on the HLA molecules that everybody inherits. TcR and HLA interactions are characterized by a high-sensitivity and low-affinity paradox, which is only a small number of TcRs that interact with APCs [595]. On the contrary, APCs are fit for almost any foreign invader encountered by the immune system, thus raising a very intriguing question of how so few receptors can transduce an activation signal [225]. It remains to be elucidated how as few as 80–100 HLA–foreign peptide complexes on the cell surface (which may express as many as 10^5 HLA molecules) are sufficient to trigger a T-cell response [47]: the answer lies in the capacity of a single peptide–HLA complex to serially engage and trigger up to ≈ 200 TcR, amplifying the signal according to T-cell biological responses [595]. C3b plays a critical role in at least two phases of recognition, as shown by the T clone response to presentation of C3b–Ig complexes. The uptake of such complexes is helped by the interactions with complement receptors virtually present on all APCs; furthermore, C3 covalent binding to specific antigen peptides can define, during the processing, which part of the molecule is selected as epitope presented to T cells [359].

Recognition of immunogenic proteins in their natural configuration is not sufficient to stimulate B lymphocytes to differentiate into plasma cell IgE, since switching steps requires T lymphocyte cooperation, which materializes via IL_2 production; so B cells and APC interaction within TcR presentation of peptide–HLA complexes involve antigen specificity and consequently B lymphocyte capacity to bind to and present peptides, even if their extracellular number is reduced. At the level of peripheral lymphoid tissues, where antigen concentration is greater, other APCs are involved in antigen processing and presentation background. The first step of B-cell activation requires signals generated upon recognition of antigen by the BcR as well as additional signals provided by cognate interaction with T cells, including the CD40–CD154 interaction [201]. Following peptide–HLA complex recognition on the B-cell surface by TcR, T cells deliver appropriate activating signals to B cells (*cognate help*); hence T cell–B cell cooperation begins, class II-restricted and antigen-specific, with formation of tightly associated conjugates [457]. Such conjugates result from peptide–HLA complex presentation from B cells; fur-

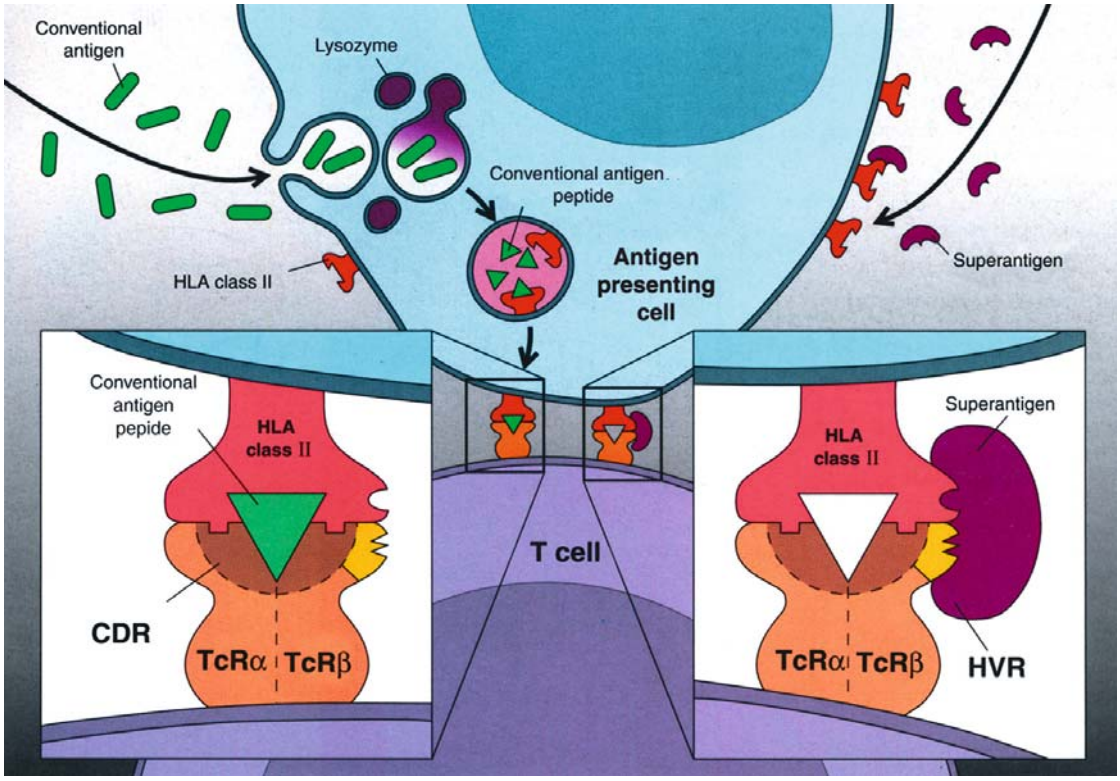

Fig. 1.41. Superantigen abbreviated presentation. Superantigens sidestep the usual pathways of antigen presentation (*left*), but are presented intact on the outside of the HLA peptide-binding groove (*right*) and activate T cells. Superantigen is recognized by a side face of TcR-Vβ, which encompasses a HVR that has been designated HVβ-4. *CDR* complementarity determining regions, *HVR* hypervariable region

Table 1.30. Prominent characteristics of superantigens (*SAs*) interacting with B lymphocytes (B superantigens, *BSA*)

SAs activate a large percentage of B lymphocytes, about 40% of human polyclonal IgM binds to SPA
SAs interact with the major part of components of V_H– gene family: SPA binds to a high rate of V_H3+IgM
SAs trigger B lymphocytes in vitro; SPA delivers activation signals to IgM V_H3+, thus triggering Ig differentiation; HIV-1 gp120 selectively induces Ig secretion by V_H3+ IgM
SAs also induce in vivo changes in B lymphocytes; it has been suggested that during HIV-1 infection the B V_H3+ cells are initially up-regulated, and then highly down-regulated
SAs interact with regions of the V_H gene domain; for SPA binding a motif between residues 75 and 84 of FR3 is involved, outside the conventional paratope
SA binding activity experiences age-related alterations

Modified from [692].
FR framework region, *SPA Staphylococcus aureus* protein A.

ther enhancement of cognate interactions depends on CD54 binding to CD11a/CD18 and CD4 to monomorphic domains of class II proteins [391]. Engagement of both the BcR and CD40 results in synergistic activation of B cells [201]. CD4 T cells bind to antigen-specific B lymphocytes; the associative recognition induces B-cell activation, clonal expansion, and differentiation, while cell division goes on as long as T cells stimulate it. Mature plasma cells are generated and secrete specific receptors, the mIgs, which bind to antigens present in the bloodstream [457]. Previous studies suggested that binding to TRAF2 and/or TRAF3 but not TRAF6 is essential for CD40 isotype switching and activation in B cells [232]. More recently a model was presented in which Btk contributes to the enhancement of the CD40 response by TRAF2 in a BCR-activated protein kinase D (PKD)-dependent manner [201].

Superantigens (SA) are antigens able to select subsets of T cells during thymic ontogenesis, playing an important role in T cell development: an example is given by bacterial toxins, some of which can be mitogen for some T cell subsets. Such SAs bypass key antigen processing and recognition steps in T cell activation, by binding more or less exclusively to lateral exposed surfaces of HLA class II molecules and TcR determinants of the Vβ region (HVβ-4), that is, not to a normal paratope. As a result of this sidestep they are able to activate greater proportions of lymphocytes, not $1/10^4$ or $1/10^5$, as with usual antigens, but whole clones up to 30% of T lymphocytes, thus amplifying their activity, and functioning as a bridge between T cells–HLA and accessory cells [275]. Figure 1.41 shows a polyclonal activation of T cells, which recognize both conventional peptides with Vα and Vβ regions, and SAs essentially with an area of the Vβ region [275]. Table 1.29 [474] details the different types of microbial SAs. NKB1 inhibitor receptor, expressed by many T cell clones and engaged by their HLA class I ligands on potential target cells, protects against cytotoxicity induced by bacterial SAs [427]. An additional means of interaction between T and B cells can occur, whereby molecules termed B-SAs (BSA) can bind directly to human BcR of a given variable V gene family [647]. This mechanism requires contributions from the FR loop away from CDRs; hence this loop is less favorably placed for antigen contact and has a greater potential for unconventional binding (Table 1.30) [605].

Lymphocyte Activation

Like many other cells of the body, T and B cells exist for most of their life span in a quiescent state or a G_0 state. To proliferate, the cells must re-enter the G_1 phase, where several proteins undergo a substantial process of biosynthesis, so these cells grow in size and prepare for DNA synthesis. In the S stage, DNA synthesis and replication of each chromosome bring about two matching sister chromatids. The subsequent G_2 and M (mitotic) phases involve the two sister separations, generation of two new nuclei, and final division of the cytoplasm to produce two daughter cells: growth factors and different environmental stimuli are required for cell cycle progression, depending on the cell type [337]. There are several *functional differences* between T and B cells and recent work has focused on their mutual interactions: T lymphocytes have a variety of signals allowing them to leave the circulation and enter tissues to reach the site of antigen exposure, both because they constitute the prevalent portion of peripheral lymphocytes and they have the central feature to recirculate. Instead, B cells encounter preferably native macromolecules *in situ,* in specialized organs and tissues; however, in an antigen-independent phase of B-cell development, it is likely that B cells do not require interactions with antigens, which will be ultimately recognized by soluble antibodies subsequently synthesized [481]. Both T and B cells need to be stimulated before acquiring the capacity of responding to specific antigens, T cells by their clonally restricted TcR and B cells by Igs, or in T-independent polyclonal systems or molecules with mitogenic properties, both experimentally and physiologically [326]. We also note some biochemical similarities in B and T cell activation: as an antigen binds to an APC, a series of defined events occur over a period of several hours. Within a few seconds, the phosphorylation of cell proteins takes place, mostly associated with CD3ε and ζ and CD79a and b receptors and membrane phospholipid cleavage. A cascade of protein activation in regulated sequence and the rise of Ca^{++} levels occur. As a result of these early activation events, TFs such as NFAT 1, 2 and NF-κB are activated to enter the B cell nucleus and promote transcription of nontranscribed specific genes. In

T cells, the most important genes include ILs and IL receptors, while B cells start to transcribe Ig genes. Within about 48 h, DNA is synthesized and cells undergo division [36, 47].

Role of T Lymphocytes

CD3, the nonpolymorphic part of the TcR complex, is a signal transducer in T cells whose activation with IL_1 contribution elicits both proliferation and activation of cell subsets. CD4 stimulation by HLA molecules and IL_1 drives IL_2 and IL_6, an intervention defined as a *synergistic promoter* [34], and additional metabolic processes lead to a final activation and proliferation of CD4 cells, of cytotoxic CD8 and, as a result, of B lymphocytes, which become antibody-secreting cells [206]. For definitive proliferation, CD3 must be escorted by accessory stimuli, one expressed by BcR, the membrane protein CD80, recognized by CD28/CD152 receptor = CTLA-4 (CTL-associated antigen-4) [242]: we stress that when appropriate signals are absent, clonal anergy ensues (Fig. 1.22 a, b).

During the processes of presentation and activation, the trimolecular complex made up of TcR-αβ/CD4 and peptide–HLA transmits signals to cells, as discussed earlier. Due to TcR binding to extracellular V regions, modulated by CD3ζ, also following second-messenger generation, TcR transduces signals initiating biochemical and conformational changes. Intracellular signals generated by TcR and transmitted to T cells appear, therefore, to be critical for proper T cell maturation and activation [276]. Transduction of activating signals by CD3-CD28 costimulation initiates multiple signaling cascades that lead to the activation of several TFs, including the activation of NF-κB family members [276]. TcR-CD3 stimulation alone is not sufficient to optimally activate NF-κB because its requires *Bc110, a CARD* associated with CARMA1 (CARD11) [504], a member of the *CARD family* also including CARMA2 (CARD14) and CARMA3 (CARD10) [621]. The CARD family also encompasses CARD/NOD a member of the *ced-4 superfamily* also including APAF-1, mammalian NOD-LRR (leucine rich repeat) proteins and CARD15/NOD2, which in turn act in LPS recognition and activate NF-κB [79] that is depressed in patients with Crohn's disease [621]. Prominent in this context is *G protein* participation with a manifold role in cellular signal transduction coupling an array of receptors at the cell surface with a variety of intracellular effectors exposed to the plasma membrane's inner surface that couple a large family of receptors to effectors, such as adenylcyclase, PLC, and ion channels [292]. The large heterotrimer G proteins have 21 Gα subunits, which are related to small G proteins, plus five Gβ and six Gγ that exist as a single complex (Gβγ). Gαs are stimulated by GAPs (GTPase-activating proteins) and Gβγ by RGS (regulators of G protein signaling) [231]. In the resting state, guanosine diphosphate (GDP) is tightly bound to Gα. When a membrane receptor is activated by binding of a first messenger, this causes GDP to dissociate from Gα and be rapidly replaced by guanosine triphosphate (GTP). GPT binding leads the Gα subunit to dissociate from Gβγ, each of them can independently transmit signals, hence activating effector cells (active state). In a subsequent phase, hydrolysis of GTP to GDP inactivates Gα, allowing it to reassociate with Gβγ (inactive state) and reset stable heterotrimers. Gβγ subunit binding to several components of the Gα subfamily could open up a new *communication pathway among second messengers* [292]. Considering this activity, G proteins oscillate between GPT- and/or GDP-bound states, and regulate diverse processes, including signal transduction [24]. G proteins also belong to a superfamily comprising a number of receptors; however, the amount of G proteins bound by a given receptor is reduced, practically restricting to one G protein signaling to one receptor. One of the best characterized among signal transduction systems is an increased formation and accumulation of intracellular cAMP (cyclic adenosine monophosphate) as a result of β-adrenergic receptor stimulation; further receptor/ligand interactions enhance Gα3 activity due to Gα3/GTP dissociation from Gβγ. Correspondingly, the activation of the enzyme chain of membrane adenylyl cyclase catalyzes cAMP synthesis in Mg ion presence. Returning G protein to its initial conformation the enzyme is inactivated, while cAMP is converted to noncyclic inactive 5-AMP by cAMP-PDE (phosphodiesterase) constitutive activity; otherwise other receptors activate another G protein, Gi, which binds to adenylyl cyclase to block enzyme activity [326].

Direct evidence suggests that, depending on the type of related cells, cAMP, a second messenger present only inside the cells, plays a role in enzyme phosphorylation, Ca++ levels increase, also affecting both gene expression and further endocellular processes [292]. In addition, the CD3ζ cytoplasmic domain interacts with two families of tyrosine kinases such as *PTK of the src and syk* (intracytoplasmic) *families* (Tables 1.31, 1.32) [157, 214, 222, 240]. Some PTK src are associated via the SH2 domain with ARAM or ITAM sequences of intracellular regions of γ δ ε chains of CD3 as well as α and β (CD79a and CD79b) of BcR and ζ or γ of CD16. To fulfill G protein effects on CD4/CD8 T cells [292], within a few seconds GTP is hydrolyzed to GDP; a cytoplasmic tyrosine kinase, ZAP70 (ζ-associated protein 70), belonging to the syk family, becomes active upon attachment to the TcR–CD3 complex [213] and in turn activates PLCγ1 [462]. The important result of PKC is PLCγ1 activation, which then acts to hydrolyze PIP2 into IP3 (inositoltrisphosphate) and DAG [462]. IP3 and DAG serve as second messengers of the T-cell activation process: IP3 with a short half-life rapidly increases cytoplasmic Ca++ levels; however, in the absence of additional signals there is no activation [337]. DAG has been shown to activate PKC, a process leading to its translocation to the

cell surface and to a cascade of downstream events, also resembling the biochemical way employed for EGF transduction signals, which activates phospholipase C (PLC) instead of PLCγ1 [454].

The increase in Ca++ concentrations by the second messenger cascade activates calmodulin, which regulates several protein kinases and phosphatases, including calcineurin (CN). This event, together with PKC phosphorylation of serine residues of the CD3 γ chain, and of tyrosine residues of the ζ chain, plays a major role in T cell activation as well as in gene transcription coding the IL_2R α chain (G_1 phase). CN also regulates NFAT activity and contains a binding site for one of its components (Fig. 1.42) [457]. In particular, CD3ζ phosphorylation appears to be *the signal for ZAP70 binding to CD3 ARAM* [462]. The significance of ZAP70 in such processes is demonstrated by its deficiency in a form of SCID characterized by the absence of CD8 T cells [544], emphasizing its prominence in T lymphocyte intrathymic selection and not only in mature cell activation. CD45 (CLA) is associated with T- and B-cell activation processes: for example, CD4-mediated signals are enhanced by cross-linking to CD45, with a rapid rise in Ca++ levels, an effect mediated by Ca++-independent PTPase activity of two domains within the CD45 cytoplasmic tail [584]. On the contrary, CD45 direct interactions with the TcR–CD3 complex could lead to dephosphorylation of CD3ζ and a down-regulation of the response [337]. CD45 is also able to dephosphorylate and activate members of the src family of kinases, a likely basis for the requirements of antigen-induced receptor signaling [395, 584]. CD45 activation of the src-family members before stimulation is consistent with the belief that src are the first tyrosine kinases required for antigen-induced signaling [395].

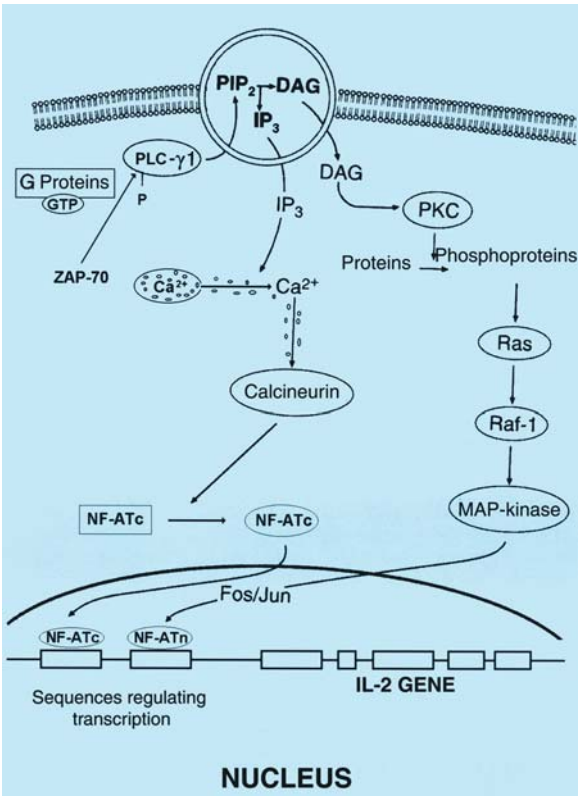

Fig. 1.42. Schematic representation of the morphofunctional aspects of T and B lymphocyte activation signals

Costimulatory Molecules

Recently stressed is the part played by CSMs such as CD2 present on T cells and its ligand CD58 on B cells. CD2 enhances antigen recognition drawing TcRs into zones of cell–cell contacts also arranging the opposing cell membranes of both T cells and APCs at the optimal distance, thus promoting TcR–peptide-HLA interactions. Thus CD2 can allow lower affinity TcRs to be utilized, thereby increasing the size of the mature T-cell repertoire [109]. CD58 for B cells stimulated by IL_4 and CD2 for T cells can provide a second signal for isotype switching to IgE; CD58 can only cross-bind to anti-CD58 lower than that of CD40 [243]. CD2 could also mediate an alternative pathway of T activation if aggregated to the TcR–CD3 complex [109]: it is postulated that molecules different from CD40L are involved in IgE synthesis. Further molecules are CD28 (expressed by the B-cell majority and CD4 as well as by ≈ 50 % of CD8 T cells) and CD152 is = CTLA-4 (present only on activated T cells), whose interactions with CD80 and CD86, main ligands for CD28/CD152, represent a very important costimulatory membrane signal for T-cell activation and are crucial for both proliferation and differentiation of T-cell effector functions [243]. Studies have also hypothesized that both ligands could follow a different model in regulating T-cell differentiation, CD86 to Th2 T cell production with IL_4 predominance and CD80 to Th1 T cell phenotype [279]. Skin CSMs are keratinocytes coming on stage when external factors shift the immunological balance toward an epithelial sphere of influence. Cells expressing CD80 can have a pivotal role in triggering immune responses, delivering costimulatory signals to resting T cells and modulating their maturation into Th2 T cells [279]. Lack of such a strategy can depend on intrinsic differences of class II HLA molecules (that is, li reduction), rather than on defects of CSM potential [381].

Role of B Lymphocytes

At first glance, the B cell first stage of activation is in the T cell area, the splenic PALS, then proliferating cells form GCs (Fig. 1.43). In the superficial cortical zone there are primary follicles, lymphoid aggregates of uniform cellular density, with mature resting B lymphocytes probably not yet stimulated by antigens, and secondary follicles containing GCs, proliferated in response to antigen stimulation. GCs are characterized by a *central dark zone* proximal to T areas, containing many rapidly dividing B cells failing to express surface Igs, the centroblasts [37], and a *basal light zone* filled with centrocytes, non-dividing B Ig^+ lymphocytes [254]. The GC reaction reaches a peak volume by day 10–12 after immunization, when PALS (Fig. 1.11) start to decline; without further antigen stimulation GCs also gradually regress until they wane around 4 weeks after immunization [37]. In GCs there are macrophages with phagocytic activity and IDCs deriving from tissue homologous cells, among which are also DCs. Naive B cells come into contact with antigens presented by DCs in the GC light zone: within a few hours B cells interact with specific CD4 cells; their proliferation reaches the apex by day 5, followed by their migration into lymphoid follicles or other peripheral sites [454]. Exponential proliferation of a given B clone leads to thousands of antibodies/min in 3–4 days that are secreted outside GCs [254]. During the course of primary response, isotype switching occurs in centroblasts, and somatic mutations accumulate in V_H and V_L regions [63]; by day 10 of the response, GCs are clearly divided into dark and light zones [37]. In the dark zone, at about 2 days B blasts differentiate into mIg-negative centroblasts which collect at one pole adjacent to the FDC network, which a little later fills up with centrocytes [37]. Studies suggested that in the apical light zone centroblasts differentiate into memory cells (small lymphocytes) or plasma cells with T-cell cooperation [256]. When FDCs form their protrusions embracing B cells to present bound antigens to BcR, the process is exhausted and plasmocytes migrate into the medulla and eventually the bone marrow, where they undergo a terminal differentiation [256]. Interestingly, light zone centrocytes re-enter the dark zone, join the centroblast population and reinitiate proliferation,

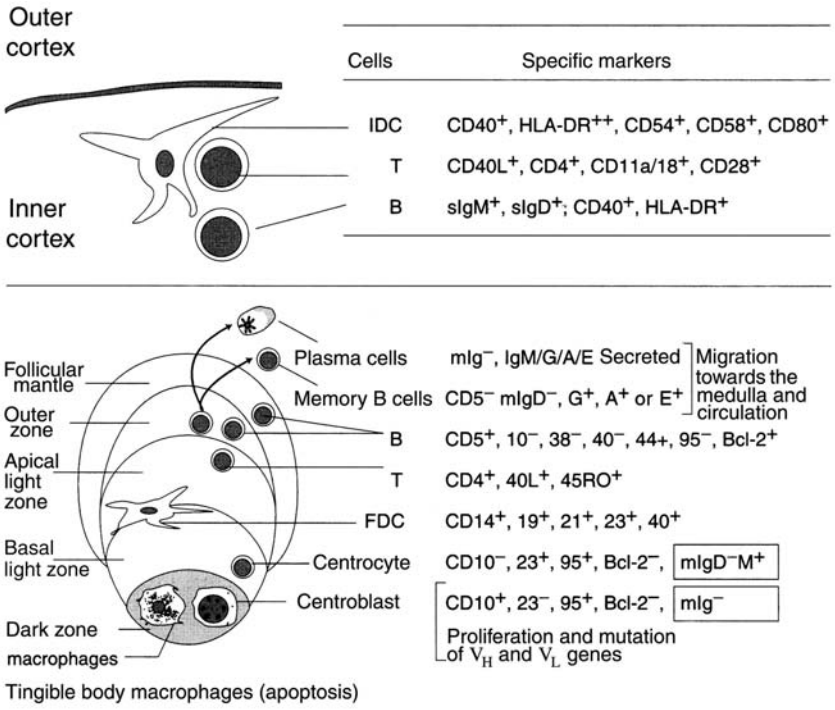

Fig. 1.43. Formation and structure of germinal centers (GC). Tingible body macrophages (apoptosis). *FDC* follicular dendritic cells, *IDC* interdigitating dendritic cells

whereas T–B collaboration in the light zone is necessary to maintain active GC reactions [256]. A principal purpose of GC formation is to direct VDJ rearrangement, and mutated Igs are first observed on day 7–10 of primary responses, coincident with GC polarization and CD86 expression on centrocytes [254]. T-cell–B-cell interactions involve signaling via CD40 and CD154 (CD40L), found in the outer zone of tonsillar GCs [71]. Inhibition of this signaling pathway also impairs GC formation [71]. Markers and/or participants in the activation process are CD19 and CD20 expressed at all stages of differentiation, CD21 (CR2) and CD22 expressed only by mature B cells; IgE^+ antibodies instead express CD5 ligand of CD72, CD32, CD38, CD45RA and CD45RO (Table 1.2). CD19 interactions with BcR markedly lower the threshold (100 antigen receptors per cell, 0.03% of total) to enable B cell activation [70], as they are consequently processed, degraded into peptides, and transported to the cell surface associated with HLA molecules [384]. Independently of signals mediated or not by T cells, BcR internalization does not require ITAM participation [453]. B cell activation by CD79a and CD79b involves triggering src and syk, which form molecular mechanisms able to transduce activation signals generated by interactions between antigen and epitope [408]. However, so that the B cell functions as an effective APC, CD80 and CD86 coexpression is necessary, while it is absent in resting B cells. Upon BcR cross-linking, PTK src are activated, tyrosine residues are phosphorylated in the ITAM, while syk is required for BcR communication with PLCγ1, IP3 generated via PIK3 activation, and Ca^{++} release [453]. Analogous to ZAP70, in addition to tyrosine kinase regions, src and syk carry a SH2 domain with high affinity for phosphorylate tyrosine residues, binding those from CD79a and CD79b [453]. Two pathways are involved in IL_4-mediated Cε transcription: the one associated with PLCγ1, leading to PKCδ translocation with cooperation of IP3, PIP2 and DAG, and the other based on PIK3 and PKCζ [659]. A growing body of evidence indicates that FcγR in B cells inhibits their activation and Ig production [337]. If properly glycosylated, CD45 may interact with CD22, an important step for cell–cell adhesion [395], which has been shown to regulate the B cell phosphatases, also regulating T cell activation. As a result of this sequence of events, 12 h after the antigenic stimulation, the blasts increase in size and, *if they receive appropriate signals from T cells,* proliferate and differentiate in plasma cells [36]. As we have mentioned, B cells can be at the center of *antigen-independent* responses, which occur early in the B cell developmental pathway and can be induced by the association of H chains with CD79b in B cells that develop to the pre-B cell stage even in the absence of L chain synthesis [408].

Expression of Genes and Transcriptional Activity

Phosphorylation of several membrane and cytoplasmic proteins corresponds to a transient stage during which both translocation of TFs and expression of new genes are modulated. It plays an important role in intercellular transduction of signals: studies on animal mast cells have shown that phosphorylation of tyrosine residues is an essential component of the signals deriving from

Data from ICI.

IL_6R is homologous to the p40 subunit of IL_{12}, which in turn may produce gp130 dimers; however, signaling takes place above all through the activation of a peptide homologous to gp130. G-CSFR is homologous to the p130 chain of IL_6. EpoR has a high degree of homology with the$IL_2R\beta$ chain. Updated from the Institute of Clinical Immunology.

CNTF ciliary neurotropic factor, *EGF* epidermal growth factor, *Epo* erythropoietin, *GH* growth hormone, *IL* interleukin, *LIF* leukemia inhibitory factor, *PDGF* platelet derived growth factor, *Tpo* thrombopoietin.

FcεRI [35, 195]. Aggregation of polyvalent antigens to the FcεRI–IgE complex results in tyrosine phosphorylation of several protein substrates, including β and γ subunits of FcεRI, and proteins such as $p72^{syk}$, $p53/56^{syn}$, $pp60^{sc\text{-}src}$, PKCγ, $p95^{svav}$, paxilline, pp105–115 and $pp125^{FAK}$: FN adhesion of cells of basophil lineage, when FcεRI is absent, reduces phosphorylation to only the last three proteins [195, 196]. Another example is NF-κB associated with IκB-α (inhibitory κBα), an inhibitor and multiform protein induced by Bc110 [24, 621], probably to prevent inadvertent tissue detriments [303]. In vitro studies show that IκB-α phosphorylation by PKCζ [118], since it does not lead to protein degradation [224], allows the NF-κB–IκB-α complex dissociation and NF-κB activation by PKCζ translocation [118] into the nucleus and fixation on κB regulatory sequences [54]. TRAF6 is thought to activate a member of the MAPK family, which directly or indirectly leads to the activation of IKK1 and IKK2. Both kinases phosphorylate IκB on serine residues, thus targeting IκB for degradation and releasing NF-κB [345]. A TF of the NFAT family, including c-*jun* and c-*fos* dimers that together form a potent transcriptional activation complex, binds via NF-κB to specific DNA-regulatory sites of many IL genes in T cells [252]. CN then dephosphorylates NF-κB, passing from a pre-existing state, NFATp, to the cytosolic state, NFATc, beyond which there are NFAT3, NFAT4 genes, etc. [207]. NFATc is then translocated into the nucleus and binds to regulatory sequences in position 5' of the promoter region of some genes, for example of IL_2 [252]. During the 30 min following ligand interactions with membrane receptors, there is the expression of proto-oncogene c-*fos*, c-*jun* and c-*myc*: their products bind to regulatory structures [454]. The association of c-*jun* and c-*fos* dimers, products of *immediate-early genes,* generates the heterodimer TF AP-1 (activating protein-1) [252]. At the T-cell level, the coordinated fixation of several TFs on regulatory elements, such as NFATc, NF-κB, the fos/jun proteins and AP-1 disposed upon a site from −300 to −63 bp upstream of the IL_2 promoter leads to the pertinent gene transcription and IL synthesis [444]. IL_2–IL_2R binding yields a progression signal allowing the complex internalization and lymphocyte progression from G_1 stage to S stage of cell cycle and DNA replication, accompanied with CD71 and HLA-DR expression [444]. Similar processes regulate IL_2R α chain and other receptor transcription, IL_4, IL_7, IL_9, IL_{13}, IL_{15}, *whose α chain is a functional component of* IL_2*-Rγ* [99, 269, 395, 483, 693] and of IL_5, IL_6, IL_{10}, the IFNs, GM-CSF and TNF-α [222, 444]. In particular IL_2, IL_4, IL_5 and TNF-α are under NFAT influx stimulated by calmodulin [588]. Recently, the GATA family of transcription factors has been characterized, which bind to DNA sequences through a highly conserved C4 zinc finger domain. Six members (GATA-1–GATA-6) of this family have been identified in avians, with homologs in mammals and amphibians [342]. Based on their expression profile, the GATA proteins may be classified functionally as hemopoietic (GATA-1–GATA-3) or non-hemopoietic (GATA-4–GATA-6) [342]. GATA-3 is expressed primarily in T lymphocytes and in the embryonic brain. Functionally important GATA-3-binding sites have been identified in TcR genes and the CD8 gene [342]. Significantly, Th2 cells contain GATA-3 protein in a constitutive fashion, which increases upon stimulation of the cells by antigen or cAMP, whereas Th1 cells express very little or no GATA-3 at the basal level [678]. T-bet, a TF member of the T-box family expressed in T cells is necessary to induce T cells to differentiate into Th1 cells and for Th1 cells to produce IFN-γ. Since IFN-γ induces T-bet expression, it is possible that IFN-γ affects T-bet expression by Th1 cells. Mice lacking T-bet do not have a functional Th1 response in vivo [556], and recent studies stress that T-bet expression is down-regulated in asthmatic patients [155]. Further, T-bet enhances IFN-γ secretion and suppresses IL_4 secretion in γδ cells, and GATA-3 fails to counterbalance T-bet-mediated IFN-γ production, accounting for the default synthesis of IFN-γ by these T lymphocytes [665].

Signal Transduction

The importance of post-receptor signals transduced by members of the IL receptor superfamily attached to JAK (Janus-family kinase) 1–3 and Tyk-2 activated family members connecting the receptors with the STAT factors is now apparent [214]. The STAT family in turn also includes erythropoietin, G-CSF, and the IFNs [214]. In the Tables 1.32, 1.33 we show two aspects of IL interactions with both JAK and STAT proteins. STAT specificity, phosphorylated and activated by different ILs, is mediated by STATs present within target cells and by affinity of such proteins to the JAK–Tyk complex [222]. In addition, IL_4-mediated expression of pertinent genes activates the JAK modulating STAT phosphorylation, three exons of which dictate the SH2 region necessary to its activation, of IL_4-NFAT (NFAT activated by IL_4), and other signaling pathways: in particular STAT6 binds to DNA sequences controlling the expression of IL-4-induced Th2 T cell response [562] (Fig. 1.44) [457], absent in mice with disrupted STAT6 genes [523]. Mice devoid of STAT6 fail to produce both IgE antibodies and Th2 lymphocytes in response to IL_4 or IL_{13} [248]. A differential expression of the IL_4 gene in Th1 and Th2 T cells is associated with a diverse regulation of NFAT binding to IL_4 CLE0 (consensus lymphokine element-0), mediated via a different TF regulation in Th1 and Th2 lymphocytes [642]. GATA-3 protein is expressed in both immature and mature T cells, but in a constitutive fashion in Th2 cells, which increases upon stimulation of the cells by Ag or cAMP. In contrast, GATA-3 is selectively suppressed in Th1 cells; thus *GATA-3 may function as a more general regulator of Th2 ILs expression* [678]. An alternative signal transduction system in activated T cells, formed by JAK-1, JAK-3, STAT3 and STAT5, is asso-

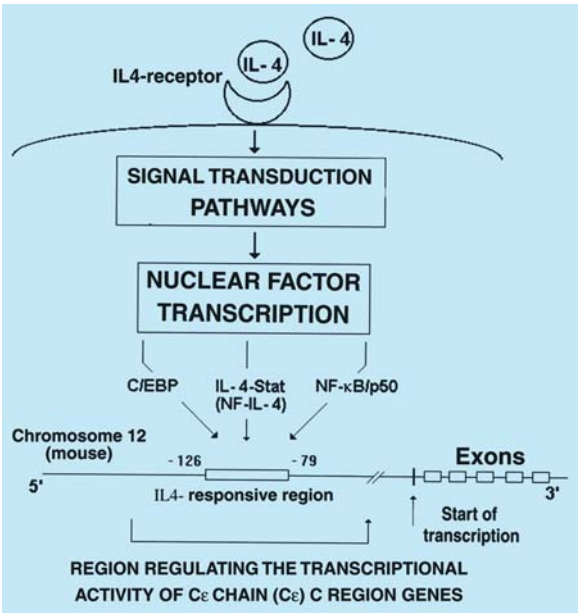

Fig. 1.44. Schematic representation of IL_4-mediated regulation of genes controlling the Cε chain synthesis of IgE antibodies

ciated with IL_2 and IL_{15} [240], JAK1 and -2, STAT1, -2, -3 and -5 by IL_{27} [245], also including IL_2R, $IL_{15}R\alpha$ and -β [557] as well as the receptors sharing the IL_2R γ chain [404]. Studying intracellular signals has led to the identification of three immunosuppressors of T lymphocyte activation: cyclosporine A (CsA), FK-506 (tacrolimus), and rapamycin (RAP) [505]. CsA and FK-506 bind, respectively, to a cyclophilin and the proteins binding to FK-506 (FKBP): the complexes thus formed bind to CN-dependent phosphatase 2B activity [505]. The CsA/FKBP/RAP-mediated inhibition of NFAT-dependent IL_2 gene transcription is overcome by CN overexpression [341]. CN is therefore essential in the lymphocyte signal transduction pathway, also leading to metachromatic cell degranulation [341].

Activation and Immunosuppression of B and T Lymphocytes and of Other Cells

The *lectins,* carbohydrate-binding gps, are active either substituting IgE antibodies on mIgs or cross-linking their H chains to carbohydrates expressed on various cells, and activating mast cell degranulation by an aspecific binding, and are also known as mitogens (proliferation inducers). Mitogen in vitro stimulation of lymphocytes is believed to mimic fairly closely specific antigen stimulation. B and T cells are activated by different mitogens: mouse B cells by LPS (lipopolysaccharide), human B and T cells by PWM (pokeweed mitogen), and human and mouse T cells by Con-A (concanavalin A) and PHA (phytohemagglutinin) [470].

The absolute counts are $\times 10^3$ cells/mm^3.
Data from [142].

T cells expressing low CN levels are more sensitive to the action of CsA and/or FK-506; similarly immunosuppressive activity of CsA or of its analogs correlates with CN phosphatase 2B activity inhibition [341]. In addition, in healthy volunteers CsA caused a rapid inhibition of histamine release from basophils or a 30%–60% inhibition of their releasability [72].

Mean Values of Lymphocyte Populations and Subpopulations and of Other Immune Cells

Immunophenotyping of blood lymphocytes has become an important tool in the diagnosis of pediatric PIDs and AIDS. The increased prevalence of these disorders, as well as of pediatric asthma, frequently makes a determination of lymphocyte subsets and of pediatric BALF necessary.

Blood values determined in normal children as a function of age are reported in Tables 1.34, 1.35 [93, 142] and 1.36–1.39 [203, 440, 458]. Lymphocyte values include the median and 25th–75th percentiles, apart from one study with a 5th–95th percentile range (Table 1.34; Appendix 1.3) [93]. Table 1.35 [142] and especially in Tables 1.36–1.39 outline relative and absolute values of several lymphocyte subsets. The age range is extended to 16 years (Table 1.34), 17 years (Table 1.35) and compared to adults (Table 1.36). In a recent study the age range is extended up to 18 years [516]. We do not agree that CB values at 5 days after birth of healthy neonates (Table 1.38) [440] can serve as a reference range in the evaluation of probable PIDs and HIV infection. We recommend determining chiefly the ab-

solute values, even if we also report relative values of lymphocyte subsets to allow a complete evaluation. As regards age variations, lymphocyte values decrease from 66% to 50% between 2–3 months and 5 years of age, but remain substantially stable [117], whereas CD4 values are constantly higher than CD8 values, with a reversed CD4/CD8 ratio returning to normal in adolescents when CD8 cells increase. Only one study [142] found that the CD4/CD8 ratio remained unchanged with age, a result limited to the 5- to 13-year age range [464], or was disputed [613]. *In the 1st year of life, CD8 cells are less than 50% of CD4 cells (41%) and B cells 22.5%* [142], with evidently negative consequences [647].

BALF CD4/CD8 ratios are lower than in adults [445] due to an increase in CD8 cells with a reversed CD4/CD8 ratio, which has not been observed in healthy adults [445, 458]. The case reports published (Tables 1.40, 1.41) [202, 445, 458] regard nonatopic children without acute respiratory infections aged 3 months to 10 years (mean 31 months) [458], or 3–16 years (mean, 8±3 years)

Table 1.37. Absolute values of lymphocyte subsets in children at various ages and in adults: (mean + 25th–75th percentile) $\times 10^3$ cells/mm^3

Data from [203].

[445] and healthy children aged 5 months to 14.6 years (median, 7.2 years) [202]. Such data derive from pooled aliquots and age-corrected volumes, where the first sample showed more ciliated cells than subsequent ones [458]; among the aliquots there is not always a significant difference [445, 458]. The analysis of the reduced CD4/CD8 ratio suggests a possible influence of the highest frequency of viral infections in the younger age groups [445].

The BALF pediatric levels of other immune cells, including macrophages, granulocytes, mast cells, etc., are summarized in Tables 1.40 and 1.41. The study in healthy children [202] examined the cells with a less invasive procedure, using a neonatal catheter (external diameter 2.6 mm), inserted prior to the start of surgery, without noting significant differences. These studies are of invaluable use in asthmatic and immodeficient children.

Table 1.38. Absolute and relative values of lymphocyte subpopulations in cord blood and venous blood (day 5): (mean + 25th–75th percentile)

CD markers	Cord blood	5 days

Central Phase of the Immune Response: Synthesis of IgE Antibodies

A Two-Signal Model for Induction of IgE Synthesis

According to the two-signal theory [606], we can distinguish a first signal delivered by IL_4 and a second one provided by interactions between $TCD4^+$ and B lymphocytes [172].

First Signal

IL_4 production by Th2 lymphocytes is for B lymphocytes a crucial factor for isotype switching to IgE plasma cells. IL_4, similarly to IL_{13} [437] is sufficient to trigger in B cells the expression of ε germline transcripts containing one exon located upstream of the ε switch region, and spliced to the C_H region codified by Cε genes [176]. According to this model, such transcripts are thought to play a critical role in IgE isotype switching by increasing the ε locus opening, which thereby becomes accessible to recombination enzymes [296]. Furthermore, IL_4 acts by altering the chromatin structure of the Sγ1 region inducing γ1 and ε transcript accumulation, and B cells activate TFs binding DNA in the region 179 bp upstream of germline ε. IL_4 can therefore be sufficient to regulate some events of recombination machinery at the B lymphocyte level [177], initiating with IL_{13} transcription of the $C_ε$ gene of Ig H chain [250]. Besides, IL_4 contributes to Fcε receptor increase on B cells and LC, increases the expression of class II HLA molecules on macrophages, inhibits their IL_1 production and primes them to differentiate into DCs [296]. IL_4R (CD140), of which $IL_{13}R$ is a component [64], assists with appropriate signals inducing Cε germline transcripts and increasing their role via PLCγ1 and PI3K, which also modulates isotype switching leading to mature Cε transcription and to IgE synthesis [659]. Moreover, CD140 evokes Th2 T cell differentiation and IL_4 production mediated by CD8 lymphocytes [4]. IL_4 and IL_{13} are in some way independent, since anti-IL_4 abrogates the effects charged to IL_4, but not those that are IL_{13}-triggered [125]. Likewise, immune responses to IL_{13} can also be mediated by IL_4, whereas the contrary is not known [64]; however, cells not expressing the γc chain, as is the case of X-SCID, respond to both IL_4 and IL_{13} [64].

Role of ILs [205, 473, 606]. Besides IL_4, several ILs take part in IgE synthesis [34, 296]. When an antigen is encountered, both macrophages and accessory cells following a signal delivered by IFN-γ release ILs starting to secrete IL_1, with a substantial effect on thymocyte proliferation stimulated by a lectin, further enhancing T-lymphocyte increase, chiefly Th2 T cells. However, on antigen recognition, IL_1 binds to Th1 T-cell-specific receptors, priming them to produce IL_2 growth factor for T cells and express mRNA for IL_2 molecules [457], although IL_7 is more powerful than IL_1 and IL_6 [470].

IL_2 receptors (IL_2-R) appear on the CD4 T-cell surface. At this stage, the role of IL_2 is played by its receptor equipped with a high, mean and low affinity: the high-affinity receptor, necessary for IL_2 proliferation, consists of three subunits: α, β and γ, of 55, 75 and 64 kD, respectively [172]. The α subunit (CD25), not expressed on resting cells, with a synthesis that does not depend on antigen signals, amplified from IL_1, TNF and IL_5, controls the production of the high-affinity receptor on T cells; preventing its synthesis is inhibited by IL_2 proliferation [34, 172]. Picomolar IL_1 levels are sufficient to drive IL_2 transcription, synthesis and secretion, as well as expressing membrane receptors. IL deficiency underlying SCID demonstrates IL_2-Rγ's crucial role in intrathymic development of human T cells.

Activated T lymphocytes produce IL_3 and IFN-γ, which stimulate APC induction, while IL_4–IL_6 and IL_{10} may drive B-cell production, maturation and isotype switching; similar mechanisms on activated cells are ensured by IFN-γ synergizing with IL_2 [480]. T lymphocytes generate IL_4 but their signaling totally depends on IL_4; otherwise mast cells and/or basophils provide autonomously for its production [174].

Several ILs may play a role in modulating or contrasting IL_4-dependent IgE synthesis [177] (Fig. 1.22).

IL_6, with powerful amplifying effects on IgE responses, acts on B lymphocytes as a main factor of effector function development, with no isotype preference except IgG secretion [28]; it also plays an obligatory role in IL_4-induced human IgE production [607].

IL_2, IL_5, TNF-α and CD23 have similar effects, CD23 recognizes FcεRII, which, interacting with CD21 ligand, plays an essential role in IgE synthesis modulation [16].

IL_5 and IL_6 up-regulate IgE production, especially when IL_4 levels are suboptimal, although these ILs do not stimulate IgE synthesis together [296].

IL_8, IL_{12}, IFN-γ, IFN-α and TGF-β seem to act at different levels:

IL_8 and TGF-β inhibit IgE synthesis either in T cell-dependent or T cell-independent systems, thereby acting directly on B cells. CD14 operates with a similar mechanism [608]. TGF-β blocks ε germline expression at a transcriptional level, while inhibition by IL_8 is isotype-specific.

IFN-γ, IFN-α and IL_{12} work only in T cell-dependent systems, thus showing an indirect mechanism of suppression: all three ILs inhibit mature Cε transcript expression, whereas only IFN-γ and IFN-α have such an effect on ε germline in PBMC cultures [606].

IL_{12} mediates specific Th1 T cell immune responses and inhibits development of IL_4 producing Th2 cells [339].

PAF blocks both ε germline and mature Cε transcripts [606].

IFN-γ is a major IL_4 antagonist and suppresses IgE production by normal human lymphocytes induced by IL_4, either directly or by reducing FcR expression for IgE antibodies from B lymphocytes. IFN-α and PGE_2 also block IL_4-induced IgE production in a dose-dependent way [421]. The IFN-γ suppressive mechanism is indirect, since no inhibition of ε germline transcripts has been reported [296], therefore suggesting that IFN-γ may prevent recombination events without affecting ε-mRNA transcript expression [205]. IL_4 down-regulates IFN-γ production, but when this is driven by T cells stimulated with allogenic cells, and in mixed lymphocyte cultures, IL_4 fails to initiate IgE synthesis. By contrast adding IL_4 early to the culture, there is IgE synthesis and suppression of IFN-γ synthesis. So the selection of isotype switching is fixed by a chronological order of secretion of diverse ILs [332].

IL Role in T-Cell Preferential Activation. Also in humans, IL_4 and IFN-γ production is under the influx of a preferential activation of Th1, Th2 T cells (and Th0) cells [644] (Table 1.10) and directed, in addition to the genetic background of the individual, by antigen nature and concentration, individual APCs, and ILs produced in the microenvironment by different cells and antigen dose. IFN-γ, IFN-α, TGF-β, IL_1 and IL_{12} evoke antigen-specific T-cell differentiation into Th0 or Th1 T cells [401], whereas IFN-γ absence or low levels and IL_4 promote Th2 T-cell expansion, while IL_2 supports all three subsets [606]. T-cell stimulation directed by IL_{12} is IFN-γ- or IFN-α–dependent [401]; similarly DCs drive Th1 T-cell expansion from virgin DC^+ in an IL_{12}-dependent scenery, in the absence of IL_4 [387], with the help of CD80 [401] or CD16 [339]. IL_1 directs T cells stimulated by SEB (staphylococcal enterotoxin B) SA to differentiate into Th1 T cells [504]. Instead, IL_4, IL_{10}, and IL_{13} not only inhibit Th1 T cell growth, but also considerably reduce IL_{12} production from macrophages [606], while IL_{10} blocks IL production from Th1 lymphocytes at a transcriptional level and induces LC toleration [139]. The IL local setting therefore takes a decisive role in selecting the predominant subset: IL_4 modulates Th2 T cell differentiation, IFN-γ that of Th1 cells [644], taking into account that NK-cell deficiency, quantitative or functional, can promote poor IFN-γ production [77]. In this setting, *the Th2 T cell prevalence could be the key of aberrant and increased IL_4 and IL_5 production, and of high IgE levels* specific to severe atopic subjects [413]. This approach is confirmed by IL_{13} presence only in atopic individuals [219]. However, severity of atopic disease is not a necessary prerequisite, since the same dichotomy is observed in patients with less severe disease [219, 318], but only in patients with high IgE levels [318]. A rationale could be the CLE0, CLE1, and CLE2 presence shared by IL_3–IL_5 and GM-CSF genes expressed coordinately after antigen stimulation [588, 645]. We stress that in the CB of at-risk newborn babies an IFN-γ deficient differentiation is operative, paralleling an excessive IL_4 production (Chap. 3): this etiopathological mechanism involves the IL_3–IL_5 trio spreading aimed at activating basophils, hence emphasizing B lymphocyte transformation in plasma cells-IgE and activating eosinophils as well [473].

Therefore, in humans, a greater part of Th1 T cells could be active within DTH reactions, while Th2 T cells could promote preferential IgE, IgA, IgG_1 and IgM production (with B-cell help) and stimulate IgE antibodies with IL_4, mast cells with IL_3 and IL_4 and eosinophils with IL_5. Th1 clones carry on even cytotoxic activities against APCs, including B cells: these data suggest that such Th1 T cells eliminate not only B cells functioning as APCs, but also Ig production, hence demonstrating poor helper activity. The studies discussed above have been further emphasized by recent observations in healthy individuals on Der p 1-specific Th1 clones' cytolytic potential, but not in Th2 clones from atopic subjects [456]. The data implicit from an increasing amount of experimental results underline that activated T cells produce factors useful for B-cell growth and differentiation and a parade of ILs *crucial in immune responses* [421]. As a consequence, the selection of ILs to be secreted and T subsets to be involved is determined by the pathway of immune response. These studies appear to suggest that chronic allergen stimulations may select IL_4 predominant intervention under allergen-specific Th2 cells influx in individuals whose T cells are intrinsically prone to secreting large amounts of IL_4 on activation [176]. IL_4, strongly supported by highly IL_4-producing CD4 clones, directs B lymphocyte isotype switching to IgE production, inducing in B cells the gene recombination that represents the critical premise for B-cell differentiating activation within IgE-secreting cells (Fig. 1.22). Allergen concentration can control Th1 or Th2 phenotype development from Th0 T cells [643]: actually, in animal models low-mean doses of peptides determine IFN-γ production from Th1 T cells and almost nonexistent IL_4 levels, whereas *increasing the doses implies IFN-γ vanishing and IL_4-producing cell release* [215]. Therefore, in allergen-specific T cells there will be a fine balance between APCs (DCs) producing IL_{12} and Th2 T cells of IL_4: the antigen dose will result in critically establishing the outcome to either IFN-γ or IL_4 [401].

IgE-BF (IgE Binding Factors). According to previous explanations, several gps with affinity for IgE and the capacity to regulate its synthesis (IgE-BF) could be implied, such as the inducer factor stimulating T cells to IgE-BF synthesis, EFA (enhancing factor of allergy), analogous to GEF (glycosylation enhancing factor), SFA (suppressive factor of allergy), IgE-PF (IgE potentiating factor) and IgE-SF (IgE suppressive factor). Apparently, lymphoid cells should be able to synthesize and release IgE-BF and to develop an isotype-specific regulatory function, acting directly on B cells. IgE-PFs demonstrate affinity for lectins, for their content in mannose-rich oligosaccharides, while IgE-SFs do not have affinity for

lectins, but bind peanut agglutinins. IgE-PFs are produced by T cells when GEF is present and IgE-SFs when GIF (glycosylation inhibiting factor) is present: indeed the serum of healthy, nonatopic individuals contains IgE-SFs, while IgE-PFs were found in patients with HIgES. Post-transductional glycosylation is regulated by two factors: GIF, released by CD8 cells, which inhibits both glycosylation and IgE synthesis, and GEF, released by CD4 cells, with opposite actions. GEF is a 25-kD peptide kallikrein-like enzyme, released after stimulation with *Bordetella pertussis*, Al salts or parasite antigens, and produces a kinin activating IgE-BF production. GIF is a 15-kD derivative of phosphorylated lipomodulin capable of inhibiting PLA_2 (phospholipase A2), produced by T lymphocytes stimulated in the presence of CSs (corticosteroids) or after treatment with Freund's complete adjuvant, inhibiting glycosylation of IgE-BFs secreted from T lymphocytes expressing, therefore, an antagonist activity for GEFs. GEF should be present in atopic subjects and GIF in healthy, nonatopic subjects, a surplus of IgE-PFs and a lack of IgE-SFs foster IgE production. IgE-PF is detected when GEF is formed, with which GIF competes, whereas IgE-SF counters with IgE-PF for lymphocyte differentiation with membrane IgE in B cell IgE producers. IgE-PFs were described in the murine model, primed by T cell FcεRII$^+$: in humans they can be produced by B-lymphocyte-FcεRII$^+$, breakdown products of FcεRII (soluble FcεRII or sFcεRII) [469]. Glycosylation does not appear to be a crucial moment for the binding of FcεRII-IgE but, on the contrary, nonglycosylated IgE bind to FcεRII with an affinity tenfold greater than that of native IgE. Also, receptor glycosylation influences its activity, because carbohydrates interfere with sFcεRII release from proteases. IgE glycosylation and its affinity with FcεRII seem to act in the same direction in precluding the receptor state of solubility: IgE glycosylation interferes with its binding to FcεRII, preventing proteolytic enzyme intervention, receptor glycosylation disguises its binding site; therefore IgE glycosylation appears to be in vivo a heterogeneous process, probably subjected to regulative laws present in rodents [553].

FcεRI and FcεRII/CD23. *FcεRI* (Fig. 1.19) is a high-affinity receptor for IgE antibodies, with 325 amino acid residues, thus another key player. A tetrameric complex (4 TM polypeptides), it consists of four chains, one α, mainly extracellular containing two domains characteristic of IgSF and most closely resembling that of FcγR, FcαR and poly-Ig receptor, one β with four TM segments and two identical γ domains, mostly intracellular with evident analogies with CD3 ζ chain [553]. The cytoplasmic regions of α and β chains contain, as the ζ chain, more binding sites with tyrosine kinases, the α chain binds IgE, the β and γ are membrane proteins; the γ chains are required for signal transduction and metachromatic cell activation after their interactions with IgE. FcεRI is monovalent, each one binds only one IgE molecule and such binding triggers mast cell and basophil degranulation and release of mediators responsible for immediate hypersensitivity reactions [176, 358]. PBMCs of nonatopic individuals express the receptor in, on average, 18% of non-IgE-binding cases; the reverse is true for atopics: such differences depend on IgE levels [452]. Zhu et al [684] have reported a strategy that takes advantage of the natural capacity of FcεRIIb to inhibit the allergenic activity of FcεRI. The FcεRI-mediated activation pathways are modulated by an inhibitory receptor such as the IgG receptor FcεRIIb. The allergen-specific IgGs produced in response to immunization have formed complexes with allergens, which can, in turn, form a bridge between FcεRI and FcεRIIb with 320 amino acid residues. Both receptors are expressed on mast cells and basophils; the Fc fragment of IgG in the immune complex binds to FcεRIIb, whereas the allergen binds to IgE, which is already bound to adjacent FcεRI. The formation of this bridge induces the aggregation of activating FcεRI with inhibitory FcεRIIb, which inhibits the activation pathways activated by FcεRI [259, 684].

FcεRII (Fig. 1.19) or CD23 [259], a counter receptor of CD21 [16], is a *low-affinity receptor* different from FcεRI for its structure, MW (70–83 kD) and affinity of binding IgE antibodies; it is the only known antibody receptor not belonging to IgSF. The TM receptor for IgE antibodies, with the support of CD21, can perform different functions, either IgE-mediated, above all IgE synthesis regulation, or non-IgE-mediated such as B-cell survival in GCs, maturation of pre-thymocytes, proliferation of myeloid precursors, antigen presentation to T lymphocytes in association with class II HLA molecules [16] and B-cell activation [259]. CD23 is included among the cytotoxicity mechanisms and the IgE-dependent release of inflammatory mediators from eosinophils, macrophages and platelets [259]. It can also be involved in adhesion interactions with epithelial cells, due to CD62E and CD62P selectins. The latter is a membrane protein associated with granules and has a domain with analogies with liver lectins [341]. Among the ligands there are platelet CD41, CD21 and IFN-α [349]. Interacting with CD11b/CD18 of monocyte-macrophage CD21, and EBV of B cells, CD23 can increase its central role in positive IgE regulation and consequently in inflammatory diseases [16]. The two diverse molecular forms, FcεRIIa and FcεRIIb, dictated by distinct exons, differ in their intracytoplasmic portion by 6/7 N-terminal amino acids [4]. *FcεRIIa* is expressed on mature B cells and FcεRIIb on IL_4-activated cells (Table 1.3) and on monocytes of nonatopic donors [452]. CD23 is able to form dimers and/or trimers, which may account for the increased IgE avidity [384]. Its C-type lectin structure does not bind to IgE molecule carbohydrates [553].

FcεRIIa, inducible also by IL_{13} [437], seems to play a role in IgE regulation with obvious effects on atopic disease [553]. Such a receptor confined to mIgM and mIgD is no longer expressed by B lymphocytes that have undergone isotype switching.

Soluble fragments of FcεRII (*sFcεRII*), 37 kD, can be involved in IgE regulation, thus initiating both humoral and CMI responses, while fragments containing the C-terminal tail behave as IgE-BFs, and sFcεRII may provide a mechanism for sIgE activation on committed B lymphocytes activated in a maturational stage subsequent to that of IL_4. All sFcεRII retain binding specificity for IgE, but smaller fragments bind with lower affinity than intact molecules: they can stimulate growth and differentiation of several cell precursors such as plasma cells, T cells, basophils regulation and thymocyte maturation [47].

Demonstration of type II receptors has shown that allergic reactions can be due to interactions between allergens and *IgE present not only on mast cells and basophils, but also on several additional cells* [174]. We stress that a common problem of atopic patients is an unremitting overproduction of IgE and, as soon as they replete high-affinity receptors, they also occupy low-affinity receptors, as evidenced by the FcεRIIb increase observed in such patients [174].

In the animal model, IgE synthesis can be enhanced by a variety of factors, including adjuvants, insoluble molecules such as $AlOH_3$, SiO_2, certain organisms including *Bordetella pertussis* and mycobacteria, parasite extracts and perhaps gasoline residues, in addition more specifically to massive doses of X-rays, ablation of the thymus and spleen and immunosuppressive drugs. On the contrary, low doses of X irradiation or of radiomimetic drugs have the paradoxical effect of enhancing IgE synthesis by interfering with CD8 production, whereas complete Freund's adjuvant, employed to accelerate isotype switch from IgM to IgG, has little effect on IgE. However, if antigens are coupled with mycobacteria, it may even suppress IgE antibodies [45].

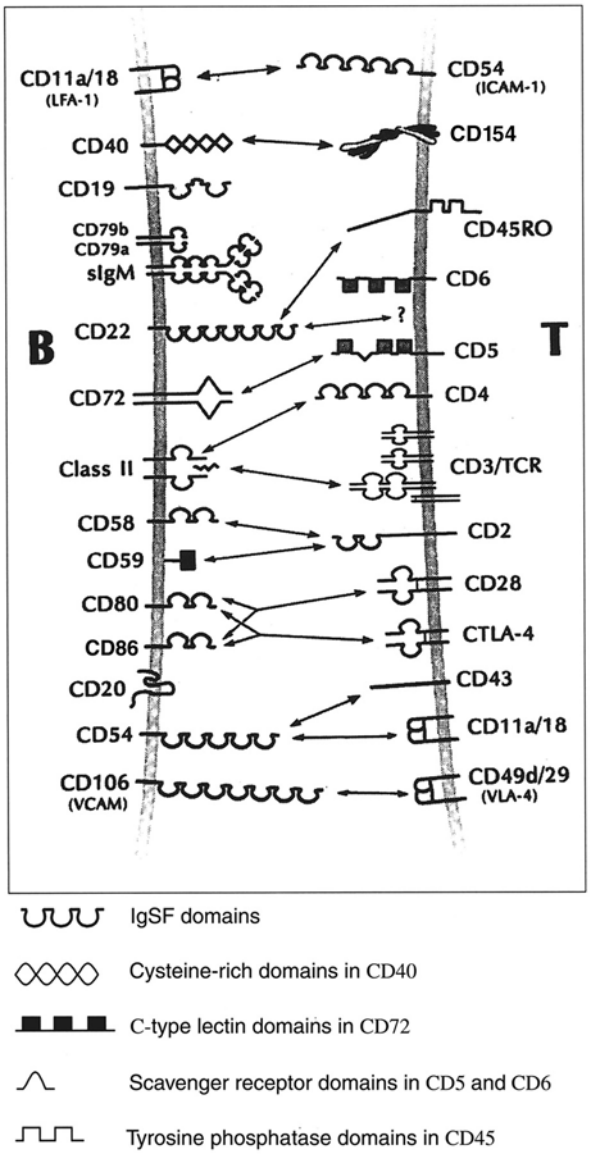

Fig. 1.45. Membrane interactions between CD4 T lymphocytes and activated B cells. *IgSF* immunoglobulin superfamily

Second Signal

The T-cell to B-cell *cognate interaction* or *associative recognition* promotes B-cell activation, proliferation and differentiation in plasma cells–IgE secretion (Fig. 1.58): T lymphocyte intervention in IgE production can be inhibited by IFN-ɣ as demonstrated in vivo from anti-IL_4 and anti IFN-ɣ antibodies [456, 473]. In this sense, activated T cells provide help for B cells stimulated by antigen molecules in two ways, either secreting ILs that regulate B-cell differentiation or resulting from an associative recognition, the HLA-dependent *cell–cell cognate interaction* (Fig. 1.45). A significant series of studies has been conducted on a tangible aspect of cooperation between T and B cells: the IgE synthesis elicited by plasma cells and IgE has led to the formation of 2,000 IgE epitope-specific/s over a few days. T lymphocytes are indispensable for IgE production and control, because B cells alone do not produce IgE, not even if stimulated [456, 473]. When *conjugated T and B lymphocytes* are cultured in close contact in the same compartment, the induction of IgE synthesis involves an associative recognition between T and B cells through a tripartite complex, allowing locus C_H rearrangement and mRNA intervention, leading to H chain formation so that IgE protein expresses ε germlines. Before this interaction, an IL profile including IL_4 in the microenvironment cannot stimulate B_{IgM} precursors to switch into B_{IgE}. However, conjugated T-B cells increase IL_4 receptor expression on B cell membranes. Consequently, Th2 lymphocytes release IL_4 and other ILs, inducing B lymphocytes to synthesize IgE [473]. The role of T cells in IgE synthesis has been further confirmed, because, in atopic patients, clones of Der p 1-specific $CD4^+$ lymphocytes occasion high IL_4 levels with a powerful amplifying effect on IgE synthesis in comparison with non-Der p

1-specific clones or with healthy individuals, similarly to CD4 clones obtained from patients with parasitosis [473]. In perspective, chronic stimulation by specific antigens seems to be able to select antigen-specific T cells in patients with T repertoires predominantly secreting high IL_4 concentrations during their activation [456].

More specific interactions between T and B cells occur following the expression of CD40L T-cell ligand, = CD154 for the CD40 molecule, surface gp of 50 kD (Fig. 1.22a), homologous to NGF and TNF-α receptors, expressed on membranes of all B cells, macrophages, FDCs and other cells able to evoke responses of activated T lymphocytes, monocytes, basophils, endothelial and epithelial cells, fibroblasts, DCs and other T cells [600]. CD154 or CD40L is similar to a 30- to 39-kD membrane gp, formed by 263 amino acids, homologous to TNF and expressed by activated CD4 T cells [446]. Subsequently to this interaction, activated B cells proliferate and acquire APC activity, generating CD80 and CD86 surface molecules, counter receptors of CD28 of T cells, which in turn also express CD152 [243]. However, CD86, because of an earlier expression, its higher levels and pro-Th2 T cells and -IL_4 orientation, may play a key part in IL_4 production. *CD40–CD154 binding amplified by CD80 and CD86 binding* [446] *is the prime stimulus for the second signal,* which plays a crucial role in responsive B cells in IgE synthesis. The ensuing IL_4 secretion and BcR binding directs gene transcription and isotype switching from IgM to IgE [132]: if CD40–CD154 are expressed on activated T cells, IL_{12} is also synthesized [524]. After the significant identification that mutations of the gene encoding CD154 on chromosome *Xq26.3–q27.1* are responsible for HIgMS, with absent IgE synthesis in the presence of IL_4 [442], studies have shown that decreased expression of CD154 inhibits the switching from IgM to IgG in 77% of patients with CVID [147] and HIgMS [442]. CD2–CD58 binding, as described above, fulfills a role in IgE induction independent of CD40–CD154: indeed the role of this pair assumes great importance in IgE production at the level of the lamina propria, where T and B lymphocytes have a major expression of CD2 and, respectively, of CD58 in comparison with their subsets in peripheral blood [600].

Second-type B-cell activating signals act in synergy with IL_4 and T cell-independent systems in the induction of IgE synthesis [205, 383, 437].

- *IL_4-dependent IgE synthesis* by *non-cognate* T–B-cell interactions has been reported in which TcR fails to recognize the HLA–peptide complex, for example, an inducible molecule associated with membranes of T $CD4^+$ clones is apparently capable of directing the B lymphocyte differentiating process toward IgE synthesis [455]. However, a latency time of 2–4 days is necessary for T-cell-activated IL_4 to deliver the signal to undergo class switching to B cells, which can drive B cells to secrete IgE independently of T cells [205]. Such data indicate that metachromatic cells select ILs able to stimulate B cells activated by T cells to produce other ILs as well as Th2 lymphocytes. Similarly, splenic non-T–non B cells produce IL_4 as a result of cross-binding to FcεRI or of exposure to IL_3 [205]. The T-cell role has been emphasized by their ability to produce ILs, thus stimulating IgE-mediated reactions by a direct action on metachromatic cells [496].
- *Stimulation with EBV and IL_4* has been shown to elicit IgE synthesis in human B cells. B_{IgE} cells obtained by activation with EBV and IL_4 contain both mature and germline Cε transcripts, whereas IL_4 alone yields only sterile μ transcripts [233].
- *IgE production* can also be promoted by direct activators of B cells, which, costimulated with rIL_4 and CD40, or anti-CD40 mABs mimicking in vitro CD154 interactions, are able to synthesize high IgE levels [233]. In nonatopic subjects, IgE synthesis is stimulated after addition of anti-CD40 and rIL_4 [294] and accelerated by adding IL_{10} simultaneously to IL_6 production [590]. However, IL_4 and anti-CD40 alone produce IgE in modest amounts (<0.1 ng/ml) [590], and IL_4 antagonizes IgE synthesis induced by B cells activated by anti-CD40 [400]. Proliferation of preactivated B cells is positively affected by IL_{10} also inhibiting Th1 cells and related ILs [480]: such processes, independent of gene restriction, could explain polyclonal IgE formation, in addition to sIgE during, for example, strong allergic reactions [176]. CD40 effects are likely to be important under physiological conditions, considering that soluble CD40 (sCD40) inhibits in vitro T-cell-dependent IgE synthesis after an appropriate second signal [132], while CD154 drives IgE production in IL_4-treated B cells [132] (Fig. 1.46) [456]. In this scenario, crucial data appear to play a significant role, since it is well known that CD154 expressed by circulating basophils and mast cells also of skin and lungs [174] and from eosinophils [175] together with CD40 [407] modulate *IgE synthesis* with the immediate implication that it takes place *not only in germinal centers of lymph nodes, but also in peripheral tissues.*
- *IgE may also be involved* in indirect mechanisms such as enhancement of APC antigen-capturing capacity: IgE-mediated presentation of a great number of allergens by interacting with FcεRI and FcεRII can activate the immune system in a continuous way, even with low allergen concentrations, thus leading to an overproduction of both IgE and Th2 cells, which in turn will induce more B cells to a switch recombination, also explaining why certain atopic patients worsen from a monosensitization to a multiple sensitization [383].
- *PBMCs* in the presence of IL_4 and hydrocortisone trigger IgE synthesis [205] and by means of FcεRI can be involved in an IgE-mediated presentation with a T-independent mechanism [384].
- *IL_{13}* is known to enhance IgE synthesis even in the absence of IL_4 [437], thus demonstrating that additional soluble mediators, as yet not well defined, are potentially involved in IgE regulation.

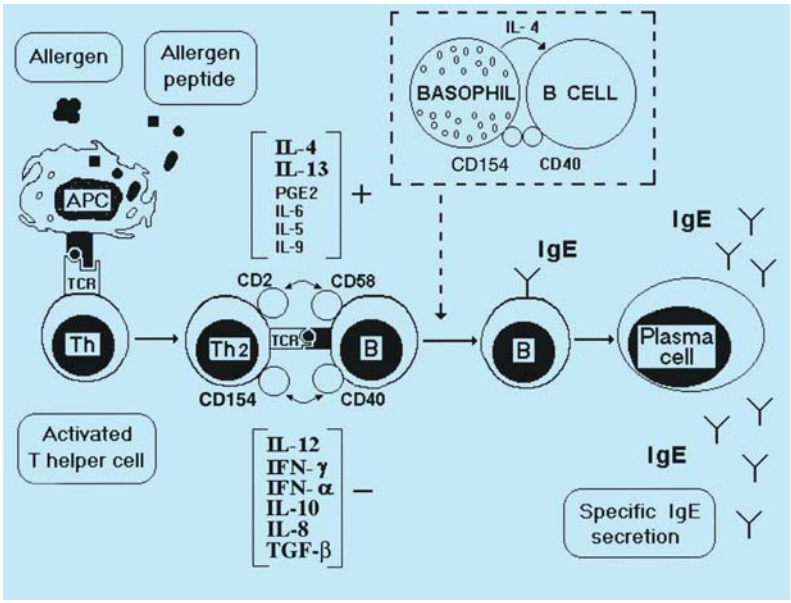

Fig. 1.46. Cellular and molecular interactions involved in the modulation of IgE antibody production. Schematic representation of the physiological aspects of IgE synthesis. (Modified from [456])

Further signals leading to isotype conversion with expression of high IgE levels are modulated by IL_5, a growth factor particularly of eosinophils, and IL_6. In a speculative way these findings suggest that IgE production can also be driven independently of T cells and that the above messengers have in common the capacity of activating the isotype switching machinery in B lymphocytes whose ε gene was activated by a transcriptional process and/or made accessible by IL_4 [176].

Immune Memory

There is wide agreement with the belief that lymphocytes preserve the memory of their first antigen encounter: when antigen is encountered again, IgE response will be more rapid and vigorous, even after decades. This reaction is due to specific CD45RO deriving from the proliferation of a specific clone following the priming, an event which induces a further expansion of production in children without an atopic background of IgG and IgA antibodies [101, 688]; such an event also explains why *vaccine booster doses* are effective. About 50%–60% of CD45 isoforms are associated with the 180-kD form, CD45RO, memory cells, and 40%–50% with the 220-kD form, CD45RA, virgin cells that are functionally inactive in the absence of antigen-driven stimulation. The RA isoform of CD45 is expressed on newly formed T cells that have not yet encountered specific antigen; during activation by exposure to specific antigen, the RA isoform is stably modulated to RO, a process that involves differential, post-transcriptional processing of the CD45 mRNA turning into CD45RO after IL_2-dependent T-cell activation. However, CD45RA and CD45RO, rather than being markers for distinct naive and memory Th cell populations [627], are probably respective markers for reversible resting and activated states; CD29 is expressed two to four times more on several adhesion molecules in addition to CD45RO cell surface than on CD45RA [23]. This cellular basis consists in antigen-specific lymphocyte expansion during primary responses, so that sensitized cells play a specific function, announcing in the bloodstream the occurred recognition, leaving a greater number of T and B cells [101]. Other memory cells undergo a rapid turnover: activated after stimulation by antigen-specific $CD4^+$ T cells are engaged to respond to a wide spectrum of APCs, and to secrete ILs and high IgG levels [326]. Memory T and B cells recirculate via peripheral blood and lymphoid organs (Fig. 1.11), and besides some cells with a short life span there are others with a long life span: their characteristics are summarized in Table 1.42 [688]. Since cytopathic viruses cause damage to fetuses and neonates when the immune protection necessary to survive is absent, particularly during a critical immunoincompetent period, mothers protect their babies passively transferring neutralizing antibodies [688]. Which signals lead to memory cell development at birth vs effector cells? One possible answer is that large antigen amounts plus costimulation in an environment dominated by inflammation may result in differentiation to effector cells, whereas the absence of an inflammatory milieu or ILs favor memory cell generation: according to this model, T cells activated in early stages of an infection would differentiate into effectors, whereas during later stages with a reduced antigen load memory T cells would prevail [7].

One theory on long-lived memory cells admits a constant stimulation of T-cell clones, according to three procedures: contact with antigens (and/or pathogens), new encounter with antigens, then with antigens bound to DCs with reconstitution of supplies [101]. According

Table 1.42. Characteristics of memory B and T lymphocytes

Characteristics	Memory B lymphocytes		Memory T lymphocytes	
	Resting	Activated	Resting	Activated
Location/migration	Recirculation blood → LN (via HEV)	Associated with persisting antigens in lymphoid organs and bone marrow	Spleen and blood possible migration blood → LN (via HEV)	Migration through tissues
Function	Secondary reaction (challenge)	Maintenance of memory, IgG levels	Secondary reaction (challenge)	Immediate killing of infected cells in periphery
Type of response	Delayed	Immediate	Delayed	Immediate
Proliferation	No	Yes	No	Perhaps yes
Site of proliferation		Germinal center		Perhaps in lymphoid organs associated with antigens
Antigen dependence	No (poor)	Yes	No	Yes
Site of antigen persistence	FDC		Unknown	

Modified from [688].
FDC follicular dendritic cells, *LN* lymph nodes.

to another hypothesis, which is gradually being widely received, memory cells do not require further contacts for their survival [7, 56, 216, 385]; hence, if a memory cell prerequisite is a persistent stimulation, one could argue that T-cell memory may not exist [56]. As a consequence, these studies have not proved that there are two types of memory, one short-term and one long-term memory, even if in 1847 a measles epidemic spared the aged infected 65 before years are the Faroe Islands [407], thus confirming earlier observations made by Thucydides. New findings are supported by demonstrations that memory CD8 CTLs persist indefinitely when associated with CD44 homing receptor, ensuring long-type memory also independently of steady antigen stimulation [291]. CD8 CTLs from a previous reaction to a given virus may in the future be reactivated and contribute to natural resistance by cross-reacting to another putatively unrelated infectious agent [512]. CD8 T-cell memory stimulation, long persisting also in the absence of the original antigen, can thereby depend not on a new encounter with known antigens, but with wholly different antigens, only if they have a cross-reaction with the first ones. Therefore CD8 long-term memory persists without antigen stimulation [216, 385]. Differential expression of memory phenotype markers CD44, CD122, and Ly6C by SOCS-1 (suppressor of cytokine signaling) IL_{15}^{-} $CD8^{+}$ lymphocytes suggests that multiple signals contributed to the memory cell differentiation program. However, the acquisition of the memory phenotype by SOCS-1-deficient $CD8^{+}$ lymphocytes does not require prior antigenic stimulation, but requires the presence of activated T cells [441].

Another particularity of CD45RO cells is to be exposed to an antigen universe precluded to virgin CD45RA cells, which can respond to antigen presented by APCs since they express increased levels of adhesion molecules [101], or on B cells exceedingly efficient at capturing even low-density antigens, unable to stimulate virgin cells [345]. Secondary immune responses are faster, with more Igs and higher affinity, provided that they are T-dependent [310]. B lymphocytes, after differentiation into effector cells or IgE producers with CD154 cooperation [71], return to a quiescent state, constituting immune memory, with mIgs and properties slightly unrelated to their ascendant with which they can interact, at the time of activation, although in a different stage of maturation; their long-term survival depends on the persistence of antigens retained in CICs by FDC networks [337].

Recent data support the so-called *decreasing potential hypothesis,* suggesting that memory T and B cells, activated after each round of stimulation, generate fewer memory cells undergoing terminal differentiation into effector cells, a phenomenon that in B lymphocytes could be more accentuated in mature cells (Fig. 1.47) [309]. Consequently, the immune system will have the resources to quickly generate large numbers of effector cells to successfully eliminate pathogens [309]. Immune memory works such that infections elicit, in most cases, a state of disease only on the first contagion, whereas subsequent contacts with the same pathogens resolve without any pathological manifestation, thanks to microorganism elimination in a rapid and sound way [474]. Another area of increasing interest suggests that it is tempting to hypothesize that *endotoxin* exposure can be used as an essential adjuvant in the induction of antigen-specific T-cell memory [303].

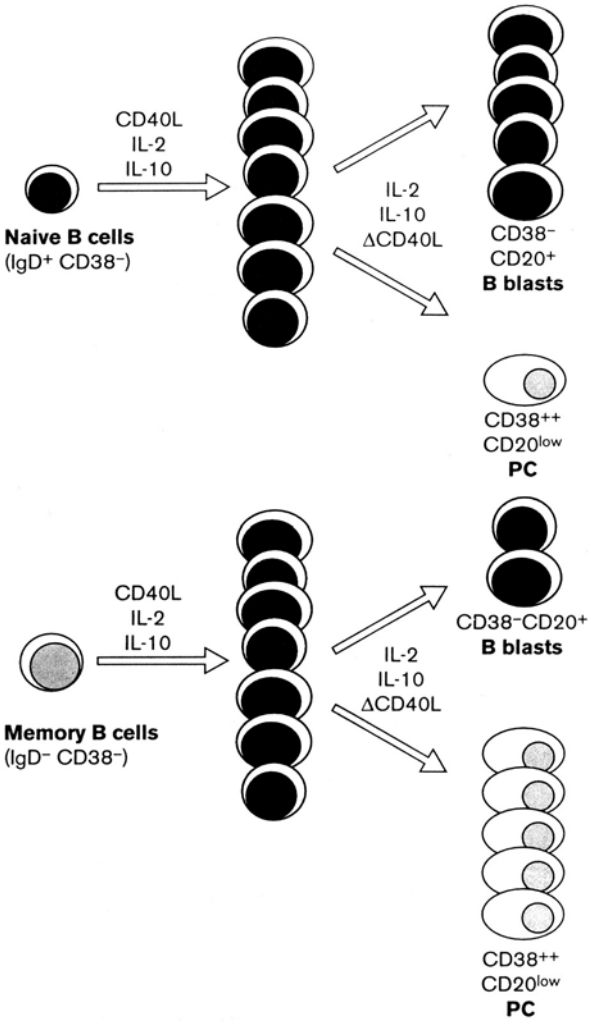

Fig. 1.47. Terminal differentiation of memory and naive B cells. Memory B cells but not naive B cells undergo terminal differentiation into plasma cells (*PC*) upon activation in vitro

Immune Responses

Not surprisingly, immunity, instead of protecting against endogenous or exogenous antigens, thus contributing to maintenance of immune homeostasis, exposes individuals to immune reactions, whose ultimate result is to damage tissues, producing clinical illness, even severe or fatal (Fig. 1.48) [34]. Such reactions are characterized in the first place by allergens according to a commonly accepted classification. Hence, hypersensitivity is a form of abnormal reactivity of the host against a non-self agent (allergen), innocuous for the majority of healthy subjects exposed to similar doses of a matching allergen. A fundamental stage of a cognitive process was the Gell and Coombs *classification system of immune reactions* [179], useful from a practical point of view for exemplification reasons. Immune reactions are particular to atopic disease and are divided into four classes, I, II, III, IV [34, 179], divided into immediate or anaphylactic, cytotoxic, IC-mediated and CMI reactions. Otherwise, the four types of reactions can overlap and almost no atopic disease is limited to only one mechanism. For example, penicillin can provoke anaphylactic shock (type I), immune hemolysis (type II), serum sickness (type III), or contact dermatitis (type IV) [470].

Immediate and Delayed Reactions

Specific studies done over the years have encouraged revisiting the Gell and Coombs historical classification. In reality, immune reactions can be subdivided into two types, immediate and delayed, according to the latency period from the appearance of allergic manifestations following the re-stimulation with the same sensitizing antigen: immediate reactions start after minutes and are IgE-mediated, while delayed reactions start after hours or days and are T-cell mediated. The main differences between these reactions, which take place expressing Th2-like ILs and, respectively, Th0 or Th1-like ILs [585], are shown in Fig. 1.49 [104]. Some perplexities have recently been aroused by focusing attention on the role of IgE antibody in DTH reactions and multifold IL interactions within inflammatory reactions. Actually, in addition to the role of IgE-mediated immediate reactions marked by effects of histamine released by mediators, recent reports have highlighted the role of DTH, characterized by release of biologically active mediators induced by IgE. The picture occurring in patients can be schematized as follows: 1. The immediate reaction; 2. A phase of relative quiescence; 3. The delayed reaction.

We underline that such distinctions have a more theoretical than practical nature, as evidenced by an almost constant association or overlapping of these two phases, not permitting a clear-cut division from a clinical point of view. Molecular studies led to recent reports on the role played by ILs, with a pattern wholly different according to reaction chronology: in acute reactions the IL_4 mRNA is very early and selectively expressed, whereas in delayed reactions IL_4, IL_5 and IFN-γ are positively regulated [105]. The practical result of the above studies is that reactions developing >24 h after allergen challenge allow for an increased number of antigen-specific T cells to invade peripheral tissues. These current investigations emphasize delayed reactions in the immune system and make it possible to elucidate the mechanisms at the base of chronic inflammation, indicating IgE heterogeneity among atopics and, indirectly, a genetically determined GPM.

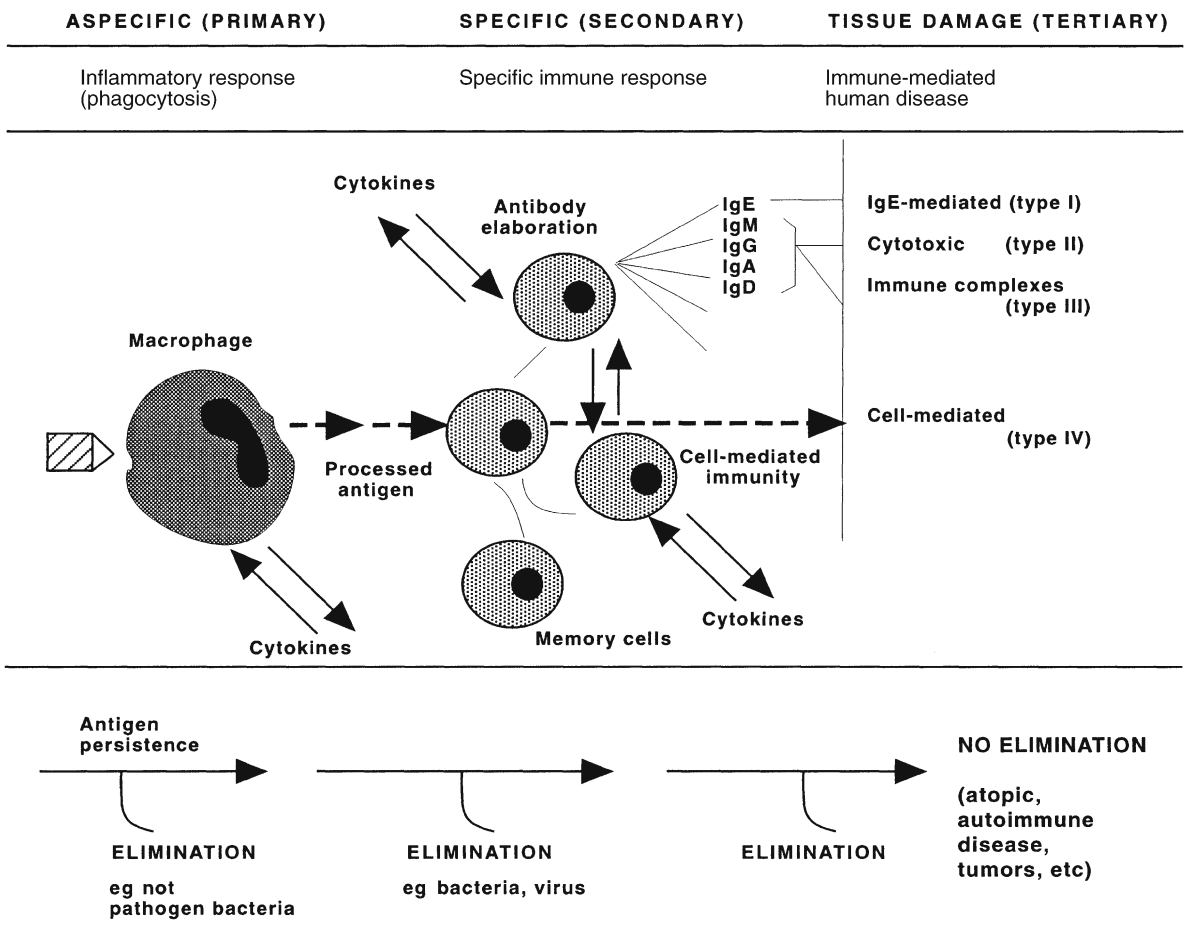

Fig. 1.48. Schematic representation of the immune reactions and the body immune capacity of eliminating foreign material. The *lower part* shows that interactions between foreign agents and the immune system may lead, depending on the antigen nature or the genetic constitution of the individual, either to elimination or persistence of the antigen with resulting alterations of immune homeostasis. (Modified from [34])

Hypersensitivity Reactions

Type I Hypersensitivity Reaction, IgE-Mediated – Anaphylactic Reactions

An immediate hypersensitivity reaction is characterized by a rapid development of clinical symptoms (a few minutes or more) when the allergen to which the patient is sensitized cross-links IgE bound to FcεRI on tissue mast cells and circulating basophils, with consequent degranulation, but IgE indosable levels are sufficient to initiate an immune reaction [367]. The sensitizing allergen, variably penetrated in the host, binds IgE fixed on the mast cell external surface. *IgE binding to FcεRI* is not wholly effective to stimulate mast cells without allergen intervention. The triggering signal of an impending immune reaction requires that the antigen is bivalent, so that it can bridge the Fab of two adjacent IgE molecules on the cell surface [349]. Signals are then activated, which, on the one hand induce transcription processes resulting in IL production, and on the other hand trigger a cascade of intracellular metabolic events, able to augment the local blood flow and to recruit a series of cells drawn to the reaction site by specific chemotactic factors.

Signaling is initiated by *mast cell activation* started by transduction signals, allowing cells to perceive changes in the extracellular environment that translate into an intracellular biochemical signal that causes an appropriate cell response (Fig. 1.50). Broad structural modifications of phospholipid components of the cell membrane follow. Biochemical events may be summarized as follows [210, 528]:

1. FcεRI cross-linking:
Interactions with cytoskeleton
2. Signal transduction:
Serine esterase activation
GPT-binding proteins
Membrane depolarization/repolarization

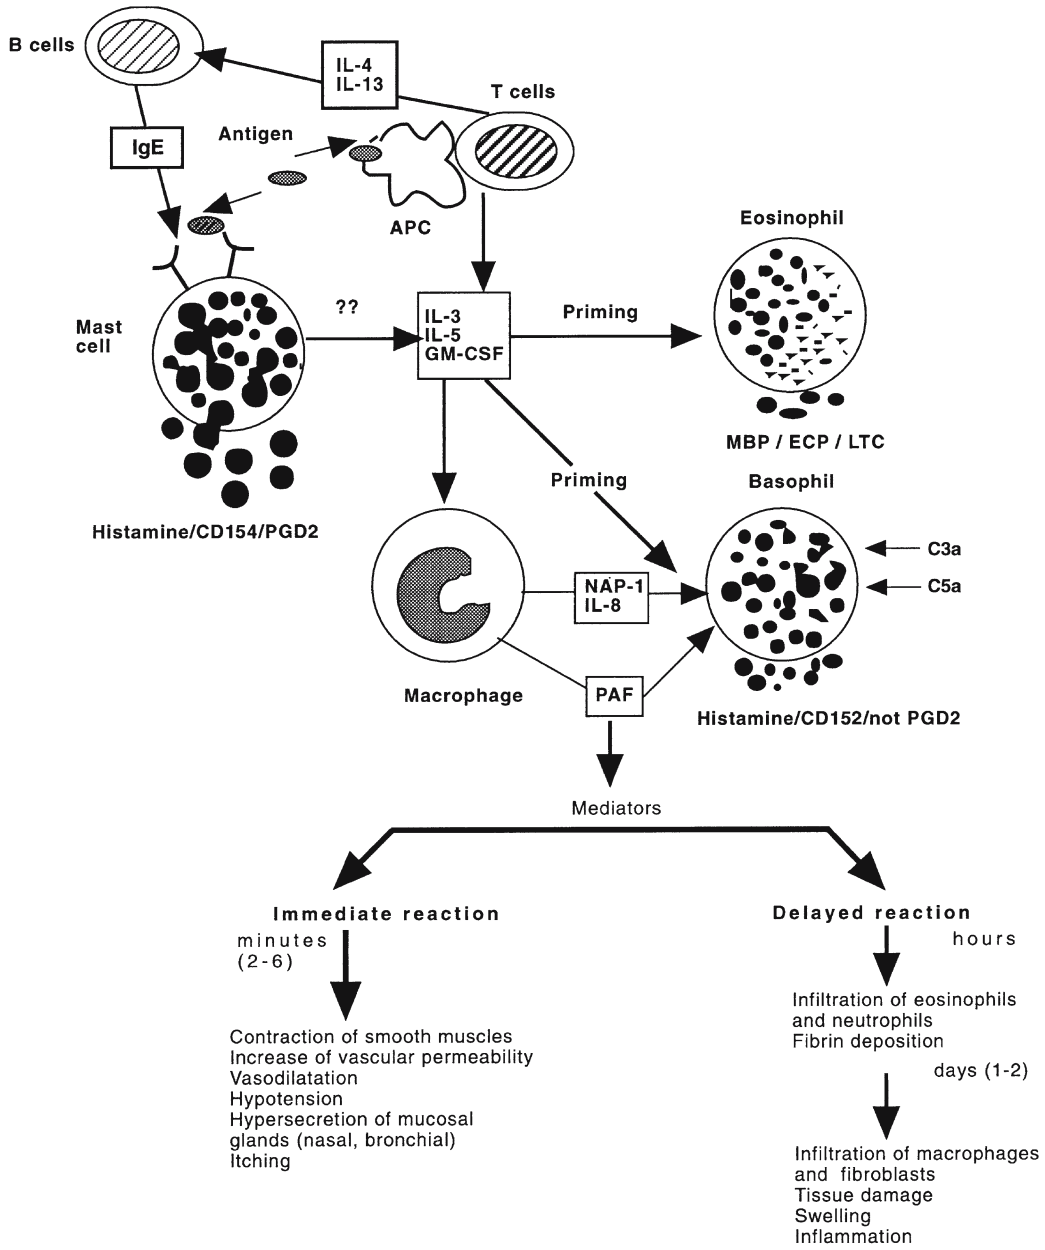

Fig. 1.49. Current hypotheses regarding the pathogenesis of immediate and late-phase reactions. Consequences of mast cell degranulation and principal differences between these reactions. *APC* antigen-presenting cell, *ECP* eosinophil cationic protein, *MBP* major basic protein, *NAP* neutrophil-activating peptide, *PAF* platelet-activating factor. (Modified from [104])

3. Signal translation and amplification (Fig. 1.51):
Development of second messengers
PLC, PLD, AA/eicosanoids, adenylate cyclase (activated by G proteins) (Fig. 1.52) with an increase in other messengers such as cAMP, cGMP (cyclic guanosine monophosphate), PKA (protein kinase A), IP3, DAG (Fig. 1.53), ion transport Ca^{++}

4. Activation of second messengers (target/effector proteins) or Ca^{++}-dependent responses:
Activation of PLC, which causes PIP2 hydrolysis, a membrane phospholipid, whose breakdown generates IP3 and DAG
Activation of PLA with AA release
Release of Ca^{++} from intracellular stores (Fig. 1.54)
5. Role of intermediate second messengers:
Activation of Ca^{++} channels and mobilization of intracellular Ca partly regulated by IP3

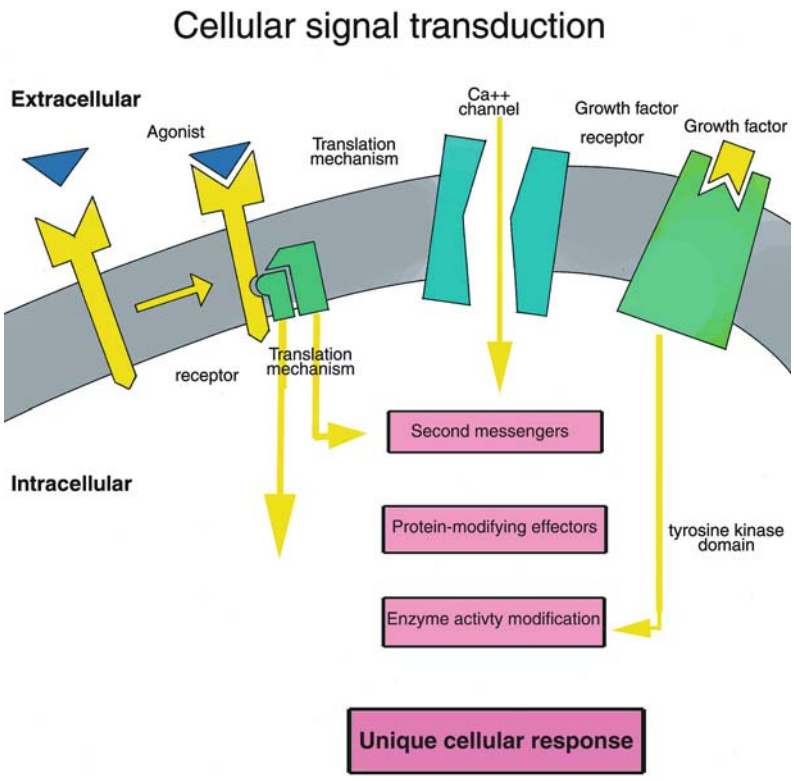

Fig. 1.50. Receptor-initiated intracellular signal transduction. Cellular signal transduction

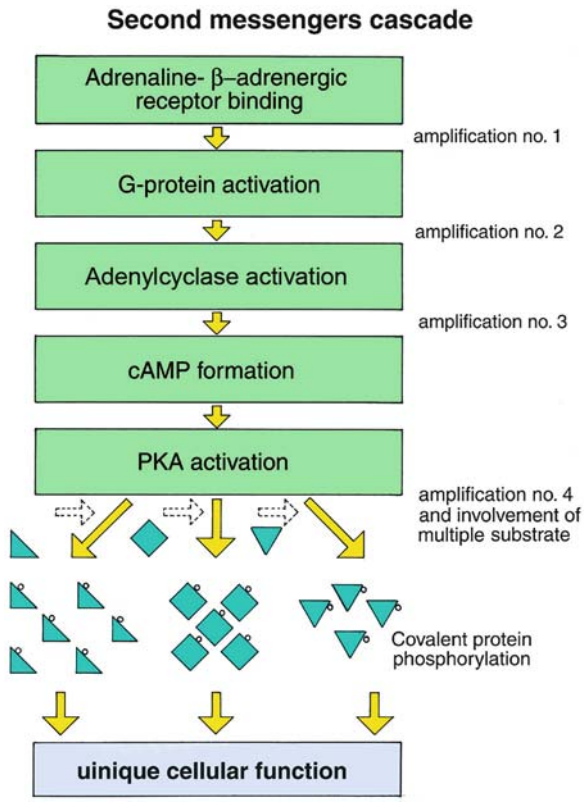

Fig. 1.51. Model of second messengers cascade. *PKA* protein kinase A

6. Effects of second messengers:
Phosphorylation and activation
Of protein kinases A and C (due to interaction with DAG)
Of calmodulin and Ca^{++}-dependent proteins altered polymerization of F-actin
7. Cellular responses:
Ca release leads to activation of glycolysis responsible for assembly of microtubules and of an ATP-dependent energy pathway due to contraction of microfilaments.
Microtubule aggregation promotes movements to the cell surface of preformed granules whose membranes fuse with plasma membranes.
Granules are then released with a mechanism of exocytosis not resulting in the loss of integrity of either the plasma membrane or granule membrane, with the support of specialized lipids called fusogens.
Granule opening leads to preformed mediator release [210, 528].

Granule release does not imply cell lysis or death. Degranulated cells regenerate and, once granule content has been revived with a de novo synthesis, are ready to resume their function.

Ca channels are of three types [29]:

- VOC (voltage-operated Ca channels), divided into L (long-lasting), T (rapid) and N (neuron) activated by different voltages
- ROC (receptor-operated Ca channels), opening in response to activation of receptors associated with these channels

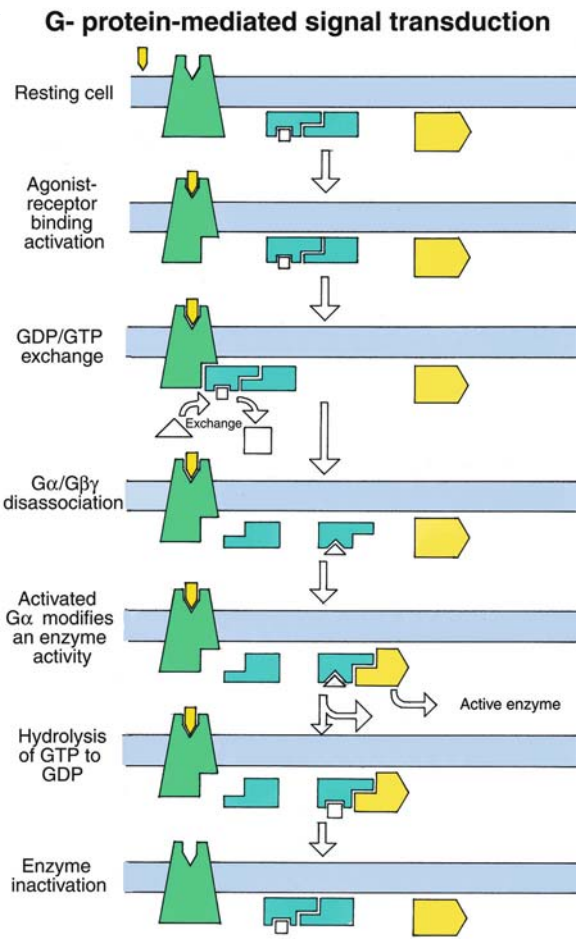

Fig. 1.52. Mechanism of G-protein-mediated signal transduction. The disassociation of the Gα/enzyme leaves Gα free to reassociate to Gβγ. *GDP* guanosine diphosphate, *GTP* guanosine triphosphate

- SMOC (second messenger-operated Ca channels)

FcεRI may activate, instead of IP3, sphingosine kinase and then sphingosine-1-phosphate, an alternative second messenger to mobilize Ca [84]. The released chemical mediators trigger the immune reaction immediate phase; meanwhile mast cells, in addition to histamine, PGs and LTs, release ILs, PAF and mediators able to induce a DTH.

Mast cell activation can also be elicited by other mechanisms [470]:

- *Immunological mechanisms:* specific IgM and IgG antibodies, anti-IgE antibodies and anaphylatoxins, MBP, IL_3, IL_5, GM-CSF, chemokines.
- *Non-IgE-mediated mechanisms* (for direct action on mast cells), such as activation of PGs, CIC-IgE, aspecific bridging due to lectins, SP, foods, drugs and a variety of chemical substances and physical agents. Mention should also be made of the degranulation effected by HRF(s) via IgE-dependent and -independent mechanisms. Non-IgE-mediated degranulation is characterized by lesser influx of Ca ions, a higher velocity (<20 s vs >5 min), a smaller LT (<18-fold) and PG (<21-fold) release and an equal histamine release in comparison with IgE-dependent degranulation [469]. However, recent results indicate that IgE-reactivity to immunoblotted human protein and IgE-dependent HRF activity

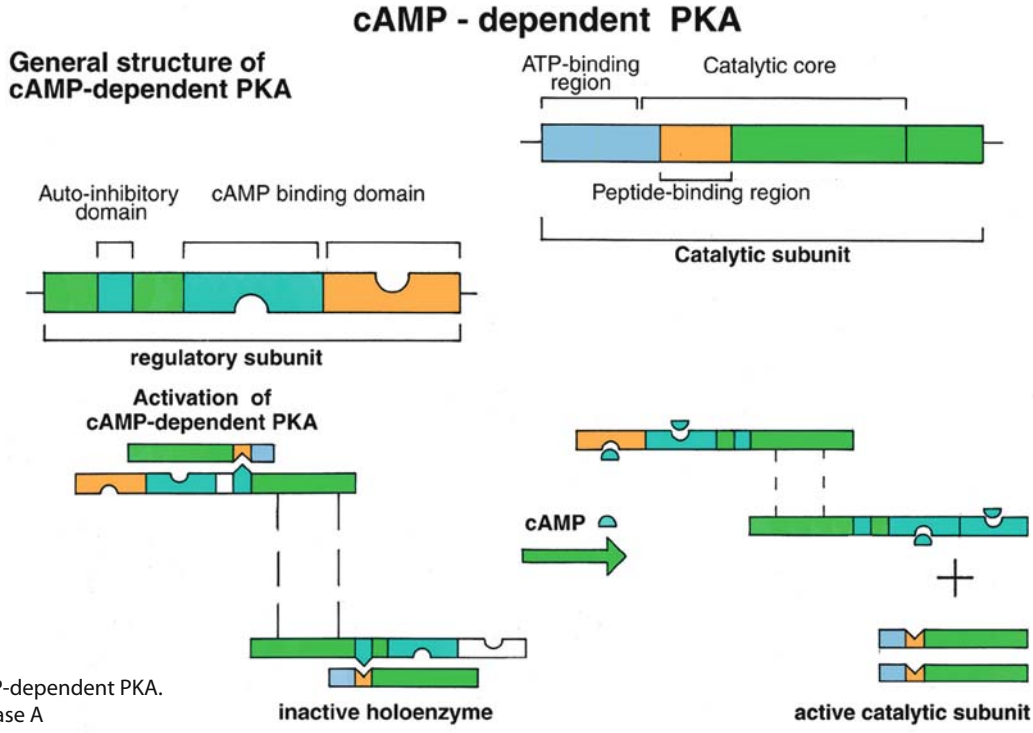

Fig. 1.53. cAMP-dependent PKA. *PKA* protein kinase A

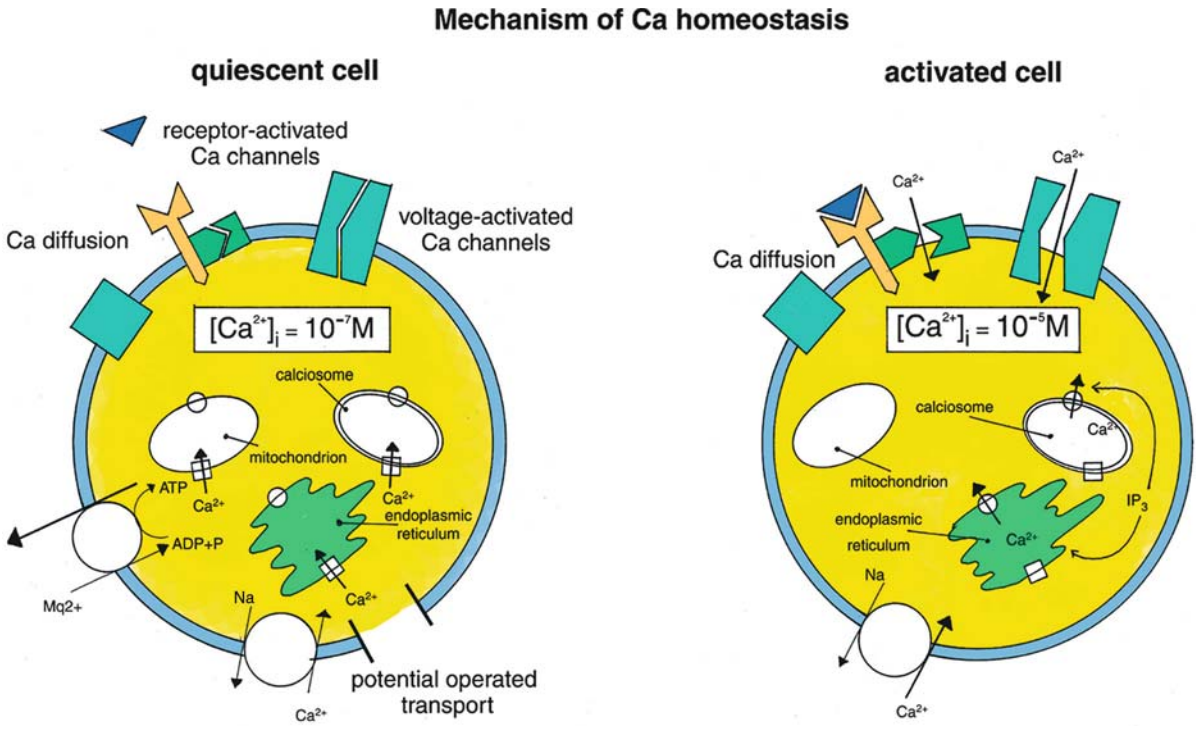

Fig. 1.54. Basic mechanism of intracellular Ca homeostasis

(IgE$^+$) are distinct entities that may co-occur in atopic patients since IgE$^+$ might be a structurally different IgE molecule which is not polymeric IgE [57].

The serum of an allergic individual can sensitize a nonallergic individual following passive transfer or Prausnitz–Küstner reaction; local hypersensitivity persists for 3–5 weeks.

Type II Hypersensitivity Reaction: Cytolytic or Cytotoxic Reactions

In type II hypersensitivity, IgG or IgM antibodies bind antigens present on target cell membranes or transported by certain molecules; antigens can be expressed on a specific cell surface (such as erythrocytes, platelets), or on exogenous (such as drugs, foods), or on haptens attached to the cell surface (CTLs and NK cells). Cytotoxic effects can be accomplished involving several effector mechanisms:

- *Activation of the whole complement cascade,* with consequent damage in various tissues, direct or indirect and subsequent cytolysis, with likely NK-cell intervention with receptors for both complement and Fc fragment of IgG. Examples include hyperacute graft rejection when a transplant recipient is preimmunized, formation of anti-erythrocyte antibodies provoking hemolysis, neutralizing enzymes, inhibiting cell receptors, etc.
- *By enhancing phagocytic cell activity* with receptors for Fc fragment of IgG, and for activated C3b are able to phagocyte target cells, such as circulating blood cells.
- *On clinical grounds* the type of reaction depends on antigen localization: on erythrocytes, hemolytic disease of the newborn from maternofetal Rh incompatibility, autoimmune or drug-induced hemolytic anemia; on several forms of leukocytes, on neutropenia, on platelet autoimmune thrombocytopenic purpura and CM-associated or drug-induced thrombocytopenia, and on other blood cell reactions due to isoimmunization.
- *The cytotoxic reaction* known as ADCC (Fig. 1.55) is performed by NK cells, macrophages and PMNs: antibodies bind to target cells through the paratope and are recognized by cytotoxic cells with FcR specific for IgG. Clinical manifestations are transfusion reactions, by Rh incompatibility, autoimmune and drug-induced [18, 454].

Type III Hypersensitivity Reaction: Immune Complex-Mediated Reactions

Circulating immune complexes of antigens and antibodies (mainly IgG) or CIC can be formed in tissues or in blood vessel walls (with an eventual deposition in the organs via the phagocyte system), overall found in antigen excess (for example, streptococcal proteins or HBsAg), with subsequent complement fixation and

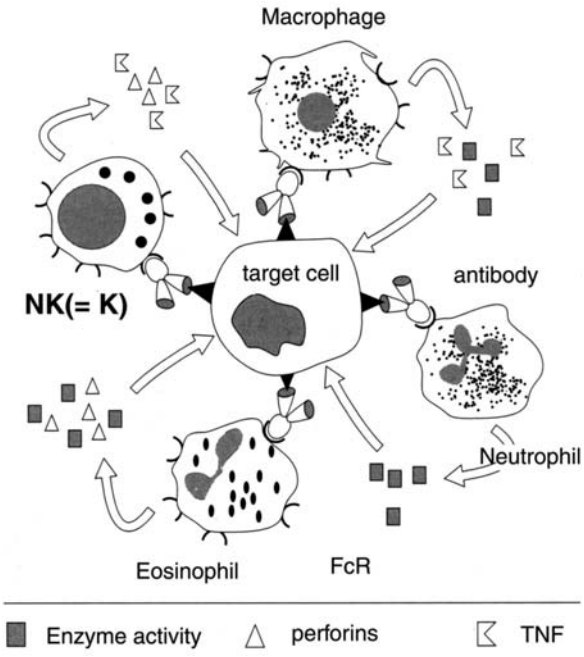

Fig. 1.55. Antibody-dependent cell-mediated cytotoxicity. *TNF* tumor necrosis factor

formation of microprecipitates at the level of small vessels. Onset of clinical manifestations is 7–14 days after primary antigen contact; following a repeated contact, the developing reaction reaches a peak intensity even in 4–6 h. When CICs are cleared in perivascular spaces, microprecipitates are formed, and if deposited in vessel walls CICs provoke vasculitis. A classic example of experimental vasculitis is the *Arthus reaction*: soluble antigen is injected subcutaneously into an animal previously sensitized to the same antigen, the antigen–antibody reaction results in high CIC local levels activating both complement and PMNs, thus provoking local inflammation. Tissue damage caused by this mechanism is in proportion to the CIC quantities and presence of vasoactive amines, which increase vascular permeability, favoring CIC deposition in tissues. First of all, there is the complement activation also increasing vascular permeability, via C2b action to activation of anaphylatoxins, and release of leukocyte lysosomal enzymes recruited by C3a, C5a, C6 and C7; then protein aggregation and lysis with vasoactive amine release; lastly activation of the prekallikrein–kallikrein system with vasoactive kinin release including bradykinin. Later complement-derived chemotactic factors recruit PMNs on the site of reaction, promoting phagocytosis and tissue damage [18].

A classic manifestation of type III immune reaction is *serum sickness,* whose relevance is presently limited, apart from some drug-induced sporadic cases (Chap. 19) or following vaccinations or sting bites. Type III reactions are also seen in infantile infections, viral (prodromic of *adenovirus* and *rhinovirus, Coxsackie,* EBV infections, infectious mononucleosis, *cytomegalovirus,* etc.), abscesses (tonsillar and abdominal abscesses, sinusitis, etc.), bacterial (mainly staphylococcus and streptococcus, mycobacteria), or chronic, in *urticarial vasculitis,* which reveals CIC with complement activation and PMN infiltration, resulting in a necrotizing vasculitis, often included in autoimmunity. We further mention polyarteritis nodosa, cryoglobulinemia, genetically determined complement deficiencies, extrinsic allergic alveolitis, allergic vasculitis such as Schönlein-Henoch purpura, nephrites and reactive syndromes from drugs and foods. Since CICs are seen both in physiological and pathological states, one cannot establish correlations between disease state and CIC levels, thus re-evaluating their pathogenetic role [18].

Type IV Hypersensitivity Reaction: CMI Reaction

A classic LPR with delayed symptoms takes up to 24–48 h after allergen contact to develop: this characteristic is different from Arthus reaction, which instead reaches the apex after a few hours. Such responses begin with lymphocytes reacting with antigens presented by APCs in association with HLA molecules. Appropriately sensitized T-lymphocytes migrate to the place where they encounter the antigen and react with target cells; while also following activation by APCs carrying antigen, other lymphocytes produce a number of ILs, often facilitating the immune response resulting in tissue damage. In reality, the scope of LPR should be that of protecting the host from intracellular parasites, such as viruses, bacteria, mycetes; however, the nature of LPR and mediator release provoke DTH.

Schematically, type I, III and IV reactions are involved in different ways in causing FA, type IV immune reaction is present in AD and in allergic contact dermatitis, type I and IV reactions in respiratory allergy, and all four in drug allergy and intolerance.

Mediators

In recent times, considerable attention has been focussed on the effector mechanisms of inflammation and has enabled us to recognize the interactions of mediators, each with potent proinflammatory properties, able to rapidly elicit the pathophysiological effects of the type I reaction. Such mediators released following mast cell degranulation are divided into primary (preformed and newly formed) and secondary (of cellular and extracellular origin) mediators [104, 210, 528, 626].

Table 1.43. Primary mediators of immediate hypersensitivity

Mediators	Structure	Origin	Functions/effects/symptoms
Preformed			
Histamine		Mast cells, basophils, platelets	VD, VP, BC, production of mucus, itching
Serotonin	5-Hydroxy-tryptamine	Mast cells, platelets, enterochromaffin cells	Specific broncho- and vaso-active effects
NCF	750 kD	Mast cells	Neutrophil chemotaxis
ECF	Tetrapeptide	Mast cells	Eosinophil chemotaxis
Proteases	Protein	Mast cells	Tissue damage, production of anaphylotoxins
Heparin	Mucopolysaccharide	Mast cells	Anticoagulant
Hydrolases	Protein	Mast cells	Function not yet clear
Newly synthesized			
PGD_2, PGE_2	AA derivatives (cyclo-oxygenase pathway)	Leukocytes, monocyte-macrophages	VD, VP, BC
LTB_4, LTC_4, LTD_4, LTE_4	AA derivatives (lipoxygenase pathway)	Leukocytes, monocyte-macrophages	Extended BC, VP
TXA_2	AA derivative (cyclo-oxygenase pathway)	Leukocytes, monocyte-macrophages	VC, BC, platelet aggregation
PAF	Phospholipid (1,000 D)	Leukocytes, macrophages, neutrophils	Tissue damage, production of anaphylotoxins

Data from [470, 626].
AA arachidonic acid, *BC* bronchoconstriction, *VC* vasoconstriction, *VD* vasodilatation, *VP* vascular permeability.

Primary Mediators

Preformed mediators, which are granule-associated with quick release, are implicated in the immediate phase of immune reaction. Among them are included: histamine, serotonin, chemotactic factors of eosinophils and neutrophils (ECF and NCF); enzymes: chymase, tryptase, callicrein, arylsulfatase, chymotrypsin, etc.; proteoglycans: heparin, etc.; acid hydrolases: β-exoglucosidase (β-glucuronidase, β-hexosaminidase, β-galactosidase), etc. (Table 1.43) [470, 626].

Histamine, from the Greek "ιστος," meaning tissue, because of its ubiquitous nature, is a dibasic vasoactive amine synthesized in metachromatic cell Golgi apparatus by decarboxylation of histidine, from where it is stored in cell granules. Normal histamine concentrations are ≤5 nmol/l in plasma, 6–24 μg/cm^3 in skin, 15–40 μg/cm^3 in lungs, and >100 mmol/l inside mast cell granules. However, histaminemia is not a valid routine test, due to its release either by basophils or mast cells and its rapid tissue turnover. Histamine has wide-ranging biological activities with an indubitable influence on allergic disease: after it is slowly dissociated from the solubilized granular matrix, histamine exercises its biological effects by binding to receptors and increases vascular permeability with subsequent fluid and plasma leakage containing C3. This is followed by tryptase and kallikrein release. Last, it drives the leukocyte diapedesis toward the site of immune reaction, where several chemotactic factors are also produced [528].

Figure 1.56 [145] shows histamine stimulated by IL_3, IL_5 and IL_8, as well as by IL_1 with consequent IL_6 production. Through negative feedback, the IL_1 increase can have an inhibiting effect on TNF-α and itself; IL_1 further potentiates histamine action on PGs and 15-HETE released by epithelial cells, while IL_3 triggers the production of histamine, IL_4 and IL_6, but has no effect on IL_2 and IFN-γ, a pattern similar to that of Th2 lymphocytes [145]. Histamine negatively influences the proliferation elicited by antigens, production of ILs and antibodies and cytolytic activity, whereas it enhances the activity of NK cells and release of mediators by other cells.

Following its release from mast cells, histamine slowly dissociates from the granule matrix to exert its large variety of effects by binding to its three receptors [210]: H_1 receptors mediate vasodilation, increase microvascular permeability acting on contractility of postcapillary venules, cause constriction of airway smooth musculature and IgE-mediated release of PGE_2 and $PGF_{2\alpha}$, generate itching, inhibit basophil chemotactic responses, while promoting that of neutrophils and eosinophils, with an increase in cAMP. Classically, *H_1 receptors* provoke the triple response consisting of *flushing, flaring*

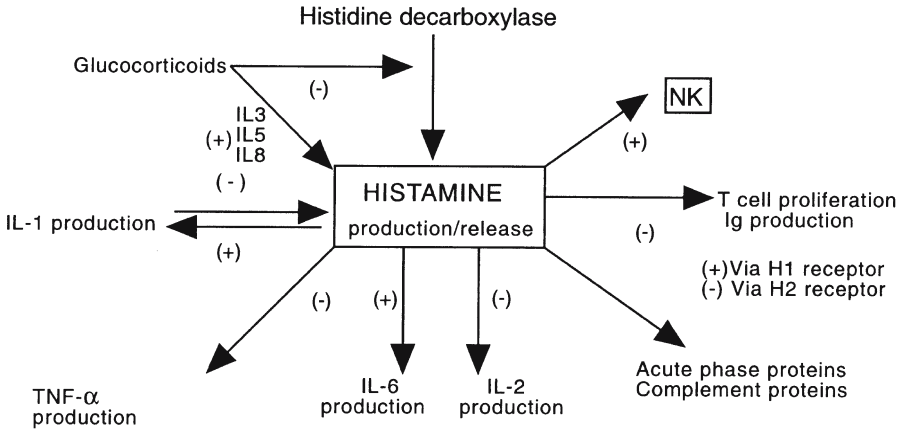

Fig. 1.56. Histamine interactions with interleukins. *Ig* immunoglobulins, *NK* NK cells. (Modified from [145])

and whealing: an intradermal injection of picomolar quantities of histamine within a few seconds yields vasodilation (flushing) by a direct effect of histamine on the microvasculature. Over the next 5–10 min the vasodilation gradually spreads away from the injection site (flaring) by an axon reflex mechanism involving antidromic neural conduction in neuropeptide-containing primary afferent nerves activated by histamine either injected or released by dermal mast cells. The final phase is the development of edema (whealing), as a consequence of contraction of endothelial cells of postcapillary venules with resulting increase of microvascular leakage, mainly due to the direct effect on blood vessel peptides released by afferent nerves.

Histamine acts on *H_2 receptors* to produce a number of negative feedback effects, including the addition of vasodilation to the triple response, reduction of C2 synthesis by monocytes and of C3 stimulated through H_1 receptors (bidirectional modulation), suppression of granulocyte-induced lysosomal enzyme release, H_2O_2 and superoxide production, and chemotactic responses from both neutrophils and eosinophils. H_2 receptors mediate gastric acid and mucus hypersecretion in the airways, the increase in cAMP cellular levels of CD8 lymphocytes and of plasma fluid leakage, as well as suppression of lymphocyte toxicity and inhibition of T-cell responses.

The concurrent stimulation of both receptors results in vasodilation, erythema, itching, bronchoconstriction, hypotension, tachycardia and headache, in addition to inhibition of chemotaxis and histamine release from basophils, and secretion of complement proteins from monocytes. However, histamine plays a positive part with H_1 receptors and a negative part with H_2 receptors, as in the paradigmatic case of APP.

H_3 receptor inhibits both histamine synthesis and release from skin and airways. Moreover, it seems that it regulates interactions between inflammatory cells and the autonomic nervous system. This receptor could play a role by inhibiting the airway cholinergic system and, in the animal model, in the control of nonadrenergic and noncholinergic bronchoconstriction, an immunoregulating action inhibiting the release of involved neurotransmitters [145].

In summary, histamine has multiple effects on various organs:

- Skin: urticaria and erythema
- Mucosa: periorbital edema, nasal congestion and itching, angioedema, pallor and cyanosis
- Upper airways: edema of oral cavity, tongue and larynx, hoarseness, stridor, sneezing, rhinorrhea
- Lower airways (with LTs and PAF): dyspnea, acute emphysema, air trapping (bronchospasm and bronchorrhea)

Among the preformed mediators there is *serotonin* (5-HT), a tryptophan metabolite and well-recognized neurotransmitter, which has effects similar to those of histamine, increasing vascular permeability and inducing airway smooth muscle constriction; 5-HT has been incriminated in the pathogenesis of migraine and has a marked pruritogenic action only if associated with PGE_2, the chemotactic mediators are the following (Table 1.43):

- NCF, distinct in two forms, one heat-stable and one heat-labile, released from mast cell granules, functions as a chemotactic factor, persisting for quite a long time, thus extending the inflammatory effects of immune reactions.
- ECF is not the principal mast cell factor and probably represents a cleavage product of a heterogeneous group of more complex oligopeptides that exhibit such activity. A more potent factor is phosphorylcholine acetyl glyceryl ether and the granule-associated enzymes.

Granule-associated enzymes include:

- *Neutral proteases,* including tryptase with a MW of 134 kD and chymase (Table 1.27). In particular TC mast cell *tryptase,* released together with histamine, cleaves C3 to yield C3a, an anaphylatoxin with degranulatory activity; the determination of tryptase levels is employed in nasal studies (Chap. 12) and in anaphylaxis diagnosis (Chap. 20). *Chymase,* at variance with tryptase, is rapidly inhibited in the extracellular environment. The evidence that it converts angiotensin I to angiotensin II and degrades bradykinin and many neu-

ropeptides suggests a role for chymase in the local control of microcirculation.

- *Additional enzymes* include kallikrein, also generated by TC mast cells, which releases several kinins with inflammatory activity from kininogen proteins including bradykinin (see "Type III Immune Reaction", p. 128), eliciting powerful effects on vasodilation, vascular permeability and airway smooth muscle. Intradermal injection provokes a triple response of a lesser degree compared to histamine not inhibited by antihistamines, equally to chymotrypsin and trypsin. Arylsulfatase has a limited capacity of regulating mediator release [418].

Proteoglycans, also of mast cell origin, found in secretory granules of many hemopoietic cells, essentially include *heparin,* with the following biological activities, in addition to the classic anticoagulant activity:

- Amplifies complement alternative pathway.
- Inhibits complement classic pathway activation.
- Stabilizes and enhances mast cell tryptase, which can express its catalytic activity.
- Potentiates C1-esterase inhibitor.
- Plays important anti-inflammatory roles by inhibiting eosinophil basic proteins provoking respiratory mucosa basement membrane thickening and airway smooth muscle hypertrophy, essential aspects of chronic asthma, whereas the inhibition caused by a powerful antidegranulating action exerted on mast cells by β_2-agonists probably leads to a breaking point in the equilibrium between inflammatory and anti-inflammatory factors (Chap. 11). Furthermore, in scarring areas, where mast cells are hyperplastic, increased heparin release improves tissue repair and the fibroblast action of structural remodeling, augments neutrophil elastase activity and recruits capillary endothelial cells into the area.

The *acid hydrolases,* present also in lysosomal granules of other inflammatory cells, include β-galactosidase, β-glucuronidase and β-hexosaminidase.

Newly synthesized mediators (membrane-derived) include [210]: PAF, PGs and LTs to which, together with TX, are ascribed DTH symptoms. Returning to mast cell degranulation, phosphatidylcholine is metabolized into lipophosphatidylcholine by PLA_2 activated by Ca, with subsequent AA release which gives rise to metabolic derivatives, the *eicosanoids.* AA is metabolized either by the 6-lipoxygenase pathway leading to LT synthesis, or by the cyclooxygenase pathway, generating PGs, PGI_2 (prostacyclin) and TX. Figure 1.57 shows how PGs and LTs derive from AA metabolism.

Biological activities of the following products of the *cyclooxygenase pathway* (Table 1.43) include:

- $PGD_{2\alpha}$: airway smooth muscle constriction, inhibition of platelet adherence and aggregation, activation of adenylate cyclase, virtual induction and increase in basophil mediator release, bronchoconstriction, facial erythema, nasal congestion
- PGD_2/I_2: vasodilation and increase in microvascular permeability, suppression of leukocyte functions
- PGE_2: bronchodilation, peripheral vasodilation and increase in microvascular permeability, inhibition of metachromatic cell mediator release, functional suppression of lymphocytes and PMNs, stimulation of pituitary function with rapid release of luteinizing hormone (LH), and conditioning of primary afferent neurones
- $PGF_{2\alpha}$: airway smooth muscle constriction, small vessel and pulmonary vasculature constriction, and stimulation of airway mucus hypersecretion
- PGI_2: pulmonary vasodilation, suppression of platelet aggregation in collaboration with NO, activation of adenylate cyclase and airway smooth muscle release, tachycardia, hypotension, facial erythema
- TX (A_2): constriction of microvasculature, stimulation of platelet adherence and aggregation [626]

Primary actions of diverse products of the *5-lipoxygenase pathway:*

- LTB_4: stimulation of leukocyte chemotaxis and activation, increased leukocyte adhesion to endothelium, functional suppression of T lymphocytes, activation of NK cells, mobilization of CA^{++} deposits, stimulation of $O_2^{\cdot -}$ synthesis, eosinophil chemotaxis and keratinocyte proliferation, infiltration of neutrophils into skin
- Cysteinyl products, powerful spasmogens of airway smooth muscles:

– LTC_4, LTD_4 and LTE_4: airway smooth muscle constriction, bronchoconstriction 200-fold to 20,000-fold more potent than histamine, vasodilation and increased microvascular permeability, mucus hypersecretion and electrolyte secretion, stimulation of gastric acid secretion, depression of myocardial contractility, mucociliary clearance impairment, inflammatory cell recruitment, and potent eosinophil chemoattractant, increased IL_1 production by monocytes, peripheral contraction, skin wheal and flare reactions, as well as LTC_4 initiation of LH release and LTE_4, BHR induction [528].

PAF, a vasoactive mediator released by numerous cells including mast cells, monocyte-macrophages, eosinophils, neutrophils, fibroblasts, vascular endothelial cells and platelets, causes a rapid sequestration of airway platelets, with TXA_2 secretion. PAF has a bronchoconstrictor activity, by recruiting and activating eosinophils and neutrophils, also because they can bind to their receptors, amplifying CD11a–CD18 and CD11b–CD18 expression and consequently both cells' adhesion to endothelium. Other biological effects include an increase in microvascular permeability, cytotoxicity, generation of $O_2^{\cdot -}$, as well as of cationic proteins and potent mediators. PAF therefore plays a prominent role in the pathogenesis of atopic disease, in addition to rapidly inducing hypotension and depressing myocardial contractility [626]. The proof of PAF pathogenicity and immunogenicity is shown by the complete defect of PAF-acetyl hydrolase, due to a mutation of exon 9, in 4% of the Japanese population, 27% of which has the heterozygote trait [535].

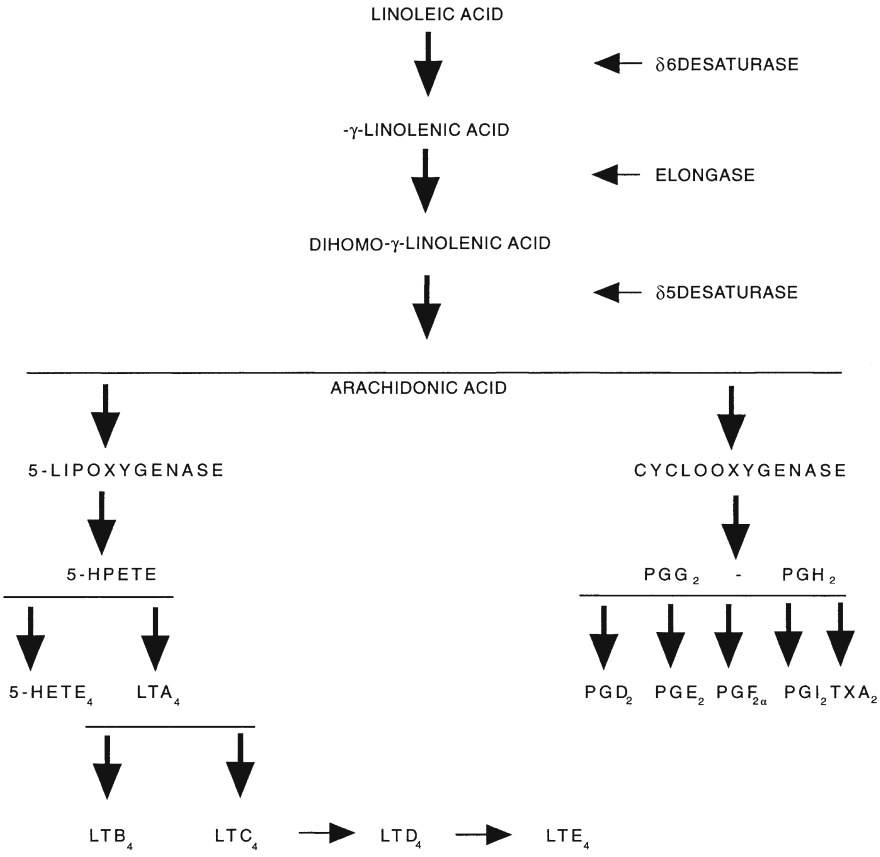

Fig. 1.57. Metabolic pathways of arachidonic acid. *HPETE* 12-hydroperoxy-eicosatetraenoic acid, *HETE* 12-hydroxyeicosatetraenoic acid, *PG* prostaglandin, *LT* leukotriene, *TX* thromboxane

Recent studies suggest that SP, a polypeptide with 11 amino acid residues, augments vascular leakage, stimulates mucus secretion in human bronchi, contracts bronchiolar smooth muscles, degranulates mast cells and is 100-fold more potent than histamine in eliciting wheal and flare reactions when injected subcutaneously [104].

Secondary Mediators

Secondary mediators are often released from primary mediators:

- *Mediators of cellular origin* released from neutrophils (toxic products of O_2, TXA_2, HETEs, LTB_4, LTC_4), eosinophils (MBP, ECP, PGE_2, HETEs, LTB_4, LTC_4), platelets (PF4, TXA_2), monocyte-macrophages, etc.
- *Mediators of extracellular origin,* from activation of complement, and of the following systems: coagulation, fibrinolytic, and kininogen-kinins

The inflammatory mediators can be also divided into:

- *Vasoactive mediators* (histamine, PGs, PAF, LTC_4, LTD_4 and LTE_4) active in the immediate phase.
- *Chemotactic mediators* (ECF-A, NCF-A, 5-HETE, LTB_4) active in the late phase (with recruitment of neutrophils, etc.) and inflammatory phase (with recruitment of eosinophils and monocytes) [626].

Several drugs inhibit mast cell degranulation and/or AA metabolism (Fig. 1.57), with very significant implications in the treatment of atopic disease [643]:

- CSs inhibit the ILs and, via lipomodulin (GIF is a fragment), inhibit PLA_2 and as a consequence AA separation from phospholipids.
- ASA and NSAIDS inhibit processes regulated by cyclo-oxygenase (they enter the cycle before the enzyme), thus stopping PG and TX formation, but not that of LTs since they augment the lipoxygenase pathway by compensation.
- Theophylline inhibits PDE-induced cAMP increase, thus down-regulating mast cell degranulation.
- β-Mimetic agents awaken the same effects because they increase cAMP levels.

Mechanisms of Cell Adhesion: Interleukins and Adhesion Molecules

As many as 51 different mostly T-cell-derived ILs of which 33 are ILs with their receptors have been identified so far (Table 1.5) as well IL receptors and signaling (Table 1.32). They comprise a heterogeneous group of intercellular regulatory proteins, with a MW of 8–140 kD ($IL_{12}R$ chain), often glycosylated, characterized by a very different biological activity and pleiotropic functions, produced singularly or associated. They were

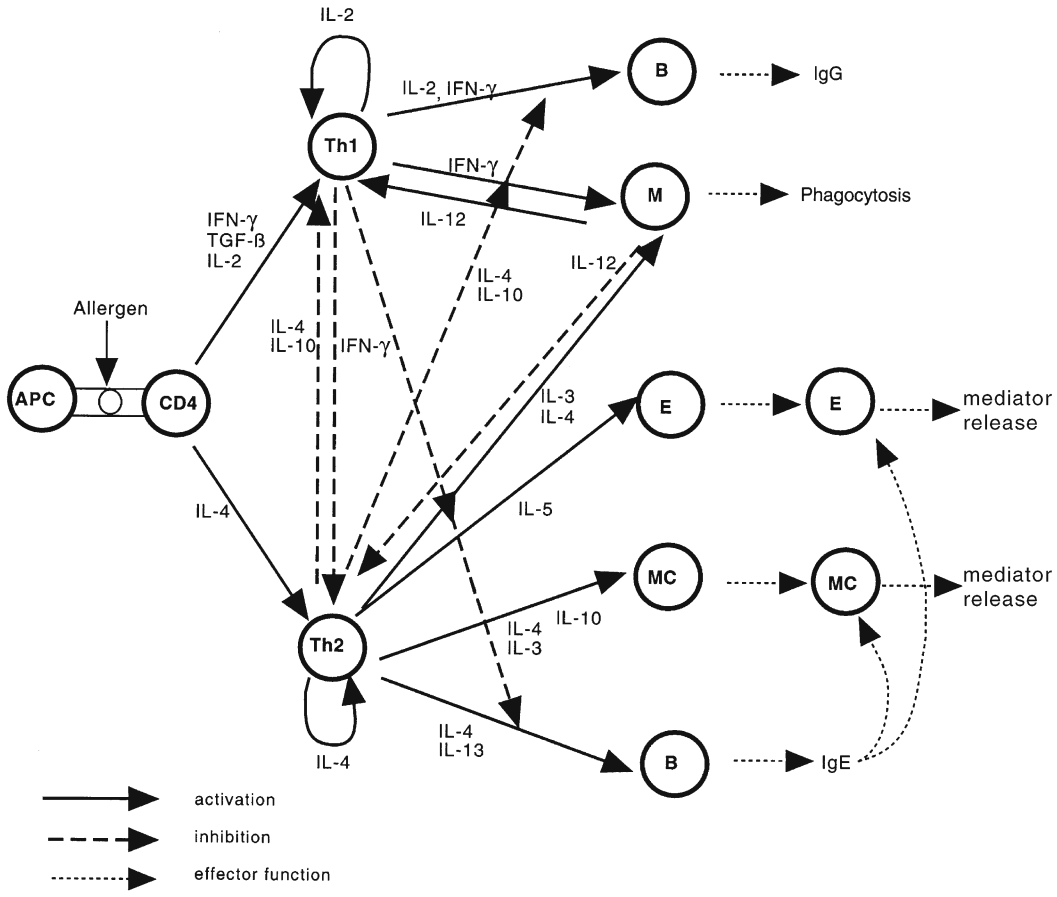

Fig. 1.58. Schematic diagram showing IL production and their activity during immune responses. *APC* antigen-presenting cells, *B* B lymphocytes, *E* eosinophils, *IL* interleukins, *M* macrophages, *MC* mast cells, *Th1*, *Th2* lymphocytes. (Modified from [619])

initially described as communication signals among leukocytes (inter-leukocytes), or soluble factors with a cellular derivation, with functions of messengers and activators of the immune system, and hence immunomodulators, regulating the growth and differentiation of immunocytes and/or many other cell types. ILs can exert a real hemopoiesis, that is, an action also on the growth and differentiation of hematopoietic cell progenitors in the area of immune inflammation where they are released, assuming a role of endogenous mediators. ILs are produced by cells exposed to inflammatory stimuli or bacterial products, or even not belonging to the immune system. They are involved in diverse stages of immune response and inflammatory reactions, greatly regulating their amplitude and duration, interacting at the cell surface with membrane receptors for which ILs have a high affinity, which transduce signals inside the cells. ILs act at picomolar concentrations and are therefore very potent, while their action is of short duration and self-limited. *A second IL cluster* has been localized on chromosome *1q32* including IL_{10}, IL_{19} and IL_{20} [45]. To IL_{12} is credited a contra-regulatory role of allergic inflammation, while a similar role could be shared by IL_{10} since it inhibits eosinophil survival [125]: these two ILs are also a pathognomonic example of opposing roles identified in the pathogenesis of atopic disease. In addition to several other ILs, the IL_{16} gene is associated with asthma, Crohn disease, and allergic contact dermatitis [59]. The numbers of IL_{16}-immunoreactive cells are increased in bronchial mucosa from atopic asthmatic patients 24 h after antigen provocation in vivo, and in allergen-induced late-phase nasal responses [283]. We have described above the relationships of human CD4 Th1 and Th2 T cells with several ILs. Recently the IL_{10} family has been shown to include IL_{19}, IL_{20}, IL_{24} (localized on chromosome *1q32*), IL_{22}, and IL_{26} (localized on chromosome *12q16*) [153]; some cardinal functions in atopic disease [457] are outlined in Fig.1.58 [619].

Recently SOCS, such as SOCS-3 induced by IL_{27} [403] and SOCS-1 and SOCS-3 genes stimulated by IL_{21} [547], have been reported to play a critical role in the inhibitory effect in a negative feedback mechanism [403]. SOCS are known to suppress DC functions and interfere with TLR4 signaling [547]. Both SOCS-1 and SOCS-3 can desensitize primary bone marrow-derived macrophages to IFN-ɣ and IL_6 signaling, respectively

[651]. Pretreatment of DC with IL_{21} inhibited LPS-induced expression of CD86 and HLA class II. Moreover, LPS-induced TNF-α, IL_{12}, CCL5, and CXCL10 production was clearly reduced in IL_{21}-pretreated cells [547]. IL_{27} inhibits CD28-mediated IL_2 production and also IL_2 responses [403].

Adhesion of immunocompetent cells between themselves, to target cells or to the intercellular matrix is a phenomenon of crucial significance in multiple immune reactions and mechanisms directing leukocyte distribution and localization. In this respect it is helpful to consider the *relationships between ILs and adhesion molecules,* which are based on vascular endothelial cells: indeed the leukocytes, when guided into circulation, must interact with such cells, which regulate leukocytes and are regulated by them. Leukocytes adhere to endothelial cells via a binding increase between leukocyte surface receptors and their *co-receptors or ligands* on the endothelial cell surface, which therefore plays a fundamental role in leukocyte migration from vascular to inflammatory sites in interstitial tissues [65]. Leukocyte adhesion to endothelial walls, chiefly of lymphocytes, is also of great magnitude for their compartmentalization and recirculation [209, 328, 534], as shown by Figs. 1.5, 1.11, and 1.58. Apart from new insights on the connections between ILs and leukocytes, the bidirectional relationships between ILs and endothelial cells are intriguing. Indeed, in addition to being targets of the action of soluble mediators of immunity, activating in vascular endothelium a large spectrum of functional interactions, endothelial cells are able to produce several ILs, some of which direct leukocyte extravasation from the circulatory system [534]. High vascular cells, the HEVs, are specialized for lymphocyte extravascular emigration into peripheral lymph nodes: lymphocytes bind selectively to HEVs, as shown by studies on the inhibition of lymphocyte–HEV adhesion done in the animal model and in humans by means of monoclonal antibodies. Therefore, it was possible to point out the role of surface structures present on HEVs. Such molecules, CD44, CD49d and others called addressins, then *selectins,* endothelial coreceptors considered to be specific for lymphatic tissues and involved in lymphocyte adhesion to endothelial cells, would bind to lymphocyte homing receptors, but with affinity for selectins present on lymphocytes [534].

Mechanisms of Cellular Adhesion

Adhesion molecules are a group of surface molecules crucial for immune system functions. In addition to promoting adhesion to the cellular matrix and modulating leukocyte adhesion to vascular epithelium and/or to ECM, they are able to direct leukocyte migration from vascular compartments to extracellular tissues, prime antigen-specific recognition by T lymphocytes, provide costimulatory signals for T-cell activation, stimulate the effector machinery for activated lymphocytes and regulate their proliferation and growth [23]. At least 70 soluble molecules and ILs are involved in lymphocyte activation and differentiation after antigen presentation. There are two different antigen-independent adhesion mechanisms between T cells on the one hand and APCs and/or target cells on the other, where CD2 (LFA-2), CD4, CD7, CD8, CD43 and CD45RO interact, as well as CD11a/CD18 adhesion molecules on T cells [328], more often Th2 T cells than Th1/Th0 cells [143]. In the first mechanism, CD2 binds CD58 and CD59 on APCs and/or B cells. In the second mechanism, CD11a/CD18 binds CD54 and CD102 expressed by APCs, where CD58 binds T-cell CD2: so both mechanisms integrate each other [23]. The largest group of these manifold and multidirectional *cell–cell adhesion molecules* encompasses integrins, selectins, etc., expressed on all surfaces and allowing cell contacts. The important molecules in the AD and asthma pathogenesis are outlined in Table 1.44 [378]: there we note the correspondence between the

two atopic diseases. Molecules of intracellular adhesion belonging to IgSF are listed in Table 1.4. CD54, a 90-kD gp controlled by IL_1 and TNF-α and -γ, plays a role of unquestionable importance in atopic disease. Of particular relevance is that CD11a/CD18 and CD11b/CD18 support leukocyte adhesion mechanisms binding to counter receptors of endothelial cells, including precisely CD54 and CD102 [23].

Integrins

A new chapter on the knowledge of surface molecules involved in adhesion mechanisms and leukocyte migration to tissue sites of inflammation was opened following the characterization of these gps with a heterodimeric structure made up of α and β chains, noncovalently associated, of 1,100 and 750 amino acids, respectively, important in the adherence of immunocompetent cells to tissues and cell surfaces. This preliminary stage, definite and representative, is related to antigen recognition from CD4 T cells (adhesion to APCs) or to effector activities (adhesion to target cells). Eight subfamilies of leukocyte integrins are as yet known, each made up of 24 different α subunits and a common β chain with 8 subunits distinct in β1–β8, noncovalently linked, forming many combinations [65, 534]. The α integrins play a key role in inflammatory processes, including leukocyte adhesion and migration. Their genes are located on the p arm of chromosome 16 [164].

β1 Integrins (CD29) are heterodimers composed of a common β chain, which can bind to variable α chains. They are the VLA proteins, very late antigens, because the first two appear on lymphocytes 2–4 weeks after antigen priming and are variably expressed on the leukocyte surface. VLAs are divided into various types, as is seen in Table 1.45 [4, 23, 226]. They are chiefly receptors of ECM components such as FN (VLA-5), fibrinogen, laminin (VLA-6), collagen (VLA-2), vitronectin, von Willebrand factor (vWF) and IgSF members [65, 534]. VLAs interact with a wide range of other cells: epithelial (VLA-3), mesangial (VLA-1), activated T (VLA-1, VLA-2), skin fibroblasts (VLA-1), hemopoietic lines (VLA-3), thymus, bone marrow, monocytes, leukocytes (VLA-4 and VLA-5), basement membranes (VLA-3), platelets (VLA-2, VLA-5), and liver sinusoids (VLA-1). VLAs are expressed on circulating lymphocytes and monocytes, like other VLAs on subsets and resting cells of the T phenotype. Thus they are important in lymphocyte homing, transendothelial migration to sites of inflammation, and interactions with ECM [226]. VLA-4 has distinct sites for VLA-5 and CD106, while $\alpha_4\beta_1$ could mediate pro-thymocyte migration from bone marrow to thymus [614].

β2 Integrins (CD29), characterized by a β2 common chain, and a higher immunological and immunopathological interest, are heterodimers formed by two covalently bound peptide chains expressed on PBMCs for the most part; hence they are called leukocyte integrins and regulate adhesion for PBMCs [226]. β2 Integrins have four receptors, each with two chains, α distinct and β common (Table 1.46) [4, 23], while $\alpha_d\beta_2$ is expressed by tissue macrophages [209]. However, a 30%–50% homology has been found between the two chains, denoting a common ancestral gene [23]. β2 Integrins recognize polypeptides with an Arg-Gli-Asp amino acid sequence, likely to be capable of blocking neutrophil adhesion to endothelial cells by a competitive mechanism. CD11b/CD18 and CD11c/CD18 (CR3 and CR4) mediate

Table 1.46. β2 Integrins

Molecules	MW	Ligands	Distribution
$\alpha_L\beta_2$=CD11a/CD18	180	CD50, CD54, CD102, CD62E	Widespread on all leukocytes
$\alpha_M\beta_2$=CD11b/CD18	170	CD54, iC3b, fibronectin, LPS	Monocyte-macrophages, neutrophils, NK cells
$\alpha_X\beta_2$=CD11c/CD18	150	CD54, iC3b, fibrinogen	Monocyte-macrophages, activated T cells, NK cells
$\alpha_d\beta2$	125	CD50>CD54	Macrophages, granulocytes, foam cells

Data from [4, 23].

Table 1.47. β3 Integrins

Molecules	Ligands	Distribution, effects
$\alpha_{II}\beta_3$=CD41/CD61, GP IIb/IIIa	Vitronectin, fibrinogen, fibronectin, vWF	Platelets, megakaryocytes
$\alpha_V\beta_3$=CD51/CD61	Vitronectin, fibrinogen, vWF	Endothelial cells, monocytes, platelets, T cells, LAK cells, mast cells, some B cells
VNR	Vitronectin, fibrinogen, fibronectin, vWF, leukocytes, platelets, laminin, thrombospondin	Endothelial cells

Data from [4, 11].

HML human mucosal lymphocytes, *IEL* intraepithelial lymphocytes.

phagocytosis binding CICs coated with iC3b and iC4b [337]. CD11a/CD18 (CR1) promotes CTL adhesion to target cells, CD11b/CD18 (CR3) functions as a receptor for iC3b, which has a domain with the same sequence [23], and finally CD11c/CD18 (CR4) binds to CD54 and iC3b. CD11a/CD18 and CD11b/CD18 are also involved in the LAD syndrome, fatal if not corrected by a bone marrow transplantation (BMT) [564]: five different types have been reported (Chap. 22).

β2 Integrins are distributed on a larger spectrum of cells:

- NK cells (CD11b/CD18 and CD11c/CD18)
- Leukocytes (CD11a/CD18 all, CD11b/CD18 and some CD11c/CD18)
- Monocyte-macrophages (CD11b/CD18 and CD11c/CD18) [610]

β3 Integrins (CD61) or cytoadhesins are given in Table 1.47 [4, 11]. Among *β4-β8 integrins* (Table 1.48) [11, 19, 226] is included CD104 expressed on thymocytes [166]. There are two β7: $\alpha_4\beta_7$ (CD49d/β7), which binds to MAdCAM-1, with two N-terminal domains with homology for CD54 and CD106, followed by a mucin-like region between domains 2 and 3 ending with an IgA-like domain. MAdCAM-1 further binds to both CD62L and $\alpha_4\beta_7$ [209], also mediating lymphocyte rolling and adhesion to epithelium, performing a double function of both a selectin and an integrin ligand [534]. Another β7, $\alpha_E\beta_7$, is the first to recognize E cadherin [76]. Thus, two *β7 integrins* may be important in GALT formation, since they provide lymphocyte trafficking to PPs and lamina propria [615]. Additional unclassified adhesion molecules (Table 1.49) [4, 11] are CD44 (ligand hyaluronic

Table 1.49. Additional adhesion molecules not classified among families

Molecules	Characteristics	Ligands	Distribution, effects
CD26	See Table 1.2	Fibronectin, collagen	Thymocytes, T and NK cells
CD35	See Table 1.2	C3b, C4b	E, B and T cells, phagocytes, splenic follicular CDs; on CDs possibly role in presentation of allergen, eosinophils
CD36	See Table 1.2	Thrombospondin	Monocytes, megakaryocytes, small vessel endothelium, platelets, reticulocytes
CD42a/d	See Table 1.2	Thrombin, von Willebrand factor	Platelets, megakaryocytes
CD44	See Table 1.2	Hyaluronic ac, collagen, laminin, fibronectin	B and T cells, E precursors, glial cells, monocytes, neutrophils, fibroblasts, myocytes, epithelia
CD73	See Table 1.2		Epithelial and endothelial cells
Laminin	140–400 kD	See "Integrins"	Integrity of basement membranes (embryogenesis, development)
Fibronectin	250–235 kD	Gelatin, fibrin, heparin, integrins (see "Integrins")	Adhesive and migratory events (embryogenesis, angiogenesis)
CD134	See Table 1.2	gp34	Adhesion of T cells to vascular endothelial cells, costimulation
Sialoadhesin	185 kD	Sialyl proteins	Contacts macrophage-granulocytes during hematopoiesis
VAP-1	?	?	Endothelial and dendritic cells, HEV of lymph nodes

Data from [4, 11].
E erythrocytes, *VAP* vascular adhesion protein.

Table 1.50. Selectins

Molecules	Ligands	Distribution
CD62E (E selectin)	ESL-1, CD15s, CD62L, CLA	Leukocytes, activated endothelia, epithelia, HEV of lymph nodes
CD62L (L selectin)	CD34, CD15s, GlyCAM	Resting leukocytes, peripheral lymph nodes, MALT
CD62P (P selectin)	PSGL-1, CD15s	Activated endothelial cells and platelets

All selectins mediate tethering and rolling of various cells (see text for details).
Data from [23, 610].
CLA cutaneous lymphocyte-associated antigen, ESL-1 E-selectin ligand 1, *GlyCAM* glycosylation-dependent cell adhesion molecule 1, *PSGL-1* P-selectin glycoprotein ligand 1=CD162.

acid), a homing receptor active in leukocyte extravasation to inflamed tissues [23], CD35, CD36, CD42, and others shown in the table.

Selectins

The *selectin family* is independent of integrins, mostly expressed on lymphocytes and neutrophils, and involved in the adhesion process with vascular endothelial cells; three molecules have been characterized so far, distinct by sequence and function homology (Table 1.50) [23, 610]. All belong to the C-type lectin family and share domains with regulatory complement proteins; CD62L also shares an EGF-like domain [4]. To these molecules with a slow expression (their peak is 4–6 h after IL stimulation, in TNF or IL_1, for example, the levels return to basal values after 12–24 h) also belong two molecules with a structure different from CD62E and CD62P, that is, CD54 and CD106 [610]. Selectins are typical lymphocyte homing molecules, to lymph nodes as well as to sites of inflammation [226]. CD62L expressed by 70% of circulating leukocytes is in part responsible for neutrophil in vivo recruitment to inflamed tissues. CD62E, a receptor of mononucleated cells, is on HEVs at sites of immune inflammation: IL-activated, both mediate adhesion to endothelium [4]. CD62P expressed by platelet α granules has the same preference of CD62E for endothelial cells, which express it after agonist stimulation (histamine, thrombin, etc.), returning to basal levels after 20–60 min. β2 integrins and CD62L can act in agreement with guide neutrophils to inflamed

Table 1.51. Cadherin classification

Molecules	Ligands	Distribution

tissues [348]. High-affinity selectin ligands are ESL-1 (E-selectin ligand 1), PSGL-1 (P-selectin glycoprotein ligand 1=CD162) related to FGF and GlyCAM-1 (glycosylation-dependent cell adhesion molecule 1) for CD62L [209]. Particularly, ESL-1 and CD162 mediate myeloid cells binding to the two selectins; CD162 also mediates CD62P-associated leukocyte binding and rolling [4].

The *cadherins* (Table 1.51) [65] are distributed in different tissues, and with their desmosomes serve as anchoring sites for the cytoskeleton to the point of Ca-dependent adhesion between adjacent cells and junction formation through which bundles of actin filaments run among cells [162]. Cadherin homophilic adhesion plays a key role in segregating embryonic tissues and in cell migration and tissue differentiation [162].

The cadherin superfamily is wide: ≈80 cadherins have been isolated. Most members are expressed in the CNS. These are homophilic adhesion molecules, and for their homophilic interactions, the ectodomains (EC) play a crucial role [657]. Over recent years *protocadherins* have emerged as a growing superfamily of molecules, with a complex picture of their structure and con-

Table 1.52. Adhesion between leukocytes and endothelial cells at the molecular level

Cells	Adhesion molecules	Ligands on endothelium
T, B, monocyte-macrophages, neutrophils, NK cells	CD11a/CD18	CD50, CD54, CD102

stitute the largest subgroup within the cadherin family of Ca^{++}-dependent cell–cell adhesion molecules [657]. This new family is large, 52 novel protocadherins were identified on human chromosome 5q31 [653]. Subsequently, 66 protocadherins were identified in cluster genes arrayed into two clusters [380]. Protocadherins are organized into α, β, and γ. The β genes in man are 19 and in mouse 22 [605]. The γ-protocadherins are expressed exclusively in the CNS [629]. A fourth group, δ, includes δ 1-protocadherins (comprising protocadherin-1, -7, -9 and -11 or -X/Y) and δ 2-protocadherins (comprising protocadherin-8, -10, -17, -18 and -19). Some δ-protocadherins appear to mediate weak cell–cell adhesion in vitro and cell sorting in vivo [451].

Tables 1.52 and 1.53 summarize the adhesion molecules involved in interactions between lymphocytes and endothelial cells at the molecular [226] and organ levels [226, 534].

Relationships Between ILs and Adhesion Molecules

Several ILs, mainly those with a tendency for inflammation, activate on endothelial cell membranes the expression of adhesion molecules for leukocytes and/or other circulating cells:

- IL_1, TNF-α and IFN-γ increase the expression of CD54 and CD102, CD62E, CD106, etc.; the first two molecules induce adhesion on all granulocytes, the last one only on eosinophils and basophils.
- IL_2 activates CD54.
- IL_3 fosters basophil adhesion to endothelial cells and CD11b/CD18 expression on basophils.
- IL_4 induces lymphocyte adhesion and can make up for lack of CD106 modulating its expression in the absence of CD54, CD102 and CD62E.
- IL_5 promotes CD11/CD18 expression on eosinophils.
- IL_6 expresses CD11b/CD18 on pro-monocytes, further CD11c and CD54.
- IL_7 primes CD11b/CD18 expression from T lymphocytes and of CD54 from T and B lymphocytes.
- IL_8 activates CD11b/CD18 and CD11c/CD18 on PMNs.
- GM-CSF provides neutrophils and granulocytes with CD11b and endothelial cells with CD18 [23, 323].

Chemokines

Chemokines [22, 179, 247] are more than 65 small protein molecules (8–10 kD) generated by leukocytes, monocyte-macrophages and platelets and activated endothelium, which can thus regulate leukocyte trafficking and that related to IL_8 identified as analogous to NAP-1. As their name suggests, *chemo*attractant cyto*kines* play the role of chemotactic molecules interested in integrin activation. Chemokines may be defined as small but potent leukocyte pro-inflammatory chemoattractants, cellular activating factors, and HRFs, that bind to specific G-protein-coupled seven-span TM receptors present on plasma membranes of target cells, which makes them particularly important in the pathogenesis of allergic inflammation. Chemokines are major regulators of cell trafficking and may also modulate cell survival and growth [280, 687]. Chemokines IL_8, MIP-1, MCP-1 and RANTES are known to recruit neutrophils, eosinophils, macrophages and T lymphocytes to the site of inflammation. MIP-1, MCP-1 and RANTES are direct chemoattractants of Th1 cells. These chemokines are promiscuously used by several receptors, but all three are ligands for CCR5, which is preferably expressed in type 1 cells. Therefore, it is of interest to note that the CCL-chemokines and their receptors are coexpressed in Th1 cells. The coexpression is not only Th1-cell-specific, but the similar expression pattern applies to Th2 cells that express CCR4 bearing thymus and activation-regulated chemokine (TARC) receptor. Structurally related, chemokines are divided into three groups based on the *chromosomes by which they are coded:* α = 4, β = 17, depending on whether the first two cysteine residues are separated by an amino acid (CXCL) or are adjacent (CCL), γ = 1, and δ is an exception on chromosome 16, interacting with receptors different from G proteins [9, 22, 178] (Tables 1.54, 1.55) [2, 9, 19, 22, 178, 247, 479, 574]. The proposed chemokine nomenclature is based on the nomenclature currently in use, derived from the one already assigned to the gene encoding the 4 families of chemokines [687], and includes CC, CXC, XC, or CX3C followed by L (ligand) or R (receptor) and then a number [667]:

- *CXCL α chemokines:* for neutrophils there are many specificities (Table 1.54), GROs are specific even for basophils [178]. Moreover, NAP-1/IL_8 chemoattractant of eosinophils can activate also basophils (Fig. 1.49) and act as a potent inducer of T-cell chemotactic and activating responses. From PBP (platelet basic protein) β-TG, CTAP-III and NAP-2 originate [19]. A further subdivision might be introduced, since mig, IP-10 and PF-4 lack the E-L-R (glutamic acid-leucine-arginine) residues [19].
- *CCL β chemokines:* (Table 1.55) RANTES is produced by fibroblasts to attract and activate eosinophils. LPS is known to induce RANTES and cause protein tyrosine phosphorylation [658]. RANTES is a chemoattractant selective for activated and resting T cells, including memory cells [552]. CD45RO, macrophages and eosinophils. MIP-1α and MIP-1β and MCP-1 are chemotactic for T subsets, macrophages, eosinophils and basophils; while macrophages in turn elicit several CCL chemokines [540]. In particular, MIP-1α favors activated B cells and CD8 migration and MIP-1β-activated T cell infiltration; both direct T-cell adhesion to endothelial cells, the former of CD8 and the latter of CD4 T cells. Basophils and eosinophils are among the more sensitive cells, mostly to CCLs, while MCP-3 combines the properties of RANTES and MCP-1 [247, 396].

Table 1.54. Main properties of α chemokines or CXCL chemokines

Name	Source(s)	Target cells and (biological effects)
BCA-1	Secondary lymphoid organs	B lymphocytes (chemotaxis)
ß-TG	Monocyte-macrophages, platelets	Monocytes, platelets, fibroblasts (growth), neutrophils (chemotaxis)
CK-α1		
CTAP-III	Platelets, monocytes	Fibroblasts (activation), neutrophils (chemotaxis)
ENA-78	Monocytes, neutrophils, NK and endothelial cells	T cells, basophils, neutrophils (activation and degranulation)
GCP-2	Osteosarcoma cell line	Neutrophils (chemotaxis)
GRO α, β, γ	monocyte-macrophages, fibroblasts, synovial cells and epithelial cells, hepatocytes, keratinocytes, neutrophils, T lymphocytes	neutrophils (degranulation, adhesion, activation, endothelial chemotaxis), basophils (in a reduced way), fibroblasts (growth), endothelial cells (angiogenesis)
IL_8/NAP-1	Osteoblasts, endothelial/epithelial cells, fibroblasts, keratinocytes, smooth muscle cells, astrocytes, B and T lymphocytes, monocyte-macrophages, hepatocytes, melanoma cells	Neutrophils (activation, chemotaxis, adhesion, killing), lymphocytes and NK cells (chemotaxis), basophils (chemotaxis, histamine release), endothelial cells (angiogenesis), keratinocytes (mitogenesis)
IP-10	Monocytes, endothelial cells, fibroblasts, keratinocytes, macrophages	T cells (activation, chemotaxis, integrin expression by T cells), NK cells (chemotaxis, cytolytic activity), endothelial cells (angiogenesis inhibition)
I-TAC	Monocytes, neutrophils, epithelial cells	T lymphocytes, Th1 and NK cells (chemotaxis)
MAD-2		
mig	Monocyte-macrophages, NK cells	T cells (activation and chemotaxis)
NAP-2	Platelets	Neutrophils (activation and chemotaxis)
PBP	Platelets, lymphocytes	
PF-4	Platelets, megakaryocytes, T lymphocytes	Fibroblasts, neutrophils, monocytes and T cells (endothelial cells adhesion, angiogenesis inhibition)
SDF-1α, β	Several tissues	Lymphocytes, monocytes (chemotaxis)

β-TG β-thromboglobulin, *CK-a1* α1 chemokine, *CTAP-III* connective tissue activating protein-III, *DC* dendritic cells, *ELC* EBI1 ligand chemokine, *ENA-78* epithelial cell-derived neutrophil-activating protein, *GCP-2* granulocyte chemotactic protein 2, *GRO-α, GRO-β, GRO-γ* growth-related gene, *IP-10* Inflammatory protein-10, *I-TAC* interferon inducible T-cell alpha chemoattractant, *MAD-2* monocyte adhesion dependent protein-2, *MCP 1/5* monocyte chemotactic protein-1/5, *mig* monokine inducible by IFN-γ, *MIP-1α, -1β, 2* macrophage inflammatory protein-1α, -1β, 2, *NAP-1* neutrophil activating factor-1, *PBP* platelet basic protein, *PF4* platelet factor 4, *SDF-1a/1β* stromal cell-derived factor.
Data from [2, 9, 19, 22, 178, 380, 459, 574].

MCP-1, MCP-2 and MCP-3 are also major attractants for monocytes, $CD4^+$ and $CD8^+$ T cells [317, 609]. MCP-1–4 bind to specific G-protein-coupled receptors, initiating a signal cascade within the cell. CCR2 is considered the major G-protein-coupled receptor for MCP-1 [616]. MCP-5, a 9.2-kD peptide that consists of 82 amino acid residues, has been identified in the mouse [614]. MCP-1 is efficacious nearly as much as C5a and, in conjunction with RANTES and MIP-1α, stimulates basophils to release histamine, even more so if IL_3, IL_5 and GM-CSF interfere. Furthermore, MCP-1 turns into a powerful chemoattractant of eosinophils, similarly to IL_8 if it loses the N-terminal region [628]. MCP 1–3 are active chemoattractants for NK cells [316], MCP-1 also for T cells of memory phenotype [67], whereas MCP-3 appears to be involved in the regulation of early responses to specific allergens [666]. Parallel to eotaxins [435], RANTES has an effect on eosinophil local recruitment, by acting on their locomotion similarly to C5a, and 2- to 3-fold more powerful than that of MIP-1α [658]. RANTES in IL_5-stimulated cells is an effective inducer of eosinophil transendothelial migration by a single mechanism, CD49d/CD106-dependent [133]. Although RANTES and IL_5 are elevated 24 h after antigen challenge, eosinophil recruitment and degranulation is associated only with IL_5 [552]. Unprimed mast cells are influenced to migrate by MCP-1 and RANTES, while IgE-activated cells respond to MIP-1α and PF4, but do not degranulate in response to chemokines [568]. C10, with homology to CCF-18, seems to involve only T-cell chemotaxis [19]. Positive correlations link the level of Syk expression and

Table 1.55. Main properties of chemokines: CCL, XCL and CX3CL chemokines

Name	Source(s)	Target cells and (biological effects)
β or CCL chemokines		
ACT-2

CKβ1, 3, 4, 6–11		
DC-CK1	Dendritic cells	$CD45RA^+$ T cells, naive T cells (chemotaxis)
ELC/MIP-3β		T cells (selective)
Eotaxin-1	Nasal epithelium	Eosinophils (chemotaxis)
Eotaxin-2	Activated monocytes, basophils, myeloid progenitors	Resting T cells (chemotaxis), eosinophils, basophils
Eotaxin-3	Eosinophils	
Exodus-1/MIP-3α/LARC	DCs (regulation and migration)	
Exodus-2	Lymph nodes, airways, appendix, spleen	
FIC		
HCC-1	Normal tissues, $CD34^+$ myeloid progenitors	Monocytes (chemotaxis)
HCC-2	Liver	Monocytes (chemotaxis)
HCC-4		T lymphocytes
I-309	Monocytes, mast cells, activated T cells	Monocytes (chemotaxis)
MCP-1	Monocytes, endothelial/epithelial cells, fibroblasts, keratinocytes, smooth muscle cells, mast cells, mesothelial cells	Monocytes (chemotaxis, adhesion, phagocytosis, killing, superoxide release, arachidonic acid activity) metachromatic cells (chemotaxis, degranulation, histamine release), basophils (LCT synthesis), T cells (chemotaxis), eosinophils; macrophages (activation, secretory activity, chronic inflammation), stem cells (colony formation inhibition)
MCP-2	Monocytes, osteosarcoma cells, fibroblasts	Has half of MCP-1 activity: monocytes, T cells, eosinophils (chemotaxis), mast cells (chemotaxis, histamine release)
MCP-3	Osteosarcoma cells	Combines MCP-1 and RANTES properties: monocytes, T cells, eosinophils (chemotaxis)
MCP-4	Endothelial/epithelial cells	Lymphocytes, monocytes, eosinophils (chemotaxis)
MCP-5	Monocytes	Peritoneal macrophages (chemotaxis)
MDC/STCP-1	Macrophages, monocyte-derived DCs	Monocytes and derived DCs, activated T cells, thymic T cells, CD8 T cells, IL_2-activated NK cells (chemotaxis)
MIP-1α now CCL3	B and T lymphocytes, monocytes, fibroblasts	B and T lymphocytes, neutrophils, monocytes, NK cells, eosinophils, DC (chemotaxis); T cells (adhesion, collagenase release, integrin expression mostly by CD8 T cells), eosinophils (cationic protein release), metachromatic cells (chemotaxis and histamine release), stem cells (colony formation inhibition)
MIP-1β now CCL4	B and T lymphocytes, monocytes, fibroblasts	Monocytes (chemotaxis), T lymphocytes (chemotaxis, adhesion, integrin expression mostly by CD4 T cells), stem cells (antagonizes MIP-1α effects)

Table 1.55. (Continued)

Name	Source(s)	Target cells and (biological effects)
MIP-3α	Liver, monocytes, lymphocytes	Mononuclear, dendritic, and T cells (chemotaxis)
MIP-3β	Lymphoid tissue, activated B lymphocytes	Activated T lymphocytes (chemotaxis)
MIP-5	Liver, intestine, lymphocytes (airways)	Monocytes, T lymphocytes (chemotaxis)
MIPF-1		Resting T cells, monocytes, neutrophils
PARC	T cells (selective), lung, lymphoid tissue	T lymphocytes (chemotaxis)
RANTES now CCL5	T cells, platelets, macrophages, endothelial cells	T cells (chemotaxis, adhesion, integrin expression mostly by CD4 T cells), monocytes, DC and NK cells (chemotaxis) specific for eosinophils (cationic protein release), basophils (chemotaxis and histamine release); additional actions are similar to those of MCP-1
SLC	Lymphoid tissue, activated macrophages	T lymphocytes (chemotaxis)
TARC	Lymphoid tissue, mononuclear cells	T lymphocytes, Th2 T cells (chemotaxis)
TCA3		
TECK	Thymic dendritic cells, small intestine, liver	Activated macrophages, dendritic cells (chemotaxis)
γ or XCL chemokines		
Lymphotactin	$CD8^+$ T lymphocyte, thymocytes, NK cells	T cells (chemotaxis)
ATAC		
SCM-1	Mononuclear cells, spleen	Lymphocytes (chemotaxis, activation)
CX3CL chemokines		
Fractalkine	Endothelial cells, monocytes	T cells and monocytes (chemotaxis)

When the chemokines are without indications, the sources and the target cells are as yet unknown.

RANTES production induced by LPS. RANTES production from nasal fibroblasts stimulated with LPS is enhanced by overexpression of wild-type Syk gene transfer [658]. Several CXCL and CCL chemokines alone or together release 11 %–43 % of basophil histamine [283] and have similar activity: for example, GRO α, γ and MCP-1 are constitutively produced in human airway epithelium and bronchoalveolar macrophages [32], while IL_8 and CCL chemokines manipulate IL_2-activated NK-cell chemotaxis [334]. The *eotaxins* have a great significance in the *atopic march*: STAT-6 is required to up-regulate eotaxin-1 and eotaxin-2 expression by chronic IL_4 stimulation [687]. Multiple other STAT molecules (STAT-1, STAT-2, and STAT-3) can be recruited to various other chemokine receptors after JAK recruitment. These activated STAT molecules can then translocate into the nucleus of the chemokine-stimulated cell and directly activate (and sometimes repress) gene expression [396]. TARC, constitutively expressed in the thymus and produced by monocyte-derived DCs and endothelial cells, is a ligand for CCR4 and CCR8 and serves for the recruitment and migration of these receptor-expressing cells, and is thus responsible for the selective trafficking of Th2 lymphocytes into sites of allergic inflammation [393]. More chemokine receptors are rapidly up-regulated following T cell activation. Th1 cells express CXCR3 and Th2 CCR3, CCR4, CCR8 [687].

- *XCL γ chemokines:* only ATAC, and a lymphotactine specific for T cells are known to date [2, 9].
- *CX3CL chemokine:* only fractalkine (Table 1.55).

their different ligands: 15 for CXCL (CXCL 1–18), 28 for CCL (CCL 1–28), 1 for CX3CL chemokines and other unclassified ones [2, 4, 690]. All have seven G-protein-linked TM-spanning domains and their signaling can be typically inhibited by pertussis toxin [2], in addition to two virally encoded chemokine receptors that may be used, together with IL_8 R and IFN-R, by viruses to subvert the host immune system [2] by altering the local conditions in favor of viral persistence and replication [11]. The inhibition of chemokine receptors by pertussis toxin (PT) suggests that Gi proteins are key to the transduction of signals. Gi proteins physically associate with multiple chemokine receptors, but there is also evidence that other PT-resistant Gi proteins, such as Gq or G16, might also associate with certain receptors [465]. AA release driven by PLA2 is important for optimal cell movement toward a chemokine gradient. The roles for activated PLD are as yet unclear. Recent studies have clearly demonstrated a key role for PI3K in chemokine receptor signaling [396, 554]. This leads in turn to activation of PIP-specific PLC, PKC, small GTP-ases, Src-related tyrosine kinase, PI3K, and PKB. PLA delivers two secondary messengers, inositol- 1,4,5 triphosphate, which releases intracellular calcium, and DAG which activates PKC. Multiple phosphorylation events are triggered by chemokines. PIP-OH-kinase can be activated by the βγ subunit of G protein, small GTP-ase or Src-related tyrosine kinases [687]. The membrane tyrosine phosphatase CD45 has also been shown to regulate CXCR4-mediated activation and phosphorylation of TcR downstream effectors Lck, ZAP-70, and

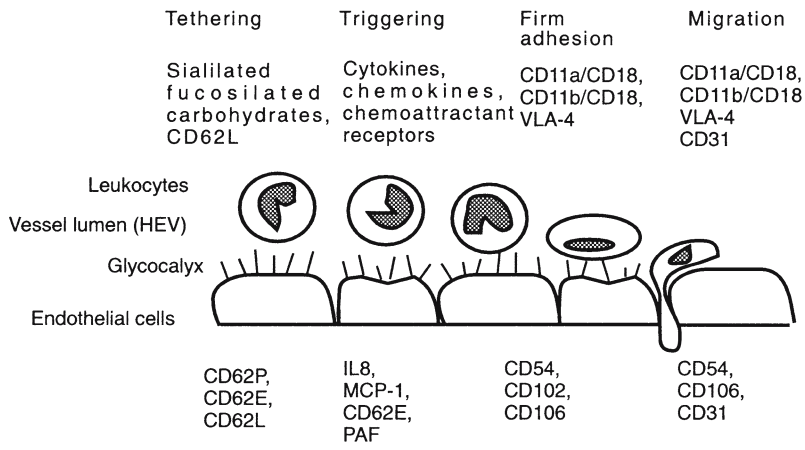

Fig. 1.59. Leukocyte trafficking and adhesion cascade. Sequential steps in leukocyte recruitment, their adhesion to endothelium and transendothelial migration (see text). (Modified from [209, 230, 328])

SLP-76. Activation of the RAFTK (related adhesion focal tyrosine kinase), a member of the related kinase family, has been shown to be induced by signaling via CXCL12 binding to CXCR4 [151]. Mitogen-activated protein kinases have also been shown to be phosphorylated and activated within 1 min after exposure of leukocytes to CCR3 ligands [247]. CXCR4 is predominantly expressed on inactivated naive T lymphocytes, B lymphocytes, DCs, and endothelial cells. SDF-1 is the only known ligand for CXCR4 [239].

The principal biological function of chemokines is contributing to leukocyte recruitment, firstly by activating integrins, as described above, and secondly by promoting leukocyte migration across endothelium and through ECM [2]. Additional functions consist in the antiviral immunity (innate immunity), hematopoiesis and angiogenesis regulation, growth and cellular metabolism [9]. The existence of so many characterized chemokines with overlapping targets is not surprising, since it is also possible that certain chemokines may have a restricted tissue expression, although their large number can actually result in a degree of redundancy [2]. However, the strong expression of IL_8 and MCP-1 by epithelial cells could also suggest that they might be key factors in leukocyte recruitment to counteract invading pathogens [141]. This notion agrees with the priming of cytotoxic CD8 T cells and NK cells by RANTES and MIP-1α [569], which can provide substantial costimulatory signals for T-cell proliferation and promotion of effector functions, also by enhancing CD80 and CD86 expression on APCs and IL_2 production from activated T lymphocytes [20]. In addition, CCL chemokines direct basophil and eosinophil migration for activation and response at DTH sites, where ILs of Th2 T cells surround and in turn stimulate the above cells, amplifying their negative effects. Nonetheless, the presently available data, even if suggestive, need to be thoroughly analyzed in the context of the pathogenetic hypotheses currently discussed.

More to the point, chemokines act in conjunction with HRFs which, like antigens, are able to trigger histamine release and to activate a large number of cells (mast cells, basophils, lymphocytes, eosinophils, macrophages, monocytes and platelets) and possibly B and T lymphocytes. By binding to sIgE, monocytes and basophils, HRFs can perpetuate histamine release, thereby inducing allergic reactions too late or too prolonged to be classified as IgE-mediated reactions. The observation that IgE of atopic subjects bind HRFs at variance with the IgE of nonatopic individuals suggests that these molecules have an unequivocal clinical weight. There is a factor inhibiting HRF (HRIF) in relation with NAP-1/IL_8 (at the same time an HRF and an HRIF), a protein of 8,000 Da derived from PBMCs, B and T lymphocytes and possibly alveolar macrophages, whose generation is augmented by normal histamine concentrations, hence suggesting a feedback mechanism inhibiting the histamine itself, which can thus regulate HRF activities. CCL chemokines are HRFs, if nothing else due to the similarity of conditions in which they are generated [687].

Leukocyte Trafficking and Migration

Adhesion processes, mediated by proteins adherent to endothelial membranes and correspondent receptors on leukocyte membranes, acquire a new impetus due to specific interactions between HEVs and lymphocytes. Transendothelial migration of activated lymphocytes from the blood into the tissues is an essential step for immune functions, which may be arrested by Zap-70 deficiency (Chap. 22). Preceded by inflammatory mediator release, causing vasodilation and blood flow deceleration, this preliminary step allowing the cascade to proceed, as mentioned in the preceding section via HEVs, influences *leukocyte rolling* [23]. Up-regulated CD62s, mainly CD62P, with a long molecular structure that extends above the surrounding glycocalyx, have the task of capturing passing leukocytes expressing appropriate receptors (Fig. 1.59) [209, 230, 328]; moreover, CD62L is localized on the tips of microvilli, a first point of contact with the endothelium [348]. Ensuing passages are orchestrated by chemokines and integrins, preceded by T-cell rolling with selectin interactions (CD15, CD62L

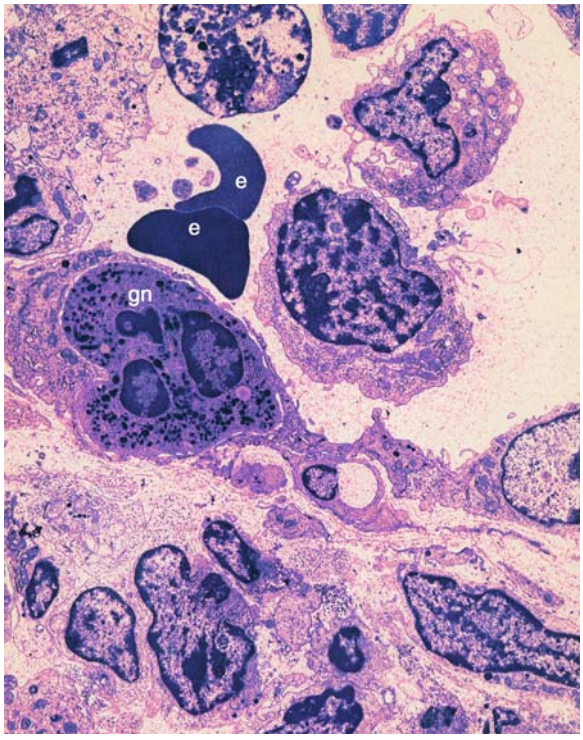

Fig. 1.60. Diapedesis. *e* Two red cells in the vessel lumen, *gn* granulocyte neutrophil while passing through the endothelial wall by diapedesis

and CLA of lymphocytes, CD62P and CD62E on endothelium) and by integrin stimulation (activated by CD31 and chemokines). Functional activation of integrin receptors on lymphocytes, above all CD2, CD28 and PDGF, and signal transduction regulating adhesion point to a PI3K primary role, in turn activated by chemokines and receptors sensitive to G proteins [521]. After conformational modifications of the cells and integrins ensure a strong adhesiveness, lymphocytes undergo diapedesis (Fig. 1.60), and their migration between endothelial cells in extravascular spaces is followed by directional cues from chemoattractants (Fig. 1.61) [534]. The process continues within the inflamed tissues, generating additional mediators and ILs. The initiation of endothelial activation, which modulates selectins binding carbohydrate ligands, often displayed on mucin-like molecules, is responsible for the initial tethering of a flowing lymphocyte to the vessel wall and for a transient rolling along the endothelial cells (step 1). Tethering contributes to chemoattractant-mediated adhesion, resulting in integrin triggering and binding to endothelial ligands (step 2). The sound T-cell adhesion is modulated by G proteins, whose signals activate strong integrin adhesiveness, which binds IgSF on endothelium (step 3) and the transendothelial migration (step 4). Eventually T lymphocytes spread via endothelial cell–cell junctions, cross the basement membrane and migrate across lymphoid tissues [522]. A recent study indicated that activation of integrin avidity to endothelial ligands by endothelium-displayed chemoattractants (or chemokines) can take place within fractions of a seconds and can promote both reversible rolling adhesions or immediate conversion of leukocyte rolling to firm arrest on vascular ligands [187]. Obviously the adhesion required is not too strong, otherwise it would lead to cell immobilization [226] (Fig. 1.61). In step 4, lymphocytes cross intercellular HEV junctions, allowing them to enter HEVs: the entire process of lymphocyte sticking to HEVs takes only 1–3 s and step 4 10 min [454]. In humans, as many as 5×10^6 lymphocytes leak from blood via HEVs every second [454]. Even if the equilibrium among variables stabilizes with speed, relatively small changes in integrin expression or integrin–ligand affinity, or cell-substratum adhesiveness, can lead to substantial changes in migration speed [406]. Several integrins govern interactions: the initial ones are mediated by CD62L recognizing CD34 and GlyCAM-1 (Table 1.50). After activation, lymphocytes firmly adhere to endothelial cells since β2 integrins interact with IgSF members on both endothelium and G-protein-coupled receptors [162]. During stage 3, CD11a/CD18 inhibit lymphocyte migration via CD54 and CD102 HEV counter-receptors, playing the major role [534]. Then lymphocytes migrate, using β1 integrins, to

Table 1.58. Molecules active in the homing, memory and inflammatory responses of lymphocytes

Lymphocyte receptors	Ligands	Distribution	Activity

a chemotactic stimulus (such as a bacterial invasion) [163], while step 4 is CD31-modulated [230]. The pathways used by lymphocytes to bind endothelium depend on the site and nature of stimuli activating it:

- *IL_1 and TNF-α,* by increasing CD54 and CD106 expression on endothelium in vitro, allow lymphocytes to bind either β1 or β2 integrins [540]: IL_4 primes only CD106 expression, VCAM, hence restricting the field to β1 integrins.

There are differences regarding the involved site: the umbilical vein endothelium stimulated by IL_1 or TNF-α expresses both CD54 and CD106, whereas cutaneous microvascular endothelium responds much better to TNF-α.

Such processes are regulated by proteoglycans well expressed on endothelium, which stimulate granulocyte and T-cell adhesion by means of the chemokines IL_8 (via β2 integrins) and MIP-1β (via β1 integrins), respectively [565].

Lymphocyte recirculation is also influenced by adhesion molecules in specific tissues: one such molecule is MAdCAM-1, an IgSF member, largely restricted to gut epithelium (HEV of PPs, mesenteric lymph nodes, and endothelium of enteric mucosa) [328], where it mediates binding of a specific subset of $CD45RO^+$ cells expressing $\alpha_4\beta_1$ integrin [38]; wherever MAdCAM-1 is mentioned, its localization is in MALT [209].

CD62E mediates T-cell binding to lymph node HEVs. Such binding to mucosal HEVs is promoted by another integrin, LPAM-1, with an α chain homologous to an α4 CD49d/29 chain, in turn a CD106 receptor.

Additional molecules involved in lymphocyte homing include CLA expressed on T cells with an exclusive tropism for binding to CD62E on skin endothelium, and VAP-1 (vascular adhesion protein) also with an endothelial origin that mediates lymphocyte binding to lymph nodes and synovial membranes [328].

Lymphocyte migration into tissues has slightly diverse phases depending either on peripheral lymph node HEV, or on PPs, or skin, or intestine (Fig. 1.5). However, the CD106/receptor CD49d/29 duo plays a leading role in binding both lymphocytes and monocytes [85]. In Table 1.58 [62, 209] are shown the molecules involved in homing (and related memory) and in lymphocyte inflammatory responses: also CD62L, CD11a, b, c/CD18, $\alpha_4\beta_1$ = CD49d/CD29 (VLA-4) and $\alpha_4\beta_7$ = CD49d are included [209].

As regards *leukocytes,* the same selectivity comes on the scene: the involved molecules are CD62E and CD106, which also promotes adhesion of *eosinophils* expressing CD49d/CD29 at the surface, unlike neutrophils [624]. CD62E governs PAF production, which together with other endothelial cells with activating properties, expresses IL_1 and integrins such as CD11a/CD18, CD11b/CD18, etc. [65]. As a consequence, the CD106/receptor CD49d/29 duo represents the greater association of adhesive molecules in eosinophil recruitment and extravasation, to be directed to in vivo inflamed sites [624]. Eosinophils, following what is outlined by Fig. 1.59, supported by CD49d/CD29, adhere to endothelial cell membranes supplied with CD106 and are activated; expressing CD11a/CD18 bind to CD54 and CD102, then transmigrate into the underlying mucosa. In brief, the key points are as follows [230]:

- *Cell recruitment* mediated by T cells by means of IL_4, IL_5, RANTES and MIP-1α.
- *Selectin* (CD62E, CD62P and CD62L) and ligand (CD34, GlyCAM-1) selective expression on endothelial cells produced by ILs and mediators.
- *Integrin* (CD11a/CD18, CD11b/CD18, CD49d/CD29) selective activation induced by ILs, CCL and CXCL chemokines and chemoattractants.
- *IgSF* (CD54, CD102, CD106) selective expression induced by ILs: above all CD106 specifically expressed by

IL_4 on epithelial cells is an important regulatory moment in eosinophil adhesion to epithelium and antigen-driven migration [578].

- *TNF-α* has been demonstrated to have an important role in the expression of adhesion molecules that induce transendothelial migration of eosinophils [534].

Neutrophils in normal conditions are absent or poorly represented on endothelium, being expressed after activation. These cells in the early phase roll on activated endothelial vessel walls, accompanied by a mast cell histamine-modulated increase in vascular permeability, a process mediated by CD62P expressed on neutrophils [154]. PAF is released at these sites and in perspective can elicit, together with SP, the chemotactic movement of parallel activated neutrophils, which strongly adhere to endothelium and proceed to transendothelial migration. Lipoxin A4 modulates transmigration of human neutrophils across intestinal epithelial monolayers [90] (see also Chap. 11). In the late phase, LPS and ILs (IL_1, IFN, TNF, etc.) with inflammatory action stimulate CD62P on endothelial cells, expression of CD54, IL_8 release, and CD62L and CD15s activation on neutrophils which, via CD15s, CD62E and CD62P specific binding, continue their rolling along vessel walls, adhesion modulated by CD11b/CD18/CD54, activation and diapedesis [19, 154]. However, cell migration can be different as a consequence of an eicosanoid exposure, although neutrophil retention in a specific anatomical site could play an important role in mucosal defense [90]. Selectins mediate the initial rolling contacts of *monocytes* with the endothelium. Firm adhesion to the endothelium is the second step and involves other adhesion molecules such as CD11a, CD11b, CD18, and VLA-4 on monocyteds and CD54 and VCAM-1 on endothelial cells. The adherence to endothelial cells is modulated by endothelin-1 via the involvement of Src (p60src), JAK1-like kinases, and vascular endothelium growth factor by an increased flt-1 expression by monocyes. The final step is monocyte transmigration into the subendothelial space [609].

A primary function of *epithelial cells* is to maintain vascular integrity. Vascular injury promptly promotes epithelial cells to release their granule content (CD62P, vWF), which is quickly deposited on ECM, where it plays a crucial role in platelet adhesion to damaged sites. *Platelet degranulation* and activation of their $\alpha_{II}\beta_3$ integrin = CD41/CD61 drives further accumulation of platelets (aggregation) and modulates neutrophil and monocyte recruitment, which participate in the repair of damaged tissues. Thus platelet rolling, analogous to lymphocyte rolling, may represent an initial step in hemostasis [163].

Although knowledge on the role effectively played by such different molecules in human physiopathology is still lacking and far from yielding logically linked reference patterns, such acquisition suggests that some molecules may play a central role in normal conditions regarding homeostasis and the pathogenesis of some morbid conditions.

Interrelations with Other Organs

Several observations clearly show that the immune system interacts with other communication systems of our organism such as the endocrine apparatus and central nervous system (CNS). There are important correlations between ILs and neuropeptides: after its release from nervous tissue termination, SP is able to increase transcriptions at the gene level and synthesize and secrete IL_1, IL_6 and TNF-α, with an effect on stromal cells, GM-CSF, G-CSF and M-CSF, and consequent neutrophil, basophil, macrophage and eosinophil adhesion and activation, thus modulating the effector stages of type I and type IV reactions. Interconnections with neuroendocrine circuits are complex: SP and VIP (vasoactive intestinal peptide) are involved in the control of IL_2 production by T lymphocytes, while IL_1 and IL_1R are present in neurones and endocrine glands. IL_2 and IL_6 alter the proliferation pattern of anterior pituitary cells, as well as GH, ACTH and prolactin secretion, while IL_5, IL_7, IL_9 and TGF-β are involved in the regulation of neurodifferentiation [493]. Indirectly, an initial event such as an infection or a tissue lesion of less impact can trigger polysaccharide or ECM protein release, which stimulates tissue macrophages to release TNF-α. TNF-α-exposed endothelial cells express adhesion molecules to attract first PBMCs and then T cells to recognize APC-expressed antigens. TNF-α acting on these cells mediates IL_1 start-up, inducing phagocytes, T lymphocytes and endothelial cells to produce IL_6 [326]. The integrin-linked kinase (ILK), colocalizing with the β1-integrin subunit, is expressed in various regions of the CNS. ILK staining revealed that it is enriched in neurons and is an important effector in NGF-mediated neurite outgrowth [353]. Some ILs induce the acute-phase response (APR) in the liver, and CSs stimulate APP production, whereas they block TNF-α, IL_1 and IL_6 actions. These ILs act independently on the hypothalamus-hypophysis-adrenal (HPA) axis, but also display synergic effects: TNF-α and IL_6 act on the hypothalamus inducing fever. In addition IL_6 causes a concentration of cortisol and corticotrophin that is higher than the levels obtained with the greatest stimulation of corticotrophin-releasing hormone (CRH). How IL_6 can reach the CRH hypothalamic neurones is not known; however, it is possible that IL_6 is produced by endothelial and glial cells stimulated by TNF-α and IL_1. CNS and the endocrine system also mount inflammatory responses: for example, they generate β-endorphin endowed with a local analgesic action. CRH and probably also arginine-vasopressin have a pro-inflammatory activity; in particular CRH is found in inflamed areas, most likely produced locally by postganglionic sympathetic neurones [326]. Appendix 1.4 [326] concludes the issue of neuroendocrine interactions with the immune system: for example, prolactin amplifies IL_2 production, β-endorphins, and melanotonin, which are active on T and B lymphocytes.

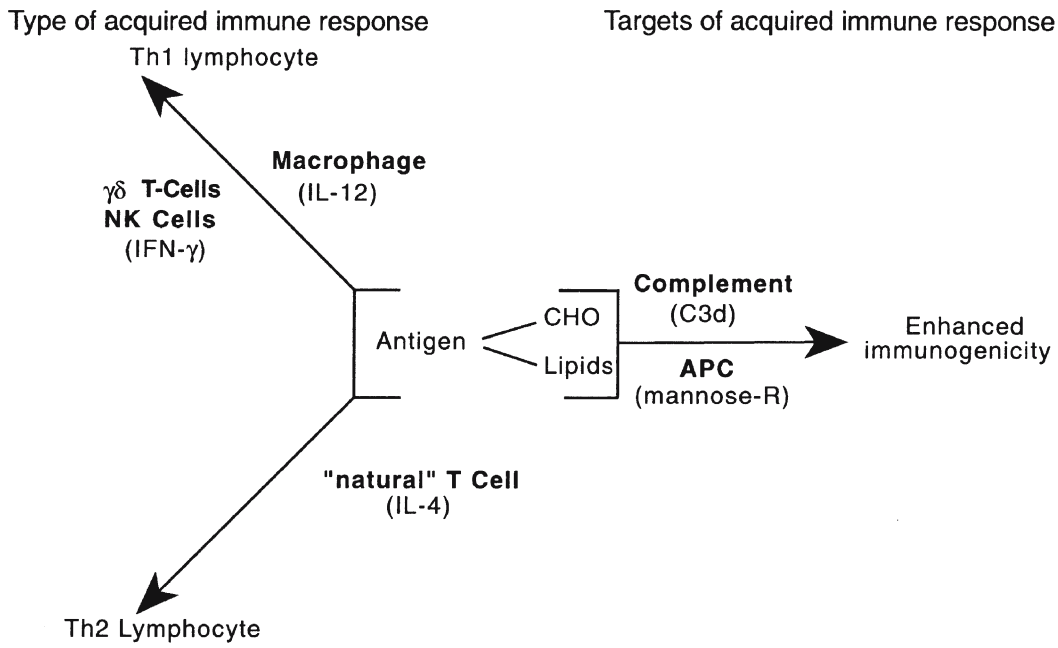

Fig. 1.62. Components of innate immunity (*in bold*), which recognizes carbohydrates (*CHO*) and lipids and instructs the acquired immune response to the antigens with which they are associated. *APC* antigen-presenting cell, *R* receptor. (Modified from [148])

Innate Immunity

Innate, or natural immunity, substantially aspecific and independent of previous contacts with pathogen agents, has evolved as the first line of defense against the constant threat of myriad microorganisms in the surrounding environment. This immunity is based on the genetic constitution of individuals. To avoid infections and prevent access of pathogens or potentially pathogenic microorganisms, present in the environment and on the body surface lying in direct contact with the environment, the host has evolved a series of *sophisticated defense systems,* closely integrated among themselves. The achievement of protective immunity against invading pathogens relies on sensing specific molecular features expressed in microorganisms and depends on the ability to elicit the pertinent type of immune response to fight a specific pathogen. Germline-encoded receptor molecules enable the cells of the innate immune system to recognize structural components conserved among classes of microorganisms [449]. The recognition of microbial products by the host innate immune system rapidly triggers appropriate responses to contain the infection and regulate the development of adaptive immunity. The exposure to microbial antigens primes several ILs and proinflammatory mediators that affect T cell differentiation and are rapidly produced by APCs, such as DCs and macrophages [366, 447]. Recent data show that IL_1R and $IL_{18}R$ are key molecules in both the innate and acquired immunity and are members of a larger family of related receptors, some of which contribute to host defense [526]. Table 1.1 shows the differences between innate and acquired immunity, which is instructed by soluble and cellular components of innate immunity to select the appropriate antigens coincidentally with strategies devised for their elimination (Fig. 1.62) [148]. Natural immunity is realized by skin, mucosal barriers and secretion protective effects, phagocyte cells, complement, and additional biological activity of nonspecific factors. Among them there are proteins coded in the germline, employed by innate immunity to recognize potentially noxious substances [148]. Such proteins are either soluble or have the form of surface receptors: for example, macrophage phagocyte particles or soluble glycoconjugates linked with the mannose receptor, a C-type lectin with a wide specificity for carbohydrates, and in addition an LPS receptor, LBP (lipopolysaccharide-binding protein) [536]. Bacteria coated with innate immune surfactants or MBP (mannose-binding protein), often including complement activated by the alternate (innate immune) pathway, are opsonized and more readily phagocytosed. In this process the receptors for antibodies and complement of macrophages and neutrophils are important, so that the coating of microorganisms with antibodies, complement, or both enhances phagocytosis. The engulfed microorganisms are subjected to a wide range of toxic intracellular molecules, including $O_2^{\bullet -}$, hydroxyl radicals, hypochlorous acid, NO, antimicrobial cationic proteins and peptides, and lysozyme [115]. LCs become activated and behave as APCs when pattern-recognition receptors on their surface recognize distinctive pathogen-associated molecular patterns on the surface

of microorganisms [345]. Such common constituents of Gram– bacteria external membrane signal infectious agents triggering IL_1, IL_6, IL_{12} and TNF-α synthesis, thus eliciting an APR [31], stimulate macrophages and other cells, as well as CD4 differentiation and growth [148]. Current data show that IL_1R and $IL_{18}R$ are key molecules in both the innate and adaptive immunity, and are members of a larger family of related receptors, some of which contribute to host defense [525] and that IL_{22} directly promotes the innate, nonspecific immunity of tissues [650]. IL_{22} induces APRs in the liver, which suggests that IL_{22} plays a role in innate immunity via induction of an inflammatory process [129]. Attractive data support the concept that potential prophylactic and therapeutic results are expected from $IL_{17}A$ and $IL_{17}F$ in host defense against bacterial infection. The IL_{25} activity associated with systemic and localized Th2 responses offers an experimental basis to modulate Th2-associated allergic diseases [249]. Some NK cells posses lectin-like membrane receptors involved in the recognition of target cells destined to cytolysis [289]. Complement is activated when the alternative pathway interacts with particles rich in carbohydrates but lacking sialic acid, or the classic pathway is stimulated by *collectins,* which bind to specific carbohydrates [210]. It is understandable why, unlike acquired immunity, *its innate immunity has a more complex organization:* constituents are soluble cells and factors with different structure and function, sometimes acting on different targets, but on the whole often become in turn integrated [148]. Recent studies have individuated the TcRγδ, which also in natural immunity precedes an αβ in antigen responses, thus influencing αβ-expressed IL pattern, discriminating between pathogens [152]. In this way, γδ could begin to supervise αβ responses to infectious agents due to their much earlier activation and conversion to memory [210]. A similar control could be extended to NK cells [287].

The natural defenses, the skin and mucosal barriers, are strengthened by mucosal secretions containing sIgA, able to complex with antigens and to identify antibodies capable of their recognition, and to complex in turn with antigens. Activation of the complement cascade can lead to directly destroying undesired hosts or to facilitating their phagocytosis. Complement and phagocytes are the first to activate when an infection approaches, supplying host defenses with notable contributions by means of a nonspecific protection against invasive pathogens, also without antibodies and/or T CTLs intervening [531]. Therefore specific immune mechanisms act in concert with those of innate immunity. We will examine:

1. Anatomic barriers: skin, mucus, and secretions
2. Proteins with anti-infectious activity (PAA):

a) Lysozyme
b) IFN
c) Complement
d) APP or pentraxins

3. Phagocytes: neutrophils and macrophages

1. *Anatomic barriers,* or physicochemical barriers, offer not only a mechanical, but also chemical protection, performed via production of biological molecules with antibacterial activity, including lactoperoxidase, lysozyme, lipase, spermine and fatty acids with bactericidal power. *Skin* is provided with the *stratum corneum,* which by means of its physiological desquamation resists penetration of a great number of microbes. In addition, it is normally impermeable to the greater part of infectious agents, because of bacteriostatic, bactericidal and fungicidal effects of triglycerides, free fatty acids and lactic acid, present in sebaceous secretions and sweat, which also contains lysozyme. As a compensation of the thinner epithelial stratum, mucus-capturing microorganisms are present on *mucosal surfaces,* subsequently removed from airways by the mucociliary apparatus. The secreted mucus layer overlays the epithelium in the respiratory, gastrointestinal, and genitourinary tracts, and the epithelial cilia sweep away this mucus layer, permitting it to be constantly refreshed after it has been contaminated with inhaled or ingested particles. Invaders are transported with a continuous cycle from bronchioles to the pharynx, a protective action that extends to the stomach HCl with bactericidal action. Saliva, swallowing, peristalsis and defecation mechanically expel microorganisms from the gastrointestinal system [353]. Salivation, lacrimation, and coughing, are further mechanisms that are very effective in reducing bacterial assaults: patients presenting with severe changes in lacrimation and salivation (Sjögren syndrome) suffer from severe eye infections and tooth caries. Nasal secretion and saliva contribution are significant, provided with mucopolysaccharides inactivating some viruses of anaerobic germs associated with the normal intestinal bacterial flora, both preventing pathogen attachment via competition for essential nutrients and/or production of inhibiting substances as well as urinary flow ensuring unremitting cleansing. Basic proteins, such as lysine, arginine, spermine, spermidine and particular gps, among others transferrin, make additional contributions [47].

2. *PAA,* important associates of innate immunity, integrate mechanisms that rapidly come into play, with a notably crucial result when the innate system faces the first encounter with infectious agents, since it will take from 4 to 15 days before elaborating antibodies and cytotoxic cells. Not all germs are assaulted with identical means and proportions: in biological fluids and interstitial spaces, the intervention of factors bound to antibodies and complement is more germane, unlike parenchyma where phenomena of cell immunity prevail (ILs, cytotoxic cells).

2a. *Lysozyme,* produced by macrophages and neutrophils, is found in salivary, lacrimal, nasal secretions, intestinal and respiratory mucus, lymph nodes and spleen. It is able to split β-glycoside bindings, in particular β 1–4 links between *N*-acetylglucosamine and

Table 1.59. Anti-infectious and anti-inflammatory activities of complement

Component(s)	Function in host defense
C1, C4, C4a, C4b	Neutralization of viruses ↑
C1q	Opsonization and phagocytosis ↑, antibody formation ↑, binding to CICs, cytotoxicity mediation
C2 kinin	Vascular permeability ↓
C3 fragment (C3e)	Release of granulocytes from bone marrow ↑
C3a	Antibody formation, antigen-induced T-cell proliferation, cytotoxicity mediated by T and NK cells ↑
C3a, C4a, C5a	Release of histamine and other mediators from mast cells ↑
C3b	Opsonization, IC phagocytosis, B-cell growth, IL_2-dependent T-cell growth, killing mediated by T and NK cells ↓, antigen presentation, clearance of CICs, antigen localization in lymphoid tissues
C3b soluble	Antigen-induced T-cell proliferation, cytokine production ↑
iC3b	Opsonization, phagocytosis, ADCC ↑
C3d, C3dg	B-cell growth↑
C3d, C3dg soluble	B-cell growth, IL_2-dependent T-cell growth ↓
C5a	Chemotaxis of PMNs inducing the influx into inflammatory sites, stimulation of phagocytes to release cytokines (TNF, IL_1),granule enzymes and O_2 metabolites, antigen-induced T-cell proliferation, antibody formation ↑
C5b6789 (MAC)	Lysis of bacteria, fungi, protozoa, viruses and virus-infected cells
Factor Ba	B-cell proliferation
Factor Bb	B-cell growth and differentiation ↑
Factor H	Growth of murine lymphocytes

Modified from [241].
IC immune complexes, ↑ increase/up-regulation, ↓ decrease/down-regulation, *PMN* polymorphonucleates.

N-acetylmuramic acid, a normal constituent of several bacterial cell walls.

2b. *IFN α, β, γ,* have several effects, including a timely antiviral activity, especially IFN-λ1–3 (*IL_{28a}*, *IL_{28b}*, *IL_{29}*) [377]. All IFN-α, -β, -ω, and -λ subtypes are expressed in influenza-virus-infected monocyte-derived DCs and PDCs [88]. It is significant that IFN-γ induce in murine B cells the IgG_1 isotype switch that increases phagocytosis, activating the complement classic pathway and linking macrophage Fc receptors [148].

2c. *Complement* [241, 633] represents, together with antibodies, the main component of the humoral defense system against microorganisms. *If activated it participates in host protection* in a specific and nonspecific way, intervening, besides phagocytosis, with functions divided into lytic and nonlytic, such as chemotaxis, opsonization and anaphylactogen activity (Table 1.59) [241]. In addition, with its receptors, it acts on B-cell antibody synthesis, immune memory, and CIC solubilization and clearance [159] (Tables 1.60, 1.61) [241, 260, 474]. From a simplistic viewpoint among immune reactions, complement is comparable to a motor vehicle, while antibody is an ignition key: indeed, once antibody has recognized the non-self molecule, it has specific functions, including complement activation and its fixation on the cell surface [633]. Complement components, provided with defensive and immunoregulatory properties, are normally present in the bloodstream in an inactive state and all act in concert, but each must be sequentially activated and in suitable conditions (a relatively small starting signal is sufficient), so that the typical mechanism of cascade reaction is triggered [633]. The primary source of such proteins is the liver, with smaller contributions from tissue macrophages, epithelial cells of the gastroenteric tract, and PBMCs. Like Igs, it is hypothesized that they arose late in evolution and are found only in vertebrates [36]. Complement is formed by >25 serum proteins interacting with nine functional components, designated C1–C9, reflecting the orderly sequence of their activation, with the exception of C4, which is activated after C1 and before C2. As regards nomenclature, a horizontal bar over a component denotes active enzyme activity of either a protein or a protein complex; proteins that become inactivated either by enzymatic cleavage or internal rearrangement are prefixed a small i (iC3); small postscripts a and b (C3a, C3b) indicate the biologically active fragments of a component; C1 subunits are designated q, r, s. The C1 complex consists of C1q, two molecules of C1r, and two molecules of C1s which bind to antibodies bound to an anti-

Table 1.60. Receptors binding complement components

Receptor(s)	Ligands	Major functional results of binding	Cell distribution
CR1 (CD35)	C3b, C4b, iC3b	Phagocytosis ↑ IC clearance, BC activation, antigen presentation, cofactor for cleavage of C3b or C4b	M, N, B, E, BC, CD4, ER, CD
CR3 (CD11b/18)	iC3b	Phagocytosis ↑ cell adhesion ↑	M, N, NK/K cells, CD
CR2 (CD21)	C3d, C3dg iC3b, C3b, EBV	Primary antibody response ↑ BC activation, also of BC memory, receptor for EBV infection	BC, CD, immature Epithelial cells
CR4 (CD11c/18)	C3dg, C3d	Phagocytosis mediated or not by FcR ↑	M, N, NK/K cells, CD
C4a/C3aR	C4α, C3α	Anaphylotoxin (see text)	M, B
C5aR	C5a, C5a des arg	Chemotaxis muscle and endothelial cells	MC, B, N, E, M, smooth
C1qR	C1q	Anaphylotoxin (see text) phagocytosis ↑ chemotaxis ↑	M, B, N, E, BC, endothelial cells, fibroblasts

Modified from [241].
R receptor, *M* mononucleates, *N* neutrophils, *B* basophils, *E* eosinophils, *BC* B cells, *ER* erythrocytes, *CD* follicular dendritic cells, *MC* mast cells, *IC* immune complexes, ↑ increase, *ND* not defined.

Table 1.61. Regulatory proteins of the complement system

Proteins	Target(s)	Biological functions
Soluble proteins		
C1 INH	C1r, C1s	Inhibits the serine proteases, binds to C1r, C1s inhibiting their participation in the classic pathway, binds to C1 inactive preventing its activation, inhibits kallikrein, plasmin and factors XIa and XIIa
C4bp	C4b	Increases decay of C3 classic convertase, cofactor of C4b cleavage mediated by factor I
Factor H	C3b	Up-regulates decay of C3 alternative convertase, cofactor of C3b cleavage mediated by factor I
Factor I	C4b, C3b	Cleaves and inactivates C4b, C3b using as cofactors C4bp, factor H, MCP
Properdin (P)		
Protein S or vitronectin	C5b-7	Binds to C5b-7 complex and prevents MAC insertion into cell membranes
SP40/40	C5b-9	Modulates MAC formation
Membrane proteins		
CR1 (CD35)	C3b, C4b, iC3b	Up-regulates decay of C3 classic and alternative convertase
DAF (CD55)	C4b2B, CebBb	Up-regulates decay of C3 classic and alternative convertase
HRF o C8bp	C8	Inhibits complement lysis
	C9	Blocks the binding of C9 to C8, preventing both MAC insertion into lipid membranes of autologous cells and complement lysis
MACIF (CD59)	C8	Blocks the binding of C7, C8 to C5b, C6, preventing MAC development and complement lysis
MCP (CD46)	C3b, C4b	Assembly and decay of C3b and C4b mediated by factor I

Modified from [260, 474].
C1 Inh C1 Inhibitor, *C4bp* protein binding C4, *C8bp* protein binding C8, *HRF* homologous restriction factor, *MAC* membrane attack complex, *MACIF* membrane attack complex inhibitory factor.

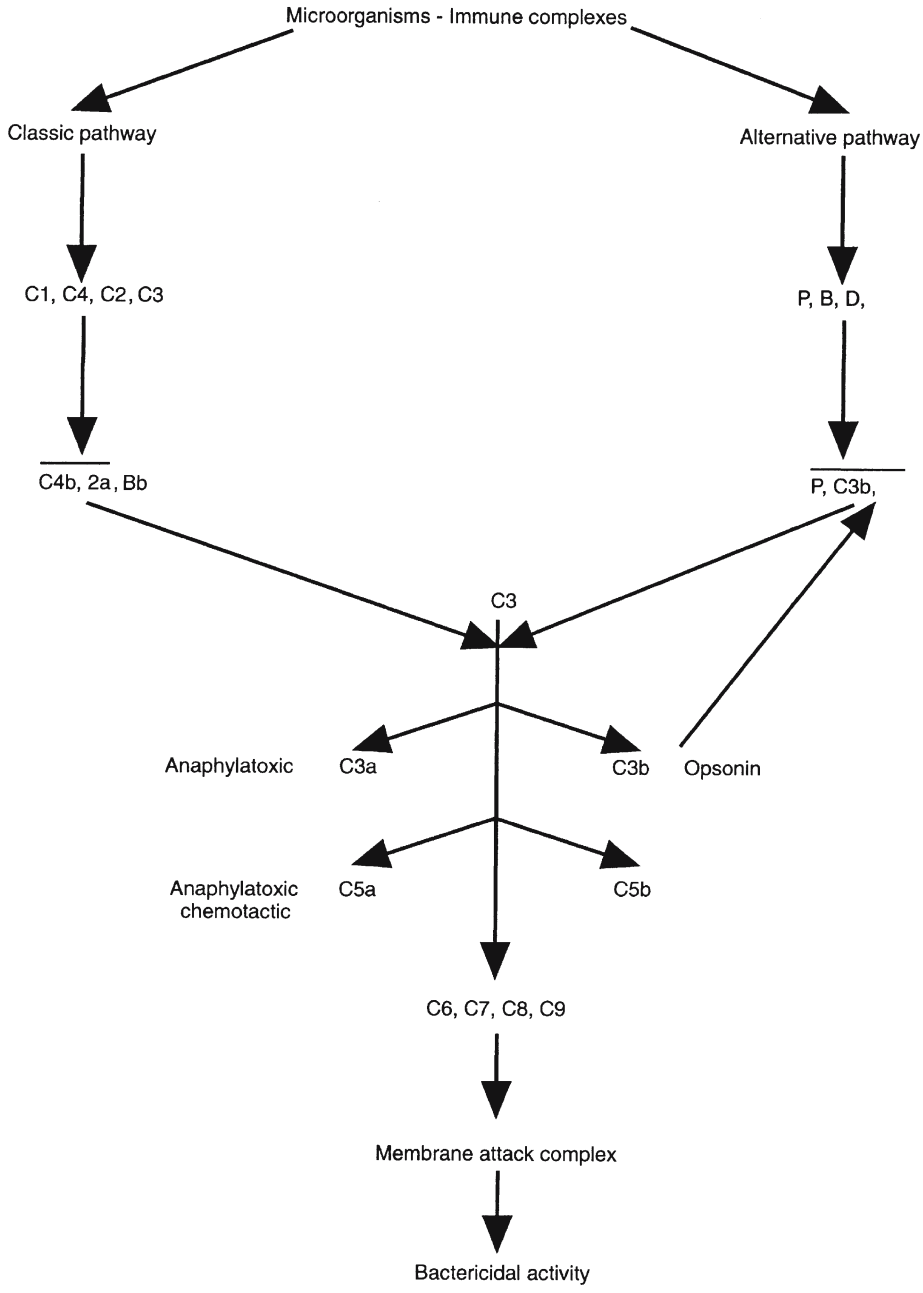

Fig. 1.63. A schematic representation of the complement system. *B* B fragment, *Bb* larger fragment of B, *D* D factor, *P* properdin. (Modified from [648])

gen on the surface of a bacterial cell [345]. Letters of the Latin alphabet, P, B, D (initials of properdin, factor B, factor D), designate the alternative pathway; factor B is divided into a small fragment (Ba) and a larger one (Bb) [648]. Proteins are activated by two pathways: the classic and alternative pathways (Fig. 1.63) [648].

The *classic pathway* is activated by antigen–antibody complexes, the alternative pathway by microbial-cell walls, and the lectin pathway by the interaction of microbial carbohydrates with MBP in the plasma [618]. This pathway is so called because it was described first, it is more effective, but to be activated requires the presence of acquired immunity. The initial seed is C1q, the first component, with a MW of 400 kD, which interacts with antigen–antibody complexes, or with IgM or IgG_{1-3}. To activate IgM, with a much higher MW, a single pentameric IgM is sufficient, with IgG_3, IgG_1 and IgG_2 following in an orderly fashion. IgA, IgD, IgE, and IgG_4 cannot bind to C1q; consequently no such antibody is able to activate this pathway. Complement interactions with natural antibodies are of crucial significance for the host, being inhibited complement-mediated autoimmune reactions [350]. More rarely, activation may be mounted by various substances, including bacterial LPS, CRP, certain viruses, etc. Activated C1q activates C1r, which, in turn, activates C1s, with MWs of 95 and 85 kD, respectively, to form a C1 complex. C1s, if activated, is able to act on its natural substrates, namely C4 and C2 [633].

C4 is a 180-kD gp synthesized by macrophages; activated C1s results in C4 cleavage into anaphylotoxin, C4a, and a larger fragment, C4b. C4b possesses several functions, especially that of binding both to molecules adjacent to the antigen–antibody complex that has initiated the cascade and the next component, C2.

C2 is a 115-kD gp; more than by C4b, it is activated by molecules next to C1s, but remains bound to a complex with C4b to form the C3/5 convertase (C4b2a), which in turn splits and activates both C3 and C5 [345].

C3 (1.2 g/l) has a central role in the complement cascade: it consists of two S-S-linked α and β chains. When C3 is activated by the convertase, two highly active biological forms produce a small peptide, C3a cleaved from the α chain, and a larger C3b fragment [159]. C3 splitting is due to C3/5 convertase, secreted through both pathways [648].

The *alternative pathway* was discovered more recently, but is phylogenetically the earlier pathway. It includes C3 and factors B and D. Activation results also from non-immunological mechanisms and yields physiologically active substances, thus achieving the complement bactericidal and opsonic effects in the absence of bound antibodies for initiation. The pathway is triggered by contact of complement proteins with LPS from cell walls of bacteria, virus, yeasts, parasites, a factor present in cobra venom, and most likely by aggregated IgA not activating the classic pathway [241].

The antibody-independent activation calls for an extreme instability of internal bonds of the native C3 molecule. Based on such potentialities, C3b binds factor B, thereby forming the C3bB complex, further activated by factor D, which cleaves factor B while bound to C3b to generate the enzymatic complex C3bBb. This complex acts as a C3 convertase and, similarly to the classic pathway, releases C3a and C3b from C3, allowing C3b to resume its properties, increasing C3 convertase and C3 activated levels. A closed circuit is established, where the alternative pathway acts as a positive feedback loop with active amplification; therefore more substrate is cleft, more C3b results. If this mechanism remains uncontrolled, it could rapidly consume the entire C3 and the subsequent components of the cascade. Consequently, this amplification is balanced by a rapid C3bBb complex dissociation. The P binding stabilizes this enzyme. C3b is also largely inactivated by factor H, which competes with factor B to bind to C3b, practically preventing C3bBb formation, and by C3b inactivator eliciting a further C3b degradation to C3c and C3dg fragments. Certainly, factor H and the proteins linked to its binding site contribute to the protection of healthy host cells, regulating C3 activity [689].

Notably, C3b is present in trace amounts in normal serum, probably because there are low concentrations of factors B and D. It is also postulated that LPS of Gram+ bacteria and other substances that trigger the alternative pathway amplification loop somehow protect the small C3b amounts from total inactivation, so that the above substances initiate the alternative pathway. There is evidence that thioesters are present in the native forms of complement proteins C3 and C4 and that their molecular conformational changes dramatically on activation [122]. C3b is a 77 amino acid residue polypeptide and following the above-mentioned changes exposes the thioester bond, which is very reactive, and interacts with amine ($-NH_2$) and hydroxyl (–OH) on proteins and carbohydrates, allowing C3b a rapid covalent link to other biomolecules, since the thioester half-life is 60 µs while that of native C3 is >200 h [470]. Therefore, thioester hydrolysis ensures that activated molecules do not diffuse away from the activation site to bystander cells of the host [122]. As is seen in Tables 1.60, 1.61, C3 is distributed to different receptors (CR1, CR3, CR2) through its ligands (C3b, iC3b, C3dg), thus being capable of interacting with different cell types and bringing about a large spectrum of biological functions (Table 1.59), considering that C3b also has opsonizing properties [18].

When the *common final pathway* is activated, C5–C9 assembly and activation constitute the lytic activity of complement on target cells. C5–C7 are globular proteins with a MW of 180, 130 and 120 kD, respectively. C3b acts as an acceptor site for C5, which is cleft to form two anaphylotoxins, a small fragment, C5a, and a larger, C5b, which binds C6 and C7 to form a C5b67 or C567 complex on the cell membrane, which in turn, through conformational changes, modulates C8 and C9 activation, two 160- and 80-kD proteins, respectively [633].

The final act is the polymerization of perforin-like C9, around the C5b678 complex, which links six C9 molecules involving the assembly of MAC (*membrane attack complex*) (Fig. 1.63) with a MW of $\approx 10^6$ D resembling perforins, since it is a molecule forming pores on membranes with walls constituted by C9; in this way there is Na influx and K outflow, with a consequent increase in membrane permeability and subsequent target cell lysis [648].

The finding that MBL (mannose-binding lectin) residues binding to mannose can initiate complement actiation was followed by the discovery of the MBL-associated serine protease (MASP) enzymes. MBL activates complement by interacting with two serine proteases 1 and 2 (MASP1 and MASP2). MBL binding to its microbial ligands activates MASP1 and MASP2. MASP2 cleaves and activates the complement components C2 and C4 and MASP1 may cleave C3 directly [338]. The cleavage products C2a and C4b then form a C3 convertase, which initiates the complement cascade by cleaving the C3 protein. The MBL complex and its proteases functions similarly to the C1 complex of the classic complement cascade [345]. These components of the complement system have been named the MBL pathway [633].

Activation of the whole cascade elicits the formation of several products with different biological activity: some adhere to external cells, altering their properties

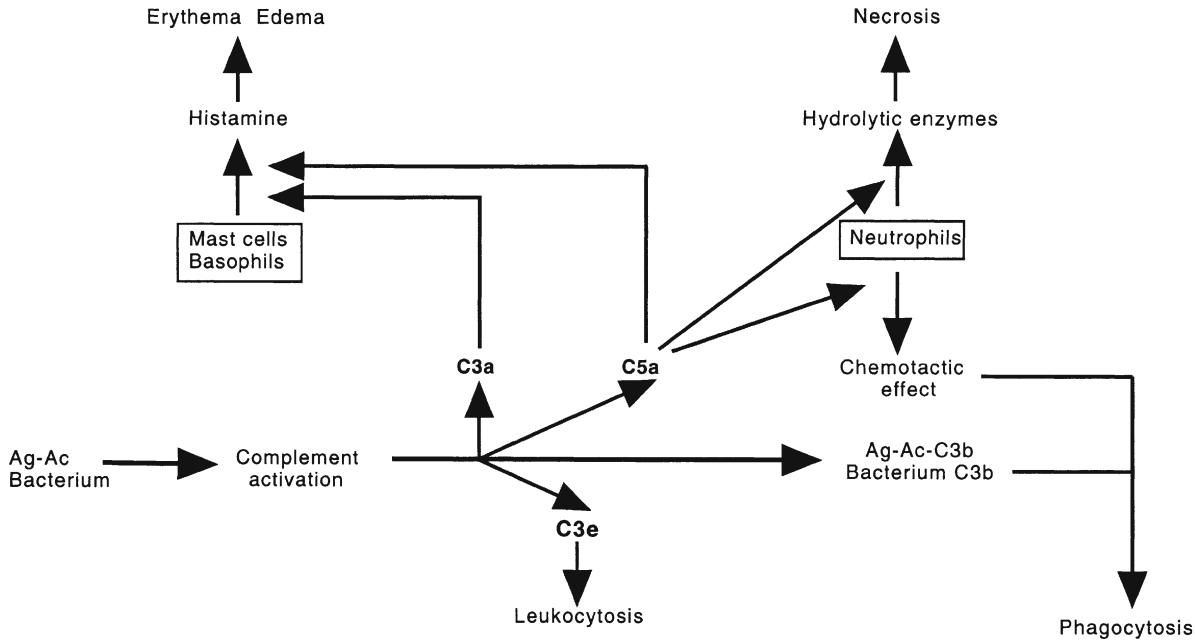

Fig. 1.64. Role of complement in inflammation. (Modified from [18])

and determining the lysis, for example, of infecting microorganisms; others provoke a local inflammatory reaction [260]. Complement thereby plays an essential role in each humoral defense system against external aggressions. A particular characteristic of this system is the lack of action specificity and intervention against harmful agents of varying nature, although antibody responses form a substantial way of activation; however, such aspecificity, if on the one hand it allows notable savings of selective defense systems, on the other hand it can foster an aggressive response against host components [159]. Table 1.59 and Fig.1.64 [18] document how complement actively participates in host defense and inflammation, and Tables 1.60 and 1.61 summarize both features and functions of complement receptors and regulatory proteins. Several cells are expressed, namely, known integrins including CR3 (CD11b/18) and CR4 (CD11c/18) [53], CR2 (CD21), able to activate B lymphocytes, and CR1 (CD35) distributed to human red cells. Some proteins act as regulators, just to control undesired activities: CR1, DAF (decay accelerating factor), CD55 and MCP (membrane cofactor protein), or CD46, prevent the formation of a full C3-splitting enzyme and related biological effects; CD59 or MACIF (membrane attack complex inhibitory factor) and C8 bp (protein binding C8) or HRF (homologous restriction factor) preclude a full MAC development [241]. During the activation C3a, C4a, C5 anaphylotoxins are up-regulated, genetically correlated, but also efficient in different ways (C5a≫C3a≫C4a), for which phagocytes, endothelial cells and smooth muscle cells express receptors, also mediating infectious germ contact with antibodies, complement and phagocytes. C5a, generated by activation of both complement pathways, is the most chemotactic for PMNs, also inducing their microbicidal activity [648]. Anaphylotoxins are active but with a negative role in inflammation, causing aspecific release of histamine and other mediators from metachromatic cells and their consequent degranulation, increasing vascular permeability. C5a is much more active in provoking bronchoconstriction and smooth muscle contraction, it binds to specific receptors on bronchial and alveolar epithelial cells, vascular smooth cells, endothelium, etc., delivering an unexpected up-regulation to various target cells. C5a also couples with a G protein transducing signals to the cell [637]. Additional active complement fragments deliver biological activity: macrophage distension by Bb fragment, Ba fragment is chemotactic, C2 kinin (C2 fragment) increases vascular permeability, and C3e (Table 1.59) increases circulating leukocyte titers mobilizing medullary reserves [18].

To confirm such collaboration of two levels of immunity, we mention that CD19, a component of acquired immunity, is associated with CD21 receptor of C3d and thus is part of innate immunity [571]. CD19 is necessary for normal antibody responses to antigens, being dependent on B–T interactions, and hence it amplifies signal transduction [571]: for this purpose a cross-linking with mIgs and a complement covalently linking carbohydrates to C3d fragment and PSAs are necessary [122]. Regarding infectious diseases, recent studies have demonstrated the substantial defense capabilities of C3 and C4. Fixation of PSAs, with C3d support, to FDCs and B cells of the marginal zone equipped with CD21 on their surface shows that an important anti-infective function is played by the spleen [423], scarce in babies

aged <2 years and absent in C3-deficient individuals [633]. C3d deposition on external membranes of noxious cells is able to perforate such cells, followed by signaling to immune cells and increasing immune stimulation; therefore a molecular adjuvant of innate immunity may select antigens for recognition by acquired immunity [116]. These results should be complemented, in this context, with pathogenetic implications, such as HIV part opsonization with C3, which widens virus diffusion, and usage of CD55 as a receptor for *Escherichia coli*, CD35 and CD21 (CR1 and 2) from virus and mycobacteria, CD46 from measles virus and M protein CD46 and/or H factor from *Staphylococcal pyogenes* for adhesion to keratinocytes [415].

Another machinery put forward by bacteria is a mimicry to hold the products of complement activation off the cell walls to resist their attack. Further capsules containing sialic acid are very poor activators of the alternative pathway in the absence of antibody, in addition to representing an effective defense barrier [159]. *Endotoxin* (an LPS) and its receptor CD14 [537] is a cell-wall component of the outer membrane of Gram– bacteria, which can thus be protected, either because they activate complement at a safe distance from their outer walls, disposing of long lateral polysaccharide chains, or because they are released directly from bacterial walls in a soluble form [97]. Early in life, endotoxin *promotes the development of Th1 CD4⁺ T cells* at the expense of proallergic Th2 $CD4^+$ T cells. Evidence suggests that the lack of endotoxin in the environment might lead to a higher incidence of asthma [537]. A further protective technique employed by bacteria is to release enzymes activating complement proteins adherent to their walls, or borrowing molecules regulatory of their function from host cells, namely, CD55 and CD59, utilized for protection from lysis, as is the case of HIV isolated from cells of patients with current AIDS [484]. There is also a chance that bacteria, virus and parasites are able to inhibit complement activation and elaborate factors with immunoregulatory properties or with a wide spectrum of noxious actions (Table 1.29), proteins with IL-like activity and molecules activating metachromatic cells [168]. Such data could justify a more focused vaccine preparation, thus suggesting that in the future strengthening the antimicrobial therapy inhibiting complement activation may be successful [415]. *Genetic defects of complement components* evaluated on ≈550 patients are marked by recurring infections that are mostly systemic, autoimmune diseases and vasculitis, in addition to pyogenic infections caused by C3 deficiency [632]. *Early in life* severe infections may be complicated with glomerulonephritis [633]. These defects represent 2% of PIDs [544]; the deficiency of the C1-INH control protein is discussed in Chap. 8.

The *liver* increases APP production during the acute phase. These proteins are host protectors since they eliminate reactive O_2 radicals, control serine proteases, activate complement [271], enhance resistance to infections, promote the repair of damaged tissue, and thus participate in the humoral machinery that makes up a second defensive strategy. AAP is a heterogeneous group of proteins such as CRP, α_2M, α_1-antitrypsin, serum amyloid P component (SAP), fibrinogen, ceruloplasmin, C3, etc. (Table 1.62) [148], several depending on NF-κB for an efficient transcription [270]. Inducible by macrophages activated together with platelets, they quickly mobilize as soon as a danger to tissue integrity is announced, including wounds, trauma, and microorganisms, to limit local damage and rapidly enhance host homeostasis, favoring both resolution and repair of damaged tissues [538]. During this process, IL_8 and MCP are synthesized by endothelium, two chemoattractants for neutrophils and monocytes, respectively, while TXA_2 and diverse PGs act on the vascular tone and mediate vasoconstriction and vasodilation, and LTB_4 has the task of attracting phagocytes. APPs are divided into two groups depending on their induction by human hepatocytes [31]:

- By IL_1, IL_6 or TNF, serum amyloid A protein (SAA), α_1 acid gp, C3 and CRP
- By IL_6 fibrinogen, α1-antichymotrypsin, haptoglobin, ceruloplasmin, hemopexin

2d. *Pentraxin* levels substantially increase in response to tissue injury or inflammation (Fig. 1.65) [31].

As is seen in Table 1.5, IL_1 especially regulates CRP, while IL_6 acts on the liver to increase APP synthesis, resulting in a reduction in albuminemia. CRP has the ability to bind to several microorganisms, containing phosphorylcholine in the membrane, the complex having the property of activating complement by the classic pathway. This enhances complement-dependent bacteriolysis, phagocytosis and production of biologically active peptides [538]. ILs raise body temperature (endogenous pyrogens) through PGE_2, also inducing EGF production, and through angiogenic activity. IL_1 and IL_6 in turn act on the adrenocortical axis with resulting ACTH production and thereby cortisol production. Negative repercussions on the acute phase are mediated by IL_4 and IL_{10}, which block the reaction within 24–48 h [31], and by SAA and SAP, which, being IL-induced, allow the adoption of strategies to reduce their levels during chronic inflammations [538].

Structurally and functionally correlated to C1q protein of the classic pathway are the *collectins* [140, 211] (Table 1.62), belonging to the lectin family, and another group of molecules active in first-line defense [140, 490]. Collectins are so named because they consist of a collagenous domain linked to the calcium-dependent lectin domain [345]. According to a fascinating hypothesis, they bind to a wide spectrum of microbes, to interact in perspective with cells or with complement as an active part in the antimicrobial defense [211, 490]. Among them we note the MBL, a plasma protein with many attributes including a crucial role in the above defense, being a member of the Ca-dependent lectin

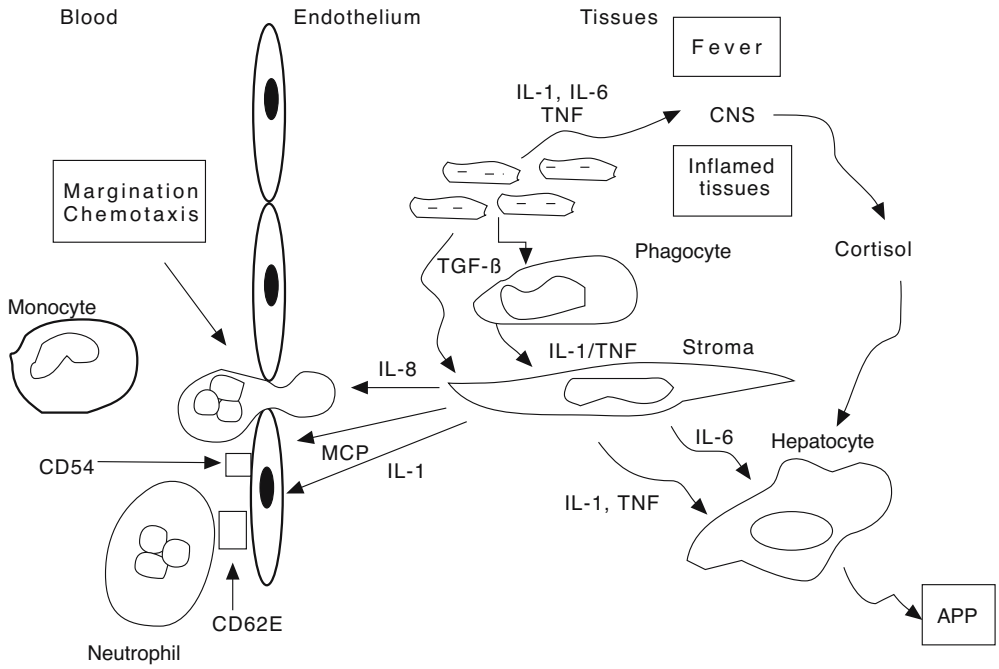

Fig. 1.65. Interactions between cells and ILs in the acute-phase response. Platelets and phagocytes release in the site of tissue lesion the first ILs, activating the adjacent stroma and endothelium, which in turn releases additional ILs. The hepatic response is activated following production of ACTH and cortisol. *MCP* monocyte chemotactic protein. For other abbreviations, see the list. (Modified from [31])

Table 1.62. Main recognition molecules of the innate immunity system

Molecules	Structure	Localization	Ligands	Function
Humoral receptors				
CRP	Pentraxin; Ca^{++}-dependent lectin	Liver synthesis; APR; increases (1 µg/ml to >1 mg/ml) in plasma	Microbial PSs, phosphatidyl-choline	Activates complement and opsonization, enhances phagocytosis
SAP	Pentraxin; Ca^{++}-dependent lectin	Liver synthesis; NL=30 µg/ml	ECM protein; microbial cell wall CHO	Enhances phagocytosis and opsonization, stabilizes ECM proteins
MBL	Collectin; has 18 CRD sites/ molecule on helical collage-nous domains	Liver synthesis; NL up to 10 µg/ml, varies with allelic variants	Microbial cell wall saccharides	Binds C1q collectin receptor; activates complement; enhances phagocytosis; modulates CD14-induced cytokine synthesis
LBP	Lipid transferase	Liver synthesis; NL=<5 µg/ml; increase to 50 µg/ml with APR to serum LPs	Transfers LPSs to CD14 and from CD14 LPSs; has bactericidal power	Enhances sensitivity to LPSs; system for inactivating LPSs; has bactericidal power
sCD14	Leucine-rich protein	Plasma protein; NL=3 µg/ml; origin perhaps from myelo-monocytic cells (unknown)	LPS; several microbial cell wall components	Enhances sensitivity to LPS 100- to 10,000-fold, complex with LPS binds to receptors on endothelium, PMNs and macrophages
C3	S_2-linked dimer	Liver synthesis; NL=1 µg/ml; induced by APR	Forms ester linkage to OH-groups on CHOs and proteins	Attachment of ligand for receptors such as CD21 and CD35

Table 1.62. (Continued)

Molecules	Structure	Localization	Ligands	Function
Cellular receptors				
Mannose receptors				
Macrophage MR	8 CRDs	Tissue macrophages; endothelial hepatic cells	Multiple CHO	Potentially targets antigens bound to class II molecules
DEC 205	10 CRDs; mannose-type receptor	Dendritic cells; thymic epithelium	Multiple CHO	Potentially targets antigens bound to class II molecules
Scavenger receptors				
Type I	Type II trimeric transmembrane protein with endothelial helical collagenous and terminal SRCR domains	Tissue macrophages; hepatic cells	Bacterial and yeast cell walls	Clearance of LPS and microbes; adhesion
Type II	Alternatively form missing terminal SRCR domain			
MARCO	Extended form similar to type I	Marginal zone of spleen; medullary lymph nodes; macrophages	Bacterial cell wall	Bacterial clearance
LPSR CD14	Leucine-rich protein; lipid-anchored glycoprotein	Monocyte-macrophages; PMNs	LPS; several microbial cell wall components	LPS sensitivity; microbial clearance; pro-inflammatory cytokine induction
Complement receptors				
CD35 (CR1)	30 SCR	Monocyte-macrophages; PMNs; lymphocytes	C3b, C4b	Enhances cleavage of C3b and C4b
CD21 (CR2)	15 SCR	B lymphocytes; FDC	iC3b, C3dg, C3d	Increases B-cell activation by antigens
CD11b, CD18 (CR3)	Integrin	Monocyte-macrophages; PMNs; NK cells	iC3b, fibrinogen, LPS	Adhesion; LPS clearance

APR acute phase response, *CHO* carbohydrates, *CRD* Ca^{++}-dependent carbohydrate recognition domain, *CRP* C-reactive protein, *ECM* extracellular matrix, *LPS* lipopolysaccharide, *LBP* lipopolysaccharide binding protein, *MBL* mannose binding lectin, *MR* mannose receptor, *NL* normal levels, *PSs* polysaccharides, *SAP* serum amyloid protein, *SCR* short consensus repeat, *SRCR* scavenger receptor cysteine-rich domain.

family that binds to microbial carbohydrates to initiate the lectin pathway of complement activation [345]. MBL is formed by a head region that binds to mannose residues and a tail with a triple helix mimicking C1q and thus activates several complement fractions, eventually killing and opsonizing the invader [490]. In particular, MBL appears to be a potent mediator of innate immunity in infants aged 6–18 months, in whom passively transferred maternal antibodies have disappeared and the immune system has not yet matured [575]. MBL levels are comparable to adult levels at 3 months of life, with a wide range (from 10 ng/ml to 10 mg/ml) that increases during APR [575]. Chapter 22 reports a susceptibility to infections caused by MBL defect; however, this phenomenon is diversely interpreted related to large interindividual variation in MBL levels [313]. Additional collectins have sparked interest, such as bovine conglutinin, another opsonin inducing Gram– bacteria eradication by coating them with C3b, which can activate opsonization [648]. The family has further expanded to include SP-A and -D (surfactant protein A and D), able to stimulate phagocytosis and agglutination of Gram–

bacteria and virus, indicating a role in the removal of particulate material from the airways [211, 490], bovine collectin-43 and two novel proteases associated with MBL (MASP) [140].

3. Phagocytes fulfill basilar functions of nonspecific defense: one of their main assignments is to present selected antigens to T and B lymphocytes. The cells are divided into circulating, including granulocytes, macrophages and eosinophils, and nondividing, the macrophages (Fig.1.32 c, d, e) distributed throughout body tissues and assuming specialized structures and functions related to the different locations where they operate such as Kupffer's cells and splenic macrophages in the red pulp (clearance of corpuscular elements and soluble factors), LCs and splenic macrophages in the white pulp and lymph nodes (processing and presentation of the antigen to T cells), and finally bone marrow macrophages (growth and differentiation of hemopoietic cells) (Table 1.63) [352]. IFN-α sensitizes macrophages to microbial recognition by up-regulating the TLR3, TLR4 expression also enhancing the MyD88 (myeloid differentiation protein gene), TIR (Toll/IL_1R), TIR domain-containing adaptor inducing IFN-β (TRIF), IKKη, RIP-1, IL_{28} and IL_{29} genes expression [529]. Mast cells are provided with phagocytic activity [348] and therefore able to orchestrate, for host protection, inflammatory responses against invading microbes, in addition to tissue damage by antibody-independent activation [168]. Mast cells are to-day seen as a sentinel in host defense against bacterial infections, and evidence for their involvement in early responses to viral and fungal pathogens is growing. Mast cells are activated during innate immune responses by multiple mechanisms, including well-established responses to complement components. Changes in vascular permeability induced by *early release of preformed mediators* and lipid mediators enhance the availability of complement components and some initial inflammatory cells to the site of infection [332, 347]. Mast cell proteases have also been demonstrated to play critical roles in vivo in the recruitment of both neutrophils and eosinophils to sites of inflammation [502] and an *immune complex hypersensitivity reaction in the synovium* [347].

Circulating and nondividing cells, *PMNs* (Fig. 1.32) have CR1, CR3 receptors, for IgG Fc fragments and several others (Table 1.64) [18]. PMNs recruited to the site of injury ingest the intruders, bacteria, foreign materials or damaged tissues: IgGs and C3b are dedicated to coating infecting particles, promoting both opsonization and subsequent phagocytosis. Prominent is the role played by monocytes, numerically inferior to PMNs, but with the advantage of not being terminal cells and changing into tissue macrophages, two to three times larger than PMNs, readily recruited during local inflammatory or degenerative processes [345]. When the inflammatory process initiates, macrophages instigate a bit of a delayed maneuver, whereas PMNs, more mobile, are the first to accrue, perhaps facilitated by IL_5 augmenting IgA production (Table 1.5), but above all by IAPs (integrin associated proteins, CD47), which activate PMNs, even in extravascular sites [302]. Such cells are also termed *professional phagocytes,* because they are provided with membrane receptors for IgG_1 and IgG_3 Fc fragments and C3b fragment. Nonspecific inflammatory reactions are the first components of innate immunity to appear in the phylogenesis, and it seems likely that such primitive responses have influenced the immune responses' evolution. In this sense, Th response polarization could have been an evolutive consequence of nonspecific responses of a divergent sign directed to counteract different types of infection [470]. *Macrophages* and NK cells exemplify the primitive limb of IFN-γ-dependent immune responses required for defense against infection with virus and other intracellular invaders, whereas metachromatic cells could have evolved to combat extracellular parasites [470]. Macrophages, perhaps the phylogenetically more ancient immune cells, can secrete IFN-γ due to their IL_{18} synthesis [669]. Stimulated, moreover, by bacterial and viral contact and primed by CD14 a receptor that functions with TLR4 in LPS responses [194] and γδ T cells [111], in the first stages, macrophages release TNF-α and IL_{12}, which synergize with T-cell generated IL_2 and macrophage-generated IL_{15} [68], and both prime *NK cells* [583] *to express IFN-γ* [146]. IFN-γ and IL_{18} form two potent stimuli to suppress IgE responses [421, 669], enhancing macrophages' microbicidal power. This power is necessary for macrophages to combat invasions by endocellular facultative microorganisms, particularly resistant to the phagocyte microbicidal action despite Igs opsonization. Microorganisms duplicate within the macrophages; however, the trapped intruders are not killed:

their intracellular growth can be blocked only by an IL intervention [251].

During the direct antibacterial activity supplemented by macrophages, NK cells and, while the response progresses, Th1-like ILs prime CSMs and HLA class II molecule expression on macrophages, thus preferentially triggering Th1 T cell expansion in concert with IL_{12}, whereas Th2 T cell response is limited by IFN-γ counterregulation [251]. However, during a chronic infection intracellular bacteria may prime HLA class II molecule expression on macrophages when CSMs are absent, thus provoking Th1 T cell anergy [251]. Th2 T cells dominate only because counterbalancing counterparts are missing and consequently play a large part in the Th1 T cell reduction in numbers [251]. Therefore NK cells and macrophages cooperate to eliminate microbial infections [25]; on the contrary, Th2-like ILs sanction their progression [365]. However, it is possible that endogenous IFN-α/β reduce IL_{12} expression, also stimulating CD8 T cells, as if NK-cell and IFN-γ protective activity should be hampered to avoid unwelcome effects for the host [43].

To adhere to microbes, *neutrophils* engage CD11b/CD18, potentially playing a vital role in cell activation and triggering the oxidative and nonoxidative apparatus in an attempt to destroy the invader (or the host tissues), while adhesion mechanisms provide an environment where killing can progress protected by tissue fluids [154]. From this viewpoint, the degranulation has three important roles in host defense with release of granules (Table 1.23):

- Azurophil is able to potentiate the digestive and microbicidal activities of phagocytes
- Secondary or specific granules enable the cells to regulate inflammation
- Tertiary, associated with translocation of receptors for CR1, CR3, FMLP (formylmethionyl leucylphenylalanin), laminin, NADPH oxidase and cyto-

chrome c and subsequent interaction with these receptors, helping neutrophils in their phagocytic activity [315, 663].

The process of phagocytosis schematically includes six different stages:

1. Adhesion to foreign particles
2. Chemotaxis leading to contact with particles
3. Opsonization mediated by IgGs interacting with peptides and enhancing their digestion
4. Ingestion
5. Metabolic activation
6. Lysis

1. Adhesion. Adhesion is mediated by cytophilic IgGs present on the surface of particles to be phagocytosed, and by their Fc receptors on phagocyte membranes. Part of the cells remain in the bone marrow as part of a large reserve pool (*fixed cells*). Two PMN pools are included in the circulation, the circulating PMN pool and marginating pool along the postcapillary of vascular endothelium. As soon as the first signs of injury or infection are manifested, fixed and circulating PMNs are mobilized and increase their adhesion to the epithelial lining of local blood vessels, supported by endothelial cells and mediated by IL_1 and other mediators of inflammation. Even if clear-cut mechanisms are not fully understood, it is likely that PMN adhesion to cells is mediated by surface glycoproteins such as iC3b, β integrins and interactions between CD11b/CD18 and iC3b for complement-coated bacteria or endothelial cells [663], which in turn synthesize CD62E. In addition, PMNs possess receptors for ECM components, laminin and FN, facilitating their adhesion to host tissues or bacteria walls [311].

2. Chemotaxis. Chemotaxis is the start of directional migration of organisms or other cells provided with motility, able to travel up to a concentration gradient of *chemotactic factors* or *chemotaxins* (chemo + "ταξις," distribution). Cell response is directed to a large extent by signals released from chemotactic factors, or cell locomotion is piloted toward sites where signals are more expanded. Differently from tissue eosinophils, present at the level of epithelial surfaces and in contact with the environment, fixed and circulating PMNs are absent from tissues until they are recruited from the bloodstream as a result of tissue damage. To meet this demand, a variety of chemotactic factors can potentially regulate PMN recruitment and migration to the site of inflammation: these stimuli yield chemotaxin production and, in ever greater concentrations, attract circulating PMNs to capillaries around the site of injury, where they actively insinuate themselves between endothelial cells. Studies have verified that if PMN migration is delayed as little as 2 h, their capacity to localize the inflammatory process is severely jeopardized [311]. Among the more known chemotactic factors, we enlist FMLP, LTB_4 and C5a, which certainly play the most important role

Modified from [663].

[345]. Others derive from cell debris, the bloodstream (C567, fibrin or collagen fragments), lipids (LTB_4, PAF), peptides containing *N*-formyl-methionine (from bacterial or mitochondrial protein breakdown), including N-FMLP with specific receptors on PMN membrane, and ILs such as GM-CSF and IL_5 [663]. Apart from bacteria, macrophages, lymphocytes, platelets, and mast cells can also attract PMNs; certain chemotaxins such as C5a, LTB_4 and PAF are specific for varying types of leukocytes and some *chemokines* for PMNs (Table 1.57). PMNs with nanomolar amounts of chemotactic factors respond by increasing both adhesion and the number of receptors specific for such factors. Binding of chemoattractants and activation of G proteins and their effector enzymes result in the cell orientation toward the higher concentration of the stimulus. Cell shape changes from a round to a triangular structure with the cell front at the triangle base. Accordingly,

rugosities are formed on the cell surface and following AA metabolism activation, membrane polarity is altered because rugosities are rapidly concentrated on a pole: here contraction waves begin and the cells utilize microactin filaments, which provide the contractile forces required for cell movements. Microtubules composed of tubulin allow the locomotion, and actin alternation of polymerization and depolymerization may be a critical regulator of microfilament contractility [311]. The HIgES shows the close correlation between efficient chemotaxis and a normal response to infection, as well as the possible influence of histamine and additional amines on PMN mobility. Table 1.65 [663] outlines the defects of chemotaxis depending on their origin: chemoattractants or cell substance deficiency (the phagocyte defects may have an 18% prevalence within PIDs) [544].

3. Opsonization. Bacteria expressing capsular polysaccharides pose a unique problem to phagocytosis inhibited by the charge and hydrophilia typical of such bacteria, especially the polysaccharide capsule of pneumococci, a virulence factor expressing a strong negative chemotactic activity. *Opsonization* (from the Greek "οφωνειν," acquire foods and therefore prepare for eating) is a not immunological contact between cells and bacteria, mediated by the *opsonin* family comprising Igs, CR3, CR4, and FN. Igs contribute chiefly via IgM, IgG_1 and IgG_3 with CD23 or CD64, interacting with epitopes on bacteria via its Fab portions, while C3b and iC3b – induced by both classic and alternative pathways – adhere to the bacterial (or other intruder) surface to approach neutrophils. Antibody fixation also allows activation of the complement classic pathway so that the Fc portion, Clq and C3 act synergically to facilitate the capture of bacteria from phagocytes. Complement proteins exercise an important conclusion of Ig-mediated opsonization, because CR and FcR concurrent involvement often fulfills a marked synergic action in activating phagocytes and stimulating their functions. In this context, addition of complement to Ig-opsonized bacteria promotes phagocytosis, in parallel reducing the Ig number necessary for an efficient ingestion of bacteria [345]. An additional, potent opsonizing stimulus is supplied by *tuftsin,* a tetrapeptide (Thr-Lys-Pro-Arg) produced by the spleen. Its action appears to be indispensable, as demonstrated in patients with familial deficiency of this peptide and in splenectomized patients, who suffer from severe infections occurring with *Candida, S. aureus,* and *Staphylococcal pneumoniae* [311]. Macrophages, IgA and IgE receptors also play a striking role in opsonization. Lectins have been identified on different cell membranes, mainly macrophages, as receptors of mannose-fucose, galactose binding laminin, sialic acid or sialoadhesine, and β-glucan with specificity for CD11b/CD18. However, there are bacteria blocking opsonization or deviating C3b covalent binding and MAC adhesion to a position on the cell surface distant from the cell membrane where no defense mechanism can be exploited, or resisting opsonization by expressing capsular polysaccharides, as mentioned above: C3b causes their breakdown by binding Factor H instead of Factor B [159].

4. Ingestion. The concerted action of two receptors multiplies hundreds of times the ingestion of phagocytosed particles previously trapped within vacuoles. The cell membrane binds and invaginates engulfed particles adhering to its surface, thus forming a *phagosome,* subsequently approximating cytoplasm and fusing with lysosomes to create the structure called *phagolysosome,* with reduced pH. The final transformation therefore takes place in phagolysosomes, membrane-bound intracellular vesicles containing a rich supply of proteolytic enzymes operating degradation, thus completing the reduction to constituents of amino acid fragments: a portion of antigen fragments thus produced is expelled and transported to the cell surface where it is expressed, but the major portion is stored internally in endosome [540].

5. Metabolic Activation. Phagocyte exposure to varying stimuli increases cell respiration and, consequently, O_2 generates reactive metabolites within the phagosome to clear target cells from the body, that is, $O_2^{\cdot -}$ then reduced to H_2O_2, as described below. Such O_2 products are highly toxic since they oxidize cell components of parasites, tumor cells and other tissues [159].

6. Lysis. After a preventive opsonization with formation of pseudopods, by virtue of FcεRII and CR3, the cells can bind more tightly to antigens, facilitating antigen uptake and internalization (endocytosis). Following lysis carried on by the C5b-9 terminal complex, the final disruption of imprisoned bacteria ensues, also mediated by MPO catalyzing H_2O_2 transformation into HOCl with bactericidal activity. Phagocytosis is the end point, therefore any interruption of the process compromises host defenses [540].

Microbicidal Activity

O_2-Dependent Mechanisms

The anti-microbial PMN activity depends on O_2-dependent or O_2-independent microbicidal mechanisms. A paradigmatic example of the lacking activation of O_2-dependent microbicidal mechanisms is *chronic granulomatous disease* (CGD) resulting from a genetically determined enzyme deficiency of leukocyte intracellular bactericidal function, thus being unable to kill ingested bacteria or fungi, particularly catalase-producing bacteria. CGD especially results from genetic defects in the various components of NADPH-oxidase, a potent enzyme that is central in the respiratory burst. This process reduces O_2 to superoxide and then to H_2O_2, thus leading to NADP formation. Activation of glucose oxidation during phagocytosis starts trouble for each

invader. A roughly tenfold increase in the activity of the hexose monophosphate shunt is provided by an increase in the NADP/NADPH ratio, determined in turn by activity of the same oxidase and a chain of redox reactions involving glutathione. This enzyme system has the goal of transforming into H_2O and O_2 the H_2O_2 produced in excess and potentially toxic for cells. Catalase-positive bacteria cannot be killed by the phagocyte MPO/halide system, since they synthesize catalase destroying any excess H_2O_2 they produce, whereas catalase-negative bacteria are killed, since they fail to stop H_2O_2 production and trigger the MPO/halide system: for this reason in CGD patients they play the role of scavenger bacteria. Two oxidoreductive groups involved in the electron transport chain, namely flavine and cytochrome b558, are defective in the X-linked from (≈ 60% of cases), but not in autosomal recessive CGD (≈ 30%). *Glucose-6-phosphate-dehydrogenase deficiency* (G6PD), inherited as an X-linked disorder, also leads to impaired intracellular killing via the reduced glucose oxidation. *MPO deficiency,* inherited with an autosomal recessive pattern, is associated with susceptibility to systemic candidiasis, since intracellular killing is reduced and/or delayed (also greatly) as a result of impaired halide system function. MPO deficiency has a greater incidence than in the past, frequently as a casual laboratory finding in healthy subjects. The underlying basis of such defects is that the oxidative metabolism requires a notable O_2 consumption: $O_2^{\bullet -}$ is generated, reacts with two NADPH molecules and acquires an electron; the reaction takes a few seconds and is followed by bacteria adhesion and phagocytosis via PMNs. The speed highlighting this reaction shows that the oxidase could be localized on PMN membrane [663].

Therefore, an unremitting influx of O_2 radicals is also achieved around and beyond the plasma membrane of phagocytosed intruders, thus intensifying the toxic effects at their expense. One product of this metabolic process, H_2O_2, carries on microbicidal activities, and because of its oxidant properties reacts with MPO stored in azurophil granules and released into phagosomes during PMN degranulation. This highly oxidant enzyme reacts in turn with halide (predominantly iodine and chloride) ions present in phagocytic vacuoles, catalyzing the halogenate reaction (iodination or chloruration), which is as toxic for microbial wall proteins. It should be noted that PNMs undergo apoptosis following an excessive *necrotizing activity* [630] (Fig. 1.34). During oxidoreductive metabolism, additional O_2 radicals are generated (normally imprisoned within phagolysosomes), including $^1O_2$ and OH radicals. *$O_2^{\bullet -}$ toxicity* for bacteria is demonstrated by the high concentrations of superoxide dismutase (SOD) (converting $O_2^{\bullet -}$ into O_2 and H_2O_2), possessed by several O_2-resistant aerobic microorganisms, whereas O_2-sensitive anaerobic organisms are devoid of SOD. Human beings are provided with low SOD levels localized in the cytosol, whose activity does not interfere with $O_2^{\bullet -}$ microbicidal activity within phagosomes, thus protecting cytoplasm from highly diffusible toxic radicals [663].

The following reaction is produced:

1) $2\ \mathrm{NADPH} \xrightarrow[\mathrm{SOD}]{\text{NADPH oxidase}} H_2O_2 + 2\ \mathrm{NADP};$

2) $2\ O_2^{\bullet -} + 2\ H_2 \rightarrow O_2 + H_2O_2;$

3) $O_2^{\bullet -} + 2\ H_2\ O_2 \rightarrow {}^1O_2 + \mathrm{OH} + \mathrm{OH}^-$

$^1O_2$ is an O_2 molecule produced by neutrophils during phagocytosis; it is highly reactive and unstable and emits luminosity (chemiluminescence) as it returns to the ground state. It is formed by spontaneous $O_2^{\bullet -}$ dismutation, or by MPO, hypochlorite and H_2O_2 reactions. This microbicidal action could depend on the ability of splitting double C atom bonds of bacterial membranes. The role played by *hydroxyl radicals* in microbicidal actions is demonstrated by their inhibition of bactericidal killing by means of hydroxyl scavengers, benzoate, ethanol and mannitol [420].

O_2-Independent Mechanisms

In addition to producing *toxic O_2 compounds,* phagocyte cells express bactericidal mechanisms, assuring a relevant defense function, eminently via bactericidal proteins of azurophil granules (Table 1.23), especially considering Chédiak-Higashi syndrome. These proteins bind lipid A and the core oligosaccharides of LPS, thus altering bacterial cell wall permeability and amino acid uptake. Such mechanisms can be particularly important in patients with CGD or MPO deficiency. For example, NO is credited with a powerful antimicrobial action. In a potential biodefense strategy *cathelicidins and defensins* are major families of antimicrobial peptides in mammals with a broad spectrum of antimicrobial activity [169]. Both peptides disrupt the integrity of the microbial membrane, which is mediated by their cationic and amphipathic properties, which enable them to bind to negatively charged microbes and insert into their membranes [342]. An emphasis was given to azurophil granules, delivering *defensins,* which cleave an array of substances, including peptidoglycans of Gram+ bacteria, cationic proteins acting at an alkaline pH, BPI fixing LPS of Gram+ bacteria perforating their membrane, proteins binding the B_{12} vitamin, lysozyme, lactoferrin, an iron-binding cationic protein that blocks the activity of Fe-dependent bacterial enzymes, neutral hydrolases (proteases, nucleases) acting at an acid pH within phagosomes, neutral proteases, etc.

Defensins (α and β) are activated by MMP-7 [118]. To date, 6 α-defensins have been identified; 4 of them are known as α-defensins 1, 2, 3, and 4, the other 2 α-defensins are known as human defensins 5 and 6. There are 14 β-defensins, however, in human beings, 4 types of β-defensins have been identified as yet, plus the ϑ defensins [169]. In keratinocytes IL_{22} activated STAT3 and directly and transcriptionally increased the expression of β-defensin 2 and β-defensin 3 [650]. Defensins form 5%–10% of neutrophil total protein content, have antibacterial or

cytotoxic properties, and are more effective at an alkaline pH, therefore before phagolysosome acidification. These disinfectants against a wide spectrum of Gram+ and Gram– bacteria and *fungi* apparently insert themselves into microbial membranes and inhibit their growth, thus activating host cell processes involved in immune defense and repair [169]. By using chemokine receptors on DCs and T cells, defensins are believed to contribute to the regulation of host adaptive immunity against microbial and viral (HIV) invasion: their killing is consequent to disruption of microbial membrane [660]. Human defensins stimulate IL_1, IL_8, TNF-α release and decrease IL_{10} release [489].

Thus, like the cathelicidins, defensins can participate in immune defense in at least 2 ways, both killing bacteria and influencing the cellular innate and adaptive immune response [169].

Cathelicidins are a class of small cationic peptides that are an active component of mammalian innate immunity and are expressed at high levels in neutrophils, in skin and in other epithelial cells and can act as natural antibiotics by directly killing a wide range of microorganisms [118, 676]. About 30 different cathelicidins have been described in mammals, but so for only one has been identified in humans and one in mice. The human cathelicidin (LL-37) and the murine cathelicidin-related antimicrobial peptide (CRAMP) are both expressed by mast cells [118]. Recent findings suggest that their function is to disrupt the integrity of the microbial membrane, which is mediated by their cationic and amphipathic properties, which enable them to bind to negatively charged microbes and insert into their membranes [118]. Thus, after proteolytic cleavage the cathelicidin-like domain can contribute to innate host defense via inhibition of bacterial growth and limitation of cysteine-proteinase-mediated tissue damage, both functions being complementary to LL-37. LL-37 also represents a multifunctional effector molecule for innate immune defense of the skin [676] and for the local treatment of pulmonary infections [622]. In addition to the antimicrobial effects, LL-37 has been shown to have chemotactic effects on mast cells, which might aid in the migration and accumulation of mast cells at the site of inflammation in several diseases [382].

A defensive role could be assigned to *scavenger receptors,* defined by their ability to carry on the following functions:

- *Macrophage* activation and homing
- *Clearance* of LPS, microbes and toxic substances
- *Phagocytosis* of cells undergoing apoptosis
- *Antigen uptake and/or processing* in the acquired immunity [420].

Macrophages use CD36, vitronectin and thrombospondin receptors to engulf cells undergoing apoptosis [165]. *Eosinophils* are additional cells active in innate immunity, since they arm against parasites and some forms of tumor cells the cytolytic activities of MBP and ECP their cationic proteins. ECP is able to perforate the membrane of a target cell, similarly to the perforins of both CTLs and NK cells.

For completeness or an alternative to antimicrobial defense, we should mention another potent defense establishing a link between innate and acquired immune systems, represented from *DCs* [352], which assure a system of sentinel receptors activated by microenvironmental cellular and tissue damage [221]. A key element supporting this hypothesis is that the innate immune system has evolved an evolutionary strategy, developing several parallel mechanisms, oriented to an immunoregulatory direction, but *sensitive to local injury.* In this context, PLA_2 which in patients with rheumatoid arthritis (RA) is associated with propagation of inflammation, also favored DC maturation and PLA_2-generated DCs stimulated IFN-γ secretion by allogeneic T cells. These effects were correlated with the activation of NF-κB, AP-1 and NFAT. Thus a transient increase in PLA_2 activity generates signals that promote transition of innate to adaptive immunity during the APR [422]. We have discussed complement, NK cells, T-cell TcR and phagocytes. DCs exemplify the pathway joining these mechanisms: activation of any of these mechanisms may be associated with a switch from DC precursors to the mature phenotype [251]. At this level, DCs act as APCs, activated by GM-CSF and TNF-α in synergy with IL_1, IL_6 and IL_{12}: their role is focused on local tissue repair and therefore amplifies a self-limiting control mechanism, to shift the balance of the response back to tolerance. When tissue injury is present, NK cells could provide a negative-feedback effect on antigen presentation [221]. Furthermore, DCs could play a triple role:

- *In viral infections* as potent inducers of CTL cells, also presenting antigens on HLA class I molecules.
- *Immune responses* triggered by the association of allergenic and toxic molecules would prime pollution-activated APC DCs to provide the necessary costimulatory signals to activate T cells specific for those allergens.
- Action *as sensitive sensory receptors,* since DC peripheral sentinels might be regarded as a kind of sensory nerve ending, susceptible to local chemical signals, and designed to monitor tissue damage [221].

The DC defensive effect is probably amplified during acute inflammation, in particular presenting viral antigens to T cells, which may accordingly protect the host against concomitant viral infection [352], or inducing T-cell-mediated tolerance to inhaled antigens, since DCs are the only cells present in airway epithelial cells expressing surface HLA antigens, a prerequisite for antigen presentation [467].

Recent studies have shed light on the pivotal role played by memory B and T lymphocytes, critical for host protection from secondary viral infections (Table 1.42) and ILs within innate immunity, which is entitled to the regulation of several of the nonspecific mechanisms discussed so far, with the objective of clearing infections [688]. Purposely we point out the inhibi-

tion of apoptosis mediated by viral genes (Table 1.19), to guarantee the species survival until genome replication and to counteract host responses to infection [192]. Several viral genes have binding sites either for NF-κB, which can assure their replication, as demonstrated for HTLV-I (human T-cell leukemia virus), or for IL and chemokine receptors (Table 1.57) [688], interfering with their activity and modulating virus evasion strategies [11]. Poxvirus proteins are able to block different arms of the host response against infection (complement activation, IL function, antigen presentation to T cells) or mimic host growth factors [11]. Thus, members of the family activating NF-κB have a key role in the induction of immune responses in mammals, including TLRs [353]. More positively, pathogen recognition, whether mediated via the TLRs or via the antigen-specific TcR and BcR, initiates the activation of distinct signal transduction pathways that activate NF-κB. Activation of NF-κB by these pathways is necessary for lymphocyte activation, expansion, and effector function in response to infection. However, IL_{10} and CSs inhibit NF-κB [470]. *Chemokines* play a versatile role in the defense against infections, even viral: a rapid inflammatory response is expected to counteract bacterial and fungal pathogens, and in this context the fast chemokine induction was observed in several animal models and in clinical studies. Deletion of endogenous genes for MIP-1α in knockout mice provoke a great delay in influenza episode resolution, as well as a reduced CD8 T cell recruitment in infected airways [95]. Above all, CCL3, CCL4 and CCL5 are in the first line against AIDS, highly expressed in the lymph nodes of these patients [9], and when some receptors (CXCR = α and CCR of β chemokine receptor) act as cofactors for HIV entry to macrophages (CCR3 and CCR5) and T cells (CXCR-4) [9, 83, 150], chemokines have an anti-HIV effect primarily competing for receptor binding; thus MIP-1α, MIP-1β and RANTES bind to CCR5 and SDF-1 CXCR-4 [405].

Human TLRs belong to a family of pattern recognition receptors (PRRs) that aid to recognize microbial products derived from several classes of microbes, as well as endogenous ligands that represent a danger signal [448]. Transcripts for TLR4 and TLR2 were expressed in whole tissue extracts of fetal gut and skin [243]. The TLR7-, TLR8-, and TLR9-dependent induction of IFN-α/β and -λ is strictly IRAK-4 dependent and plays an important role in protective immunity to most viruses in humans. IRAK-4-deficient patients may control viral infections by TLR3- and TLR4-dependent and/or TLR-independent production of IFNs. Thus 5 TLRs seem to play a crucial role in this innate immune response [662]. However, *children who had defective signaling* in the molecule IRAK-4 had a greatly increased risk for pyogenic infections [431]. TLRs are structurally characterized by a cytoplasmic TIR domain that, via the signal transduction factor essential for several TLR-mediated responses MyD88, connects the receptor to the intracellular signaling machinery shared by IL_1 and IL_{18} [448]. *LPS are associated with TLRs.* TLR4 and TLR3 recognize LPS from Gram– bacteria [345]. The recognition of microbial components by TLRs leads to activation of innate immunity: progress in elucidating the molecular mechanisms for LPS tolerance has been made through the analysis of TLR-mediated signaling pathways [491, 561]. *So far the TLR family includes* 11 *members that have been identified* [677], *which bind to microbial products, activating host defense responses.* These TLRs and their signaling pathways are represented in such diverse creatures as mammals, fruit flies, and plants, and several of them appear to recognize specific microbial products, including LPS, bacterial DNA. TLR signaling represents a key component of the innate immune response to microbial infection [299]. The analysis of DC and PBMC activation has shown that TLR2 agonists are able to block the induction of IP-10, $IL_{12}p35$, and IFN-γ, but not IL_{15} and IFN-β by TLR3 and TLR4. TLR2 stimulation led to rapid release of IL_{10} that is responsible for inhibition of IP-10 and $IL_{12}p35$ induction [448]. TLR4 agonist specifically promoted the production of the Th1-inducing $IL_{12}p70$ and IP10, which is also associated to Th1 responses. Instead, TLR2 stimulation failed to induce $IL_{12}p70$ and IP-10 but resulted in the release of the IL_{12} inhibitory p40 homodimer, producing conditions that are predicted to favor Th2 development. TLR2 stimulation also resulted in preferential induction of IL_8 and p_{19}/IL_{23} [449]. Thus TLR primary responses to their agonist may be modified by cross-talk between different TLRs [448]. The receptor superfamily also includes $IL_{18}R$ [131]. *Ligands* and chromosomes [537] *for* 10 TLRs, such as TLR1 (4p14), TLR2 (4q32), TLR3 (4q35), TLR4 (9q32-33), TLR5 (1q32-33), TLR6 (4p14), TLR7 (Xp22.3), TLR8 (Xp22) TLR9 (3p21.3) and TLR10 (4p14), *have been characterized* [50, 191, 333, 448]. Stimulation of resting B cells with anti-μ and anti-CD40 antibodies increased expression of TLR9 and TLR10 [50].

The newest member of the TLR family to be identified is TLR11; however, it is not clear whether humans express TLR11, as the murine Ser119 residue appears to be replaced by a stop codon in humans [187]. TLR10 is notably expressed in lung tissue, where involvement in the innate immune responses of the lung to common respirable exposures such as allergens may be a *potential asthma candidate gene* [285], thus suppression of TLR responses may reduce excessive inflammation in chronic diseases [185]. All TLRs with the exception of TLR3 can signal via MyD88, TLRs 2 and 4 utilize MyD88, and TLR3 and 4 can engage TRIF and TRAM (TRIF-related adaptor molecule) under certain circumstances [188, 658]. TLR4 recognizes LPSs and lipoteichoic acids from Gram– and Gram+ bacteria, respectively, and TLR9 is critical for recognizing bacterial DNAs [345]. A CpG oligonucleotide, a TLR9 agonist, also stimulated TLR9 expression in B cells [50]. TLR4 and TRAF6 [374] were shown to induce the activation of the NF-κB signaling pathway: by this pathway, TLR4 activation

induces the expression of a variety of ILs and CSMs [345]. IFN-γ up-regulates TLR4 expression, and was shown to counteract the LPS-induced down-regulation of TLR4 [50]. Recently the TIR domain-containing adaptors have increased in number: they include MyD88, TIRAP (TIR domain-containing adaptor protein), TRIF, and TRAM [491, 560, 658]. These TIR play essential roles in TLR signaling. MyD88 is essential for inflammatory IL production via all TLRs, whereas TRIF is involved in TLR3- and TLR4-mediated MyD88-independent induction of IFN-β [560]. These findings confirmed that TLRs may function as receptors of the innate immune system [345, 560]. Moreover, the activated TLR4 recruits the *MYD88/IRAK signaling* pathway. Further downstream, IRAK and IRAK-2 interact with the adapter molecule TNRF6 that bridges them to the protein kinases TAK1 (transforming growth factor-β-activated kinase) and NIK [261, 372]. Once activated, the MyD88/IRAK signaling cascade bifurcates and leads to the activation of a TF NF-κB and c-jun N-terminal kinase (JNK), which initiate the transcription of proinflammatory IL genes that subsequently drive the transcriptional induction of several IL genes (see above) [374, 563]. However, a dominant-negative version of MyD88 specifically inhibited TLR4-induced NF-κB activation, lending functional credence to the interaction occurring between TLR4 and MyD88 [373, 374]. Genetic, gene transfer, and dominant-negative approaches have involved TLRs 2 and 4 in LPS recognition and signaling [374]. The new IFN, FLN29, is a negative feedback regulator of TLR signaling in innate immunity; FLN29 may thus play an important role in endotoxin tolerance [335]. Two members of the NOD family, NOD1 and NOD2, together with TLRs, have also been shown to be involved in the innate immune response as sensors of specific bacterial components [429]. Genetic variation in the genes encoding the NOD-LRR proteins, and NOD2 in humans and Naip5 (neuronal apoptosis inhibitory protein 5) in mice, is associated with inflammatory disease or increased susceptibility to bacterial infections [79]. NALPs [NACHT (neuronal apoptosis inhibitor protein)], LRR- and pyrin domain (PYD)-containing proteins 1–14 have been defined in the human genome. NALP1 protein forms a large, signal-induced molecular platform, the inflammasome, *resulting in the activation of proinflammatory caspases* [582]. Instead, IL_{32} synergized with the NOD1- and NOD2-specific muropeptides of peptidoglycans for the release of $IL_1\beta$ and IL_6 via a caspase 1-dependent mechanism; the marked expression of IL_{32} in colon mucosa suggests a role of IL_{32} in the pathogenesis of Crohn's disease (CD) [379]. NOD2-S is preferentially expressed in the human colon and is up-regulated by the antiinflammatory IL_{10}. Overexpression of NOD2-S down-regulates NOD2-induced NF-κB activation and IL_8 release. NOD2-S also interferes with the maturation and secretion of pro-$IL_1\beta$ downstream of NOD2 and its adaptor molecule receptor-interacting protein kinase 2. Increased levels of NOD2-S can abolish residual NOD2 signaling by the CD-associated R702W variant. However, interfering with the delicate balance of NOD2 signaling in inflammatory bowel disease, e.g., by changing the ratio of NOD2 splice variants, may have detrimental effects on the CD course [475]. Until recently, most TLR/ligand interactions had been shown to favor Th1-like responses rather than promoting the Th2 responses commonly associated with allergic disease. However, this concept was recently challenged in rodent models, in which both TLR ligand concentration and the route of immunization were shown to induce *a Th2 immune response* [450]. How might this shift be achieved? [537]. Depending on the early environment of the individual, this might lead to Th cells that are dominated by allergy-prone Th2 cells, which support the production of antigen-specific B cells. The increase in the Th2 cells comes at the expense of Th1 lymphocytes [450]. The synergistic interactions of TLR ligands and antigen might have relevance to the exacerbation of IgE-mediated allergic diseases by infectious agents [438]. In addition to host defense against pathogens, the TLR-dependent pathways are involved in a variety of immune responses [560]. Therefore, an important challenge for the future will be to develop suitable suppression of TLR responses to reduce excessive inflammation in chronic diseases [187].

A prominent role in innate immunity is played by *keratinocytes* expressing both TLR2 and TLR4 at the mRNA and protein levels; TLR2 and TLR4 are present in the normal human epidermis in vivo and their expression is regulated by microbial components [432]. The expression of MyD88 has been demonstrated in keratinocytes. LPS and IFN-γ increased the expression of TLR2 and TLR4 50-fold and fivefold, respectively [432].

A prevalent dogma is that a key defense mechanism belongs to Th1 and Th2 T cells mediating killing, Th1 T cells of intracellular and Th2 of extracellular parasites. However, everything can be modulated by ILs, their number [31] and chronology of intervention. Th1 and Th2 T cells are potentially activated by signals deriving from phagocytes and NK-CMI. Moreover, we speculate that Th2 T cells act only in immune reactions independent of phagocyte cells: several ILs generated by both T cells inhibit macrophage functions potentially provoking severe damage to the host [471]. IL_{12} establishes a bridge with acquired immunity and provides defense against infections at different levels: it influences rapid IFN-γ production from T and NK cells, modulates virgin T-cell differentiation into Th1 lymphocytes due to their capacity for *up-regulating IFN-γ titers and reducing IL_4 production* from virgin T cells, and is also necessary for the optimal proliferation of IFN-γ producing Th1 cells in response to antigens and APCs [181]. Thus, IFN-γ and IL_{12} form a positive feedback system amplifying IFN-γ levels to activate macrophages and IL_{12} to promote proliferation and activation of NK and Th1 cells [181]. Recently, the primary function of IL_{12} has been shown to up-regulate adhesion molecules, and IL_{28} and IL_{29} medi-

Table 1.66. Primary antibody-mediated defenses against pathogen microorganisms

Immunologic function	Pathogens affected	Main Ig involved	Nonspecific cofactors required
Opsonization	V, B, M	IgG, IgM	Phagocytes and complement (in some cases)

ate antiviral activity in cells in response to viral infection [519]. In addition, activated T cells generate additional ILs with a multitude of functions, including the widening of antimicrobial activities of immune cells, macrophages, neutrophils and NK cells [299]. Most CTLs are CD8 and also a CD4 T cell subset and HLA class I or II restricted. Similarly, T cells can directly kill microorganisms not expressing HLA molecules: this direct antimicrobial activity can also occur when HLA restrictions are absent [299]. CD8 T cells, unlike NK cells, also attack *Candida albicans* and show a direct antiparasite activity, although several of their activities are played together with NK cells [299]. Loss of direct T-cell activity could contribute to AIDS and other severe PID infections [299]. *Mice lacking T-bet* fail to control a Th1-dependent infection, yet interesting evidence suggests a pathogenic role of Th1 cells in autoimmunity [556]. Also suggestive is an antibacterial defense achieved via the innate immune system, such as innate opsonins, complement components, and certain antimicrobial peptides, leading to a polyvalent machinery formation presumably yielding a lymphocyte pathway of recognition and activation [194]. For example, opsonins, by binding to microbial cell walls and flagging them for recognition by the complement system and phagocytes, could be effective antibacterial agents [345]. As a corollary, pathogens with components capable of inducing phagocytes to produce IL_{12} already in the early events of infection elicit Th1-like responses [106]. Instead, the optimal responses against organisms with a complex structure, for example, intestinal nematodes cannot be rapidly killed because they are so large, are thus susceptible to active attack by Th2 T cells, which directly inhibit parasite growth without killing them

[592], also trying to prevent Th1 responses and bypassing macrophage activation. Tables 1.66 and 1.67 [360, 688] include antibody-mediated defenses against pathogen microorganisms related to memory effector mechanisms critical for newborn protection (Table 1.67).

Because innate immune stimulation is thought of as a broadly applicable strategy for biodefense and potentially a boon for vulnerable special populations, such as the *very young*, as well as *children* and *adolescents* whose adaptive immune systems are impaired by chemotherapy or HIV, innate immune function in different age groups and disease conditions requires that the exciting possibility that powerful inborn defenses against infection is manipulated to provide a counterweapon against broad classes of bioterror agents and newly emerging infectious diseases [194]. Such defenses are more realistic because of a growing understanding of the *pathogen genomes* [183].

In *human neonates,* despite normal basal expression of TLRs and membrane CD14, innate immune responses of mononuclear cells to LPS are characterized by a strikingly reduced release of the pro-inflammatory Th1-like TNF-α and IFN-γ with relative preservation of antiinflammatory Th2-polarizing ILs. These differences extend to a range of TLR agonists, including bacterial lipopeptides (BLPs), and are due to differences in soluble factors present in blood plasma. The suppressed TLR-induced TNF-α release from monocytes by soluble factors in neonatal blood plasma is likely to alter both innate and adaptive immune responses in neonates profoundly. Thus, neonates are at increased risk of overwhelming infection, yet the mechanisms underlying this susceptibility are incompletely defined [297]. Moreover, exposure to reduced levels of sCD14 in the fetal and neonatal gut is associated with the development of atopy, eczema, or both. A supply of sCD14 [of which breast milk is rich (Chap. 2)] could affect disease outcome, although the IgE- and non-IgE-dependent consequences of this require elucidation [243]. In contrast to the protective effects of TLR9, immunization with Ag in the context of TLR2 ligands, can result in experimental asthma [450]. Furthermore, TLR10 may be a potential asthma candidate gene: TLR10 is notably expressed in lung tissue, where a *potential asthma candidate gene* my be involved in the innate immune responses [289].

Neonatal deficiency of innate cellular immunity includes a reduced IFN-γ production by neonatal lymphocytes, hyporesponsiveness of neonatal macrophages to IFN-γ activation, a reduced production of IL_{12} by CB mononuclear cells, defective STAT-1 phosphorylation in CB monocytes, a high IL_{13} production by neonatal T cells, a hyper-methylation at CpG sites within the IFN-γ promoter region, a defective production of IL_{18} by CB mononuclear cells, a reduced Myd88 expression in newborn monocytes, and an impaired response by neonatal monocytes to multiple TLR ligands [329].

Therapeutic Perspectives

Following the leitmotif of the unabated flood of data that has taken us from the early studies on immune cells to some of the most complex areas of research in today's basic immunology, the important advances in the range of strategies heralding possible and interesting developments, which have been or will be focussed to hit specific targets, in particular allergic inflammation. We note that the task appears to be ever more challenging as the intricacy of immune mechanisms unravels.

Substantial evidence shows that *synthetic peptides* (Chap. 13) are able to disarm potentially harmful allergen-reactive T cells and/or inhibit IgE binding to allergens and/or compete with IgE antibodies for receptor binding. Logically a census of all relevant epitopes present on allergenic molecules is presently inconceivable, and certainly cross-reactivity imposes a further but not indifferent obstacle; however, this arm of immunology is making rapid progresses, as is shown in Fig.1.66 [404]. The functional inactivation can be selectively referred to as specific clones of T lymphocytes (*arrow 1*) or to a subset of T cells with different specificities, and TcRs with particular features but reciprocally common (*arrow 2*), or lastly to the substitution of epitopes bound to the disease with inert peptides at the level of the peptide–HLA complex combination site (*arrow 3*). Another option, devoid of toxic effects for human beings, is that of employing synthetic peptides corresponding to linear sequences of HLA class I molecules (residues 56–69, 60–84, 99–113 and 222–235) to cause T-cell anergy, increasing the influx of intracellular Ca and interrupting the normal pathway of signal transduction [277]. To these strategies down-regulating T cell modulation to

promote apoptosis or, on the contrary, to render T cells unable to respond to IgE synthesis, experiments have offered new insights into the inhibition of IgE binding to metachromatic cells or, alternatively, IgE conjugated with toxins able to dampen mast cells, or synthetic IgE fragments with deletion of specific responses.

Characterization of IgE receptors can provide specific clues to potentially blocking IgE binding to other cells: the use of anti-IgE IgGs with a double epitope specificity could modulate IgE-producing B lymphocytes, either bridging IgE bound to FcεRI or blocking IgE binding to its receptor, increasing or, respectively, abolishing their activity [358, 514].

Atopic individuals have *natural anti-IgE antibodies* directed against the IgE Fc region, different from anti-idiotype antibodies, which are not directed against allergen-specific IgE and therefore possess an immunoregulatory effect on IgE antibodies. Furthermore, anti-idiotype antibodies cannot establish a cross-linking with basophil IgE inducing their degranulation, thus blocking allergen binding to cells expressing IgE receptors [638]. However, to accomplish a therapeutic intervention, the degranulation impact should be very limited, but in view of the scarce number of metachromatic cells expressing the corresponding idiotypes, several authors deem this goal feasible [638]. Moreover, taking into account the particular convex structure of IgE antibodies [553], a strategy blocking IgE bound to FcεRI without triggering mast cell degranulation should be based on natural autoantibodies directed toward an IgE region (residues 305–313) across the FcεRI *locus* (residues 330–345) [513].

As an alternative, *IgE synthesis could be directly inhibited* (as well as synthesis of other Igs); incrementing CD14 engagement on monocytes increases monocyte activation, since the exerted block is at the B cell level, which is conceivable in either T-dependent or T-independent systems. CD14 delivers a negative signal that terminates T-cell proliferation, the repercussions of an event about which too little is as yet known [608].

What is most likely to be successful is the attempt to inhabit IL_4, the factor triggering IgE synthesis:

- In a *mutant IL_4*, substituting the aspartic acid of a protein with a tyrosine residue in position 124 (IL-4.Y124D) blocks IL_4R activation while leaving the binding capacity, and a IL_4- and IL_{13}-induced dose-dependent inhibition of IgE synthesis. By increasing the dose 100-fold, the inhibition increases up to 95% [437]. Moreover, the addition of an IL_4 binding protein, a sIL_4R, blocked the IgE enhancement by $CD8^+$ T cells [346]. However, if the peripheral blood of atopic patients contains long-lived B cells with a previous isotype switch to IgE, these antibodies cannot be directly influenced by ILs [125].
- The intervention of a *potential suppressive factor* of transcriptional events, inversely regulating IL_4 transcription of a not yet identified protein, determines a high capacity of binding to Th1 T cells at the moment of T-cell activation, coupled with a virtual absence of IL_4 after 16–24 h; instead, the high binding capacity of Th2 T cells is expressed with not yet stimulated cells. However, it is decreased when Th2 are activated. Such events are correlated with high inductive signals for IL_4 after the same time span [206].
- Increasingly, soluble *sIL_4R* may be able to block in vitro IL_4-mediated B cell activation, proliferation and differentiation in human PBMCs and therefore both IL_4-dependent IgE synthesis and CD23 induction on B cells. The clinical basis of using sIL_4R is the location in the blood, rendering sIL_4R a potentially stimulating candidate. Moreover, IL_4-deficient mice obtained via gene targeting do not display immune abnormalities, except for their inability to produce IgE [172]. A contrary effect has been assessed [492].
- An interesting subject is the demonstration that *anti-CD23 antibodies* block IgE synthesis in an isotype-restricted fashion, that is, inhibiting B lymphocyte differentiation in IgE-producing cells under the IL_4 influx [16].
- STAT6 is phosphorylated by IL_4, so any agents that *block STAT6 function* may be useful for treating atopic disease [562].
- Even more interesting is the likelihood of inducing a *peptide-mediated IL_4 anergy*. Using a clone of T cells incubated in a culture medium or with a specific peptide in either an immunogenic or nonimmunogenic dose, and stimulating again with a nonimmunogenic specific peptide and the related APCs, it was elucidated that T cells becoming unresponsive completely lose the ability of secreting IL_4, but fully maintain the ability of producing IFN-γ [138].
- In the animal model, the concerted action of IL_{12} together with IL_{18} and anti-CD40 *inhibits IL_4 and IgE synthesis* by induction of IFN-γ production from activated B cells, however, without inhibiting B cell proliferative response [669].
- A significant series of experiments in the animal model with synthetic peptides assure relevant implications for SIT. Administering a peptide along with an adjuvant in APCs induces T-cell proliferation and development of immunity. If a peptide able to activate T cells is administered, but disregarding the adjuvant (or CD28/CD80 interaction is missing), the *2nd signal is abrogated*. T-cell *clonal anergy* ensues as does the eventual apoptosis that drives to tolerance, as discussed in "Apoptosis" [138] (Fig. 1.22c). A similar option could prove successful in atopic patients [276].
- Ongoing studies on single amino acid substitutions have paved the way to assemble a peptide with a T epitope possibly able to *interrupt T/B interactions* and the consequent isotype switch to IgE, exciting IFN-γ production or inhibiting CD4 proliferation. However, skin prick tests (SPTs) with a modified allergen failed to drive immediate reactions [223].
- A potentially promising candidate is *clonal deletion* [138], a process of negative selection following, for

example, a self-HLA–antigen complex interaction, an event leading to apoptosis and thereby a powerful mechanism aimed at inducing tolerance to self-antigens (Fig. 1.22).

- The armamentarium of T epitopes has intriguing repercussions for SIT, based on the *switching of immune responses* from Th2 to Th0 T cells. A prominent feature, however, is a feasible switch to Th1 and DTH (Chap. 13).
- Administration of peptides corresponding to T epitopes (at least 10–12 amino acids) elicits a *T cell tolerance* to a complete antigen in humans [404], hence immunodominant T cell epitopes of an allergen actually also function as high inducers of T-cell nonresponsiveness [619].

What was summarized above on sCD40 makes it feasible to consider an isotype switching inhibition after the second signal expressed by ILs, to stop T–B interactions via CD40 and CD154 thus far achievable in vitro [132]. In addition, CsA abrogates CD154 stimulation in mast cells [174]: such data explain why CD154 regulatory effects are inhibited on APCs and IL_{12} as regards the stimulation of adhesion molecules useful for T cells and macrophage production of inflammatory ILs [187].

- A not yet explored and totally different strategy has the objective of suppressing B_{IgE} cells in patients with IgE-mediated atopy using mABs activated by a procedure tested on B cells expressing membrane-bound IgE, more precisely including amino acid residues and Ig membrane-anchoring segments extending from the C-termini of H chains. One potential application could be a methodology that can modulate isotype-specific antibody production to suppress B cells undergoing switch recombination, but not circulating IgE or IgE bound to mast cells [108].
- A fusion protein of 2 major allergens bypasses IgE binding and mast cell/basophil IgE FcεRI cross-linking and protects from IgE development [282].
- A recent study that certainly has striking consequences on AD treatment has shown that FK-506 and CSs inhibit both NFAT and AP-1, and hence IL_5 transcription [394]: since TFs are alike for diverse ILs, it is probable that further studies will report the inhibition of additional ILs.
- As outlined in Chap. 22, atopic children, some with HIgES, have been successfully cured with intravenous IgGs (IVIgs), suggesting that *IVIgs inhibited IgE production* of PBMCs (T cells) cultured in vitro and stimulated by IL_4, without influencing IgA and IgM levels, and also of normal B cells stimulated by IL_4 + anti-CD40.
- The significance of CSMs results from their ability to block antibody production following in vivo administration of CD152-Ig and anti-CD86 [115]. CD152-Ig specifically abates IL_4 production and if administered early after the start of an infection *blocks its progression* [242, 685].
- A new strategy *to inhibit or,* depending on the case, to *cause apoptosis* (Tables 1.68, 1.69) [576] acts on NF-κB as well as TNF-α [599], or modulates bcl-2/ced-9, or alternatively ICE/ced-3 [267, 661], or ced-4: if a mammal homolog is identified the issue could encompass all changes deriving from apoptosis dysregulation.
- A recent approach could be aimed at *eliminating eosinophil influx* into airways, which has been achieved treating animals with anti-MIP-1α, anti-RANTES and anti-MCP-3. So the rationale to focus CCR3 antagonists is available, a potential mediator of CCL chemokine effects on eosinophils [9].
- Another strategy is *the blockade of chemokine receptors:* CCR3, CCR4 and CCR8 are the most obvious targets for therapeutic investigation.
- Attention is also turning to small molecular weight (SMW). SMW IL_4 inhibition seems to *decrease IgE synthesis,* lung eosinophilia and mucous production and could be used to treat asthma and other atopic disorders.
- The development of new therapies for atopic allergy is now focusing on local Th1-driving IL_{12}-promoting substances to target both the development of new Th2 cells and the persistent population of established allergen-specific Th2 cells to *revert established effector*

Modified from [576].

Th2 cells in humans into predominant Th1 phenotypes [530].

The newly described IFN-λ and $IL_{27–29}$ that mediate antiviral activity in cells in response to viral infection are the major initial weaponry against most viruses (Table 1.5).

The development of new therapies for atopic allergy is now focusing on local IL_{12}-promoting substances to target both the development of new Th1 cells and the persistent population of established allergen-specific Th1 cells:

- IL_{27}/WSX-1 plays an important role in the down-regulation of BHR and lung inflammation during the development of allergic asthma via its suppressive effect on IL production [357].
- Since IFN-γ induces T-bet expression, T-bet would be an attractive target to identify anti-asthmatic drugs [155].
- Anti-human IL_{13} antibody also looks promising for lowering tissue eosinophil levels and is in preclinical trials [44].
- Antagonists of proteinase-activated receptor or inhibitors of proteases that activate this receptor may be worthy therapies for asthma [502]. Tryptase is a therapeutic target in asthma and selective tryptase inhibitors can reduce allergic airway inflammation [392].
- CD300a was shown as a future potential target for the treatment of allergic and eosinophil-associated diseases. By suppressing the activity of human eosinophils, cross-linking of CD300a on the eosinophils inhibited the IL_5/GM-CSF antiapoptotic effects and blocked the release of TNF-α, $IL_1β$, IL_4, 3T3 fibroblast proliferation, IL_5-mediated JAK2 phosphorylation, eotaxin- and IL_5/GM-CSF-mediated ERK1/2 and p38 phosphorylation, but also blocked IFN-γ release [366].
- Selected defensins and/or chemokines may be good candidates for the development of vaccine adjuvants, since they are believed to enhance adaptive immunity markedly [660].
- The effect of dietary vitamin E on atopic disorders is beneficial since it blocks TF binding to two pivotal IL_4 promoter binding sites for NF-κB and AP-1 and interferes with promoter activity upon T cell activation [311]. Moreover, vitamin E suppresses CD95L (APO-1/Fas) mRNA expression and protects T cells of HIV-1-infected individuals from CD95-mediated apoptosis, evidence that vitamin E can affect T cell survival [312].

Allergens

Following the increased prevalence of atopic disease, it has become even more necessary to have at hand purified allergens to obtain more characterized diagnostic and therapeutic tools [94, 127, 433, 639, 675]. Allergens responsible for immune reactions are mostly proteins and are classified into major, intermediate and minor allergens based on the frequency with which an IgE-mediated allergy occurs. This characteristic can be analyzed with laboratory methods; CRIE (crossed radioimmunoelectrophoresis) is the most frequently used technique in two phases. In the first phase, all proteins of a given allergenic substance are separated electrophoretically and recognized as precipitates in specific rabbit antisera. In the second phase, a pool of RAST sera positive for the substance under scrutiny is applied to the procedure:

sIgE will only fix to allergenic proteins, subsequently read by autoradiography utilizing anti-IgE antisera marked by radioactive tracers. Thus *major allergens* are defined as components that bind IgE in 50% of the sera from a group of patients with the same allergy, *minor allergens* when components react with 10% of the sera, and *intermediate allergens* when components share halfway properties. Most commonly, an allergenic source may enclose allergens belonging to the three above types: for instance, egg white contains at least 20 different proteins, but only four or five of these proteins are allergenic. Actually only major and minor allergens are taken into account. However, not all patients recognize all major allergens and some patients only recognize allergens that are not recognized by the majority of allergic patient sera (Chap. 13). From a clinical point of view, allergen sources can be classified as inhalant allergens: pollens, mites, animal danders, molds, chemical/pollutant substances, drugs; ingested allergens: foods, chemical substances, drugs, etc.; insect allergens: insect venoms; and contact allergens: foods, chemical substances, topical drugs, cosmetics, etc. [94, 126, 433, 639, 675].

Table 1.70. Completely cloned allergens (recombinant DNA) with the pertinent amino acid sequence

Insects	Api m 1, Api m 2, Bla g 2, Bla g 4, Dol m 1, Dol m 2, Dol m 5, Myr p 1, Ves v 5

Data from [112, 496, 604].

Allergen Standardization

Standardization regards commercial allergens, provided that they correspond to the main rules established with respect to their content of major and minor allergens, safety and potency or biological activity. It is highly necessary because crude allergen extracts incorporate all components of original materials, hence not only all potentially sensitizing allergens, but also irrelevant material with potential primary irritant activity. We define allergen extracts as complex mixtures of substances with a known composition, reflecting that of a relevant allergen source material that could include even 100 proteins, but with a known total allergenic potency that is constant between batches [126]. However, the extracts may vary according to the quality of the initial material and be insufficiently purified and also unstable. Therefore, allergen extracts contain major allergens in inadequate concentrations, and are contaminated by irrelevant components to which the patients are not sensitized, or important allergens are lost during extractive procedures due to proteases purified together with allergens [126]. In addition, measurement of allergen levels present in planned extracts is often difficult because of a mixture complexity, or because allergen components vary from one supplier to another, either for allergen potency or quality, or from one year to another or one production lot to another of a single supplier [112]. *It is not possible to compare the potency of allergen extracts produced by different manufacturers, even if quantified with the same techniques* and if done, it might lack the indication of major and minor allergens [112]. To ensure uniformity among future batches, units of measure have been introduced. As a consequence, manufacturers can employ appropriate, although of varying calibration, methods for allergen extracts, provided that such methods are clearly documented and constant. The WHO/IUIS has established International Units (IU), the Biologic Units (BU) are widely used in northern countries and in several European countries, and in the US are expressed as Bioequivalent Allergy Units (BAU). Such methods are expensive and demanding; therefore promising improvements in the procedure are currently *recombinant allergens* (RA) (Table 1.70) [112, 496, 604, and Internet data, August 2006].

Standardization Techniques

Allergen standardization consists in the adoption of methodologies ensuring both uniformity and reproducibility between different batches of the same allergen extract, that is, the procedures to select the raw materials, assemble and control allergen extracts, which allow suppliers to produce different batches with the same allergen provided with wholly matching characteristics. The system based on SQ units (standardized quality unit), crossed immunoelectrophoresis (CIE) and CRIE makes it possible to demonstrate the single epitopes of standard extracts. For each new extract, the existence and amount of all allergens is controlled by autoradiography; subsequently the batches presenting quantitative differences are equilibrated to standard concentrations using quantitative immunoelectrophoresis [126]. Reference internal extract (in-house standard) is prepared to guarantee the protein composition of allergen ex-

tracts via immunochemical analyses, such as CIE, CRIE, sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE), high-performance liquid chromatography (HPLC), isoelectrofocalization (IEF) and other molecular biology techniques. Currently, it is necessary to employ in vitro and in vivo standardization methods, both based on interaction between allergens and sIgE produced by sensitized patients [675].

In Vitro Standardization Methods

The most important in vitro standardization techniques are based on binding inhibition of pooled sera containing sIgE to allergens and on gel precipitation.

RAST inhibition quantifies single allergens or total allergenic potency of raw extracts: soluble antigens, identical or cross-reacting with antigens of solid phase, are combined with the serum pool. The resulting binding inhibition of anti-IgE antibodies labeled with I^{125} to solid phase antigens shows the identity of the soluble antigen with that bound to the solid phase. Consequently, varying amounts of soluble allergen extracts are added to the RAST first phase as inhibitors. Dose-response inhibition curves may determine activity relative to reference extracts: parallel inhibition curves indicate similar composition, while nonparallel curves do not. The necessary reagents require:

- *Allergens* derived from high-quality materials where all major and minor allergens are represented.
- *Pooled sera* containing IgE from a panel of patients characterized for their sensitivity to the allergen in question.
- *Reference extract* of high quality.

Similarly, ELISA inhibition, rocket electrophoresis, isoelectric focusing, gel electrophoresis, etc. are used [94].

Analysis of single allergens is accessible only when major allergens have been identified, thereby anti-allergen-specific antibodies allow subsequent allergen quantification with an immunological essay. For this purpose, several techniques are utilized, for example, an enzymatic essay to characterize the extracts as regards *Hymenoptera* venoms equipped with several enzymes [433].

Gel precipitation techniques include CIE, CRIE, immunoblotting and histamine release by basophils.

In Vivo Standardization Methods

The standardization method established in Scandinavia expresses the results as HEP (histamine equivalent potency), the allergenic activity of an extract is estimated measuring the skin response to the extract in a pool of subjects with known allergy to the tested allergen. SPTs test the quantity of the extract that produces a wheal the same size as the wheal size produced by histamine hydrochloride at the concentration of 1 mg/ml: this result corresponds to one HEP unit. However, the results are now usually expressed as BUs, which is defined as the wheal equivalent to histamine 1 mg/ml = 1,000 BU/ml. The BU gives valid indications on total biological activity, but not on the presence in the extract of single allergens; BUs are referred to as the in-house standards of each manufacturer, and therefore depend on patient selection, reactivity and compliance [112]. An analogous technique is skin activity reference allergen/histamine (SARAH) [433]. The approach established in the US based on AUs (allergy units) is valid for mites and other allergens: reference controls regarding the extracts are Der p-sensitive individuals intradermally tested with increasing doses, with subsequent evaluation of the flare rather than the wheal size as with HEP units. The reference standards for subsequent allergen dilution is the sum of erythema diameters. For other allergens, the AU provoking reactions of the same diameter in patients with multiple sensitizations is defined as BAUs. However, extracts standardized in BAUs are not comparable with corresponding BU extracts, since the techniques do not reduce the likelihood of detecting a different potency in lots of the same allergen extract produced by different manufacturers, nor the variability among lots of the same manufacturer, nor the problems of related extract potency between BUs and two different societies [112]. There is variability due to isoallergens, different isoforms of the same allergen, contained only in varying levels in the extracts [551]. Finally, besides the variations between the techniques used by laboratories, we must also take into account different subjects in patient pools [94].

Units for SPTs and SIT

Both the US FDA (Food and Drug Administration) and Nordic guidelines prevailing in Europe can be followed. In the first case, an allergen concentration is defined that can be recommended for SIT and is based on intradermal skin testing of the most sensitive patient: 100,000 AU/ml. In the second case, the unit is based on SPTs done on patients with average sensitivity and corresponds to the concentration eliciting a wheal that is the same size as the wheal produced by 10 mg/ml histamine and equals 10,000 BU/ml [126]. The ideal extract should comprise definite quantities of all major and minor allergens of each biologically potent allergen: such analyses obviously play a highly relevant role in assembling SIT extracts, which should include only allergens (or allergen epitopes) pertinent to the single patient [112]. According to Scheiner et al, SPTs have a high sensitivity (82.1 %) and specificity (66.3 %); to their detriment are the rapid denaturation of some natural allergens (such as the apple) during extraction processes. Furthermore, in the extracts the allergen levels can be naturally reduced (such as the cypress), or following destruction via enzymes present there [496].

Advantages of Standardization

The principal advantage is the testing of standardized extract biological effects, and the variability in relative titers of major allergens is much lower than extracts that have not been standardized (two- to threefold vs ten- to >100-fold). Another point in favor is clarified by the therapeutic effectiveness: consistent data show that when SIT maintenance doses correlated with major allergen levels are reached, evident improvements in patient symptom scores are noted [126].

Among the more recently achieved results in above-mentioned studies, we include the delineation of antigenic or allergenic epitopes, either major or minor and/or dominant in individual antibody repertoire, using techniques based on recombinant DNA. In addition, cloning single-helix DNA cDNA to an RNA chain, which was synthesized by inverse transcription, cDNA-coded protein amino acid sequences drawn from cDNA libraries were established, a complex of DNA cloned fragments representing the whole genome [443]. Hitherto, several allergen amino acid sequences have been determined, above all arthropods and pollens, employing cDNA-based techniques and it is auspicious that the list is so extensive that it includes all allergens [360] and Table 1.70. We stress that with knowledge of primary tools, it is reasonable to predict spatial conformation, and that computerized programs can help disclose both biochemical properties and biological functions. These results will bring out and make it possible to evaluate protein allergenicity [678]. Moreover, using synthetic peptides based on known sequences, it is practical to determine T and B cross-reactive epitopes, as well as the regions of molecules containing them [551]. The dominant epitopes referred to as Amb a 1, Bet v 1, Lol p 1, Poa p 1 and Sin a 1 were identified in parallel, even if studies done on mice are not always applicable to human beings [501, 511].

Several RAs are now available (Table 1.71) [319, 498, 604]. RAs should be preferred without exception: RAs can be precisely manipulated, targeted, engineered and formulated at defined concentration and potency. They may be produced in suitable purity and batch consistency and hence might offer a perfectly standardized diagnostic material. A WHO and IUIS international committee has fixed in IUs some standardized allergenic extracts, to which laboratories should refer, thus providing more quantitative and meaningful extracts than methods that are by now obsolete [675]. However, the majority of foods and molds have not been even partially characterized. In the US, the assortment is wider: the FDA (last updated: 2, 26, 2006) has also approved cat epithelium, Can d, Der p, Der f, several *Hymenoptera* venoms Api m, Dol a, Dol m, Pol a, Ves g, Ves p spp, pollens (Agr a, Ant o, Cyn d, Dac g, Fes e, Hev b, Lol p, Ole e), Phl p, Poa p, Amb a and Amb e (ragweed), although for Lol p 1, Lol p 3 and Ole e the complete amino acid sequence is available [94, 496, 501]. Standardized allergen extracts are commercially available. The FDA has established that all missing allergens should be standardized [94]. In several countries of the European Union, allergen extracts are subjected to registration and/or a strict quality control. For example, with RAST inhibition, it is controlled that the levels of biological potency of produced lots remain constant. Since ≈50 major allergens might cover up to 90% of all IgE specificities, commercialized but not standardized extracts will be excluded from such regulations regarding only small groups of patients residing in specific geographical areas [94].

Table 1.71. Recombinant allergens

Weeds	Art v 1

References [319, 498, 604] and Internet data, August 2006.

From this point of view, particular observations refer to *profilins,* vegetal panallergens present in many organisms (Table 1.72) [468, 594, 596–598, 602], prominent allergens in the *pollens of trees, grasses and weeds,* all involved in cross-reactivity observed in pollinosis patients between foods and pollens of only distant phylogenetically correlated plants, even in latex [597, 603].

Cross-reactions among allergens are outlined in Table 1.73 [17, 52, 128, 134, 406, 417, 434, 518, 598, 603, 604]. Above all, pollinosis patients suffer from cross-reactions and type I reactions between isoallergens of group I pollens with a MW of 26–32 kD, especially of Phl p and Lol p, with a marked degree of analogy in amino acid sequences. Furthermore, Phl p 1 has several T epitopes [497]. Mal d 1 has homology with *Fagales* group I [543]; Mal d 1, Api g 1 and Cor a 1 belong to the group of proteins related to pathogenesis, expressed by vegetables in stress conditions.

We now examine the allergens thus far identified and characterized, underlining the most recent updating, based on recent revision [639]. Allergens have the C or P letters depending on whether the related data on amino acid sequences are complete or partial [667]. In addition, we found Lol p 11 as the second allergen after Bet v 2 present in the pollens of vegetables and trees [134], and others [348, 543] (Table 1.74) [8, 15, 17, 60, 89, 98, 112, 121, 128, 134, 149, 199, 204, 265, 295, 310, 319, 348, 355, 365, 397, 384, 416, 405, 434, 471–473, 478,

Technically, the allergens are classified according to linnaean nomenclature, where any species is indicated using a binomial composed of two Latin names: the first three letters of the abbreviations indicate the genus and the first letter of the species name, followed by a number, progressive, referring to epitope historic or temporal identifications. Instead of Roman letters, Arabic numerals are used to show the identification order [639]. For some allergens not included in the above-mentioned revision, we kept the previous specifications [397] with the Roman numerals already attributed.

Table 1.76 [601] summarizes the T epitopes of many allergens and Table 1.77 [601] the association of single allergens with HLA molecules and IgE responses, with several factors of relative risk.

Fig. 1.75. *Parietaria officinalis*

We show the foods derived from genetically modified organisms (GMO) or crop plants in Tables 1.78 and 1.79 [110, 348]. In GMOs, insect protection is achieved by means of plants producing insecticide proteins not toxic for human beings, while herbicide tolerance is mediated by plants provided with enzymes disarming herbicides. A prerequisite is that such products be subjected to extensive assessments to ensure food safety and digestibility [348]: however, it is feasible that genes of a given plant are transferred to a nearby one and that other genes damage the so-called useful insects, also including fish deriving from monosexualization or maternal DNA doubling. Therefore, verification of potential allergenicity of transgenic food modified with genetic engineering now appears to be necessary, such as in the case of soy (Fig. 1.81) [42]. The challenges posed by GMOs and bovine spongiform encephalopathy (BSE) will be discussed in Chaps. 9 and 24.

	Pru av 4				LTP [499]
Asparagus (*Asparagus officinalis*)	Aspa 01	9	P		LTP
Atlantic salmon (*Salmo salar*)	Sal s 1	12	C		Parvalbumin
Avocado (*Persea americana*)	Pers a 1	32	C		Endochitinase
Banana (*Musa paradisiaca*)	Mus xp 1	16	C		Profilin
Barley	Hor v 1	15	C	52	α-Amylase/trypsin inhibitor [348]
(*Hordeum vulgare*)	Hor v 9	30	C		
	Hor v 15	15	C		
	Hor v 16				α-Amylase
	Hor v 17				β-Amylase
	Hor v 21	34	C		Hordein
Black walnut (*Juglans nigra*)	Jug n 1	19	C		2S albumin
	Jug n 2	56	C		Vicilin-like protein
Brazil nut (*Bertholletia excelsa*)	Ber e 1 Bet e 2	9 29	C C		High-methionine protein, composed of two subunits
Carrot	Dau c 1	16	C		Hom: Bet v 1
	Dau c 4		C		Profilin
Celery (*Apium graveolens*)	Api g 1	16	C		Hom: Bet v 1, ribonuclease
	Api g 4				Profilin sharing IgE-binding epitopes with Bet v 2 [498]
	Api g 5	55/58	P		
Cherry (*Prunus avium*)	Pru av 1	18	C		Hom: Bet v 1, ribonuclease
	Pru av 2		C		Hom: thaumatin C
	Pru av 3	10	C		LTP
	Pru av 4	15	C		Profilin
Chicken (*Gallus domesticus*)	Gal d 1	28	C	34	Ovomucoid, protease inhibitor
	Gal d 2	44	C	32	Ovalbumin, hom: serine protease inhibitors
	Gal d 3	78	C	47	Ovotransferrin or conalbumin, iron transport protein
	Gal d 4	14	C	50	Lysozyme
	Gal d 5	69	C		Serum albumin
Cod fish (*Gadus callarius*)	Gad c 1	12	C		β-Parvalbumin, diffused cross-reactivity with other fish

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
Corn (*Zea mays*)	Zea m 1	21	P		Lol p1 homolog [348]
	Zea m 11	14	C		The clone C13 is an Ole e 1 homolog [348]
	Zea m 14	9	C		LTP, a 50-kD corn protein that does not correspond to any known corn allergen, has been reported [416]
Cow (*Bos domesticus*)	Bos d 1	25			
	Bos d 2	22			
	Bos d 3	22			Ca-binding S100 hom
	Bos d 4	14.2	C		α-Lactalbumin
	Bos d 5	18.3	C		β-Lactoglobulin
	Bos d 6	67	C		Serum albumin
	Bos d 7	160			Immunoglobulin
	Bos d 8	20–30			Caseins
Cow's milk (Table 1.74)					
Cucumber (*Cucumis sativus*)		13			Profilin [468]
Grape (*Vitis vinifera*)	Vit v 1	9	P		LTP
Hazelnut (*Corylus avelana*)	Cor a 1	17	C	>90	Four variants of Cor a 1, 5, 6, 11, 16, all Bet v 1 hom [348] In 4 other variants IgE reactivity to Cor a 1.0401 was in 95%, to Cor a 1.0402 in 93%, to Cor a 1.0434 in 91%, to Cor a 1.0404. in 74% of sera [319]
	Cor a 2	14	C		Profilin
	Cor a 8	9	C		LTP
	Cor a 9	40	C		11S globulin-like protein
	Cor a 10	70	C		Luminal binding protein
	Cor a 11	48	C		Vicilin-like protein
Kiwi (*Actinidia chinensis*)	Act c 1	30	P		Recognized by IgE in 100% of cases, cross-reacts with Phl p and Bet v [417], cysteine protease
	Act c 2	24	P		Thaumatin-like protein
Lentil (*Lens culinaria*)	Len c 1	16	P		Vicilin
	Len c 2	66	P		Seed biotinylated protein
Lettuce (*Lactuca sativa*)	Lac s 1	9	LTP		
Muskmelon (*Cucumis melo*)	Cuc m 1	66	C		Serine protease
	Cuc m 2	14	C		Profilin
	Cuc m 3	16	P		PR-1 protein 13-kD components of melon, cucumber, watermelon, and zucchini were strongly recognized by the IgE antibodies of patients with melon allergy and were identified as profilins [468]
Mustard (*Sinapsis alba*)	Sin a 1	14	C		2S storage albumin
Mustard, oriental (*Brassica juncea*)	Bra j 1	15	C		Divided into IE-L, 2S albumin large chain, and IE-S2S albumin small chain

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
Mustard, rapeseed (*Brassica napus*)	Bra n 1	15	P		2S albumin
Mustard, turnip (*Brassica rapa*)	Bra r 2	25	P		Hom: prohevein
Pea (*Pisum sativum*)	Pis s 1	44	C		Vicilin
	Pis s 2	63	C		Convicilin
Peach (*Prunus persica*)	Pru p 3	10	P		LTP, Pur p I contained in the peel [310]
	Pru p 4	14	C		Profilin
Peanuts (*Arachis hypogea*)	Ara h 1	63.5	C	>90	Vicilin seed storage protein
	Ara h 2	17	P	>90	Conglutin and others with ± concern [60]
	Ara h 3	60	C		Glycinin seed storage protein
	Ara h 4	37	C		Glycinin seed storage protein
	Ara h 5	15	C		Profilin
	Ara h 6	15	C		Hom: conglutin
	Ara h 7	15	C		Hom: conglutin
	Ara h 8	15	C		PR-10 protein
Pear (*Pyrus communis*)	Pyr c 1	18	C		Hom: Bet v 1
	Pyr c 4	14	C		Profilin
	Pyr c 5	33.5	C		Hom: isoflavone reductase
Pepper (*Capsicum annuum*)	Cap a 1w	23	C		Osmotin-like protein
	Cap a 2	14	C		Profilin
Pineapple (*Ananas comosus*)	Ana c 1	15	C		Bromelin, hom: papain and group 1 of mites
Pistachio nut					Four antigenic fractions of 34, 41, 52 and 60 kD; the first one seems to have the highest binding capacity to IgE [384]
Plum (*Prunus domestica*)	Pru d 3	9	P		LTP
Potato (*Solanum tuberosum*)	Sola t 1	43	P		Patatin
	Sola t 2	21	P		Cathepsin D inhibitor
	Sola t 3	21	P		Cysteine protease inhibitor
	Sola t 4	16+4	P		Aspartic protease inhibitor
Rana esculenta	Ran e 1	119	C		α-Parvalbumin
Rice (*Oryza sativa*)	Ory s 1		C		Allergens RAP and RAG 1, 2, 5, 14, 17 [348]
Rye (*Secale cereale*)	Sec c 20				Secalin
Saffron crocus (*Crocus sativus*)	Cro s 1		P		
Sesame (*Sesamum indicum*)	Ses i 1	10	P		2S protein
	Ses i 2	7	C		Albumin
	Ses i 3	45	C		Vicilin-like globulin
	Ses i 4	17	C		Olesin
	Ses i 5	15	C		Olesin

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
Shrimp					
Metapenaeus ensis	Met e 1	34	C		Tropomyosin [295]
Penaeus aztecus	Pen a 1	36	P		Tropomyosin, major allergen [543]
Penaeus indicus	Pen i 1	34	C		Tropomyosin, or seralbumin, with diffused cross-reactivity [543]
Penaeus monodon	Pen m 2	40	C		Tropomyosin
Snail (*Helix aspersa*)	Hel a 1	36	P		Tropomyosin
Soybean (*Glycine max*)	Gly m 1	7	P	>90	Glycoprotein, MW of the monomeric form; Gly m is divided into 7 subunits: the best known are Gly m 1A and Gly m 1B [348], then the Kunitz tryptic inhibitor (3 subtypes)
	Gly m 2	8	P	>90	
	Gly m 3	14	C	>90	Profilin, β-conglycin 3 major subunits, α-1, α-2 and β with MW at 76, 72 and 53 kD, respectively, and lectin
	Gli m 4	17	C		SAM22, Pr-10 protein [265]
	Gly m Bd	30			Isolated from the crude 7S-globulin fraction, β-conglycinin, a trimer with MW at 150–200 kD
	Gly m Bd	60			Glycinin, a hexamer with MW at 300–400 kD, A5–B3 subunit
		30			Component from soybean constituted by two polypeptides (A5 and B3) that cross-react with CM caseins [478]
		25			Protein of GMO soybean reacting with IgE of some patients [674]
		50			Allergen pertaining to soy aeroallergen (asthma outbreaks during unloading of soybean from ships with significant hom with chlorophyll A-B binding protein precursors from tomato, spinach, and petunia [89])
Squid (*Todarodes pacificus*)	Tod p 1	38	P		Tropomyosin
Tomato (*Lycopersicon esculatum*)	Lyc e 1	14	C		Profilin, Ole e 1 homolog
	Lyc e 2	50	C		Isoallergen
	Lyc e 2	50	C		β-Fructofuranosidase
Walnut (*Juglans regia*)	Jug r 1	19	C		2S albumin
	Jug r 2	56	C		Vicilin
	Jug r 3	9	P		LTP
Watermelon (*Citrullus lanatus*)		13			Profilin [468]
Wheat					
Triticum aestivum	Tri a 18	17			Wheat germ agglutinins A and D [348]
	Tri a 19	65	P		Gliadin
Triticum durum					Wheat germ agglutinin [388]
Zucchini (*Cucurbita pepo*)		13			Profilin [468]
Other fruits					Strawberry, banana, tangerine, cherry and kiwi (Chap. 9)

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
2. Fungi (molds)					
Alternaria alternata	Alt a 1	28	C	<80	Similar to Alt a-29, Alt a bd 29 and Alt a 31-kD I_{1563}, 70-kD glycoprotein (GP70)
	Alt a 2	25	C	42	Aldehyde dehydrogenase [348]
	Alt a 3	70	C		Heat shock protein
	Alt a 4	57	C		Isomerase
	Alt a 5	45	C		Enolase
	Alt a 6	11	C	8	P_2 acid ribosomal protein [348]
	Alt a 7	22	C	7	
	Alt a 8	29	C		Mannitol dehydrogenase
	Alt a 10	53	C	51	Aldehyde dehydrogenase [543]
	Alt a 11	45	C		Enolase
	Alt a 12	11	C		Acid ribosomal protein
Aspergillus flavus	Asp fl 13				Alkaline serine protease
Aspergillus fumigatus	Asp f 1	18	C		Mitogillin toxin/ribonuclease [348]
	Asp f 2	37	C		
	Asp f 3	19	C		Peroxisomal protein
	Asp f 4	30	C		
	Asp f 5	40	C		Metalloprotease
	Asp f 6	26.5	C		Mn superoxide dismutase
	Asp f 7	12	C		
	Asp f 8	11	C		Ribosomal protein
	Asp f 9	34	C		
	Asp f 10	34	C		Aspartic protease
	Asp f 11	24			Peptidyl-prolyl isomerase
	Asp f 12.	90	C		Heat shock protein
	Asp f 13	34			Alkaline serine protease
	Asp f 15	16	C		
	Asp f 16	43	C		
	Asp f 17		C		
	Asp f 18	34			Vacuolar serine protease
	Asp f 22w	46	C		Enolase
	Asp f 23	44	C		1.3 ribosomal protein
Aspergillus niger	Asp n 14	105	C		β-Xylosidase
	Asp n 18	34	C		Vacuolar serine protease
	Asp N 25	66–100	C		3-Phytase
	Asp n ?	85	C		
Aspergillus oryzae	Asp o 2		C		
	Asp o 13	34	C		Alkaline serine protease
	Asp o 21	53	C		TAKA-amylase A

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
Candida albicans	Cand a 1	40	C		Three more allergens at 37, 43, 48 kD [543]
	Cand a 3	20	C		Perixosomal protein
Candida bodinii	Cand b 2	20	C		
Cladosporium herbarum	Cla h 1	13		>60	
	Cla h 2	23	C	43	Enolase [348]
	Cla h 3	53	C	36	Aldehyde dehydrogenase [348]
	Cla h 4	11	C	22	Acid ribosomal protein P2 [348]
	Cla h 5	22	C	22	
	Cla h 6	46	C	20	Enolase [543]
	Cla h 8	28	C		Mannitol dehydrogenase
	Cla h 9	55	C		Vacuolar serine protease
	Cla h 12	11	C		Acid ribosomal protein P1
Coprinus comatus	Cop c 1	11	C		Leucine zipper protein
	Cop c 2				
	Cop c 3				
	Cop c 5				
	Cop c 7				
Fusarium culmorum	Fus c 1	11	C		Ribosomal protein
	Fus c 2	13	C		Thioroedoxin-like protein
Malassezia furfur	Mala f 1				
	Mala f 2	21	C		Peroxisomal membrane protein
	Mala f 3	20	C		Peroxisomal membrane protein
	Mala f 4	35	C		
	Mala f 5	18	C		
	Mala f 6	17	C		
	Mala f 7		C		
	Mala f 8	19	C		
	Mala s 9	37	C		
Malassezia sympodialis	Mala s 1	18	C		
	Mala s 5	17	C		
	Mala s 6	17	C		
	Mala s 7		C		
	Mala s 8	19	C		
	Mala s 9	37	C		
	Mala s 10	86	C		Heat shock protein
	Mala s 11	23	C		Mn superoxide simutase
Penicillum brevicompactum	Pen b 13	33			Alkaline serine protease
Penicillum chrysogenum	Pen ch 1	33		100	Two more allergens at 64 and 62 kD [543]
	Pen ch 13	34			Alkaline serine protease
	Pen ch 18	32			Vacuolar serine protease
	Pen ch 20	68			*N*-acetyl glucosamine

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
Penicillum citrinum	Pen c 3	18			Peroxisomal membrane protein
	Pen c 13	33			Alkaline serine protease
	Pen c 19	70	C		Heat shock protein
	Pen c 22w	46	C		Enolase
	Pen c 24		C		Elongation factor 1β
Penicillum oxalicum	Pen o 18	34			Vacuolar serine protease
Psilocybe cubensis	Psi c 1				
	Psi c 2				Cyclophilin
Saccaromyces cerevisiae					Two allergens at 40 and 48 kD [543]
Trichophyton rubrum	Tri r 2		C		
	Tri r 4		C		Serine protease
Trichophyton tonsurans	Tri t 1	30	P		
	Tri t 4	83	C		Serine protease
3. Grass pollens					
Gramineae					Nearly all allergens show hom: groups 1–3 [543]
Agrostis alba (redtop)	Agr a 1	?	P		
Anthoxanthum odoratum (sweet vernal)	Ant o 1	34	P		
Cryptomerica japonica	Cry j 1	38	C		Cry j 1 is divided into 1A and 1B [348]
	Cry j 2	37	C		Of the same allergenicity [199]
Cynodon dactylon (Bermuda grass)	Cyn d 1	32	C	100	Has several isoforms
	Cyn d 7		C		
	Cyn d 12	14			Profilin
	Cyn d 14	9	C		
	Cyn d 15	9	C		
	Cyn d 22w				Enolase
	Cyn d 23	9	C		
	Cyn d 24	21	P		PR-protein
Dactylis glomerata (orchard grass)	Dac g 1	32	P	>95	
	Dac g 2	11	C	75	
	Dac g 3	C			
	Dac g 5	31	P	>90	
Festuca elator	Fes e 1	34	P		Moreover, Fes e 1A and Fes e 2B [348]
Festuca pratensis (meadow fescue)	Fes p 4w	60			
Helianthus annuu (sunflower)	Hel a 1	34			
	Hel a 2	15.7	C		Profilin
	Hel a 5				Expansin
Holcus lanatus (velvet grass)	Hol l 1	11	C		

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
Lolium perenne (rye grass)	Lol p 1	27	C	>90	Group 1
	Lol p 2	11	C	60	Group II
	Lol p 3	11	C	70	Group III
	Lol p 4	57	C	74	
	Lol p 5	11	C	80	Lol p IX, Lol p Ib, ribonuclease (unknown)
	Lol p 9				90% of patients allergic to darnel recognize it together with Lol p 1 [43]
	Lol p 10	12			Cytochrome C, hom: group 10
	Lol p 11	18	65		Hom: trypsin inhibitor, 44% of homology with Ole 1 [189], further Lol p IV, 11 kD and 3 allergens at 30, 34 and 50 kD [347]
Phalaris aquatica (canary grass)	Pha a 1	34	P	77	Hom: group 1
	Pha a 5				Has 4 isoforms [476]
Phleum pratense (Timothy)	Phl p 1	27	C	80	Cross-reacts with group 1 allergens [497]
	Phl p 2	10, 12	C	62	
	Phl p 3	10, 12	C		
	Phl p 4	50, 60	P		Significant hom: Amb a 1/2
	Phl p 5	32	C	80	Ribonuclease (unknown) is divided into 5a and 5b [348]
	Phl p 6	11	C		Additional allergens Phl p of 32 kD and Phl p of 38 K [348]
	Phl p 7		C		
	Phl p 11		C		Trypsin inhibitor hom
	Phl p 12		C		Profilin
	Phl p 13	55–60	C		Polygalacturonase
Poa pratensis (blue grass)	Poa p 1	33	P		All with unknown sequence and group 10 homology
	Poa p 5	31/34	P	>95	
	Poa p 9	29, 35	C		In 3 forms: KBG31, KBG41, KBF60 [348]
	Poa p 10	29			Cytochrome C
Sorghum halepense (Johnson grass)	Sor h 1		C		
Zea mays (maize)	Zea m 1	21	P		
	Zea m 11	14	C		
Euphorbiaceae					
Hevea brasiliensis	Hev b 1	58	P	23–>80	Major allergen, rubber elongation factor
	Hev b 2	34/36	C	21	Major allergen, β-1,3-glucanase, microhelix component
	Hev b 3	24	P	36	Prenyltransferase
	Hev b 4	50–57			Component of microhelix complex
	Hev b 5	16	C	56–92	Major allergen (Table 1.73)
	Hev b 6.01	20	C		Hevein precursor
	Hev b 6.02	5	C		Hevein

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
Hevea brasiliensis (continued)	Hev b 6.03	14	C		C-terminal fragment
	Hev b 7.01	42	C	83	Hom: patatin from B-serum, cross-reacting with avocado, potato and tomato
	Hev b 7.02	44	C	23	Hom: patatin from C-serum defense-related protein
	Hev b 7.03				Inhibitor of rubber biosynthesis
	Hev b 8	14	C	>90	Latex profilin structural protein
	Hev b 9	51	C		Latex enolase
	Hev b 10	26	C		Mn superoxide dismutase
	Hev b 11	33	C		Class I endochitinase defense-related protein
	Hev b 12	9.3	C		LTP
	Hev b 13	42	P		Esterase
Ricinus communis (Castor bean)	Ric c 1	11	C	96	Small chain, 4 kD, large chain, 7 kD, 2S storage albumin
	Ric c 2	47			Crystalloid protein [543]
4. Weeds compositae					
Ambrosia artemisifolia (short ragweed)	Amb a 1	38	C	>90	Pectate lyase; hom: Amb a 2, Cry j 1, tomato and maize
	Amb a 2	38	C	>90	Pectate lyase; hom: Amb a 1, Cry j 1, tomato and maize
	Amb a 3	11	C	51	Shows homology with electron transport proteins
	Amb a 4	23			
	Amb a 5	5	C	17	Ra 5
	Amb a 6	10	C	21	Ra 6, lipid transferase (?)
	Amb a 7	12	P	20	Ra 7, shows hom with electron transport proteins
	Amb a 10	12			Cytochrome C
Ambrosia psilostachya	Amb p 5				Hom: Amb a 5
Ambrosia trifida (giant ragweed)	Amb t 5	4.4	C		Hom: Amb a 5
Artemisia vulgaris (mugwort)	Art v 1	27–29	C	>70	
	Art v 2	35	P	33	
	Art v 3	12	P		LTP
	Art v 4	14	P		Profilin
Mercurialis annua	Mer a 1	14–15	C		Profilin
	Mer a 2				
Mercurialis perennis, etc.					
Parietaria judaica	Par j 1	12	C	100	[511] or 2 proteins at 8.8 and 9.8 kD, respectively, with allergens homologous to those of Par o 1 and di *P. mauritanica* and with great cross-reactivity [17]
	Par j 2		C		LTP
	Par j 3		C		Profilin

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
Parietaria officinalis	Par o 1	15	P	100	[397] or 3 proteins at 8.8 and 2 9.4 kD, respectively, R 100, with several isoallergens with similar MW [98]
	Par o 2	11		82	Phospholipid transfer protein
Parthenium hysterophorus (feverfew)	Par h 1	31			Extensin
5. Tree pollens					
– Betulaceae					
Alnus glutinosa (alder)	Aln g 1	17	C	>90	Hom: Bet v 1 [348]
Betula verrucosa (birch)	Bet v 1	17	C	>95	PR, isoform Bet v 1 N
	Bet v 2	15	C	10	Profilin
	Bet v 3	20	C	<10	Profilin [348]
	Bet v 4	8	C		
	Bet v 6	33.5	C		Hom: isoflavone resuctase
	Bet v 7	18	P		Cyclophilin
Carica papaya (Papaya)	Car p 1	23	C		Papain
Carpinus betulus (Hornbeam)	Car b 1	17	C	>90	Bet v 1 hom [348]
Castanea sativa (Chestnut)	Cas s 1	22	P		Hom: group 1 of Fagales [543] and with Bet v 1 [348]
	Cas s 5				Chitinase
	Cas s 8	13	P		LTP
Cupressus arizonica	Cup a 1	43	C	81	[355]
Cupressus sempervirens	Cup s 1	43	C	81	
	Cup 3 3w	34	C		
Fraxinus excelsior (ash)	Fra e 1	20	P		
Juniperus ashei	Jun a 1	43	P		Pectate lyase
	Jun a 2		C		
	Jun a 3	30	P		Hom: thaumatin, osmotin, amylase/trypsin inhibitor
Juniperus oxycedrus (prickly juniper)	Jun o 4	29	C		Hom: calmomodulin
Juniperus rigida	50	100			[543]
Juniperus sabinoides (mountain cedar)	Jun s 1	50	C		
Juniperus virginiana	Jun v 1	43	C		
Ligustrum vulgare (privet)	Lig v 1	20	P		
Quercus alba (oak)	Que a 1	17	P		Hom: group 1 of Fagales [543] and with Bet v 1 [348]
– Oleaceae					
Olea europaea	Ole e 1	16	C	>90	Allergens present also in Fra e 1, Lig v 1, Syr v 1 [369] hom: soybean trypsin inhibitor and Lol p 11
	Ole e 2	15–18	C	25	Profilin
	Ole e 3	9.2			Ca^{++}-binding protein
	Ole e 4	32	P	80	Hom: Ole e 1
	Ole e 5	16	P	35	Superoxide dismutase

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
Olea europaea (continued)	Ole e 6	10	C		Cysteine-rich protein
	Ole e 7		P	47	
	Ole e 8	21	C		$Ca2^{+}$-binding protein
	Ole e 9	46	C		β-1,3-glucanase
	Ole e 10	11	C		Hom: Glycosyl hydrolase
Phoenix dactylifera(date)	Pho d 2	14.3	C		Profilin
Syringa vulgaris	Syr v 1	20	P	16	
– Plantaginaceae					
Plantago lanceolata	Pla l 1	18	P		English plantain
Platanaceae					
Platanus acerifolia	Pla a 1	18	P		Major allergen [15]
	Pla a 2	43	P		Major allergen [15]
	Pla a 3	10	P		LTP
– Taxoidiaceae or Pinales					
Cryptomeria japonica	Cry j 1	41–45	C	>85	Pectate lyase, hom Amb a 1
	Cry j 2	57		76	Polymethylgalacturonase
6. Animals					
Cat (*Felis domesticus*)	Fel d 1	38	C	>80	Allergens in sebaceous glands and saliva; cross-reaction with pig meat [127]
	Fel d 2		C	23	Albumin
	Fel d 3	11	C		Cystatin
	Fel d 4	22	C		Lipocalin
	Fel d 5w	400			IgA
	Fel d 6w	800–1000			IgM
	Fel d 7w	150			IgG
Cavia porcellus	Cav p 1	20	P		Lipocalin hom
	Cav p 2	17	P		Allergens present in hairs, urine, saliva
Oryctolagus cuniculus	Ory c 1	17			Present in saliva
Dog (*Canis domesticus*)	Can f 1	25	C	>70	Allergens present in skin, saliva, parotid gland
	Can f 2	27	C	23	Parotid gland
	Can f 3	69	C	40	Albumin
	Can f 4	18	C		
Horse (*Equus caballus*	Equ c 1	25	C	100	Lipocalin, the allergen is in the horsehair
	Equ c 2	18.5	P		Lipocalin
	Equ c 3	67	C		Albumin
	Equ c 4	17	P		
	Equ c 5	17	C		Two more 14- and 39-kD proteins [149]

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
– Rodents					
Mouse (*Mus musculus*)	Mus m 1	19	C		Prealbumin; allergens present in urine, liver
	Mus m II (Ag3)	16			Reciprocal homology [543]
Rat (*Rattus norvegius*)	Rat n 1	21	C	60	Allergens in urine, saliva
	Rat n 2	16	C	90	
	Rat n III	>200			
7. Worms					
Anisakis simplex	Ani s 1	24	P		
	Ani s 2	97	C		Paramyosin
	Ani s 3	41	C		Tropomyosin
	Ani s 4	9	C		
Ascaris lumbricoides	Asc l 1				[348]
Ascaris suum (worm)	Asc s 1	10	P		
Thaumetopoea pityocampa	Tha p 1	15			Amino acid sequence with no homologies to any other protein described [365]
8. Insects					
American cockroach (*Periplaneta americana*)	Per a 1	20–25	C	50	Cr-PII, Per a 1 reacts with Bla g 1 [434]
	Per a 3	72–78	C	83	In addition, a protein of the allergenic fraction, Cr-PI, perhaps major allergens [616]
	Per a 7	37	C		Tropomyosin
Australian jumper ant (*Myrimecia pilosuls*)	Myr p 1		C		
	Myr p 2		C		
Black fire ant (*Solenopsis richteri*)	Sol r 1		P		
	Sol r 2		C		PL
	Sol r 3		C		
Bumble bee (*Bombus pennsylvanicus*)	Bom p 1	16	P		PL
	Bom p 4		P		Protease
Cat flea (*Ctenocephalides felis*)	Cte f 1				
	Cte f 2	27	C		
	Cte f 3	25	C		
Midge (*Chironomus thummi*)	Chi t 1–9	16	C		Hemoglobin
	Chi t 1.01	16	C		Component III
	Chi t 1.02	16	C		Component IV
	Chi t 2.0101	16	C		Component I
	Chi t 2.0102	16	C		Component IA
	Chi t 3	16	C		Component II-β
	Chi t 4	16	C		Component IIIA
	Chi t 5	16	C		Component VI
	Chi t 6.01	16	C		Component VIIA
	Chi t 6.02	16	C		Component IX

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
Midge (*Chironomus thummi*) (continued)	Chi t 7	16	C		Component VIIB
	Chi t 8	16	C		Component VIII
	Chi t 9	16	C		Component X
European hornet (*Vespa crabo*)	Vesp c 1	34	P		PL
	Vesp c 5	23	C		Antigen 5
German cockroach (*Blattella germanica*)	Bla g 1	20–25	C	50	30%–50% prevalence of IgE antibody
	Bla g 2	36	C	58	Aspartic protease
	Bla g 4	21	C	40–60	Lipocalin
	Bla g 5	22	C		Glutathione transferase
	Bla g 6	27	C		Troponin
	Bla g Bd	90			77% of patients with IgE antibodies [204]
Honey bee (*Apis mellifera*)	Api m 1	16	C		PLA_2, in addition Api III, V and VI at 49, 23 and 105 kD, respectively
	Api m 2	41	C		Hyaluronidase
	Api m 4	3	C		Melittin
	Api m 6	7–8	P		
	Api m 7	39	C		Serine protease
Mosquito (*Aedes aegiptii*)	Aed a 1	68	C		Apyrase
	Aed a 2	37	C		
Paper wasp (*Polistes dominulus*)	Pol d 1				
	Pol d 4	32–34	C		Serine protease
	Pol d 5				
Red fire ant (*Solenopsis invicta*)	Sol i 1	37	P		PL
	Sol i 2	13	C		
	Sol i 3	24	C		Hom: vespid group 5 allergens
	Sol i 4	13	C		Hom: Sol i 2
Tropical fire ant (*Solenopsis geminata*)	Sol g 2				
	Sol g 4				
Solenopsis saevissima	Sol s 2				
Giant Asian (*Vespa mandarina*) hornet	Vesp m 1				
	Vesp m 5				
Vespula flavopilosa	Ves f 5	23	C		Antigen 5
– Wasp					
Polistes annularies	Pol a 1	35	P		PLA_1
	Pol a 2	44	P		Hyaluronidase
	Pol a 5	23	C		Antigen 5
Polistes exclamans	Pol e 1	34	P		
	Pol e 5	23	C		Antigen 5
Polistes fuscatus	Pol f 5	23	C		Antigen 5
Polistes metricus	Pol m 5	23	P		Antigen 5
Wasp (*Vespula vidua*)	Ves vi 5	23	C		Antigen 5

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
White face hornet (*Dolichovespula maculata*)	Dol m 1	35	C		PLA_1
	Dol m 2	44	C		Hyaluronidase
	Dol m 5	23	C		Antigen 5
Yellow hornet (*Dolichovespula arenaria*)	Dol a 5	23	C		Antigen 5
Yellow jacket (*Vespula flavopilosa*)	Ves v 1	35	C		PLA_1: has 67% of sequential identity with Dol m
Vespula germanica	Ves g 5	23	C		German yellow jacket, antigen 5
Vespula maculifrons	Ves m 1	35	C		Eastern yellow jacket, PLA_1
	Ves m 2	44	P		Hyaluronidase
	Ves m 5	23	C		Antigen 5
Vespula pennsylvanica	Ves p 5	23	C		Western yellow jacket, antigen 5
Vespula squamosa	Ves s 5	23	C		Southern yellow jacket, antigen 5
Vespula vulgaris	Ves v 1	35	C		PL
	Ves v 2	44	P		Hyaluronidase: has 92% of sequential identity with Dol m
	Ves v 5	23	C		Antigen 5: has 69% of sequential identity with Dol m and 60% with Pol a; it is possible to set an order of cross-reactivity hyaluronidase >antigen 5> PLA_1 [577]
9. Mites					
Acarus siro	Aca s 13	14	C		Fatty acid binding protein
Blomia tropicalis	Blo t 1	11–13		>47	Cysteine protease
	Blo t 3	24	C		
	Blo t 4	56	C		
	Blo t 5	14	C	70	Shows hom: other allergens
	Blo t 6	25	C		Chymotrypsin
	Blo t 10	33	C		Tropomyosin
	Blo t 11	110	C		Paramyosin
	Blo t 12	16	C		
	Blo t 13		C		Fatty acid binding protein
	Blo t 19	7.2	C		Anti-microbial pepsin homology
Dermatophagoides farinae	Der f 1	25	C	79	Cysteine protease, hom: Der p 1, Eur m 1, papain, cathepsins B and H
	Der f 2	14	C	83	Variants 2.1, 2.2 and 2.3
	Der f 3	34	P	42–70	Trypsin, hom: Der p 3, Der p 6, Der f 6, other trypsins and proteases
	Der f 6	30		31	Chymotrypsin, hom: Der p 3, Der p 6, Der f 3, other chymotrypsins and proteases
	Der f 7	22		46	86% homology and cross-reactivity with Der p 7 [469]
	Der f 9				[112]

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
Dermatophagoides farinae (continued)	Der f 10	39	C	81	Tropomyosin, hom: Mag44, highly reactive with IgE like Der f 1, 2 [8]
	Der f 11	98	C		Paramyosin
	Der f 14		C		Mag3, apolipophorin
	Der f 15	98	C		Chitinase
	Der f 16	53	C		Gelsolin/villin
	Der f 17	53	C		Ca binding protein
	Der f 18w	60	C		Chitinase
Dermatophagoides microceras	Der m 1	25	P		Cysteine protease
Dermatophagoides pteronyssinus	Der p 1	25	C	>90	Cysteine protease, hom: Der f 1, Eur m 1, papain, cathepsins B and H
	Der p 2	14	C	>90	Lysozyme?
	Der p 3	28/30	C	51 to >90	Trypsin, hom: Der p 6, Der f 3, Der f 6, other trypsins and proteases
	Der p 4	60	P	25–46	Amylase
	Der p 5	14	C	>55	
	Der p 6	25	P	39	Chymotrypsin, hom: Der p 3, Der f 3, Der f 6 and other chymotrypsins and proteases
	Der p 7	22–28	C	53	IgE and monoclonal antibody bind to Der p 7 [518]
	Der p 8	26	C		Glutathione transferase
	Der p 9	28		>90	Serine protease, hom: groups 3 and 6 of mites
	Der p 10	36	C		Tropomyosin
	Der p 14		C		Apolipophorin-like protein
Dermatophagoides siboney	Der s 1	25			
	Der s 2	14			Correlated with Der f
Euroglyphus maynei	Eur m 1	24	C		Cysteine protease, hom: Der p 1, Der f 1, papain, cathepsins B and H [543]
	Eur m 2		C		
	Eur m 14	177	C		Apolipophorin
Glycyphagus domesticus	Gly d 2		C		
Lepidoglyphus destructor	Lep d 1	14–16	P		Hom: group 2 of mites
	Lep d 2				
	Lep d 5		C		
	Lep d 7		C		
	Lep d 10		C		Tropomyosin
	Lep d 13		C		
Tyrophagus putrescentiae	Tyr p 2		C		

Table 1.74. (Continued)

Name (species)	Allergens	kD	C/P	R	Notes and reference (if related)
10. *Homo sapiens* human autoallergens [639]					
	Hom s 1	73	C		
	Hom s 2	10.3	C		
	Hom s 3	20.1	C		
	Hom s 4	36	C		
	Hom s 5	42.6	C		

Allergens are usually ordered according to their common name: those corresponding to foods are listed among foods.
B column shows the percentage of reactivity [543]. All the known homologies are included [543]. The Der (p, f, m) 1 are considered major allergens, similarly to Der (p, f, m) 2; the latter ones, contrary to the first group, are thermostable and pH resistant; 80%–90% of Der p I is contained in the stools and 10% in the body. All insect allergens correspond to the primary antigen 5 and have identical MW; Can d is employed parallel to Can f, *Canis fidelis* [639].
Updated from [639], other data from [8, 15, 17, 60, 89, 98, 112, 121, 128, 134, 149, 199, 204, 265, 295, 310, 319, 348, 355, 365, 397, 384, 416, 405, 434, 471–473, 478, 497–499, 511, 543, 549, 551, 577, 604, 639, 652, 674].
C/P complete or partial availability of data, *hom* homology, *LTP* lipid transfer protein, *PL*, *PLA*$_1$, *PLA*$_2$ phospholipase, phospholipase A$_1$, phospholipase A$_2$, *PR* pathogenesis related protein, *RAP* rice allergenic protein, *RAG* rice allergen, *R* risk.

Table 1.75. Cow milk allergens

Allergens	MW (kD)	g/l	%	Stability at 100°C	Allergenicity
Caseins (Bos d 8)		24–28	80	+++	++
αs1	23–27	15–19	42		
αs2	23				
β	24	9–11	25		
κ	19	3–4	9		
γ_{1-3}	12–21	1–2	4		
Whey proteins		5–7	20		
β-Lactoglobulin (Bos d 5)	36	2–4	9	++	+++
α-Lactalbumin (Bos d 4)	14.4	1–1.5	4	+	++
Serum albumin (Bos d 6)	69	0.1–1.4	1	±	+
Immunoglobulins (Bos d 7)	0.6–1	2	–	+	
IgG	150–170	0.5–0.8	1.7		
IgM	900–1,000	0.05–0.1	0.2		
IgA	300–500	0.02–0.05	0.1		

Casein is the major antigen and allergen [121].
β-Lactoglobulin has four genetic variants.
Data from [24, 121].

Table 1.76. T-cell epitopes of allergens

Allergen source	Allergen	Size[b]	T-cell epitopes	Individuals tested	T cells
Perennial allergens					
Acarids					
Dermatophogoides pteronyssinus	Der p 1	24 kD, 222 aa	45–67, 94–104, 117–143	2	TCC
	Der p 1		110–119, 110–131	1	TCL and TCC
	Der p 1		1–14, 1–56, 15-94, 57–130, 95–208		
			188–222, 209–222	18	PBMC
	Der p 2	15 kD, 129aa	1–15, 11–24, 20–33, 29–42, 38–51		
			47–60, 56–69, 92–105, 101–114, 116–129	5	TCL and TCC
	Der p 2		1–20, 11–35, 22–50, 36–60, 51–77, 61–86		
			78–104, 81–96, 91–105, 87–112, 105–129	18	PBMC and TCC
	Der p 2		11–25, 16–31, 21–35, 22–40, 71–86		
			81–96, 82–100, 111–129	1	TCL and TCC
	Der p 2		20-33	2	TCC
	Der p 2		1–15, 11–25, 21–35, 31–47, 41–55, 51–65		
			61–75, 71–86, 81–96, 91–105, 101–115		
			111–129	24[a]	PBMC
Mammals					
Felis domesticus	Fel d I	17 kD	39–52, 53–66 (chain 1)		
		70–92 aa	9–21, 22–35, 57–70 (chain 2)	4	TCL and TCC
	Fel d I	(dimer)	1–17, 9–25, 18–32, 29–42, 37–55, 44–60		
			56–70 (chain I)	53[a]	TCL
			1–22, 12–33, 23–48, 34–59, 49–68, 60–82		
			74-92 (chain 2)		
Seasonal allergens					
Trees					
Betula verrucosa	Bet v I	17 kD, 159aa	2–16, 11–22, 61–72, 77–88, 85–96		
			113–124, 145–156, 147–158	6	TCC
	Bet v I		1–16, 27–40, 35–48, 75–92, 77–92		
			93–110, 141–156	2	TCC
	Bet v I		1–16, 11–26, 61–76, 63–78, 65–80, 75–90		
			77–92, 95–110, 97–112, 111–126		
			113–128, 127–140, 141–156	9	TCC
	Bet v I		1–15, 8–23, 19–33, 29–43, 46–63, 58–73		
			65–79, 73–87, 82–96, 90–104, 117–131		
			99–113, 126–140	3	TCL and TCC
Cryptomeria Japonica	Cry j I	41–45 kD, 353 aa	327–346, 337–353	1	TCC

Table 1.76. (Continued)

Allergen source	Allergen	Size[b]	T-cell epitopes	Individuals tested	T cells
Grasses					
Lolium perenne	Lol p I	34 kD, 240 aa	191–210	1[a]	TCC
	Lol p I		Several[c]	6[a]	PBMC
	Lol p I		1–20, 11–30, 21–40, 31–50, 41–60, 50–70		
			71–90, 91–110, 101–120, 111–130		
			121–140, 131–150, 141–160, 151–170		
			171–190, 181–200, 191–210, 221–240	8[a]	TCL and TCC
	Lol p I		Several[c]	6[a]	PBMC
Phleum protense	Phi p I	34 kD, 240 aa	22–36, 25–39, 34–45, 70–84, 73–84		
			91–102, 97–111, 91–102, 100–114		
			109–123, 121–134, 127–138, 130–141		
			142–155, 157–168, 169–183, 211–225,		
			226–240	9	TCC
Poa protense	rKBG60	28 kD, 268 aa	peptide 5. 99–118, 109–128, 149–168		
			159–178, 169–188, 199–218, 219–238		
			229–248, 239–258, 249-268	13[a]	PBMC
Venom allergens					
Insects					
Apis mellifero (honey bee)	Api m I (PLA_2)	19 kD, 134 aa	50–69, 83–97	1	TCL
	Api m I (PLA_2)		45–62, 74–91, 76–93, 81–92, 81–98,		
			107–124, 111–128, 113–124, 114–131	40[a]	PBMC and TCC
Food allergens					
Birds					
Chicken	Ovalbumin	43 kD, 385 aa	1–33, 198–231, 201–213, 261–277	4	TCC

[a] Even though the presence of several T-cell epitopes was described, T-cell epitopes that were recognized by more than 50% of all individuals tested have been identified in these studies.
[b] Sizes are shown as SDS-PAGE mobility of the native protein (in kD) and as number of amino acids (based on the recombinant sequence).
[c] These papers describe reactivity with several peptide pools. Exact amino acid sequences are not clear.
aa, Amino acids, *PBMC* peripheral blood mononuclear cells, *PLA_2* phospholipase A_2, *TCC*, T-cell clone, *TCL* T-cell line.

Table 1.77. Allergen association with HLA molecules and IgE responses

Allergens	HLA-DR	IgE^+ (%)	IgE^- (%)	RR
Amb a 5	DR2/Dw2	100	24	65
Amb a 6	DR5	85	14	35
Amb a 6	DR5	40	6	23
Lol p 2	DR3	47	15	5.3
Lol p 3	DR3	43	18	3.5
Lol p 3	DR3	57	7	18
Alt a 1	DR4	26	16	1.9
Der p 1	DR3	16	17	>1
Der p 2	DR3	19	16	>1
Bet v 1	DRw52a/c	62	33	2.5
Bet v 1	DRB3*0101	51	30	2.5
Fel d 1	DR1	16	9	2.0
Lol p 1	DR3	36	7	7.3
Lol p 1	DR3	33	14	3.1

Some allergens are shown twice since they are reported in different studies.
Data from [601].
RR relative risk.

Table 1.78. Transgenic or genetically modified foods

Introduced proteins	Crop products and targets
ACC deaminase, antisense PG, antisense ACC synthase	Delays without impairing the tomato's natural ripening and softening to obtain a more concentrated juice
Phosphinothricin acetyltransferase	Renders corn tolerant to herbicides
Neomycin phosphotransferase II	Protects potato from insects and delays tomato's natural ripening and softening
Glyphosate oxidoreductase	Renders corn tolerant to herbicides
Btt-HD1 insecticidal protein	Protects corn and tomato from insects
Btt-HD 73 insecticidal protein	Protects potato from insects
CP4 EPSPS synthase	Renders corn, soy and sugar beet tolerant to herbicides
β-D-glucuronidase	Renders soy tolerant to herbicides

There were controversies regarding GMO. Prohibitions and/or restrictions are expressed almost everyday in several countries.
ACC 1-amino- 1-cyclopropane-carboxylic acid, *Btt Bacillus thuringiensis* subspecies *tenebrionis*, *Btk* = *Bacillus thuringiensis* subspecies *kurstaki*, proteins from strains HD-73 and HD-1, *CP4 EPSPS* 5-enolpyruvylshikimate-3-phosphate synthase from *Agrobacterium* strain CP4, *PG* polygalacturonase.
Modified from [347].

Table 1.79. Additional GM foods

Apple	Carrot	Kiwi	Rapeseed oil	Rye
Apricot	Cauliflower	Lemon	Orange	Soybean
Asparagus	Celery	Lettuce	Papaya	Spinach
Barley	Chicory	Licorice	Pea	Strawberry
Bilberry	Colza	Lotus	Peach	Sugar beet
Black currant	Eggplant	Maize	Plum	Sweet potato
Broccoli	Fennel	Melon	Potato	Tomato
Buckwheat	Grape	Mustard	Raspberry	Walnut
Cabbage	Horseradish	Oats	Rice	Wheat

Modified from [110].

Fetal and Neonatal Immunology and the Mucosal Immune System

Immunodeficiency and Immaturity

Immunodeficiency and immaturity are two distinct concepts, both characterizing the neonatal period: it is a transitory period for the immune system, opening exquisitely new problems [86]. Immunodeficiency depends on the immaturity at the molecular and functional level of immunocompetent cells, and to accomplish diverse and sophisticated roles such cells should complete their differentiation. The neonatal incapacity to respond to sudden exposures to antigens and microorganisms is not exclusively a consequence of immune immaturity, but also of a missed immune experience. Neonates should leave a situation of immunological dependence, dictated by the necessity of avoiding maternofetal reactions during pregnancy, to adapt to the new requirements of extrauterine life. During intrauterine life, the fetal immune system (FIS) is modulated in a suppressive direction so that the reactions directed against the maternal HLA antigens do not occur, in concert with mechanisms of maternal tolerance correlated with fetal genetic and antigenic heterogeneity, to avoid a graft-versus-host disease (GvHD). There is a wealth of evidence showing that both fetus and placenta are provided with a number of HLA antigens encoded by paternal genes, thus representing a paternal allograft to the mother. The lack of convincing evidence explaining why this foreign tissue is not rejected is a gap with deep origins, whereas the FIS, immunologically primed by the second trimester, could in turn prime GvHD [48, 221, 229]. A type of maternofetal balance is thus created that can be outlined as follows:

- The syncytiotrophoblast (the syncytial outer layer of the trophoblast) supplied with HLA class I- and II-negative antigens is interposed between maternal uterine cells and the conceptus, thus acting as a partial barrier to maternal immunogenic material [48].
- There is production of class II-dependent antibodies, but not of class I-restricted cytotoxic T lymphocytes (CTLs) [229].
- Specific antibodies prevent generation of paternal-antigen-directed cell-mediated immunity (CMI) at the syncytiotrophoblast level [229].
- Nonspecific serum factors limit the effects of CMI, either systemic or local [221].
- In the presence of adequate mitogens and antigens, fetal T lymphocytes are inclined to suppress adult lymphocyte proliferating responses and further differentiation, that is stimulated by Th2-like ILs of activated fetuses [169], thus avoiding that maternal T cells prime a GvHD in the conceptus [229].
- Th2 T lymphocytes in particular produce IL_4, IL_5, IL_{10} at the maternofetal interface during the entire pregnancy, thus inhibiting suppressor Th1 T cells and related Th1-like interleukins (ILs), insuring fetal survival until birth even if ILs depress immune responsiveness by impairing responses against maternal and fetal pathogens [221].
- Prevalence of Th1-like ILs, unless there is a shift to Th2 T cells, induces "immune" abortions or recurrent spontaneous abortions of unexplained etiology [85], as demonstrated by Th1-like IL production from an abortion-inclined placenta [221].
- Presently, deleterious Th1-like ILs can compromise pregnancy: IFN-ɣ activates NK (natural killer) cells able to damage trophoblast tissue and with a potential role in immune abortion, also inhibiting IL_4, IL_5, IL_6 involved in various phases of B-cell development and Th2 T-cell proliferation [219].
- IL_{10}, in synergy with IL_2, is believed to stimulate activity of LAK (lymphokine-activated killer) cells (Chap. 1), which discriminate between self and non-self, thereby contributing to fetal protection shutting off maternal immune responses biased toward humoral immunity [219].
- Trophoblast cells, although devoid of HLA-A or HLA-B molecules, when in contact with maternal cells directly express HLA-G molecules but are not able to protect from NK-cells killing specific targets not expressing HLA molecules [160].

Successful pregnancy is therefore associated with a bias toward Th2-skewed IL response [167] postulated to limit cellular damage in embryonic tissues [102]. Repeated contact with common environmental allergens during the postnatal period probably redirects the fetal Th2-skewed immunity toward a Th1-skewed immunity in nonatopic babies, whereas the Th2-dependent allergic sensitization is reinforced in atopic babies [166].

As a corollary, at the end of pregnancy there is a shift to humoral immunity and a gradual maturation of Th1-like T-cell ILs and IFN-ɣ, NK-cell and TNF production,

to mount a rational strategy of antimicrobial defense, whereas the active Th2 response results in protective immunity for neonates that have not developed an endogenous immunity [221, 229].

Fetal–Neonatal Immune System: Immunocompetence or Immune Depression?

The particular susceptibility of newborns having left the protective husk of the maternal uterus to food, inhalant and infectious antigens, who remain exposed to a relevant antigenic stimulation, objectively critical, has induced several investigators to provide insights into the functional and phenotypic characteristics of the immune system components during intrauterine life and the B- and T-cell ontogenesis [224]. The human fetus has a genetically programmed capacity to recognize and respond to a great number of antigens, while the neonatal immune system, not yet "educated" to the extrauterine world, is unprepared for the new functions allowing the fetus to elicit an effective specific immune response [225]. However, after the termination of passive immunity, babies' chances of survival will depend on their induction of adaptive defense mechanisms. As a consequence, T and B lymphocytes, immature at birth, should establish contact with numerous environmental antigens to organize an adequate immune defense [144].

Recent studies on experimental animals underline that *neonates are immunocompetent,* thus immune responses to antigens do not differ practically from those of adult subjects [59, 171, 183]. In this respect, the neonatal period should no longer be considered in ontogenesis as a passive immune window, essential to acquire the tolerance of subsequent years, but as an immunologically normal and active period [59]. The concept of a *window period* dates back to a 1945 report, after which the theory of tolerance was postulated, based on two cattle twins injected at birth with HSCs from a genetically nonidentical donor, later able to accept transplants from the same donor [156]. This report has long influenced the understanding of the neonatal period, and was followed by studies by Burnet and Medawar.

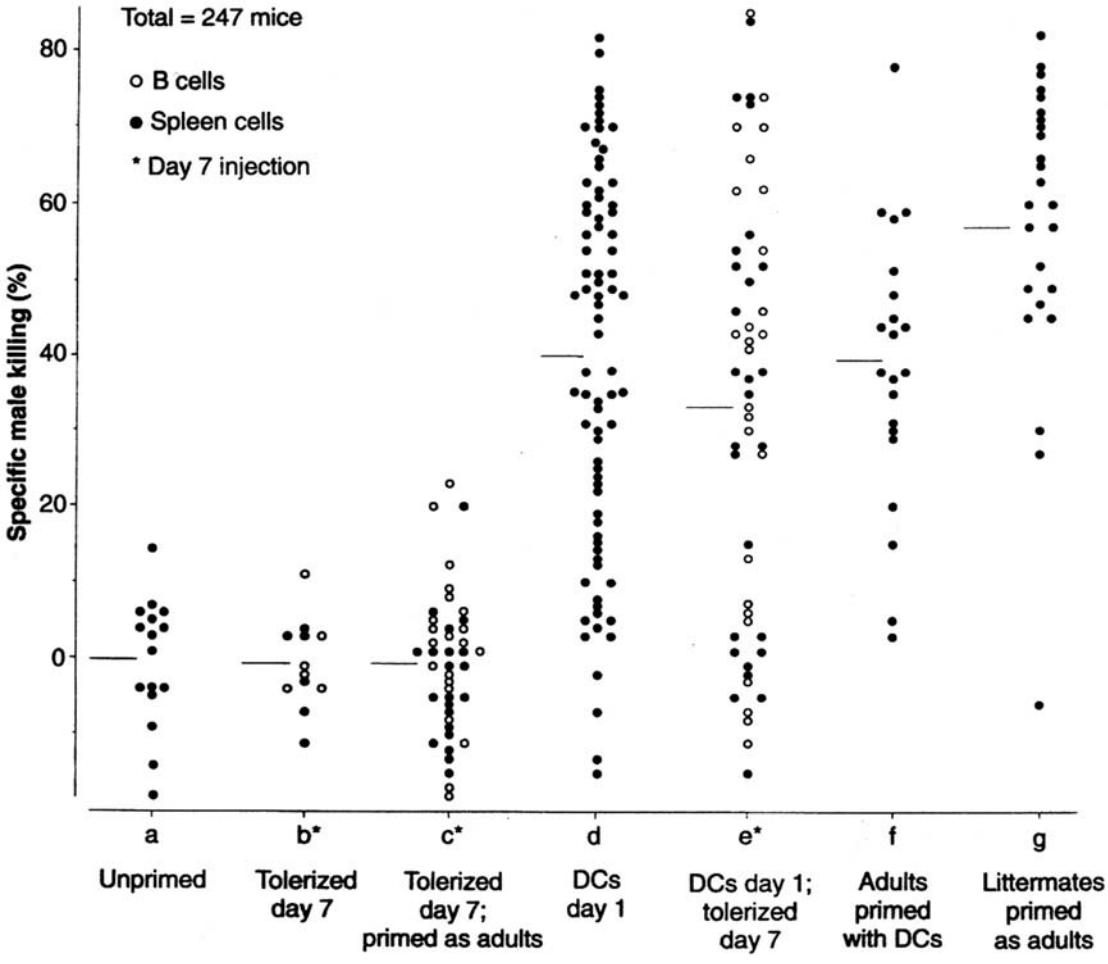

Fig. 2.1. Neonatal T cells first primed with dendritic cells (*DCs*) are resistant to tolerance induction

Additional and interesting reports have cast greater light on these aspects of neonatal immunology, including research on development and behavior of HLA molecules, IgA antibodies and secretory component (SC) in premature infants and full-term neonates who were either stillborn or who died during the first 3 weeks of extrauterine life or in the postnatal period [174]. The enigma of nonmaternal antibodies in newborns of hypogammaglobulinemic mothers [73] has further documented the role of idiotype/anti-idiotype antibodies [74].

Since the immune system is still maturing in neonates during the first days of life, they may be suddenly confronted with a vast array of potentially dangerous microorganisms, which would take up residence and circulate to the intestinal mucosa [40]. The detrimental action mediated by certain bacteria may put into effect the adhesion of additional organisms that normally do not challenge the intestinal mucosa; however, the immune system response to virus primes a Th1 or Th2 response and is thus critical in the development of protective immunity [183]. Neonates are not immunologically naive, but can mount significant immune responses to environmental antigens, a possible result of prenatal sensitization. Neonatal immunocompetence has been demonstrated by newborn mice that were given dendritic cells (DCs) on day 1 and were fully able to activate neonatal immune T cells (Fig. 2.1, d) to the same extent as were the adult female controls (Fig. 2.1, e) [171]. In the spleen, the essential organ for defense against capsulated bacteria, the marginal zone and CD21 (C3d receptor) are absent in neonates, thus making its role difficult [162]. Instead, the marginal zone is active in infants and the CD21 levels are still low; however, CD35 (C3b receptor) primed to common antigens [134] is found in the B-cell zone [162]. However, the neonatal inadequacy to mount an effective antimicrobial response, *is amplified by IFN-γ deficiency* and upstream reduction *in memory T cells*, as well as by several functions, as detailed in Table 2.1 [25, 29, 38–40, 50, 53, 55, 71, 82, 83, 127, 130, 137, 140, 152, 158, 164, 168, 170, 172, 201, 210, 222, 223, 225, 232–234, 239]. Moreover, CMI induction is delayed, the CTL response is decreased (Table 2.2) [71, 101, 130, 219, 224, 225], and immunoglobulin (Ig) class switching is limited [201]. Fetal and neonatal IFN-γ and IL_4 levels are depressed (Table 2.3) [3, 71, 102, 127, 158], especially when family history of atopy (FHA) is positive [126], even for several years [3, 168]. The fetus (human amniotic fluid at 16–17 weeks of gestation) has 0.0 pg/ml of IFN-γ [102]. No differences in the very low or undetectable CB (cord blood) levels of IL_2-, IL_4- and IFN-γ-producing Th and T-suppressor/cytotoxic lymphocytes were found between neonates from atopic and nonatopic parents [71].

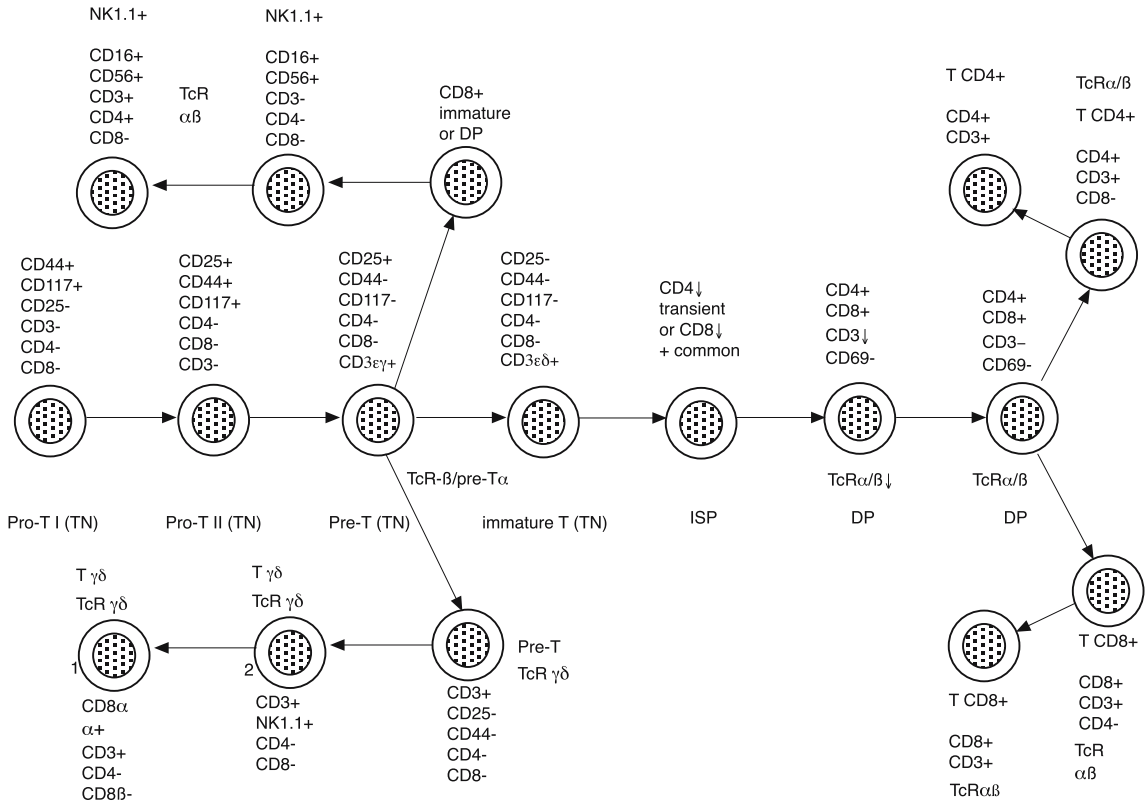

Fig. 2.2. Lymphocyte CD4, CD8, and NK cell development and receptor expression. The negative cells (–) are present but not expressed. TcR-γδ cells shown as *1* are found predominantly in intestinal epithelium. The cells shown as *2* are found in nonintestinal epithelial surfaces, e.g., skin. *TN* triple negative, *ISP* immature single positive, *DP* double positive *NK1.1* NK cells. (Modified from [1])

Ontogeny of the Immune System

In the fetal liver HSCs generate specialized cells, such as polymorphonuclear (PMN) cells and macrophages, DCs, NK cells, and mediators of inflammation, such as mast cells, basophils and eosinophils [123]. T and B lymphocytes, derived from pluripotential HSCs in the fetal liver [123], unlike other cells of the organism are characterized by a biphasic differentiation, according to whether they depend on antigen stimulation. The inductive phase occurs in the thymus for T cells and in the bone marrow for B cells, where both types of lymphocyte undergo an irreversible differentiation, consisting in genetic rearrangements leading to TcR (T-cell receptor) and BcR (B-cell receptor) expression [137]. By 18–20 weeks of gestation, the human thymus differentiation appears to be complete and T lymphocytes are provided with TcR. From the first trimester, T and B cells start to express clonal diversity, while the CTL production, one of the more outstanding effector functions of T cells, begins in the middle of fetal life. From this period onward, a specific antibody response may also be present, quantitatively and qualitatively different from adult responses: fetal and neonatal B cells possess a fully limited skill of synthesizing antibodies of IgG and IgA isotypes, even if precursor B cells expressing such isotypes are present. In the central phase, a selection process takes place since the lymphocyte's fate is not the same for all of them: during maturation the cells interact with HLA proteins localized in thymus positioned on the APCs (antigen presenting cells) surface associated with peptides for T cells and antigen epitopes interacting with BcR for B cells. The first selection concerns T lymphocytes with TcR that recognize both exogenous and autologous antigens, always in the context of HLA molecules: the lymphocytes with affinity for autologous antigen, that is self-reactive clones, are removed or anergized and die (apoptosis) and only T cells with specificity for exogenous antigens survive [159] (Fig. 1.22, Tables 1.16–1.19). During fetal life, the immune system undergoes an active proliferation of elements and functions (Table 2.4) [102, 120, 130, 144, 149, 159, 215, 219]. A still unclear crucial progress is the early expression of a pre-receptor on the cell surface, in both T and B cell development. The pre-TcR on thymocytes is formed by a TcR-β chain associated with a structure called pre-Tα. The equivalent pre-BcR contains an H IgM chain associated with two invariant surrogate L chains: λ_s and $V_{pre\text{-}B}$. Even if the ligands for these pre-receptors are not yet known, signaling from these molecules is necessary to continue molecular development [179, 225] (Fig. 2.2 [1], Tables 2.5, 2.6 [130]).

Table 2.4. Development of immune system in fetus

Gestation (weeks)	
5	First rudiments of spleen
5.5	Synthesis of complement detected (C3)
6	Start of myelopoiesis
6–7	Fusion of thymic lobes
7	Hemopoietic cells in liver
7–8	Lymphocytes appear in peripheral blood (1,000/mm^3), pro-B cells in liver
8	Synthesis of complement (C2, C5)
8–9	Lymphocytes in thymus
8.5–10	T-cell receptor (TcR) development in thymus, TcR-γδ before TcR-αβ
9.5–11	Maturation of pro-B cells in liver and spleen with IgA, IgD, IgM, IgG surface markers, serum IgM levels detectable
10	Corticomedullary differentiation appears
10–11	Lymphocytes in bone marrow and intestine
11	IgE antibodies in liver and airways CD40 abundantly expressed HLA class II expression
11–12	Intraepithelial lymphocytes in the gut
11–24	Gut expressing CD3, CD14, CD20, CD28, CD40, CD68, CD86, CD154, CTLA-4 HLA class II and APC (antigen presenting cells)
12	Hemopoietic cells in thymus and spleen Mononuclear cells in spleen, antigen recognition Stem cells in bone marrow
12–14	Pre-B cells in bone marrow, first identifiable Peyer's patches in the gut
12–15	Thymus becomes lymphoid
13	Graft-versus-host reactivity is present IgE antibodies in the amniotic liquid Transplacental HIV transmission
14	Response to passive hemagglutination by thymus lymphocytes First MALT and tonsil rudiments $CD3^+$ cells detectable in increasing numbers
14–16	Mature neutrophils, first rudiments of ethmoidal and maxillary sinuses
15	Complete differentiation of T and B cells, Langerhans' cells in tonsils
15–16	Lymphocytes in blood, first cytotoxic T cells
15–17	Serum NK cells and IgM levels detectable
16	Corticomedullary differentiation complete, primary follicles in tonsils First lymphoid follicles start forming $CD20^+$ cells abundant in the lymphoid follicles of rudimentary PPs CD83 immunoreactivity detectable (mature DC cells) $CD154^+$ and $CD152^+$ cells detectable in the lymphoid follicles
16–17	IL_{10}, TGF-β (full levels)
17	Serum IgG levels detectable First PBMC proliferative response to PHA. Some PBMCs may release IFN-γ
18	Lymphocytes migrate into lymph nodes, complement levels detectable

Table 2.4. (Continued)

Gestation (weeks)	
18–20	Complete differentiation of T lymphocytes with TcR γδ TcR T cells in the epithelium Lymphoid follicles and Peyer's patches with primary B follicles and T zones FIS is active (see Tables 2.5 and 2.6)
20	Maturity of thymus, memory lymphocytes the ability to synthesize immunoglobulins is complete
20–25	Lymphocytes in blood about 10,000/mm^3, T cells = Th1+Th2 Increased B-cell traffic
21	IgE antibodies in spleen
21–22	CD25$^+$ levels reach 50 % of neonatal levels The FIS may be primed by maternal allergens
22	Complement levels detectable in serum PBMC proliferative response to more antigens The fetus can react to food and inhalant allergens of maternal origin
22–24	Secretory component in duodenal mucosa and trachea
24	Peyer's patches are scattered throughout the gut
25	Differentiation of white and red pulp in spleen
30	IgA level detectable in serum
31	B cells with membrane-bound IgD detectable in serum
33	IgG levels reach maternal levels

T Cells

T cells arise from bone marrow hemopoietic precursors and at around the 8th week of intrauterine life colonize the fetal thymus, where the lymphoid cells or thymocytes undergo different degrees of differentiation, each characterized by changes in surface antigens. Immature thymocytes are identified in the cortical zone at 8–9 weeks and in the medulla at 10 weeks, where the thymocytes undergo further differentiation at 18 and 20 weeks of gestation [3]. This process regards 5% of the thymocytes escaping apoptosis; negative selection occurs next and is mediated by bone marrow-derived APCs, which eliminate autoreactive cells by clonal deletion or anergy (Chap. 1). Lymphoid cells (about 5%–10% of thymic lymphocytes) express antigens shared by bone marrow cells of the hemopoietic lineage. Figure 2.2 shows different stages of lymphocyte development, including CD4, CD8, NK cells and receptor expression: not shown is the common origin of cell lines from a common precursor, CD34, an early marker of hemopoietic precursor cells, which binds to bone marrow stromal cells [1]. At 7–8 weeks of gestation lymphoid cells with the CD7 phenotype migrate into the prethymic mesenchyme, membrane CD7 is the marker of mature cells, along with the ε chains of cytoplasmic CD3. By 10 weeks thymocytes acquire new antigens identified by means of monoclonal antibodies: CD1 (expressed only during the thymic residence), CD2 (which remains for the entire life-span) and CD3 [321, 123], as well as by 8 and 14 weeks, CD71, CD2, a receptor for sheep erythrocytes, identified also by anti-CD2 antibodies and expressed in all thymocytes and circulating T cells [6]. CD2, CD3, CD7 belong to IgSF (immunoglobulin superfamily) (Table 1.4).

By 15 weeks of gestation, CD7 and CD3 undergo varying stages of differentiation [32], are TdT-positive (terminal-deoxynucleotidyl-transferase), and then express CD4, CD8 and the TcR-β chain. The next stage is marked by membrane expression of both CD3 and TcR-αβ, whereas TdT cannot be detected at the passage from cortical to medullary regions [32]. More than 90% of CD3 and CD7 express CD38, a transducer of activation signals (Table 2.6), which along with CD71 are not specific markers of T cells, since they also belong to cells of other lineages [123]. By the stage of immature T cells, there are TN (triple-negative) cells expressing the IL_2 receptor (CD25), CD34 (mediates apoptosis) and CD117 (signal transducer) [1]. Only in the next stage do ISP (immature single positive) cells express CD4 or CD8, until cortical cells (70%–80%) express $CD4^+CD8^+$; however, in the medullary stage they divide (10%) into two subpopulations with TcR-αβ (Fig. 2.2). Although immunocompetence is already acquired in this stage, it is unlikely that qualitative changes take place while lymphocytes remain in the sheltered intrauterine environment [123].

From a molecular point of view, the first developmental stages of T cells imply the rearrangement and expression at the cell surface of TcR genes. At this level, selection can start, more precisely at the earlier stage fetal TN thymocytes (Figs. 2.3, 2.4). The γδ receptor of T cells (TcR-γδ) is the first receptor in human ontogenesis associated with CD3, soon followed in order by TcR-αβ expression (about 8.5–10 weeks of fetal life) [72]. At a later stage, thymocytes expressing TcR-γδ progressively decrease in number: as summarized in Table 2.6, γδ TcRs at 18–20 weeks of gestation are 4.5%–7.8% αβ TcRs [130]. At 12 weeks of gestation, antigen recognition is present, around 14 weeks T cells acquire surface markers, leave the thymic environment for further differentiation, expressing $CD45RA^-$ and $CD45RO^+$. At 18–20 weeks of intrauterine life, the distribution of diverse subpopulations is roughly comparable with that of a mature thymus [144] with CD4 T cells that are twice the number of CD8 T cells [130]: at 20–25 gestational weeks, 10,000 T cells/mm^3 are found in blood [144].

Compared to adults, there are evident quantitative differences, as demonstrated by the lower numbers of CD3 and a reversed CD4/CD8 ratio due to the scarce number of CD8 [130, 147] (Table 2.5). By 19 weeks of gestation, $CD3^+$, $CD4^+$ and $CD8^+$ T cells gradually increase in number, reaching a peak at about 6–7 months after birth [174], whereas CD45RO neonatal levels

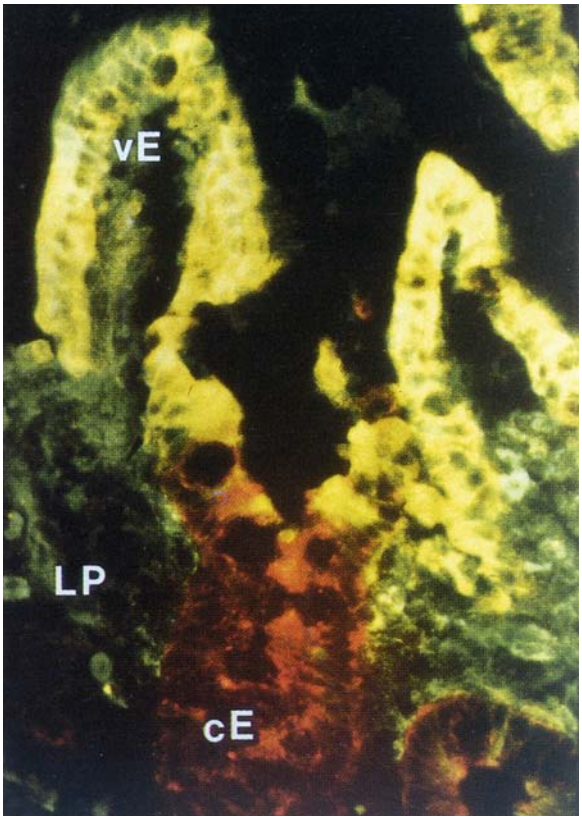

Fig. 2.5. Duodenal mucosa of a 1-week-old neonate. The cells are stained *green* for HLA-DR and *red* for keratin. The keratin-positive vE is also intensely positive for HLA-DR. *cE* crypt epithelium, *LP* lamina propria

Table 2.7. ILs promoting the proliferation and differentiation of thymocytes in vitro

IL(s)	Responding cells	Effects
IL_2	H DN	Proliferation, $IL_2R\alpha$
IL_4	H CD3 DN	Proliferation and maturation; TcR-γδ maturation
IL_7	MSP	Proliferation and differentiation
	H CD3 DN	Proliferation and maturation
IFN-γ	MDN day 15 fetal	IL_4-mediated inhibition, proliferation
TGF-β	M total thymocytes	Inhibition of proliferation

Only the effects induced by unstimulated ILs have been included.
Data from [34].
IL(s) interleukin(s), *H* human, *M* murine, *DN* double negative, *SP* single positive.

Table 2.8. Evident effects that IL(s) modulate the proliferation and differentiation of thymocytes in vivo

IL(s)	Effects
IL_1	The majority of day 13–17 M fetal Thy constitutively express IL_1R
	Fetal Thy epithelial and bone-marrow-derived stromal cells constitutively produce mRNA for $IL_1\alpha$ and $IL_1\beta$
IL_2	H fetal Thy express $IL_2R\alpha$, especially in pre-T cells (SP, SN, DN)
	Day 15 fetal Thy constitutively express IL2 and IL_2R genes
	Day 14–17 fetal Thy constitutively express high- and low-affinity IL_2R
	IL_2-IL_2R intervention seems to be necessary for M fetal Thy differentiation
	Anti-$IL_2R\alpha$ antibodies administered to pregnant mice block T-cell development in neonatal offspring
	Anti-$IL_2R\alpha$ antibodies inhibit the thymic regeneration in sublethally irradiated mice
	$IL_2R\beta$-human $IL_2R\alpha$ heterodimer induce the accumulation of T-cell precursors in the thymus and periphery
IL_3	Originates from T cells, mRNA expression is reduced, but mononuclear cells produce high levels of IL_3 after LPS stimulation
IL_4	Day 15 fetal Thy constitutively produce IL_4 mRNA and express IL_4R
	Populations of adult mice DN Thy express IL_4R
	The constitutive production of IL_4 in IL_4-transgenic mice inhibits DP Thy and mature peripheral T-cell development
IL_6	Promotes the differentiation of Thy -1^+ IL_2R^+ donor Thy after intrathymic transfer into irradiated hosts
IL_{10}	Promotes the growth of progenitors of the erythroblastic series and immature Thy in synergy with IL_2 and IL_4

Data from [3, 34, 115].
Thy thymocytes, *M* murine, *DN* double negative, *SN* single negative, *SP* single positive, *LPS* lipopolysaccharides.

Table 2.9. ILs promoting the growth, proliferation and differentiation of intrathymic T cells

? Not clear.

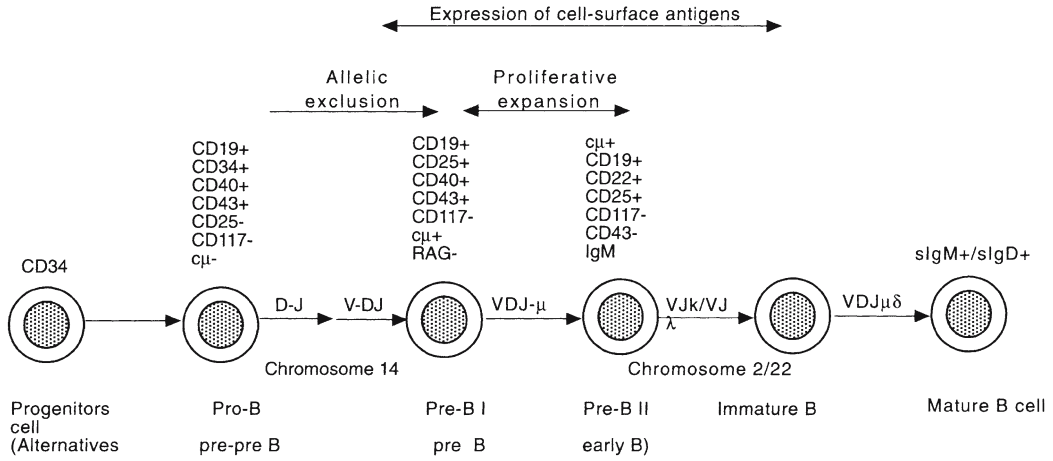

Fig. 2.6. Stages of B lymphocyte development and receptor expression. The CD-negative cells (–) are present but not expressed: *cμ* are H chains of cytoplasmic IgM antibodies. (Data from [1, 31, 122])

remain stable (Table 2.6). So fetal thymocytes, still expressing several functional capacities, at birth appear in a stage of substantial maturation. HLA class I antigens are ready in the fetal intestinal epithelium [174, 179], whereas HLA-DR expression, scarce in CB (cord blood) [147], is positive in the gut by 1 week of postnatal life [174] (Fig. 2.5). Between 11 and 16 weeks of gestation, both HLA class II and costimulatory molecules are present, CD40-CD154 and CD86-CD28/CD152 counter-ligands of B-cell CD80 and CD86 provide the costimulatory signals required for the initiation of antigen-specific reactivity in the human fetal gut as early as 16 weeks of gestation [102].

In distinct stages of T-cell ontogenesis, several ILs have positive effects (Tables 2.7–2.9) [3, 34, 64, 115]. Table 2.1 outlines their deficits or delayed activation: an intrinsic abnormality of CD4 T cells is associated with the pathogenesis of atopic disease.

NK cells derive from CD8 DP T cells and acquire CD16 and CD56 (Fig. 2.2), which are IgSF members.

B Cells

As the primary site of hemopoiesis shifts from the fetal liver to the bone marrow, by 12 weeks the latter becomes the site of B-cell generation during the fetal life; at birth this function relies almost exclusively on bone marrow and to a lesser degree on the spleen, immature in the neonate [162]. B cell functions, after leaving the bone marrow, where IL_7 and IL_{11} contribute to B-cell maturation, are always under the control of T cells, until the final differentiation in plasma cells [179, 225] (Fig. 2.6) [1, 31, 122]. B-cell maturation is characterized by differences in the expression of genes dictating H and L chains and the organization of different chains. In the earliest phase, lymphoid HSCs generate pro-B cells, which are identified in the liver from 7–8 gestational weeks and characterized by CD106 provision of CD45, TdT enzyme, IL_7 and SCF (stem cell factor), equal to CD117 receptors and DJ rearrangement on both pairs of chromosome 14, dictating two H chains (one for each parent) [123]. Pro-B are dividing cells, free of recombinations and expressing different L-chain genes that have begun the process of H-chain gene rearrangement, distinctively have no detectable Ig on cytoplasmic membranes, and express HLA class II molecules: CD19 and CD22 (Fig. 2.7). As early as 9 weeks of fetal life, the first pre-B I cells appear following a VDJ rearrangement and the production of Hμ chains, characterized by the expression of μ cytoplasmic chains, but not of L chains. Pre-B cells no longer present the TdT enzyme, but IgM or IgD, C3, CD20, which along with CD19 remain until the stage of blasts [106]; active partners are the adhesion molecules (CD49d/CD29 and CD44), SCF, IL_3 and IL_7 produced by the same cells. On chromosomes 2 or 22, B cells start the VJ rearrangement of λ or κ genes, the L chain synthesis and expression of a monomeric IgM receptor [123]. When pre-B I differentiate into pre-B II cells, L chains are also expressed and display IgM or IgMs (surface) [31]. The BcR function is present from the pro-B stage and active from the pre-B stage (Fig. 2.8).

From Fig.2.4 the similitude of the two pre-receptors is evident as concerns Ig-like domains (*ovals*) and ITAM (*boxes*). Any further gene rearrangement flops since RAG-1, RAG-2 or other recombinase components are lost (Chap. 1): IgMs (surface) antibody is regarded as essential for the closure signals. By 12 and 14 weeks of gestation, immature B cells differentiate into B cells co-expressing IgM and IgD, both with the same V region, and acquire the Fc receptors for IgG [144]. During ontogenesis, all B cell clones derive from progenitors expressing IgM or IgMs; many B cells express all three isotypes together [3]. Immature B cells expressing IgAs or IgGs also co-express IgMs and IgDs, whereas co-expres-

Fig. 2.7. Surface antigens of B cells. *T* T lymphocytes, *M* Monocytes, *Pla* plasma cells

sion of IgAs or IgGs is uncommon. All the maturation up to this point has taken place in the bone marrow and is antigen-independent. The presence of mitogens or an appropriate combination among antigens, T cells, T-cell-derived ILs, macrophages and accessory cells is necessary thereafter [122]. Mature B cells interacting with antigen lack membrane IgD (mIgD) and expose the other isotypes in sequence on their membrane. The end stage of B-cell development is the differentiation into plasma cells, when surface Igs, HLA-DR, CD19, CD20, CD21 and CD22 are lost; to complete Fig.2.6, CD19, CD20 and CD22 are expressed continuously from the pre-B-cell stage [106]. B-cell surface antigens are summarized in Fig.2.7. Pre-B cell production occurs in the bone marrow by 12 weeks; by 11–16 weeks of gestation, pre-B cells are as high as 1–4% of nucleate cells and outnumber B cells with mIgM with a ratio of 2:1. By 30 weeks of gestation, there is no detectable pre-B cell in the fetal liver [3]. The pre-B cell proportion in the spleen and bloodstream is lower than that of B cells. In the adult, pre-B cells are produced only in the bone marrow [144].

By 11 weeks of intrauterine life, the human fetus synthesizes IgE antibodies in the liver and lungs, which, similarly to IgA and IgM, do not cross the placenta [120]: elevated fetal levels of IgM and occasionally of IgA have been associated with intrauterine infections [169]. IgG are seen by 17 and IgA by 30 weeks of gestation (Table 2.4). The expression of SC is in the duodenal mucosa [174] and fetal trachea with increasing levels [204] at 24 weeks of fetal life (Fig. 2.9) [204], until SC reaches normal values at 1 week after birth, a production stimulated by both TNF-α and IFN-γ [19]. Therefore, a normal fetus can rely on IgG antibodies, as an exclusive result of active and gradual transplacental transport from the mother, until at 33 weeks of gestation fetal IgG achieve maternal levels [120]. IgE antibodies, practically absent *in utero,* are synthesized after birth, rising slowly at about 3 weeks [174, 204] (Fig. 2.10) [204], despite reports of CB IgE levels also in nonatopic babies, independent of maternal diet during pregnancy [82].

Phagocyte Cells

Phagocyte cells appear beginning in the 2nd month of intrauterine life: the differentiation and subsequent maturation of progenitor cells is promoted by hematopoietic CSFs (colony-stimulating factors) stimulating colony proliferation and differentiation, distinct in GM-CSF (granulocyte macrophage-colony stimulating factor) and M-CSF (monocyte/macrophage-colony stimulating factor) and by IL_3. In the liver and peripheral blood of fetuses 8–21 weeks of gestation, several CFU-GM (colony forming unit – granulocytes and monocytes) have been identified. Mature monocytes are found in lymph nodes and spleen by 4–5 months of gestation. Macrophages mature gradually during the fetal life: before birth and in the neonatal period, they are scarce in number and immature in the lung alveoli; however, soon afterwards a massive influx of mature cells in the airways is noted [86]. Chemotaxis is relatively deficient in neonates [238] and is 79% of the mean adult value [54] (Table 1.65).

Complement Factors

Complement has been identified in fetal tissue by 6 weeks of gestation and serum levels are detected at 30 weeks (Table 2.4); however, C1q, C2, C3, C4, C5 concentrations are modest in neonates (C3 0.60%–0.79% and C4 0.41%–0.59% of the mean adult value) [50], and correlated with gestational age (GA) [53]. Significantly, the impact of GA in the deficit of components (and of opsonization) is more evident in neonates with a lower GA [50]. Hemolytic complement titers of normal full-term neonates are about 50% that of the mother [169]. Concentrations increase rapidly, reaching mean adult

values by 3 and 6 months [50], with the exception of both C1q and properdin levels, which, although approaching 90% and 71% of adult levels, respectively, in term neonates [235], they remain low until 12–18 months of age [53].

Neonatal Immunodeficiency

As pointed out previously (Table 2.4), the fetus is able to recognize and respond to a wide assortment of antigens because this capacity is genetically programmed. To reach this objective, an elaborate interrelation among several components of the immune system is necessary, dependent on their developmental cycle, which even though in unending evolution [40], is not free from severe deficits of B and T lymphocytes. If the intestinal mucosa is a frequent entrance for several infectious agents, it is because fortunately Mother Nature, always a provident protector of the human species, has selected a seat such as the intestinal mucosa, passively protected by the immune factors present in breast milk, for the first contact with potentially pathogenic substances [155]. Human milk supplies the vulnerable newborn not only with critical nutrients, but also with the powerful Ig defense against the assaults of antigenic macromolecules and of infectious agents [27]. The particular characteristics of the neonatal immune system are summarized in Tables 2.1, 2.2, 2.5, 2.6; see also Tables 1.34–1.39. Table 1.38 shows significant differences between CB and venous blood of the same children at 5 days of life.

Cellular Immunity

In CB and in term and preterm neonates aged 1 day, of adequate weight for GA, an absolute proportion of cells positive for CD4 and CD8 monoclonal antibodies is found, significantly more than the counts in low-birthweight (LBW) neonates for GA. A neonate of whatever GA has an absolute number of T lymphocytes greater than adult values, as well as quite a number of cells positive for CD6, CD9, CD10 [225] and CD1, *an index of normal lymphocyte development* [86]. These positive data are matched by the persistent CD4/CD8 ratio increase (Tables 1.38 and 2.5) and the clear activation deficit of both CD2 and CD3 [165] equal to about 64% and 52% in CB, respectively (Table 2.5), corresponding to the initial low density of the memory $CD45RO^-$ cells also in CB (Table 2.6) and virtually of the whole $CD4^+$ subset (10%), in parallel with the scarce proportion of $CD45RA^+$ compared to adult vales (15% vs 50%) [86, 164]. The high expression of CD38 is a marker of immaturity when associated with CD45RA cells and of immune activation when co-expressed by CD45RO cells; we can hypothesize that CD38 makes immature fetal and neonatal CD45RA cells more responsive to signals mediated by previously encountered antigens during ontogenesis or at early stages of their functional maturation [130]. The selective shortage or depressed expression of IL genes may be ascribed to poor CD2 and CD3 levels [6], whereas TcR and CD8 modulation is unchanged 165]. The contrast between the initial activation and subsequent decrease in T cells is confirmed by the apparent hyperreactivity to mitogens at 1–2 days and the reduced T-cell proliferation at 5 days of life [17], thus suggesting an inadequate maturation and/or a shorter T-cell life cycle, mainly of CD8 [225]. Neonatal T-cell immaturity demonstrated by a scarce proliferation via CD2 and CD3 stimulation [6] is stressed by the IL_2R restoration of neonatal PBMC (peripheral blood mononuclear cell) unresponsiveness to CD2 and CD3 [164]. IL_2 binding to its receptor, with normal neonatal levels [217], induces T-cell proliferation [164], therefore there are transitory supernumerary T cells, perhaps reflecting an excessive activation in response to the first exposure to environmental antigens of the immature immune system. A demonstration may be the transient peak of IL_2R serum levels, which remain above adult ranges over 2–3 years, independently of T-cell levels, thus suggesting that IL_2R activators are T cells isolated in the periphery, maybe in mucosal sites [46]. $CD45RA^+$ $CD45RO^-$ T cells predominate among neonatal circulating lymphocytes until an antigenic challenge occurs. A study has postulated that $CD45RA^+$ T cells may suppress or alternatively prime Ig production [181], thereby explaining, at least in part, the unusual susceptibility to infections of the neonatal age. The persistence of naive subsets of CD45RA during the first years of life, even following antigenic challenges, as shown by an *increased expression of $CD45RO^+$ cells soon after birth,* although with lower levels when compared with adult levels [236], might be responsible for the deficit of CD2 and CD3 [165] or of CD11a/CD18 [147]. The apparent immunodeficient status of T-cell subsets could persist until the age of 4–5 years [164]. Subsequently, CD45RO levels gradually increase (as the responses to CD2 and CD3) until they match adult levels at 10–15 years of age [86, 147], whereas CD45RA levels progressively decrease [164]. Phenotypic analysis indicates that about 75% of neonatal and 87% of fetal CD3 T cells co-express CD28, important for interactions with CD80, however poorly expressed by fetal and neonatal B cells [130]. Obviously the deficits of all lymphocytes are quantitative, as demonstrated by the number of T and B lymphocytes and of total T lymphocytes, which in the first 2 years of life are 2–3-fold more elevated than in normal adults [149] (Table 2.1).

The generation and activation of CTLs are only 60% of those in adults [215]: this is an additional factor favoring the neonatal susceptibility to infections. Phenotypic characterization of neonatal NK cells has demonstrated substantial differences compared to adults [40], in neonates the levels were only 50% of the adult values [232], thus suggesting a defect in the initial activation of the neonatal precursor cells [86]. Studies show that NK

cells reach adult levels at 1–5 months of age, while the activity induced in vitro by IL_2 (LAK activity) is normal or increased [232]. The number of cells with CD11b, CD16 and CD56 phenotype or NK cell surface markers shows that these cells are increased during infancy to early childhood and are significantly greater than in adults; the CD57 values reduced up to age 4 but only at 9–13 years does no difference exist between children and adults [232]. IFN-α at the single-cell level did not enhance the binding ability of NK-cells at any period, whereas IL_2 had augmentative effects on NK cells [232], present in normal concentrations [158, 201]. However, in neonates the lytic and CTL activity is poor, hence the defense against infections by HSV (*Herpes simplex* virus) and *Cytomegalovirus* may remain uncovered [222].

Interleukins, particularly the production of IL_6 after stimulation with IL_1, similarly active in the antimicrobial defense, have a low concentration in fetal and term and preterm neonatal cells, but the levels can be normal at birth if opportunely stimulated [234]. Fetal levels of IL_2, IL_{12} and IFN-γ are undetectable, levels of IL_{10} and TGF-β were detectable in all fetuses [102]. In neonates, the T-cell ability of secreting bioactive ILs such as IFN-γ and IL_4 (0.8 % and 0.3 % in adults, respectively) (Table 2.3), IL_3, GM-CSF, IL_6, IL_{10}, IL_{13}, TNF-α (50 %) [225], IFN-ɣ, and IL_2 [71] is markedly reduced (Table 2.1). T-bet, a member of the T-box family of transcription factors, is repidly induced in early developing Th1 cells and is absent in developing Th2 cells. IFN-γ requires the introduction of T-bet into T cells which preferentially induces the conversion of these T cells into IFN-ɣ producing Th1 cells [208]. T cells of infants who manifested allergic symptoms produced higher levels of IL_{13}, compared with those of nonatopic infants [154]. Babies at risk for atopic disease in infancy displayed defective IL_{13} production at birth when compared with babies with no FHA [223]. A correlation was found between $CD4^+IL_{13}$ from CBMC lymphocytes derived from atopic mothers and the occurrence of wheezing and/or asthma during the 1st year of life [200]. IL_6, a central differentiation factor for activated B cells and in the induction of IgAs B cells to become sIgA cells [138], is also deficient [167]. The amounts of IL_4 and IFN-ɣ as shown in Table 2.3 are <1 % of adult values, consistent with their antigenically naive status [127] or with a neonatal maturative defect, perhaps because the cells are unable to sustain the expansion of T-cell clones. Impaired IL_4 production may depend on an altered CD21 and CD2 on B-cell expression by CBMCs that may limit IgE production [211]. However, the majority of fetal PBMCs release IFN-ɣ beginning in the second trimester of pregnancy [219], while CB production is poor compared to the initial activation [17]. As discussed earlier, neonatal defects (CD2, CD3, CD45RO) appear to occasion the low production of IFN-ɣ, IL_3 and IL_4, which play a crucial function in modulating antigen-specific and not antigen-specific immune responses [164, 165]. This maturational immaturity may impair T-cell normal function, thus

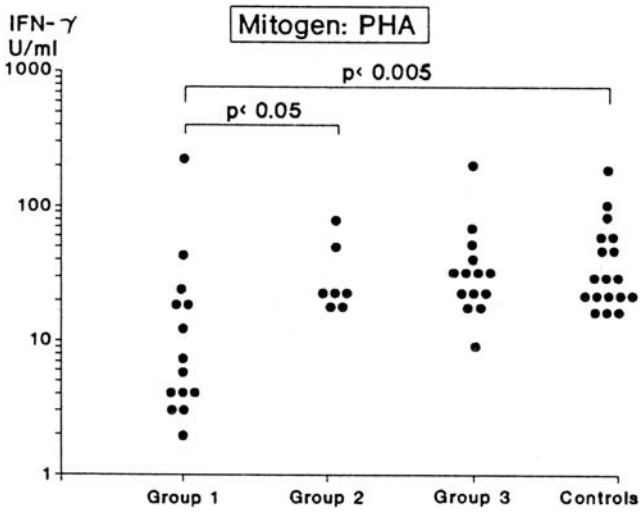

Fig. 2.11. IFN-γ production induced by PHA. Group 1 neonates with positive family history of atopy (FHA), group 2 with FHA and high cord blood IgE (CBIgE), group 3 only with high CBIgE. *Group 1* neonates showed a significantly decreased PHA-induced IFN-ɣ production compared to controls. *PHA* Phytohemagglutinin [172]

contributing to reducing both generation and activity of antigen-specific CTLs, and B cells through a lack of cognate help, or to suppressing Ig production, until it interferes in the modulation of the specific and unspecific immunity afferent phase [127], and to compromising the neonatal resistance to infections, including AIDS [222]. In this context, IL_{15} is important. It has an activity that regulates T-cell growth, T-cell cytotoxicity, and NK activity [3]. Animals that lack IFN-γ that binds to the IFN-γR, or the Jak-STAT signaling pathway to which IFN-γR is coupled, display disruption of both innate and adaptive immunity [208].

As regards IL_4 inhibition by IFN-γ in the neonatal age, IFN-γ appears to increase IgE synthesis by lymphocytes, instead of suppressing it [161]. IL_4 production seems to increase after birth by reaching greater levels in atopic babies than in nonatopic infants and by playing a critical role in IgE synthesis, while IFN-ɣ maturation (as well as of other ILs) is complete only at 3–5 years [127]. IFN-ɣ deficiency in the first months of life may stem from different causes such as an intrinsic inability of T cells to synthesize it, an increased sensitivity of T cells to PGE, or an ineffective activity of accessory cells such as macrophages [217], which neither produce nor activate IFN-ɣ [137]. *IFN-ɣ deficit* (Fig. 2.11) [172], independent of IL_4, but paralleled by CD45RO decrement [127], is based on the increased incidence of certain infections (Table 2.10) [28, 84, 144], and *facilitates the onset of atopy in neonates, especially in at-risk neonates*, when they are unable to react [26]. However, the APCs encountered with antigens may result in the production of IL_{12}, which on the one hand up-regulates IFN-ɣ expression and on the other hand, acting on

Table 2.10. Causes of the increased neonatal susceptibility to serious bacterial infections

Impaired opsonizing activity
Up-regulated opsonizing activity more evident vs Gram bacteria
Absence of opsonins specific for group B streptococci
IgM antibody levels = 0.05 % of normal adult level
Chemotactic defect
Relative defect in the generation of chemotactic activity
C3, C4, C5 levels = 50 % of maternal levels
Incomplete development of complement pathways
Functional defects of polymorphonuclear (PMN) leukocytes and monocytes
Decreased phagocytic and bactericidal activity
Reduced GM-CSF expression and production
Significant decrease in neutrophil chemotaxis
Decrease in Clq and C4 levels
Impaired cAMP and cGMP intracellular levels
Membrane defects[a]
Reduced actin polymerization
Prevalence of band PMNs with reduced chemotactic activity
Dysfunction of microtubule system
Defects in signal transduction
Defects in cell surface receptor up-regulation and motility
Cytoskeletal rigidity
Defects in deformability
Defects in microfilament contraction
Defects in O_2 metabolism
Defects in intracellular antioxidant mechanisms
Reduced candidocidia in preterm babies[a]
Defect in CD11b/CD18 and CD62L activity[a]

Data from [28, 84, 144].

CD45RA, induces the production of IFN-ɣ by neonatal human CD4 Th1 cells [230].

The analysis of the connections between malnutrition and immunodeficiency has shown deficits of CMI in neonates of mothers with vitamin B_6 deficiency (Chap. 21). Crucial is the function that EGF (epidermal growth factor) and TGF-α, present in the human fetal intestine in the second trimester [143], can have in facilitating the growth of mucosal epithelial cells, thus amplifying the anatomical integrity of the protective barrier and favoring early gut closure [143]. The passage of antigens that occurs during the first 3 months of life gradually decreases [142]. A specific danger may come from maternal smoking, which may reduce EGF levels in milk and colostrum (Chap. 24) and delay the process of intestinal maturation.

Humoral Immunity

Data on B lymphocytes are abundant, but often contradictory. The whole Ig production, including IgE antibodies, is deficient in neonates who are also atopic; this deficiency may be caused by an intrinsic immaturity of lymphocytes not favoring antibody synthesis or secretion [86]. CD4 T cells, even if present in neonates in great concentrations, have a reduced ability to regulate the antibody responses belonging to IgG and IgA isotypes [202], since the amounts of such antibodies expressed by stimulated neonatal B cells are markedly less than those produced by adult B cells [201, 220]. Supplementation of neonatal B cells with IL_2, IL_4 or IL_6 results in the correction of the above deficits and production of all major Ig isotypes, thus the consequent deficiency of these ILs results in an inconsistent antibody synthesis in neonatal B cells [202]. This depressed activity may also depend on a CD154/CD40L deficit, an important factor contributing to B cell immaturity [154], which could affect switch events, as seen in hyper-IgM and common variable primary immune deficiencies (PID). This deficit might be balanced by colostral CD3 T cells expressing in vivo CD154, with levels significantly higher than those in the circulation [13]. The majority of neonatal peripheral B cells express CD5 and activation markers such as CD21 and IL_2R, and in lesser amounts CD1c [9, 52]. Neonatal B-cell proliferation is endorsed by IL_2 or IL_4 without needing further signals such as anti-μ or mitogens compared to their adult counterpart [9, 220], reportedly due to a preactivation by exposure to transplacentally acquired antigens or, alternatively, by an intrinsic property of the CD5 subset [86]. A significant proportion of neonates is possibly equipped with B subsets expressing mIgD, mIgM, CD23 and CD11b, on which CD5 expression is variable [9]. CD5 could be associated with sIgA activity [149]. Some immature B cells with mIgM, even if stimulated with mitogens, secrete only the IgM isotype, thus denoting a further CD4 deficit. Moreover, B cells spontaneously secrete IgM autoantibodies against a range of autoantigens: a role in overall regulation of B-cell development has been postulated [9].

Maternal IgG transfer across the placenta to the fetus by 16 weeks of intrauterine life gradually increases during the last 3 months, mostly during the last 4 weeks, thus explaining why IgG concentrations in the CB of term neonates are 5 %–10 % higher than maternal levels, and preterm infants have IgG concentrations lower as their GA is short. They are therefore at a greater risk of

being susceptible to infections [62] and having a profound and prolonged physiological hypogammaglobulinemia (hgG) between 3 and 6 months of age [169] compared to full-term infants. This hgG is transient (Table 1.15) when maternal IgG levels gradually fall and the infant has not yet synthesized IgG in sufficient amounts, so that serum IgG levels in full-term infants drop up to 300–400 mg/dl [26]. Therefore, in preterm infants intravenous (IV) IgG substitution is indicated, which also significantly increases IgG subclasses [2]. Since IgG subclasses cross the placenta in different concentrations, a hierarchy ($IgG_1 \rightarrow IgG_3 \rightarrow IgG_4 \rightarrow IgG_2$ [62] or $IgG_1 \rightarrow IgG_3 \rightarrow IgG_2 \rightarrow IgG_4$ [50]) can be hypothesized, with the levels similar in all GA groups: 70%, 7%, 20% and 3%, respectively [50].

The importance of adequate IgG concentrations originates from phagocytes requiring specific antibodies to eliminate capsular polysaccharide antigens [137]. The close correlation between neonatal antibody status and susceptibility to bacterial infections is clearly demonstrated for group B streptococci, which are the predominant causative agents in neonatal infections from Gram-positive bacteria [144]. Unlike adults, during their convalescence neonates and infants with bacteremia synthesize high titers of specific antibodies of IgM class for the most part, which in adults mainly belong to IgG isotypes: this difference may depend on neonatal B-cell restriction of the IgG responses induced by suppressor T cells [169]. Antibody responses to somatic antigens of several Gram-negative bacteria (*Escherichia coli, Salmonella, Shigella*), belonging to the IgM isotype, do not cross the placenta [120]. Instead a small quantity of IgG antibodies to *Bordetella pertussis* pass, reflecting the very reduced level of maternal serum [36]. However, neonates and infants may be at risk following pertussis vaccination, a source of intriguing controversies, due to an overestimation of the risk of probable chronic neurological sequelae, actually of 1:310,000 DPT (diphtheria tetanus pertussis) doses = 0.000003% [90]. Large trials have provided a trend inversion favored by the introduction of acellular pertussis vaccines. The tetanic and diphtheria antitoxins are instead transferred across the placenta in adequate levels and confer an efficient passive protection during the first months of life [36].

Innate Immunity

Normal full-term neonates have a physiological deficit of complement functions compared to adults, particularly in preterm infants [63]. Measuring the values of both pathways of complement activation, compared to normal serum, the classic complement activity in the sera of term and preterm neonates was 52%±36% and 41%±29%, respectively, and the alternative complement activity was 59%±25% and 49%±12%, respectively [63]. A transient deficit of the bactericidal activity in term neonates, more enduring and marked in preterm neonates, can be responsible for the deficient opsonic activity [84], possibly corrected by the addition of IV IgG [45]. Although borderline, phagocytosis may also be deficient, owing to a diminished opsonic activity for staphylococci, *Streptococcus pneumoniae* and *E. coli*, possibly ascribed to a decrease in antibodies and complement levels [84, 121]. This deficit may be more evident in stressed newborns, especially preterm neonates [121]. Recent trials have shown a decrease in precursor HSCs, as well as a functional disorder of neonatal neutrophils (NN) or PMN cells, especially in times of stress or infections [28, 84], independently of GA and birth weight [169]. NN deficits include their differentiation, activation and functional activity, so they are less adherent and more rigid than those from adults, which results in impaired diapedesis and chemotaxis [84]. NN microbicidal and oxidative functions, such as phagocytosis, are delayed transiently in term neonates and more lengthy in preterm ones, likely due to the demonstrated MPO (myeloperoxidase) deficiency in the granulocyte cytoplasmic granules, implied in bacterial killing [28, 84]. In close relationship with this deficit is the poor IFN-α production induced by HSV-infected cells [37]. PBMC ability to normally migrate and eventually localize to sites of inflammation is mediated by interactions with gelatin and fibronectin to a degree comparable to that of adult cells [177]. GM-CSF expression and production by neonatal PBMCs are <50% compared to adult PBMCs [56]. Recombinant GM-CSF primes in vitro PMN activity [29]. As seen in Table 2.10, several functional deficits cause the unique neonatal susceptibility to bacterial infections [84]: in particular, PMN chemotaxis values, low at birth, increase by 11 and 32 days of life up to normal adult levels; the deficit persists longer in preterm babies [54]. There is evidence that the responsible mechanism [237] resides in the membrane deficiency leading both to greater cell rigidity, probably dependent on poor PMN locomotion, and a reduced membrane deformability, preventing the interactions between chemotactic factors and membrane receptors [144]. Studies show that a decreased actin polymerization could explain the observed abnormalities of PMN chemotaxis, possibly secondary to a negative regulation of profilin, coinciding with a decreased passage from monomeric G-actin to filamentous F-actin [81]. PMN mobility is nearly insignificant (the values at the age of 15 years are 50% of the mean adult value). However, the pathogenesis of NN impaired adhesion, diapedesis and migration, although provided with secretory vesicles and granules [110], depends on the deficit of both CD11b/CD18 [212], expressed by NN at only 60%–70% of the mean adult value, and CD62L [24, 212], whereas fetal neutrophils express normal levels of CD62L [196]. Adhesion molecules initiate a process that allows PMN extravasation into inflamed tissue with the goal of neutralizing the inciting stimulus [112]. Similar dysfunctions have been noted in eosinophils [194, 195]

and monocytes [212]. These findings may relate to the poor CB expression of NN receptors, or to a reduced gelatinase release or a poor ability to synthesize the peroxidase-negative proteins of granules [110]. However, delayed apoptosis and the subsequent survival of neonatal PMN lead to their prolonged persistence in tissues and to an enhanced up-regulation of CD11b, thus contributing to the pathogenesis of inflammatory disorders [112]. NNs express IL_1 [44], thus compensating for the missing IL production by neonatal macrophages, but fail to respond to both LPS (lipopolysaccharide), up-regulated by IL_{19} and TNF-α, which at low doses stimulates NN functions [20]. NN chemotaxis and adhesion deficits, the cause of LAD (leukocyte adhesion deficiency), might instead protect neonates from bronchiolitis that never develops in the first few months of life.

Neutropenia is defined as a neutrophil count of 100–500 cells/μl or an absolute count $<2.0\times10^9$/l based on the complete blood cell count, significantly correlated to a birth weight <2.5 kg [7]. During a 20-month study period, 87 neonates with neutropenia made up 6% of all admissions to a neonatal intensive care unit: 41% of episodes could be attributed to infections; the mean duration of neutropenia was 2 days and 70% of all episodes lasted for about 7 days [7]. We stress that differently from what occurs in granulocyte PIDs (Chédiak-Higashi syndrome, chronic granulomatous disease, etc.), hitherto no biochemical basis has been demonstrated that accounts for the myriad of functional deficits reported in newborns. Additionally, the clinical manifestations of patients with a primary disorder of chemotaxis are classically characterized by a selective localization of infections to the skin and subcutaneous (furuncles, abscesses), otitis media, pneumonia, and lymphadenitis [238], while newborns are predisposed to a high incidence of sepsis secondary to phagocyte defects [28, 84]. It appears that diverse dysfunctions of adhesion molecules, complement, opsonins, phagocytes, and aspecific factors may contribute to the high neonatal susceptibility to bacterial infections and a trend to become systemic (Table 2.10). O_2 consumption, H_2O_2 and superoxide production are normal, thus confirming a regular function of O_2-dependent bactericidal mechanisms [121, 197]. Macrophages have been studied very little: the circulating cells show quantitative values and phagocytic and bactericidal activity overlapping adult cells [121]. The recruitment of the above cells into inflammatory foci is delayed, a major factor explaining the usually low skin test reactivity of neonates [86], who also show an IL_6 deficiency [168, 233], TNF-α [55] enhances IL_{10} secretion [3], which is also reduced [168], and vital integrins [212]: this may contribute to the poor inflammatory activity. Macrophage function as APC is rare in neonates, due to a reduction in HLA antigens [174].

Mucosal Immune System

The lymphoid tissues of the mucosal surfaces of gastrointestinal (GI), respiratory tracts, etc., on the whole called MALT (Fig. 2.12) [11], in addition to the primary function of keeping the delicate epithelial surfaces sterile in contact with the external environment, should also be able to recognize the external antigens and to respond by sensitizing CD4 T cells. If there is a malfunction in normal functions, the host is at risk of enduring cell-mediated tissue damage: inappropriate responses of T cells underlie chronic allergic disease. CMI resembles a double-edged sword, since many aspects of this cascade imply the immanent risk of being detrimental to the structures to be protected. Thus it is clearly necessary to reduce the CMI impact on mucosal surfaces by limiting this impact to the minimum needed for the appointed goal, the elimination of pathogenic antigens [33].

Although manifold defense barriers, both natural and immune (such as sIgA), provide reliable defense lines for the epithelial external surfaces, the high solubility and low MW of many nonpathogenic antigens, either inhalant or dietary, make antigen penetration within epithelial tissues a frequent event. In the lungs, the contact between T cells and environmental antigens is potentially immediate, due also to the intervention of T cells

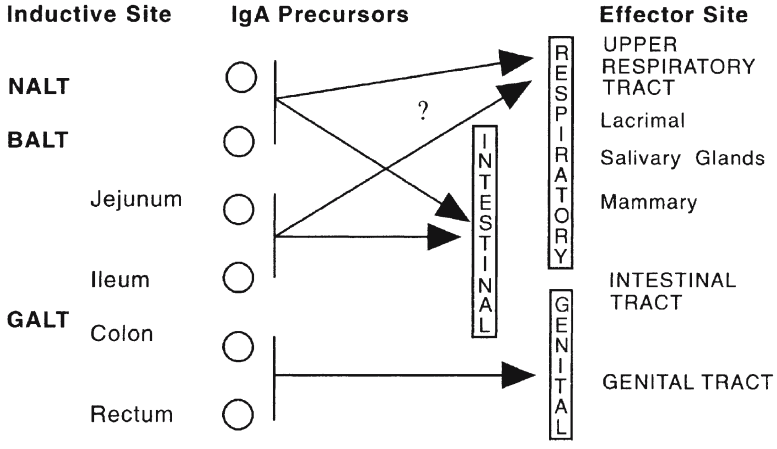

Fig. 2.12. The MALT: inductor and effector sites. *MALT* mucosa-associated lymphoid tissue, *BALT* bronchus-associated lymphoid tissue, *GALT* gut-associated lymphoid tissue, *NALT* nose-associated lymphoid tissue. (Modified from [11])

patrolling adjacent structures, above all beneath the alveolar epithelial surface. Similarly the GI tract is the seat of equally sound T-cell subsets [188]. There should be specific control mechanisms to restrict lymphocyte responses to antigens that are harmless to the organism. The concept of MALT is universally accepted: the cooperation with a variety of organs and systems has operated so that the mucosal immune system interacts with the peculiar properties of these organs, and has evolved exquisitely refined strategies to concert a balanced and differentiated regulation of T-cell activation, well suited for the specific requirements of the unique tissue microenvironments [79]. At birth MALT structures are absent: aggregates of lymphoid cells to be considered as MALT precursors have been found in the intestine [22] and the lungs [68] at about 14 weeks of gestation in the human fetus; lymphoid aggregates more identifiable with MALT appear about 7–10 days after birth and increase later on during childhood and adolescence [187]. Therefore, neonates should be prepared to deal with new problems such as the bacterial colonization of the gut, toxic by-products of bacteria and virus (enterotoxins and endotoxins) and intervention of exogenous factors. These substances, if allowed to penetrate the defense barrier, can cause either a local response (with a variable immune mediation), or potential dangers, both general or localized to distant shock-organs, with modality and severity linked to the type of immune response, not always univocal [19]. As a consequence, the first line of defense in order of time, including MALT, is against the absorption of food antigens: therefore the important neonatal adaptive changes to the extrauterine environment include the development of a mucosal barrier against the penetration of antigens and their fragments present chiefly in the intestinal lumen [187].

Immune Components of the Intestinal Mucosa

At 11 weeks of gestation, T cells migrate into the fetal gut; however, their numbers are low in the epithelium and lamina propria, where cells similar to macrophages and DCs are mostly present [133]. Between 11 and 24 weeks, APC markers and costimulatory molecules are seen within human fetal gut associated with expression of HLA class II (a), CD14 (b) and CD68 (c) (APC), CD20 (B cells) (d), CD83 (DCs) (e), CD40 (f), and CD86 (costimulatory molecules expressed by APCs) (g) and control (h) (Fig. 2.13a–h) [102]. Mature DCs are seen at 16 weeks, associated with immunoreactive CD86 [102]. By 14 weeks, isolated T cells and aggregates of B and T cells can be identified in the lamina propria and within 20 weeks distinct cellular zonation develops; plasma cells are absent [133]. Figure 2.14a–e [102] shows human fetal gut expression of CD3 (a), CD28 (b) CD40L (CD154) (c), and CTLA-4 (CD152) (d) and control (e). Surprising is the abundance of HLA class II and CD154 expression. Immunohistochemical studies of fetal small intestine have shown that lymphoid aggregates appear in the lamina propria at 14 weeks, and express $CD3^+$ and $CD4^+$ or $CD8^+$ antigens, with predominance of $CD4^+$ T cells, with a steady increase in the numbers after birth [199]. Intraepithelial lymphocytes (IEL) until 11 weeks of gestation are 0.03% of epithelial cells, at 11 weeks $CD3^+$ IEL can also be seen and by 17–19 weeks are 2%–5% of epithelial cells: only 50% of IEL express $CD8^+$, the remainders are $CD3^+$, $CD4^-$ and $CD8^-$ (about 10%), $CD3^+$, $CD4^+$ and $CD8^+$ (about 6%) and $CD3^-$, $CD7^+$ (about 12%) [133]. Heterodimer TcR consists of both αβ and γδ chains; the IEL γδ population mainly contains double-negative T cells; however, the number of γδ TcR is higher compared to adult levels (about 20%) [133, 199]. By 18–21 weeks, about 50% of IEL are γδ TcR [133]. CD3, CD4 and CD8 IEL are consequently very few in number in the fetal intestine [133]. We deem that low IEL numbers in infants and children denotes that IEL levels increase after birth and that antigen-driven stimulation is not the only factor leading to lymphocytes populating the intestinal epithelium [188]. *Peyer's patches* [163] (PP) in maturation (Table 2.4) do not comprise T or B lymphocytes, but HLA-DR aggregates and CD4 T cells: continuing the differentiation, by 19 weeks they contain distinct T and B zonations [199]. In the center, B cells are IgMs, IgDs and express CD5, surrounded by T-cell zones, mostly $CD4^+$; every cell is class II^+ [133]. At birth, PPs contain abundant lymphoid tissue, but there is no evidence of a germinal center (GC) and of secondary lymphoid follicle formation, also due to the low antigenic exposure of the intestinal mucosa (Fig. 1.43). This explains why B cells concentrate in primary follicles and are sparsely distributed in the lamina propria of the fetal intestine [199]. After antigenic challenge, both sensitized T cells and Ig-secreting precursor cells migrate from PPs to mesenteric lymph nodes, then they enter the systemic blood circulation via the thoracic duct. After further division and subsequent maturation, B cells migrate to the lamina propria where they differentiate into Ig-secreting plasma cells [179]. B cells with IgM are the first to appear and predominate during the early formative period, and later on B cells with IgA are prevalent; this difference is upheld, so that at age 2 years the ratio is 1:4 [114]: parenterally fed preterm neonates fail to develop Ig-secreting cells (IgSC), possibly due to their lacking specific stimulation [111]. B-cell definitive maturation probably involves regulatory T-cells, macrophages, and IL_{4-6}; several of these B cells apparently belong to clones of previous differentiating states, provided with J-chain (J = joining) (a polypeptide with MW = 15.6 kDa), synthesized by plasma cells, which binds to two H chains of IgA via covalent bonds independently of the Ig expressed [22]. After birth, GCs develop in PPs due to intestinal colonization from luminal bacteria: mucosal B cells are produced and during the first months of postnatal life, plasma cells originating from antigen-stimulated B lymphocytes

populate the lamina propria. GCs, along with lymphoid follicles, at about 12–24 months reach levels comparable to adult levels, but plasma cells only at about 2–10 years [199].

The report of IgG+ and IgA+ antibodies in fetal intestinal tissues suggests the *fetal origin of B-cell differentiation* independent of antigenic stimulation, a fetal immune response to an intrauterine infection, or an immune response induced by anti-idiotype antibodies from the mother [141]. The fetus responds to infections by the early production *in utero* of IgA and IgM antibodies; moreover, the striking finding of sIgA and sIgM (secretory) to *Escherichia coli* 0 and poliovirus type 1 in amniotic fluid and meconium, urine and saliva already at birth speaks in favor of the hypothesis of a *fetal isotype switch* [141] in response to the transplacental passage of IgG anti-idiotype antibodies [74]. Therefore, since it is unlikely that the fetus has been exposed to poliovirus antigen *in utero*, the intervention of idiotype/anti-idiotype anti-poliovirus antibodies of maternal origin is possible [141]. However, the report of aggregates of B_{IgA} lymphocytes confirms that isotype switch of B lymphocytes occurs *in utero*, as demonstrated by the finding of sIgA and sIgM in the saliva of neonates of hypogammaglobulinemic mothers [73]. These observations have moved the experimental studies on *maternofetal immunology* far forward, establishing that the amniotic fluid from an IgA-deficient mother contained IgA antibodies, which were also found in the neonate, thus suggesting a fetal origin: we emphasize that in Sweden where the study was conducted, an inactivated poliovirus vaccine has been used for many years [73]. The detection in CB of anti-idiotype anti-poliovirus antibodies suggests that once transferred via the placenta they can prime specific immune responses in the fetus [138]. However, anti-idiotype antibodies have

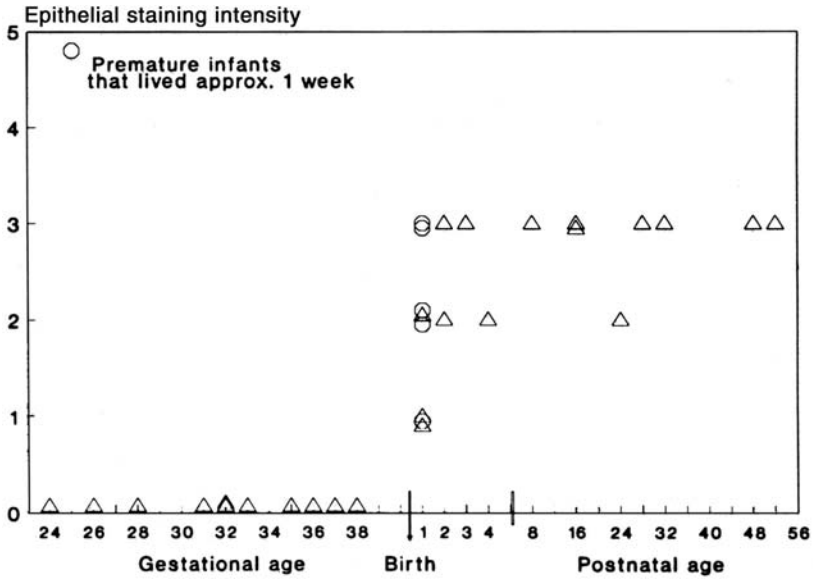

Fig. 2.15. HLA-DR expression in tracheal wall according to gestational and postnatal age

been found also in maternal serum and milk [74]: anti-idiotype anti-poliovirus and anti-*Escherichia coli* antibodies transferred from the mother can therefore actively induce specific immune responses in the fetus without previous exposure to transplacentally transferred antigens, or by being passively transferred to the newborn via breast milk [74]. Such a transmission can have two-way effects: it can either enhance the ability of the fetus and young infant to mount a protective immune response or increase the risk of developing allergy during early life [8, 74].

At birth, both T cells and accessory cells of the mucosa are comparatively better developed; in the lamina propria several HLA class II^+ macrophages and DCs are identified. Furthermore, $CD3^+$ T lymphocytes are identified both in the lamina propria and at the epithelium, crucial in the postnatal period when the intestinal epithelium permeability is greater [187]. Activation of lamina propria T lymphocytes elicits their proliferation and increases lamina propria density and IEL numbers [205]. The source of mucosal T cells during the postnatal period is unclear: studies in the animal model indicate that certain IELs develop from T cells activated by antigens within PP. Subsequently, T cells, through a pathway similar to that of B lymphocytes, recirculate back to the lamina propria [205]. When class II^+ macrophages are recruited in sufficient number, in the proximity of T $CD4^+$ cells, intraluminal antigens may trigger reactions of T cells [188]. Recent evidence has demonstrated that the fetus does not express immunologically regulated epitopes because no expression of HLA class II antigens is detected on the fetal intestinal epithelium or that of 1-day-old neonates [179], but HLA class II^+ cells were detectable from 11 weeks of gestation [102] and HLA class I expression is present [179]. From the 2nd postnatal week, HLA-DR molecules may appear in the intestinal epithelium to interact with CD4-antigens, apparently reflecting a response to environmental substances [174, 204] (Fig. 2.15), even if class II complexes are not yet uniformly distributed [174].

Immune Components of the Mucosal Barrier

An important adaptation of the neonatal GI tract is the development of a mucosal barrier opposing the transmucosal passage of antigens and antigenic fragments, which is an elaborate system of immunological and nonimmunological defense mechanisms, at the very critical moment when the local and systemic immunity is still immature, to combat potential dangers such as the bombardment of microorganisms and the invasion of antigenic substances. The immunological components are either humoral, sIgA sIgM, IgA, etc., or cellular, lymphocytes, mast cells, neutrophils, macrophages and eosinophils of the gut mucosa, cells of the mucosal coat and reticuloendothelial system (RES) and potential erythrocyte growth factors, among which EGF is in the first line [42] (Table 2.11) [19, 33, 42]. Therefore, the local immune system plays a crucial role in the local defense against infectious and food antigens. Above all, it has been postulated that sIgA may block the uptake of ingested antigens, and that IgA, IgG and IgM make it possible to eliminate the macromolecules penetrated into the gastroenteric tract.

There are *two IgA subclasses,* namely IgA_1 and IgA_2, accounting for 90% and 10%, respectively, of the daily serum IgA, but because of GALT B-cell expansion, there is a shift toward more IgA_2 production in postnatal salivary glands in the first weeks of life; during the first 3 months after birth the IgA_1/IgA_2 ratio approaches the normal adult value [22]. This may imply an ongoing postnatal influx of IgA precursors from PPs where the IgA_2 subclass predominates [22]. The sIgA system is

expressed in higher proportions in secretions, especially in the large bowel (59%) and mammary (37%) and salivary (34%) glands. Additionally, IgA_2 of the GALT tends to produce the J chain with a greater frequency than sIgA [193], until both IgA immunocytes express elevated levels of J chain (94%–97%) [22]. Such increased results are extremely useful since IgA_2, at variance with IgA_1 immunocytes, by strong, noncovalent bonds with SC, are highly resistant to bacterial proteases, rich in the gut [187]. Because of its unique structure, sIgA is thus able to adversely affect proteolytic enzymes while carrying the immune functions of enteric mucosa. sIgA immunocytes have a dimeric or polymeric form, unlike the monomeric form of serum IgA antibodies: the J chain appears to facilitate IgA polymerization [22]. SC is a glycoprotein found on the basal and lateral aspects of local epithelial cells. SC has receptor characteristics, belongs to IgSF, its gene is located at the long arm of chromosome 1 and binds to dimeric IgA [188], generated by IgA-producing plasma cells [22]. J-chain-containing dimeric IgA is transported actively by transmembrane SC via a process of endocytosis, from the luminal face to the mucosal layer of intestinal epithelial cells, and is then transferred into secretions [22]. SC is an integral part of the latter cells' membranes: in particular it plays a crucial role in the bowel lumen, protecting IgA molecules from degradation by enzymes and toxins [188]. IgM and IgG plasma cells bind neither to SC nor to J chain, which is produced and degraded by these Igs more frequently than the cells of peripheral lymph nodes [193].

However, at birth the maturational immaturity of the GI tract is unmistakable: only IgG of maternal origin are seen and other IgG are received by breast-milk-fed neonates [33]. Serum IgGs are reduced in infants beginning in the 3rd month of life: in children aged 2–15 they represent only 5% of total Igs (vs 80%–90% of IgA immunocytes). IgG_1 is the preponderant subclass in normal ileal and colonic mucosa (as well as in the airways and in normal serum), while IgG_2 cells are usually more abundant (20%–35%) than IgG_3 cells (4%–6%) in the distal gut mucosa, at variance with the levels observed in the upper airways [186]; such disparities may be influenced by different local stimulatory agents [206]. IgA, appearing late in both phylogenesis and ontogenesis, are undetectable at birth compared to the other Ig classes and sIgA in the usually sterile intrauterine environment [170]. Three studies have examined Ig-producing cells in the trachea [204] and intestinal mucosa [174, 179] in neonates aged 1 day [179] and by 24 weeks of fetal life until the first postnatal months [174]; however, in 1- to 5-day-old infants no Ig immunocytes were detectable [179, 203]. A few IgM and IgG immunocytes were present during the entire period investigated: by 2 weeks of life some B_{IgM} cells were observed in the lamina propria of neonates [174] and the first B_{IgA} cells appeared [204]. IgSCs are scarce (mostly B_{IgM}) within the first 5 days of life, but by 1 month the levels are increased in 77% of infants, primarily B_{IgA} with levels at 0.8 IgSC/10^6 PBMCs (mean 1±1) [203]. Thus, IgA immunocytes are present by 2 weeks of extrauterine life (Fig. 2.16) [204] (Fig. 2.17) [174], increasing parallel to IgMSC [174], until the levels were similar at 6 weeks of age [174]; IgM antibodies slowly increase (Table 1.15) at about 5–6 months of life. However, within the 1st year of life, IgM antibodies predominate on the other isotypes, whereas in the adult intestine the ratio IgA: IgM: IgG is 20: 3: 1 [187].

For the first 6 months, there is an admixture of IgD-producing cells in the parotid glands, highlighting the dichotomy of MALT between NALT and GALT [22]. The levels of sIgA increase by 1–2 weeks of life [140, 190] and mean adult values are approached by 4 weeks in 92% of infants [190] or by 2 [25] to 12 [140] months, certainly after local exposure to antigens. Using more sensitive methods, IgA_2 antibodies in saliva are <15% 2 weeks after birth and by 6 months 24.4% of total sIgA, with 15.5% of maternal levels by 4 months [58]. CD_{154} expressed by colostral T cells could trigger isotype switching to IgA and sIgA [13]. Recently, salivary sIgA were found in 75% of neonates aged one day (190.2 mg/ml) and in 77.1% of neonates aged 2–10 days (216.4 mg/ml) [179]. In turn, IL_6 has a key role in the conversion of IgA into sIgA [138]. A study on salivary and fecal IgA antibodies has recently found measurable IgA levels during the 1st week of life. The levels peaked at the age of 30 days but decreased and remained stable from 3–8 months, but no differences were found between breast-fed and cow's-milk(CM)-fed infants. However, the ratio of fecal IgA was reversed [116]. At 2 weeks of age an increase in SC levels was observed, concluding that SC synthesis seems to be independent of B lymphocytes: its increased expression shortly after birth along with HLA-DR and $CD3^+$ T cells suggests that T-cell-derived ILs may be responsible for the induction of both SC and HLA-DR [204]. The SC-mediated selective epithelial transport of dimeric IgA and pentamer IgM antibodies ensures a first line of defense against environmental factors active in the first 3–4 weeks of life [22]. Moreover, *sIgA existing in colostrum and breast milk* exclude macromolecular absorption, facilitating their removal via the feces, thereby elaborating a unique immune system passively protecting the vulnerable neonate before the development of the mucosal barrier and the provision of secretory Igs [218]. The endogenous synthesis of sIgA antibodies starting before the appearance of both serum IgA and food antigens is likely antigen-driven, resulting from the colonization of the mucosal surfaces by commensal bacteria, and represents a sufficient stimulation for sIgA levels, which gradually increase in the first months of life [58]. Serum IgA antibodies develop more slowly, attaining adult levels only at about 10 years of life (Table 1.15), but breast milk may have a stimulatory effect on IgA production in neonates and/or may favor IgA concentration in the colon [116].

The more rapid maturation of IgA antibodies suggests that they play a positive role that is more important than serum sIgA antibodies, at least in the first periods of life. An indirect support of sIgA antibody effectiveness comes from the knowledge that in subjects with IgA-selective deficiency there is a steady increase in sIgM titers to food antigens [214]. However, it seems paradoxical that newborns are deprived of secretory Igs in the first days of life, when this immune and anti-infectious protection is of crucial importance [114]. It is of great significance that in the saliva of neonates IgM antibodies are also included, IgM with the SC glycoprotein, probably delivered to secretions over the pathways normally used by sIgA antibodies; thus when IgA are scarce or absent, the transport mechanism becomes available for IgM antibodies. In spite of their poor stability compared to sIgA, sIgM antibodies may play an active role in the mucosal defense until sIgA is up-regulated upon repeated antigenic exposure [170].

Furthermore, it has been demonstrated that *low sIgA levels may be associated with an increased risk of atopic disorders* [135], and that *colostral sIgA and sCD14* [184] *levels are significantly reduced in the mothers of neonates developing CM allergy (CMA)* compared to mothers of nonallergic children [185]. The sIgA increase from 15.5% to 52% of maternal levels was more rapid in exclusively breast-milk-fed infants compared to bottle-fed infants [58]. The prominent localization in both the stomach and the intestine acquires a particular significance, since activation of mucosal immunity should protect the underlying tissues without inducing inflammatory responses damaging the fragile epithelium [22]. At this level, particular emphasis is placed on the polyvalent sIgA and its striking avidity for antigens. sIgA are equipped with four paratopes (which are formed by dimers), thus making sIgA more effective than serum IgG and monomeric IgA antibodies in the agglutination mechanisms; also lacking opsonizing activity, they do not induce phagocytosis mediated by local and/or circulating macrophages, nor do they induce the classic complement activation devoid of the pertinent receptors [170].To perform this job, the mucosal immune cells acquire several properties *peculiar to mucosal sites* [57]. Therefore IgA molecules transported across the epithelial cells of the mucosa are able to prevent both invading organisms and potential macromolecular antigens from adhering to or penetrating the mucosal surface [186].

sIgA spread within the coating mucous film to constitute a protective *antiseptic paint,* so to speak, which neutralizes the invading virus, interferes with bacterial colonization, prevents the uptake of heterologous macromolecules and plays a role of immune exclusion since binding to sIgA blocks intraluminal antigens and prevents their transport across the epithelial barrier [19]. As a consequence, foreign molecules lose their ability to trigger immune reactions also in sensitized subjects, and since they preclude their absorption, are finally digested by intraluminal proteolytic enzymes [205]. The high concentrations of sIgA and IgA cells in the MALT milieu attest to their local significance [218]. As stated above, the absence or paucity of sIgA cells in babies with CMA is perhaps a consequence of lacking or poor colostrum and breast milk ingestion, which may provoke a statistically significant reduction in antibody-producing cells when compared to regularly breast-fed infants [193]. sIgA rise in number in children acquiring CM tolerance [92].

Much interest has focused on sIgA antibodies, synthesized in great part by MALT B_{IgA} lymphocytes, present in several mucosal tissues, including BALT, which supports the existence of a common mucosal immune system [19]. *A chief role is played by T cells:* it has been demonstrated in animal models that B_{IgA}-cell precursors are sensitized by antigens in the lymphoid tissues of gut mucosa (PPs), then migrate to mesenteric nodes for further maturation, enter the systemic circulation and are guided by homing receptors. Independently of the meeting point, they recognize the HEVs (high endothelial venules) (Fig. 1.3) along mucosal surfaces of the intestinal, respiratory, and urogenital tracts and mammary gland, where they produce IgA-secreting plasma cells, due to CD4 T-cell cooperation [188] (*enteromammary axis*). Figure 2.18 [198] depicts this immune system, a very prominent and unique means of delivering maternal IgA to protect the immature surfaces of infant gut [19, 198]. Lactogenic hormones may promote the circulation of B_{IgA} cells toward mammary glands, thus synthesizing sIgA cells produced against a large variety of antigens previously penetrated in the intestinal lumen [26]. By a reverse and complementary route, mammary gland plasma cells release sIgA against heterologous substances present in the maternal gut [198]. As a demonstration of the close relationship between GALT and mammary glands, it was found that the TcR-$\gamma\delta^+$ proportion was twofold to fourfold greater in the mammary gland than in the bloodstream [15]. Moreover, 85%–95% of colostral TcR-$\gamma\delta^+$ co-expresses CD103 (HML-1) [12]: thereby, such TcR-γδ, differently from the bloodstream where CD103 are absent, have a phenotype similar if not identical to that of intestinal TcR-γδ. This finding suggests that both types may come from common precursors of MALT or in turn that a lymphocyte homing process, including TcR-γδ directed there, may occur between the gut and the mammary gland over the last trimester of pregnancy and the whole breast-milk feeding period [15]. The concept of an enteromammary axis is also indirectly confirmed by a series of animal experiments that have noted that early milk leukocytes are able to resist digestion with trypsin, a characteristic that allows them to survive in the GI tract [16, 93], and that orally administered milk cells are measurable in the gastric and duodenal content of neonatal mice, and were shown to cross the gut mucosa and enter the circulation and the spleen of neonatal lambs [16, 93].

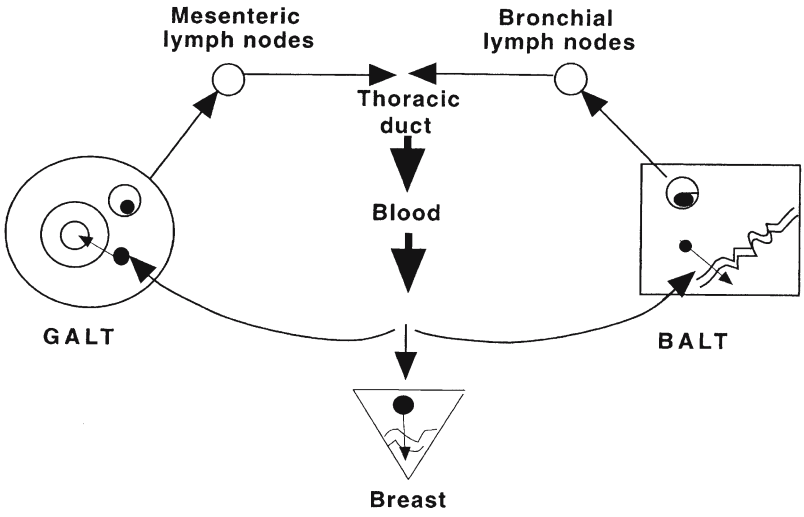

Fig. 2.18. A diagrammatic view of the enteromammary axis. *GALT* gut-associated lymphoid tissue, *BALT* bronchus-associated lymphoid tissue. (Modified from [198])

Maturation of gut mucosa B cells is stimulated by CD4 and depressed by CD8 T cells; both subpopulations are not static, but by complex circuits remain in a state of dynamic equilibrium: the CD4 T cells on the one hand stimulate B cells and on the other hand activate CD8, which inhibits antibody responses (feedback suppression) [26]. Several lines of evidence suggest that CD4 and CD8 specific for the diverse Ig classes acquire a particular finality between the various highly specific immune regulator mechanisms characterizing MALT [19, 206]. To enhance the selective production of IgA antibodies, T cells coming from GALT promote in B lymphocytes the isotype switching from IgG and IgM to IgA antibodies, with a double duty of assuring a lesser absorption of antigens and preventing systemic reactions due to complement activation [57]. A regulating role is also played by breast milk through proteins present there, with the capacity to both stimulate and suppress T-cell proliferation. Above all the suppressor effect may influence the depression of systemic immune responses, in synergy with the contemporaneous GALT activation [145]. Within oral tolerance, much interest is focused on the expression of suppressor activity of both CD8 cells and HLA class II molecules, in addition to surface epithelial cells possibly inducing anergy/apoptosis of Th2-like $CD4^+$ lamina propria T cells (Chap. 1). Moreover, *the circuit of T contrasuppressor cells,* moves from PPs [57], or the TcR-γδ IEL population [188], to prevent the CD4 T-mediated suppression, thus releasing IgA (and possibly IgM) immune responses. The outline may be completed by T cells with *suppressor effects on IgE synthesis* [188]. In conclusion, the intestinal barrier regulation against antigenic macromolecules involves an intricate network of cellular interactions that ultimately could favor secretory immunity, via the above IgA-associated contrasuppressor activity [57].

Food macromolecules can be taken up intracellularly – through epithelial or membranous cells – or intercellularly – via the tight junctions. Endothelial cells lead to absorption via the process of *endocytosis* (by which the greatest part of antigens are processed) from the *microvillous membranes* (MVM) [41]. Polypeptide macromolecules are therefore surrounded by MVM as microvesicles that then fuse originating, as stated earlier, phagosomes that fuse with lysosomes, creating phagolysosomes, where the macromolecular constituents of the ingested particles are degraded. However, some unmodified macromolecules escape the final digestion and via *exocytosis* are released into the intercellular space. Hence, the barrier can be crossed by food antigens via *microfold cells (M cells)* [181], membranous epithelial cells overlying PPs (<1% in humans) derived from Lieberkühn crypts. They have few microvilli (in the gut) or vibratile cilia (in the airways), a richly vacuolated cytoplasm, an only slightly developed glycocalyx and few lysosomes able to endocyte macromolecules that transport to PP lymphoid tissue [206]. The number of M cells is low in humans, but they perform important tasks, since they can contribute to the uptake and processing of polypeptide macromolecules and transfer of antigenic information to immunocompetent cells, thus playing the role of connection between the gut epithelium and subepithelial system [170]. M cells also transport HIV-1 [182]. However, the follicle-associated epithelium overlying PPs does not secrete IgA, so there is a gap in the barrier and, despite the ongoing sIgA response, a microbial invasion is likely [22]. The tight junctions are impermeable in healthy intestine, but if they suffer from pathological insults during the inflammatory processes, they loosen and become leaky, thus facilitating the passage of antigens and their fragments [187]. The macromolecular degree of absorption is correlated to the antigen concentration in the bowel lumen: so the early bottle-fed infants are subjected to a huge antigenic assault; consequently *pinocytosis* is extended to all mucosal epithelial cells, paralleling the massive penetration of undigested macromolecules [182]. If the first line of barrier defense is disrupted, both local IgG production and serum IgG antibody exudation are increased: if these critical defense mechanisms are insufficient, additional

defenses made up of the nonimmunological components are ready to take on these functions [33].

Nonimmunological Components of the Mucosal Barrier

The factors constituting the second line of mucosal defense, working independently and in concert with the local mucosal immune system, enter the circulation to control the proliferation of microorganisms passed into the gut, augment their adhesion to limit the absorption of antigens able to overcome the local immunological defense mechanisms and to dismantle the mucosal barrier (Table 2.11). In concert with the elaborate local immune system already developed, these factors make the gut impermeable to CM proteins, thus preventing the upregulation of immune reactions in the majority of cases, despite the presence of IgE. The defense factors, all of which help to provide maximum protection, include [33]:

- *Gastric barrier* and enzyme content of the GI tract. Neonates have a physiological deficit of such factors: the achlorhydria, facilitating the microbial proliferation and the enzyme deficiency, predisposes to a reduced breakdown of food macromolecules, thus favoring antigen absorption.
- *Gut microflora.* It is formed by two different populations: one autochthonous population proliferating in a stable way, and one allochthonous population proliferating only following the ingestion of particular foods. Along the enteric tract, true ecological niches are found, which, depending on the type of microorganism, are characterized by optimal conditions different for their development. Bacteria can attach to mucosal surfaces via their structures provided with antigenic power; the acidulous bacterial flora in particular plays a crucial role in preventing or limiting the gastroenteric infections that facilitate allergen access [76]. For example, lactobacilli, such as *Lactobacillus bifidus* predominant in breast-milk-fed neonates' microflora, are able to produce antibacterial substances and/or prevent microorganism growth competing with receptors or nutritive factors [84]. However, differences in the composition of the gut microflora might play a role in the allergy prevalence.
- *Peristaltic movements:* a physical barrier to prevent bacterial proliferation, likely to be present in case of intestinal content stasis. Moreover, conditioning the duration of the transit time of a food bolus plays a primary role in the function of intestinal absorption of nutrients [218].
- *Intestinal surface* secretions include:

1. The saliva, which contains lytic enzymes (lysozyme) and polymers, limits the bacterial attachment to epithelium.
2. The chlorhydropeptidic gastric secretion contributing to fragment and denature intraluminal antigens.
3. The pancreatic and enteric proteolytic enzymes.

- *Mucosal surface.* This surface, consisting of the MVM and its overlying mucus layer, forms with secretions a glycoprotein layer on epithelial cells, an important protective barrier acting as a mechanical obstacle to foreign antigens and bacteria, incorporating and removing them from intestinal walls. However, in the neonatal period specific phospholipid changes may contribute to a disturbance of the protein/phospholipid ratio of the MVM membrane [41], of the composition and thickness of the mucus protective layer [218], and might interfere with defense functions (Chap. 3). Likewise malnutrition may reduce secretions and bottle-feeding may reduce the intrinsic qualities of the mucus, thereby reducing the mucosal barrier defense function, a clinical disease state unknown to breast-milk-fed neonates receiving mucin with more fucose and glucosamine and fewer sulfates compared to bottle-fed neonates [213].
- *Liver filtration* of luminal antigens: the liver, with *Kupffer cells,* is the second line of mucosal defense, in order of importance, after sIgA and the anatomical, functional and enzymatic systems of intestinal mucosa. All foreign substances taken up by the bowel gain access to the portal circulation: the more active and ready the clearance capacity is, the more harmless the antigenic aggression is [218].

Several observations suggest that local immune defenses contribute widely to protecting the host against potential dangers of aggression across the mucosal barrier, especially when they operate in a mutual accord. To understand the complex atopy pathogenesis, we consider evaluating the host general immune reaction of prime importance [19, 33].

Additional Defense Factors

Some *aspecific factors of defense* protect the intestinal surface when the defense mechanisms of the complicated milieu of the intestine are incompletely developed to prevent antigen aggressions. They act by expanding specific immune reactions thanks to substances with aspecific inflammatory action, such as ILs generated by activated T lymphocytes, mast cell and basophil chemical mediators and proteins with enzymatic action belonging to the complement cascade. In case the expansion of immune responses is dramatically heightened, these aspecific factors can provide the basis for the onset of hypersensitivity reactions, normally inhibited by sIgA [218].

Nutrition and Absorption of Antigenic Macromolecules

In neonates, especially in preterm neonates, the sophisticated system of *oral tolerance* is not yet completely developed, and is linked to a network of unique and

elaborate immune mechanisms that should ensure simultaneously a local strong antibody barrier and a block of the dangerous systemic overflow of Igs and therefore of CICs [57]. The intestinal mucosa, particularly in the first weeks of life, is physiologically vulnerable to pathological penetration of potentially harmful macromolecules, and is consequently susceptible to hypersensitivity reactions [33], a significant result since both neonates and preterm infants absorb more food allergens than adults. Bottle-fed neonates have an increased permeability to β-lactoglobulin (βLG) [118] and preterm infants may develop a CM sensitization more frequently than term infants [129]. In neonates, the rapid substitution of breast milk with CM led to concentrations of anti-CM protein IgG significantly higher than those found in gradually weaned infants; the results further confirmed how important breast milk sIgAs are in developing a protective role within the intestinal mucosa, reducing the absorption of detrimental antigens [78]. Irreconcilable conclusions are suggested by a methodologically correct study using questionnaires after 11 years [186].

Immunology of Breast Milk

Even during recent years it was presumed that breast milk was devoid of immune factors [26]. The relations between immunological factors, including ILs, EFA, and eicosanoids in breast milk, may influence the delicate balance of the gut immune milieu of the infant and thus may have health effects on the breast-fed infant [119]. It is increasingly manifest that breast milk contains a wealth of immune factors, which are designed to nourish and protect the vulnerable newborn during the critical postpartum period. Thanks to the *mammary gland, a true immune organ* [16, 67], breast milk is an excellent immune protection for neonates during the critical period of intestinal vulnerability, it is a remarkable protection against the dangers of a deficient intestinal defense system, based on unique immunological, anti-infective, anti-inflammatory and immunomodulating factors functionally interacting among themselves (Tables 2.12, 2.13) [12, 16, 27, 61, 65, 67, 80, 94, 105, 107, 119, 142, 153, 178, 198, 228, 231].

- Together with colostrum and in addition to T and B lymphocytes and Ig, *breast milk* provides IFN-γ, complement components and other bioactive molecules to protect against bacterial and viral infections [169]; it *is rich in vital cells (up to 10^6/ml),* thus ensuring a continuing supply of factors with an important immune role in the defense of the vulnerable infant. IgA and sIgA antibodies inhibit or prevent the penetration of harmful luminal antigens [135]. IgA and sIgA have the potential to lessen or abrogate possible hypersensitivity reactions [16, 27], with levels up to 0.5–1 g/daily or 0.2–0.3 g/kg of sIgA [228], in addition to anti-infective factors to protect infants against pathogens during the critical period, such as anti-VRS sIgA [77]. Accordingly, breast milk stimulates IgA and sIgA secretion, thus actively facilitating the maturation of the neonatal immune system, unlike bottle-fed neonates [5]. It appears that sIgA are significantly more elevated in the saliva of breast-milk-fed babies [58], whereas the production is developmentally delayed in the recipient baby: 4 weeks to 12 months are needed for sIgA maturation, with 1–2 years for lysozyme and about 2 years for memory (CD45RO) cells [67] in children deprived of *both breast milk and colostrum.*
- *Idiotype/anti-idiotype antibodies* may have lasting effects on the offspring immune system, activating both B- and T-cell clones, and thus priming protective immune responses [78], also inducing tolerance to environmental antigens such as food antigens [78, 79]. In 4-month-old breast-milk-fed infants, such antibodies generate serum and secretory responses to vaccines (tetanus and diphtheria toxoids) statistically more significant than in bottle-fed babies [75], and can also explain the occasional CB findings of IgE antibodies to several antigens [73, 140].
- *EFA,* polyunsaturated (PUFA), long chain (LCPUFA) C20 and C22: arachidonic (AA, 20:4ω6), docosahexaenoic (22:6ω3), dihomo-γ-linolenic (DGLA 20:3ω6) necessary also for intellectual development [43], notably the ratio 18:2ω6/18:3ω3 allow the incorporation of 22:6ω3 into the neonatal neural tissue and the retina [69]. The levels shown in Table 2.14, higher than the levels in control babies and in infants fed supplemented formulas [5], regularly absorbed [89], are present in breast milk at least over 8 weeks with a ratio ω-6:ω-3=5:1 [49]. ω-6 EFA are twice the amount of ω-3 in the brain and 1.3 times in the retina [69], linoleic acid (ω-6 series) and its isomers form collectively the conjugated linoleic acid (CLA) with levels between 0.2% and 0.4%. CB studies suggest a preferential and selective maternofetal transfer of LCP [113]; therefore the breast-milk-fed premature infants receive a higher LCP supply [131] and overall a threefold higher dietary LCP phospholipid concentration than LCP-enriched formulas, apparently because the infants transform dietary LCP into structural lipids, sparing them from oxidation [113]. Supplemented formulas may improve visual acuity in infants fed so [43]. Table 2.15 [49, 113] lists the factors possibly influencing LCP metabolism. Although EFA levels are variable, taking into consideration the marked differences in methods and dietary composition of the population studied [113], most EFA levels are comparatively similar in several European studies [70, 113]. Generally, ω-6 PUFAs, as well as eicosanoids derived from them, are considered proinflammatory, whereas ω-3 PUFAs are considered anti-inflammatory [30]. However, evidence is accumulating to suggest that ω-6 fatty acids may actually be anti-inflammatory via the effects of Th3 or Tr-1 (T-regulatory 1) cells and thus via TGF-β_2 and IL_{10} production. Recent results suggest that in addition to ω-6 fatty acids, the proportion of total PUFA and of total saturated fatty acids may be an important regula-

Table 2.12. Breast milk components with immunological, anti-infective, anti-inflammatory and immunomodulating activities

Components	Properties
sIgA 240 µg/mg/protein/day until 3rd day, ≈20 µg/mg/protein/day from 15 days to 6 months	Does not activate complement, suppresses PMN chemotaxis, blocks adhesion of microbial pathogens, prevents infections, limits the allergenic penetration
IgM about 100 mg/day	Activates complement, forms antibodies against bacteria and virus, retains opsonic activity after traversing the intestinal canal
IgG about 70 mg/day	Activates complement, has heat-stable opsonic activity, blocks toxins and virus
IgG subclasses	Anti-infective activity
IgD	Forms antibodies against bacteria
α-2-Glycoprotein associated with pregnancy	Inhibits the lymphocytes, lymphocyte blastogenesis, ADCC, and immunoglobulin production
Antioxidants: ascorbic acid, cysteine, β-carotene, α-tocopherol	Contrast superoxide production
Arylsulfatase	Degrades leukotrienes
Catalase	Degrades H_2O_2
Cytokines [61, 80, 178, 231]:	
IFN-γ (0.5 UI/ml)	Increases chemotaxis and opsonization, enhances Th1 and antagonizes Th2 cells
IL_1 (1 ng/ml)	Activates T lymphocytes
IL_6 (50 pg/ml)	Enhances IgA production and favors oral tolerance
IL_{10} (3,000 pg/ml)	Carries out anti-inflammatory activity in the infant gut, has effects opposed to those of IFN-γ on Th1 and Th2 cells
M-CSF, GM-CSF	Induces macrophage differentiation
TGF-β (1,000 ng/ml)	Enhances isotype switching to B_{IgA}^+ cells and favors oral tolerance
TNF-α (500 pg/ml)	Induces proliferation of epithelial cells from G-CSF; activates macrophage motility and SC production
Glycoproteins, glycolipids	Antiviral activity, offer protection against bacterial colonization
Fibronectins	Membrane protein, mediates cell interactions and adhesion Plasma protein with opsonic functions
Histaminase	Catabolizes histamine
Inhibitors of proteases	Reduce inflammation
α-1-Antichymotrypsin α-1-Antitrypsin	Degrades the enzymes active in the inflammatory reactions
Inhibitors of viruses	
Lactoferrin	Inhibits complement and inflammation, is a bacteriostatic and iron-binding factor
Lipids	Inhibit superoxide production, disrupt enveloped virus
Lysozyme	Inhibits PMN chemotaxis and free radical formation, antibacterial activity
Macrophages	Have sIgA, produce lysozyme and PGE_2, which reduces intestinal permeability
Modulators of growth	
EGF	Enhances maturation of epithelial cells: levels in "mature" BM 20–111 ng/ml, vs pasteurized CM 155 ng/ml [142]
NGF	
Neuropeptides: GIP, bombesin, cholecystokinin, gastrin, etc.	
Taurine	
Oligosaccharides	Receptors for certain microbes, block their attachment to mucosal sites; are prebiotics that promote the growth of probiotic bacterial strains
Polyamines	Spermine and spermidine
Prostaglandins	Inhibit degranulation of neutrophils, activation of lymphocytes, are cytoprotective, promote intestinal and cellular integrity, release brush-border enzymes
Protein binding B_{12}	Antibacterial activity, is bacteriostatic
Receptor analogs	Anti-infective activity, protection of mucosal barrier

ADCC antibody dependent cell mediated cytotoxicity, *EGF* epidermal growth factor, *GIP* gastric inhibitory peptide, *NGF* nerve growth factor, *TGF*-β transforming growth factor-β, *TNF* tumor necrosis factor.

Table 2.13. Evaluation of breast-milk immune activity

Poor or absent cellular reactivity

- Absence of basophils, mast cells, eosinophils, platelets
- T lymphocytes respond weakly to allogenic cells
- Poor activity of NK cells and ADCC
- Slow motility of neutrophils

Active cellular reactivity

- Macrophages contain IgA, produce IFN and lysozyme, modulate phagocytosis, epithelial growth, immunoregulation
- Neutrophils contain IgA, regulate chemotaxis, phagocytosis
- B lymphocytes promote Ig synthesis
- T lymphocytes promote cellular immunity, produce IFN, modulate cytotoxicity, immunoregulation

Features denoting that breast-milk lymphocytes are activated [105]:
- T cells: IFN-γ, CD45RO, CD25, HLA-DR ↑
- Macrophages: motility ↑ CD11b ↑ CD62L
- Neutrophils: chemotactic response ↓ CD11b ↑ CD62L ↓

Number of lymphocytes and other cells/mm^3 (mean±SD) [16, 94, 107]
- Total lymphocytes = 1,196.7±358.7
- B lymphocytes = 376.2±138.1
- T lymphocytes = 222.3±251, CD4=504.2±155.3, CD8=318.4±98.6; CD4/CD8=1.6±0.15
- Macrophages = 2,325.5±660.5
- Neutrophils = 948.9±368.3

Determinants (% of positive cells±SD) [12, 65]
- CD3 (T lymphocytes) 25.6±14.9
- TcR-αβ 24.5±15.6
- TcR-γδ 4.0±3.6
- CD4 13.6±8.7
- CD8 12.2±7.0
- CD14 (macrophages) endotoxin receptor 64.0±18.2
- CD19 (B lymphocytes) 10.2±5.3
- CD103 4.7±1.6
- IL_2R 10.5±4.6

TGF-β2 was detected in all breast-milk samples, whereas TNF-α and IL_{10} were detected in 16% and 9% of the samples, respectively [119]

Breast milk EFA are shown in Table 2.17, and nucleotides in Tables 2.16 and 2.17.
Data from [12, 16, 27, 61, 65, 67, 80, 94, 105, 107, 119, 142, 153, 178, 198, 228, 231].

Table 2.14. Essential fatty acid (*EFA*) composition of breast milk (*BM*) and of formulas supplemented or not with EFA (mean values, range)

EFA	BM	S+F	Control subjects	AA+DHA	DHA
12:0 Lauric acid	1.4–6.5	17.5	12.9	11.1	14.1
14:0 Myristic acid	3.8–10.2	7.2	5.1	4.5	5.7
16:0 Palmitic acid	19.8–24.0	10.2	7.7	9.0	7.9
18:0 Stearic acid	7.1–9.0	4.2	3.1	4.0	3.2
18:1 Oleic acid	30.7–38.2	16.1	39.5	42.1	40.2
18:2ω6 Linoleic acid	5.7–17.2	34.2	21.9	21.7	20.7
20:4ω6 AA	0.2–1.2	0	0	0.43	0
Total ω6	5.7–17.7	34.2	21.9	22.1	20.7

tor of the breast milk immune milieu [119]. Recently, it has been reported that ω-6 LCPUFAs contained in breast-milk protect infants against atopy and respiratory disease by favoring an enhancement of the Th1 response [47] or Th2/Th1 switching [43].

Table 2.15. Factors potentially affecting neonatal LCP metabolism

Neonatal factors
Body stores at birth
Endocrine regulation (cortisone, insulin)
Energy balance
Energy expenditure
Enzyme and receptor activity
General health condition (stress, infection, etc.)
Growth rate
Rate of fat oxidation
Environmental and methodological factors
Composition of the maternal diet
Cultural and ethnic traditions
Dietary intake of energy: carbohydrates, protein, fats, etc.
Geographic background and socioeconomic status
Humidity
Methods used for measurements
Milk sampling conditions
Temperature

Data from [49, 113].
LCP long-chain PUFA.

- *Nucleotides*, monomeric units of polymeric DNA and RNA, present in breast milk (% of nitric products) five times more than in CM (Fig. 2.19) [66], are essential in energy metabolism, enzymatic reactions, and during rapid growth, have been reported to be especially important for the growth and maturation of the developing gut, in addition to enhancing immune system potentials in neonates [124]. The human body synthesizes nucleotides to cover its metabolic needs, and is also dependent on external supplies such as dietary nucleotides, whose metabolism is shown in Fig.2.20 [66], also denoting the contribution of dietary nucleotides. Breast-milk levels are delineated in Fig.2.21 [10], in Table 2.16 [124] and in comparison with supplemented formulas (Table 2.17) [210]. Breast milk is provided with the complete enzyme sequence to convert purine nucleotides to uric acid [210]. Nucleotides influence several indices of neonatal immune function [35]. They are essential nutrients for normal development, maturation and repair of the GI tract, since rapidly growing tissues such as the intestinal epithelium and lymphoid cells have limited *de novo* synthetic capacity and require exogenous sources of purine and pyrimidine bases [214]. Dietary purines are not significantly incorporated into

Table 2.16. Nucleotides as such and total potentially available nucleoside (*TPAN;* µmol/l) in a pool of 100 samples of breast milk (*BM*) distinct by stage of lactation

Type of BM	Uridine	Cytidine	Guanosine	Adenosine	TPAN
Colostrum Mean+(range)	26 (21–30)	71 (33–84)	21 (15–26)	21 (13–26)	139 (82–164)
Transitional BM Mean+(range)	32 (23–37)	86 (76–100)	30 (19–43)	29 (17–42)	177 (144–210)
Early mature BM Mean+(range)	48 (30–67)	102 (79–146)	45 (23–91)	46 (21–97) 240	(172–402)
Mature BM Mean+(range)	47 (36–58)	96 (73–124)	28 (22–40)	31 (24–49)	202 (156–259)

– Not measurable. [a] Nucleic acid expressed as nucleotide equivalent. Modified from [210].

hepatic nucleic acids, but pyrimidines are: both are taken up by gut cells, which convert into uric acid the excess purines [214]. Carver [35] has documented that breast-milk-fed infants have higher NK cell and IL_2 production compared with a group of healthy babies fed a CM formula supplemented with nucleotides (41.7±4.7 vs 32.2±3.4), and levels significantly higher than infants fed a standard non-nucleotide-supplemented formula. At 4 months only breast-milk-fed babies maintained the statistical differences vs the standard CM-fed group [35]. Principally in preterm infants [166], dietary nucleotides may influence the conversion to LCPs of

linoleic (ω-6 series) and α-linolenic (ω-3 series) acids. High levels of NK cells and IL_2 may be a defense against pathogenic invasion [35].

- The *nucleic acids* contained in breast milk in a much higher quantity than CM are capable of inhibiting the Th2-mediated responses, thus in the breast-milk-fed infant they may redirect the original (fetal) immune responses toward the Th1 phenotype [207].
- Several factors ensure a nonspecific protection against potential pathogens, including the enteric colonization with nonpathogenic bacteria, lectins, additional carbohydrates different from lactose, providing a protective effect for the developing mucosa, lipids with antibacterial, antiviral and antiprotozoan activity, and growth factors stimulating gut closure, etc. [67].
- The leukocytes consist of neutrophils 55%–60%, macrophages 35%–40%, lymphocytes 5%, 80% of which are T lymphocytes [105], including memory T cells [226]. The total lymphocytes, B and T cells, CD4 and CD8 lymphocytes, macrophages and neutrophils are present in preterm babies in a significantly greater number [94].
- More *T cells* are present than those identified in peripheral blood such as TcR-γδ, CD8 and CD103 and an increased proportion of activated cells, which impart to breast milk cells a mucosal phenotype [65], and CD14, which inhibits IgE synthesis on monocytes (Table 1.2), whose reduced levels in amniotic fluid and breast milk and therefore in the neonatal GI tract are associated with the subsequent development of atopy, AD, or both [101]. Maturation of sCD14 plasma levels continued after birth, with adult levels achieved only by 4 months of age [101]. Probably for that reason, human breast milk contains high levels of the critical coreceptors *sCD14*. In addition, breast milk provides the neonate with a *TLR* (Toll-like receptors) signaling regulator, sTLR2. sTLR2 was found naturally expressed in plasma and breast milk. Milk sTLR2 levels mirrored those of the TLR coreceptor sCD14. Depletion of sTLR2 from serum resulted in an increased cellular response to bacterial lipopeptide [125]. Breast milk cells also expressed mRNA for TLRs (Toll-like receptors), TLR1, *TLR2, TLR3, TLR4, TLR5, TLR6, TLR7, TLR9, CD14,* and *LL-37*. In this way, an excessive local inflammation of the neonatal gut following bacterial colonization could be avoided [4].
- Regarding *defensin* mRNA expression in the breast milk cells, the concentrations were 33.0 μg/ml for human β-defensin 2 (HBD-2), 2.4 μg/ml for HDB-5, 1.7 μg/ml for HDB-5 and 3.1 μg/ml for human α-defensin 6 (HNP-6) [4]. Human *cathelicidin LL-37* mRNa was detected in human milk cells with an increase in relative expression levels at 30 and 60 days after parturition. The antimicrobial activity of LL-37 against *Staphylococcus aureus,* group A *Streptococcus,* and *Escherichia coli.* Thus cathelicidin secreted in mammary gland and human milk has antimicrobial activity against both Gram+ and Gram– bacteria, and can contribute to the anti-infectious properties of milk [148].
- *Macrophages* are functionally active by means of M-CSF present, with levels 10- to 100-fold above those found in human blood [80], an average of 30-fold [65], ready to bridge the early neonatal deficits, since they are provided with receptors for sIgA and may be activated via these receptors [170]. Breast-milk macrophages may increase sIgA levels to up to 5%–10% of breast milk content [228], yet they encompass intracellular sIgA, a valid means to progressively transport the antibodies directly into critical areas [173], in addition to phagocyting the CICs formed by sIgA to exclude potential pathogens invading breast milk. Macrophage concentration is greatest on the 6th day but can persist and act up to the 6th month [16]. They can also be primed to release large amounts of O_2 metabolites and could thus contribute to the protection of newborns against invading microorganisms [197]. In keeping with these findings, the ability of immunocompetent cells to survive sticking to the intestinal mucosal sites [93] and to secrete their soluble products is also a means to potentiate the local immune responses of neonatal gut as well as their systemic responses. A study on the cellular composition of breast milk has warned that the risk of the breast-fed infant developing CMA is moderately high if breast milk fulfills at least two of the following criteria: either <91% macrophages, or <52% macrophages, >5% neutrophils, and at least 1% eosinophils (odds ratio, OR 4.5, p=0.01) [98].
- In addition to *the ILs* listed in Tables 2.12, 2.13, almost all generated by macrophages, there are several others, including $IL_{1α}$, $IL_{2–5}$, IL_8 [191] and IL_2 produced by T cells [226]. Such ILs are therefore able to meet all requirements of breast-milk-fed neonates. Moreover, properly stimulated leukocytes produce TNF-α [175] and mononucleates GM-CSF as well [191]. In particular IL_{10}, present in placental lysates of second and third trimesters and in amniotic fluid [219], could be a bridge among the anti-inflammatory and immunomodulating factors forming the defense system of breast milk [61], also because it is necessary for the synthesis of IgA antibodies [123]. The undetectable expression of IL_{10} in preterm babies [100], as confirmed by the decreased secretion by neonatal monocytes and T cells [38], is related to severe respiratory manifestations and can predispose preterm neonates to chronic lung inflammation [100].
- Regarding the *chemokines* IL_8 and RANTES (regulated on activation normal T expressed and secreted), an intriguing hypothesis has been put forward that they facilitate the transfer of maternal cells into breast milk, their adhesion to intestinal walls and their migration into infantile immune tissues, leading to the modulation of neonatal immunity [231].
- Some *oligosaccharides* (Tables 2.12, 2.13), including lactadenin (glycoprotein associated with mucin), contribute to augmenting the potential defense of babies against infectious agents, acting as receptors for *E. coli* and *Vibrio cholerae*, preventing their adhesion to the intestinal mucosa, thus decreasing mucosal inflammatory reactions. Galacto-oligosaccharides are *prebiotics* that

C colostrum, *BM* breast milk, *S* serum.

foster the growth of probiotic strains of bacteria, restore normal fecal flora, enhance nutrient bioavailability and reduce gut permeability, thus promoting neonatal gut endogenous host defense mechanisms [152] (see also Chap. 7).

- Anti-infective, anti-inflammatory and immunomodulating factors functionally interact among themselves (Fig. 2.22) [60].

Immunology of Colostrum

It took centuries for the alimentary value and the immunological value of nutritional sources to be acknowledged. Colostrum contains:

- IgA, IgM, IgG. As a compensation for poor quantity of IgG (3% of maternal IgGs), colostrum and breast milk contain significant concentrations of subclasses, ≈50% of maternal titers [55]. Table 2.18 also shows the salivary values [108].
- sIgA, macrophages and EGF with titers higher than those found in breast milk (Table 2.19) [14, 94, 98, 107, 108, 142, 182]. IgA antibodies [5–10 g/l) are transferred to newborns during the first 3 days after delivery: IgA can represent up to 80% of the total content of proteins [228, 231]. CD154 expressed by colostral T cells could trigger *isotype switching* to IgA and sIgA [13].
- Nucleotide levels not much lower than those of transitional breast milk (Table 2.16).
- Factors binding IgE and specifically *suppressing IgE synthesis* by B cells of atopic individuals [182] as well as IL_4 production [21].
- Factors eliciting a nonspecific protective function at the level of the mucosal barrier because the existent

Table 2.19. Immunological factors in human colostrum

Colostrum contains:

Lymphocytes (about 10%–15% of total cells) × ml ($\times 10^4$)
CD3 74.7±2.5
CD4 50.6±2.3
CD8 24.0±1.7
(mean±SEM)
T4/T8 cell ratio higher than that of circulation

(Mean and range)	Colostrum	Autologous blood
CD3+	69 (55–81)	75 (65–84)
CD3+/CD45RA+	12 (4–31)	49 (28–69)
CD3+/CD45RO+	78 (56–98)	54 (40–85)

Immunoglobulins (Igs)

IgA (mg/dl) days 1–2:	619.0±110.6	days 3–4	239.3±55.8
IgG (mg/dl) days 1–2:	31.4± 12.3	days 3–4	14.1± 5.0
IgM (mg/dl) days 1–2:	38.3± 7.8	days 3–4	5.3± 1.6

IgG subclasses (about 50% of maternal levels. see Table 2.18)
sIgA with levels higher than BM levels

IFN-γ (U/ml)

	Colostrum	Autologous blood
Anti-CD3	39.5±9.6	33.8±10.7
Anti-CD2	20.6±6.5	22.3±6.2

Macrophages 30%–47% of total cells (levels higher than BM levels)

Antioxidants (may serve to block neutrophil-generated toxic oxygen metabolites)

EGF
Precolostrum 130–180 ng/ml
Colostrum 35–438 ng/ml

Enzymes and proteins (levels higher than BM levels)

Lactate-dehydrogenase

Trace elements (levels higher than BM levels)

Human colostrum activities:

Hastens the development of an intact mucosal barrier

Enhances brush-border enzyme production (lactase, sucrase, and alkaline phosphatase)

Cytotoxic activity
ADCC
Lectin-dependent
NK cells

Decrease in antigen penetration in neonates

Presence of IgE suppressor factors

No. of lymphocytes and other cells/mm^3 (mean±SD)
Total lymphocytes = 1,532±520.2

Table 2.20. Immunomodulating agents in breast milk

Colostrum
Levels of $CD45RO^+$, T ($CD3^+$) and IFN-γ cells have a considerable positive role in the context of the shortage of such cells in nursing infants. There is a double TcR-γδ supply compared to peripheral blood
Factors specifically suppressing IgE synthesis by B cells of atopic children
Human milk
Promotes the production of IgA and sIgA antibodies, thus actively favoring the maturation of the neonatal immune system
Idiotype/anti-idiotype antibodies prime both B and T cells to promote tolerogenic responses during exposure to environmental antigens, especially food allergens
Such idiotype/anti-idiotype antibodies generate better vaccine responses in breast-fed than in bottle-fed infants
IL_{10} represents a bridge between the anti-inflammatory and immunomodulatory factors in the breast milk defense system
Fibronectin modulates the infant immune response by binding to specific sequences of cellular DNA, thus inducing DNA transcription
There is a growing body of recent studies suggesting that breast-fed infants are at lower risk for developing atopic disease, including asthma, and type 1 diabetes mellitus, Crohn's disease, or secretory otitis media later in childhood

Modified from [67].

antibodies, not absorbed, stick to the intestinal wall, providing a function of *passive defense* [187]. In addition, they provide a *quantity of EFA equal to the recommended quantities* [176].

- Titers of $CD45RO^+$ and T-$CD3^+$ cells mostly expressing CD103 and of IFN-γ, which assume a highly positive significance in the context of the inadequacy of such neonatal cells alluded to above [14]. Moreover, there is a double volume of TcR-γδ cells compared with that in the peripheral blood [12] IL_5 and IL_{13} production is enhanced. However, this is offset by an increased IL_{10} production [21].
- HNP-1, HDB-2 and HD-6 were present in *significantly higher levels in colostrum* than in mature milk [4].
- Substances able to accelerate the development of an intact mucosal barrier, enhance the production of brush-border enzymes (lactase, sucrase, alkaline phosphatase), and decrease food antigen penetration through an anti-inflammatory activity within the intestinal mucosa (Table 2.19).
- Antioxidant substances that could inactivate O_2 toxic metabolites derived from excessive neutrophil secretion [23] (Chap. 1).
- Colostral B cells respond with Ig secretion to antigen stimulation [192]. Similar growth has been observed in culture; therefore, such results have given credit to the theory that B cells partially maintain their functional activities after having colonized the colostrum/breast milk [192]. This hypothesis was not confirmed since the IgE concentrations, similar in atopic and nonatopic mothers, are so low that they have no significant effect on IgE regulation in the neonatal age [51].
- In addition to breast milk, colostrum is rich in TGF-β, which may prevent the development of atopic disease during exclusive breast-feeding and promote specific IgA production in breast-fed babies [103].
- Together with TGF-β1 and β-2, colostral sCD14 is a co-receptor with TLR-4 for lipopolysaccharide (LPS) from Gram-bacteria needed for CD14-negative cells [184].

In conclusion, it seems *unscientific and against medical common sense* to deprive neonates of colostrum and transitional breast milk in the very first days of extrauterine life and thus add to the risk of potential infections [77].

All evidence yet gathered tends to prove that the maternal breast is an immune organ belonging to MALT [170]: breast milk not only has components protecting the vulnerable infant against the first infective and inflammatory episodes, but is also the vehicle for the transfer of immune regulation from the mother to her offspring, thus contributing to the maturation of the immune system of the newborn infant (Fig. 2.22). Several immunomodulating factors present in breast milk (Table 2.20) [67] that may actively modulate the immunological growth of the baby many of which are produced and are common to other mucosal sites, often share synergic features and provide a protective activity without inducing inflammation. Moreover, their production decreases with the duration of breast-milk feeding and in synchrony with the increased secretion of those factors from the neonate [60]. In addition, EGF has been shown to play a role in reducing macromolecular absorption and in promoting the functional maturation of the epithelial cells of the gut barrier (Tables 2.12, 2.13 and 2.19): indeed the proliferation of the intestinal epitheli-

Table 2.21. Mechanisms by which breast-feeding can delay atopy development in genetically at-risk neonates and infants

Protects from gastrointestinal and respiratory infections including bronchiolitis
Lessens exposure to antigens early in infancy
Stimulates intestinal mucosa maturation, thus limiting the penetration of free antigens
Transfers cell-mediated immunity
Transfers interleukins
Enhances secretory IgA production to exclude intestinal absorption of macromolecules
Has a positive effect on the gut microflora

um is more rapid in breast-fed animals compared to CM-fed ones [142]. However, pasteurized CM contains nearly similar EGF values, which likely do not resist subsequent handling [235].

sIgA is the major antibody of breast milk [16, 27, 170, 218]: primed B_{IgA} cells home to the mammary gland through the enteromammary axis and are transferred to the suckling newborn, where they act against noxious intraluminal antigens and also respiratory microorganisms [187]. In the neonatal gut, specific sites where maternal sIgA antibodies bind the glycocalyx of epithelial cells more firmly than the endogenous ones were detected. Furthermore, maternal IgA antibodies have been shown to block the antigen entrance into breast milk effectively [193]. Clearly, maternal MALT is in turn "educated" and, again through the enteromammary pathway, contributes to the *de novo* synthesis of sIgA. Studies on anti-idiotypic antibodies show that they are favored in infants by maternal antibodies [74, 169]. Maternal T cells are equally divided between CD4 and CD8 T cells, whereas in the bloodstream the ratio is 2:1, and they play a relevant role in that they promote the secretion of maternal IgA antibodies [169]. Even breast milk macrophages have a place in the local protection of the infantile gut [173]. Beginning from the first week of breast-milk feeding, the baby receives *spermine and spermidine*, with a virtual protective effect on food allergy (FA) [175]. Consequently, the immune defense provided to the offspring appears to be pivotal, first by colostrum and then by breast milk, in a particularly critical period concerning a possible sensitization [26], in which the maturation of the GI barrier and the antibody secretion are still inadequate [114]. Tables 2.21 [67] and 2.22 [19, 231] show how breast-milk feeding can prevent atopy development in genetically at-risk newborns and infants and promote the maturation of the GI tract with several mechanisms. Table 2.23 [217] lists the conditions potentially associated with an immature mucosal barri-

er, for instance the elimination of gut microflora following the increased use of antibiotics in infancy. It is not out of place to state that the *most common immunodeficiency* may be that of the *young infant deprived of breast milk,* with the ensuing deficiency of sIgA and other immune and defense factors [76]. This is demonstrated by the study of 24 variables, as presumed causes of neonatal septicemia: only the protection ensured by breast milk vs CM or formula reached statistical significance ($p<0.001$) [76].

As regards possible effects of *malnutrition* on breast-milk feeding, neither nutritional status nor ethnic origin influence the immunological components. Instead *Rotavirus* infections may cause a significant rise in intestinal permeability to antigenic macromolecules (βLG) [91, 216], in particular if associated with malnutrition [216], so that introducing CM can trigger an inflammatory reaction if the local microflora is depressed or absent [95]. A retrospective analysis confirms that the infection is associated with AD during the first 2 years of life, but excludes this association with FA [117].

Experimental Studies on Neonatal Tolerance and/or Immunocompetence

The neonatal period appears to have a major role in establishing tolerance to environmental antigens: in most species it is possible to induce a specific and long-lasting tolerance to orally administered antigens during this time span [146]. In neonatal mice, immune system immaturity favors priming to oral antigens instead of inducing tolerance; proteolysis is also immature and peptide fragments predisposing to intolerance cannot carry tolerogenic messages [79]. Such a delay may be due to T-cell clones and T-like IL immaturity (Table 2.1). Potential tolerance does not start before 4–7 days of life, and until 21 days is dose-dependent, since very low doses of antigen are able to prime young mice, which may develop an IgE response [146]. Young rats become tolerant to an antigen introduced in their weaning diet for 2 weeks, whereas adult rats fail to become tolerant, even if fed the same antigen for several weeks [227]. Pigs equally become tolerant when weaned onto an antigen, or alternatively if they receive a large dose of antigen at birth before gut closure [79]. Rodents are born much more immature than other species, therefore there is a *lower age limit for being able to develop oral tolerance* [206]. Oral tolerance to ovalbumin in mice can be prevented by agents that activate the RES (estrogens, muramyl-dipeptide, GvHD), while activation of APC, with a similar effect on tolerance, may interfere with the production of CD8 [146]. Recent evidence has shown that feeding one antigen to naive mice is associated with transient RES activation, and prevents induction of tolerance by feeding a second antigen [79], a finding of clinical relevance to the possible effects of the early introduction of solid foods (Chap. 4). Other studies emphasize that induction of tolerance is possible only in immunologically naive animals, because once stable memory is established in $CD4^+$ Th2 cells, persistent IgE responses develop. Further exposure to the relevant antigens only boosts the ongoing responses [139]. This form of tolerance is preferentially directed against IgE and the pertinent Th2-dependent IgE production, while preserving an ongoing Th1-dependent IgG response [131]. The crucial concepts of sensitizing low doses [97] and CD8-mediated immune deviation [139] will be analyzed in Chap. 4.

Infancy		Atopic march

Fig. 2.23. Atopic march. (Based on a Symposium on Atopic Dermatitis in Children held in Brussels, October 11, 1995)

Recent experiments have demonstrated the clonal elimination of thymic autoreactive T cells: T cells expressing TcR Vβ able to deliver reactivity to endogenous superantigens (SA) are deleted in the thymus of mice expressing SA [104]. In transgenic mice, restricting the TcR specific for H-Y antigen to males, the TcR developed normally in female mice, but was eliminated in the thymus of males [109]. Comparable deletion of autoreactive thymocyte occurs, inducing tolerance in neonates [132]. Subsequent studies have partially defined the mechanism by which newborns fix their defense. As yet, two main categories of interpretation are convincing. Passive models suggest a negative selection of T-cell reactive clones after neonatal challenge with their own or foreign antigens. Active models suggest instead that following an early antigen contact, neonatal lymphocytes generate suppressive, anti-idiotypic, or deviated Th2 immune responses, thus paving the way for the atopic march (Fig. 2.23). However, these hypotheses do not explain why some viruses induce tolerance if given neonatally and others provoke an immune response with formation of related specific antibodies [171]. Three recent studies [59, 171, 183] re-examine the prevailing theories, putting the APC role in the top position. They conclude that the neonatal period is not an immunologically privileged window in ontogeny. Tolerance or sensitization

depends on APCs and the type of signals sent to T lymphocytes, which must decide which response is pertinent [171]. Neonatal cells are neither innately tolerizable nor able to make only Th2 responses: tolerance induction in adult animals was achieved by inoculating an increased dose of cells inducing tolerance. Therefore, these responses, relative to tolerance induction, are only quantitatively different [171] (Fig. 2.1). As a consequence, the susceptibility of neonates to virus-induced disease reflects not an "uneducated" immune system, but the type of response of lymphocytes, which in murine spleen are 2000-fold less than adult cells. Infection of neonatal mice with a dose of murine leukemia virus results in virus replication within 2 weeks in mice spleen and brain, but virus infection in 3-week-old mice leads to a vigorous protective CD8 CTL response that blocks viral replication [183]. Equalizing the dose to T-cell number resulted in an intensity of protective CTLs response that was inversely proportional to viral dose. Inoculation of neonates with high doses of virus leads to the induction of a nonprotective type Th2 response, thereby not caused by the immunological immaturity of the recipients [183]. Following the classic protocol, an antigen was subcutaneously injected into mice within 24 h of birth and the same antigen was reinjected at the adult age. Mice injected at birth displayed an impaired response in the lymph nodes but a marked proliferation of spleen cells [59]. T cells recall responses to antigens and so do not migrate into lymph nodes. Technical restrictions limited earlier studies to lymph nodes, so neonatal injections do not tolerize but induce memory cells [59]. Activation of the neonatal immune system was detected in CB immune cells (Tables 2.5 and 2.6), where we find [87] T cells, CD25 and CD45RO at different levels based on FHA [87, 130], moreover recording T responses to food and inhaled allergens [87] (Chap. 4). If memory cells are a prerequisite of tolerance, the related deficit can influence the subsequent exposure to allergens negatively. However, during fetal life and at birth poor T-B cooperation and lack of CD28-mediated signals may contribute to development of T-cell anergy and consequently to tolerance induction [130].

Local Immunity in the Respiratory Mucosa

The neonatal lung is a *secretory organ:* in animal fetuses, 2–3 ml/h/kg of fluid is secreted. This fluid flows to the oropharynx as a result of fetal respiratory movements and by contraction of smooth muscles, then is swallowed or added to the amniotic fluid. The protein content of such secretions is tenfold lower than plasma or lymph, thus suggesting that fetal epithelium is impermeable to macromolecules early in development. Given the importance of sufficient quantities of surfactant for normal neonatal airways, nodal points are the presence in fetal lungs of constitutive proteins including SP-A and the release of palmitic acid from alveolar capillaries, used by pneumocytes to synthesize surfactant [209].

Table 2.24. Anatomical and physiological systems involved in pulmonary defense

Phagocyte cells
T-cell-mediated cellular response

Modified from [11].

BALT aggregates are uncommon in human fetuses: some follicles are seen in fetal lungs of 18-day-old mice transplanted into syngeneic adults [18]. BALT cluster cells appear at 7–10 postnatal days even though in infants aged <1 year, BALT is developed and organized when larger and more confluent aggregates appear [68]. BALT is a system with structures equivalent to PPs – with a scant division into distinct structural and functional areas – and also to GALT lymphoid tissues. BALT consists of numerous lymphocytes, with a predominance of B cells, organized into follicles and other lymphoid structures, while GCs are relatively rare. Lymphocytes are localized along the main bronchi of all lung lobes and around bifurcations into bronchioles, and also in the epithelial tissue found among the branches of the pulmonary trunk; the epithelium overlying BALT has no cilia and goblet cells [18]. BALT is provided with an elaborate blend of capillaries, arterioles, venules and efferent lymphatics: Holt therefore suggests that it *can control the antigenic traffic* both in the bronchial lumen and bloodstream [86]. M cells overlying the lymphatic follicles of BALT are similar to that of GALT [157]. BALT functions are also carried out by tonsils and adenoids, by 3–5 months of intrauterine life infiltrated by lymphoid tissue and favorably placed to mediate the airway and intestine immune protection (Chap. 15).

Table 2.24 [11] summarizes the number of anatomical and physiological components of pulmonary defense: the mucociliary apparatus develops in the first weeks of intrauterine life, at birth it is able to fulfill its function, and is very effective in removing >90% of particles >than 2–3 µm. Particles between 0.5 and 3 µm

penetrate to distal portions where 90% are deposited [11]. Expression of physiological and nonimmunological defense is the phagocytic system completed by B-cell antibodies, cell-mediated responses, and a set of biological amplification systems including complement [11]. Also of importance are the different cellular and extracellular nonspecific mechanisms such as surface fluids encompassing mucus, surfactant, fibronectin, etc. and epithelial defenses (cilia, goblet cells, mucus, serous glands and type I and type II cells) [11]. Table 2.25 [151] outlines several immune components involved in pulmonary defense. As the table shows, macrophages support the work of lymphocytes, Igs, etc. However, having previously alluded to such notable defenses, we underscore their immaturity in lung alveoli in the neonatal period (chemotaxis, microbicidal activity) in connection with respiratory distress, infections and O_2 toxic metabolites [11]. SCs, proteins (α_1-antitrypsin, α_2-macroglobulin, lysozyme) that protect pulmonary structures from the action of proteases (collagenase and elastases), destroying or inactivating them, are important. A further defense mechanism has been partially characterized: in the airways TcRs may not have the conventional αβ chains but the γδ chains. Hitherto their role and specificity do not appear to be convincingly defined in this field, but it is tempting to speculate that such receptors may have a wider specificity than the normal αβ TcR. In addition, γδ T cells could exhibit responses to SAs, particularly microbial and mycobacterial, with essentially polyclonal modalities. Thereby γδ TcR could play a crucial role as a first line of defense by killing infected epithelial cells before infection spreads across the basement membrane, that is before T-cell intervention, and the ensuing tissue damage [96]. From this, the increased γδ localization to certain mucosal surfaces, such as intestinal and respiratory surfaces, could protect the epithelial cells from inflammatory damage, selectively *suppressing IgE responses* [86]. A role in the defense of respiratory mucosa has also been credited to IgG_4, the only IgG not activating complement by the classic pathway and relatively present in secretions. HLA class II molecules are entirely absent, while after birth consistent aliquots of $CD3^+$ T cells appear and those of IgM and IgA produce cells [215]. However, even 1-day-old neonates have demonstrable levels of $IL_{1\alpha}$, $IL_{1\beta}$, IL_6, IL_8 and TNF-α in their airways [128].

This accumulation of varied observations points to neonatal immunodeficiency: as previously noted, the first 6 months of life are a period at high risk of sensitization to aeroallergens. Exposure to mites, animal epithelial, pollens, etc., in the first months of life increases the risk of respiratory allergy [86]. Neonates are exposed to a notable respiratory load: what neonates breathe is not made up only of normal components, but also by a large pool of pollutants (Table 2.26) [11]. Evidence that early and intense exposure to allergens and the result of several triggering factors in the first months of life can enhance T-cell recognition of aeroallergens and the consequent generation of immunological memory, thus leading to specific immune responsiveness. This might explain why over this period the immune system appears to be more susceptible to initial sensitizations caused by such allergens compared to subsequent sensitization, because children born outside the pollen season (when the immune system has more time to mature before its initial exposure to pollen allergens)

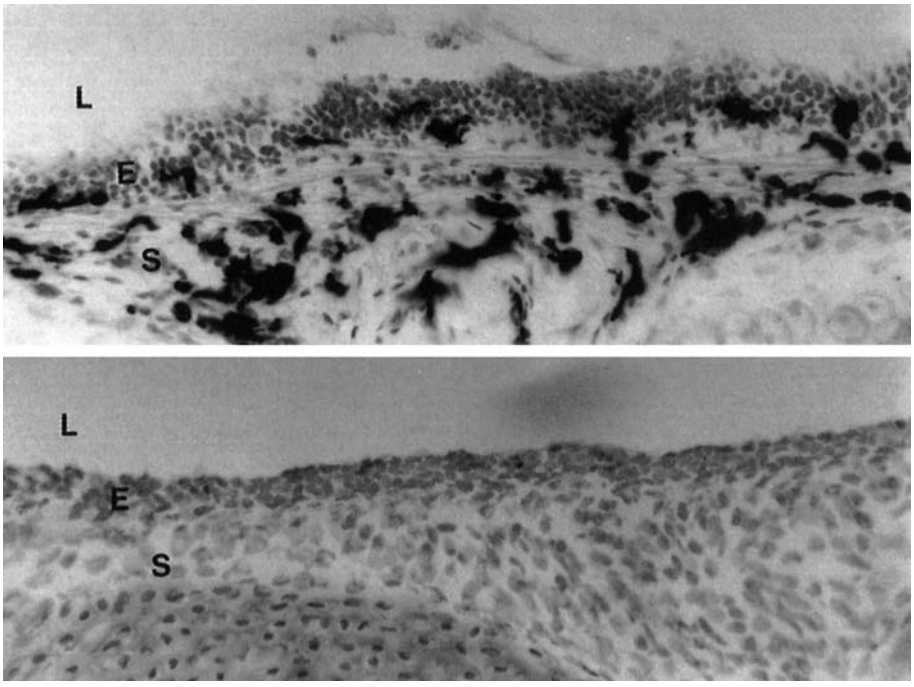

Fig. 2.24. Dendritic cells (DCs) in an adult and 8-day-old rat trachea. In the *upper panel* (adult) note DCs in and below airway epithelium, compared to preweanling (*lower panel*). *L* Airway lumen, *E* airway epithelium, *S* submucosa

are less likely to manifest pollen allergy during childhood [151].

Epidemiological studies have shown that atopic children infrequently show IgE antibodies to inhalant allergens before the second birthday, when they can instead produce IgE to foods during the first year of life. Since this transient defect is restricted to inhalant and not food allergens, it is possible that a BALT intervention, which in some way blocks T cells susceptible of sensitizing children to aeroallergens, thus preventing transfer of immunological memory, acquired during early infancy, into active IgE production. In experiments on animal models, it was suggested that failure to recognize inhaled allergens in the first months of life may depend on a selective maturative defect in local respiratory mucosa immune function [151]. In the rat model it seems to be due to the *absent or marked reduction in DCs at birth and their slow postweaning maturation* (Fig. 2.24) [88], demonstrated by HLA-negative precursors at the expression site of high HLA levels in adult rats [150]. Thus, the slower rate of increase in the peripheral lung DC population, in infant rats, the only cells expressing HLA [151], may determine the failure to recognize aeroallergens [151] and a sort of protection of the delicate tissues from potentially detrimental T-cell responses [150]. A parallel network of these intraepithelial cells is present in the lungs of human adults [68]. Concerning human neonates and nurslings, there is so far no definite information available, therefore the topic is open to speculation. In this context, it is likely that the key may be located in the BALT. We conclude with Table 2.27 [88], illustrating the factors that, in the nonimmunologically exposed host, might interfere with tolerance acquisition to inhalant allergens.

Table 2.27. Host and environmental factors associated with evasion of protective tolerance to aeroallergens

Risk factors	Possible negative effects
Diesel particulate	Promotes IgE responses
Estradiol	Affects macrophage and T cell function, increases TGF production
Histamine	Increases vascular and epithelial permeability
N dioxide	Induces respiratory epithelium damage
Pertussigen	Affects T cell function, increases vascular permeability
Virus	Induces respiratory epithelium damage
	Affects T cell function
	RSV promotes IgE responses

Modified from [88].
RSV respiratory syncytial virus.

Local Immunity in the Skin

In Chap. 7 we shall discuss the skin immune system (SIS), which makes up a complex system of immune surveillance at the skin level and is formed by lymphocytes, DCs, keratinocytes, etc. At 23–26 weeks of intrauterine life, the epidermis is still immature, formed by only 2 or 3 cell layers (the stratum corneum is poorly developed). At birth there is an accelerated maturational process and by 2 weeks of age, including in extremely LBW neo-

nates, the epidermis resembles that of term infants, almost similar to that of older ages [180]. LCs enter the fetal epidermis during the first trimester, and their number continues to increase over the entire length of gestation, forming Birbeck granules in the second trimester, when the relative distribution is different in skin layers, perhaps with reference to certain skin characteristics such as its structure and function [180]. Unlike airway DCs, HLA expression is very rapidly seen after birth [150].

Pediatricians and Neonates

Pediatricians welcome neonates that come into the world equipped to begin an immunologically normal and active period. They are without "windows," thus expanding the range of tolerance acquisition: therefore neonates grow well. It is the environment, as we shall see, that tends to spoil them, even with the air they first breathe. Food allergens exemplify the most frequent cause of sensitization in the first weeks of life, when the intestinal barrier is more permeable to harmful macromolecules. The mechanisms acting to control antigen exclusion and elimination are physiologically immature, thus allowing food allergens to penetrate across the intestinal barrier. The immune protection entrusted to neonates by breast milk intake is therefore significant. Several prospective studies confirm the protective value of breast-milk feeding vs atopic sensitization: in the neonatal age, frequent exposure to small doses of antigens are more harmful than high doses. Antigens can prime a critical IgE-specific response, according to Jarrett's stimulating studies. However, factors present in human colostrum suppress IgE synthesis. Hence pediatricians have an essential function, that of ensuring that neonates enjoy a healthy life, following the natural cadence of breast-milk feeding, which, during the critical period of intestinal vulnerability, provides substantial immune protection because of rich immunological, antimicrobial, antiviral, anti-inflammatory and immunomodulatory factors, functionally interacting among themselves. Clinical and scientific evidence suggests that the protection assured to neonates from breast-milk feeding is greater when it is exclusive and of suitable duration.

Neonatal Immunology: The Neonate at Risk of Atopy

The Neonate at Risk: Predisposing Factors

Since it is not possible to act on the genotype, the scientists' research and the clinicians' experience are directed at eliminating or at least reducing exogenous predisposing factors. It is consequently necessary to combat the potential danger of such factors at birth and, if permitted, even before (Table 3.1) [122]. As a result of the incomplete maturation of the mucosal barrier, the risk of an allergic sensitization is higher [84, 117, 122, 127], because of the resulting immaturity of the local immune defense system [11], including Th1 cells, IFN-γ, B cells, sIgA and sIgM (secretory) antibodies, neutrophils, macrophages, and complement. Thus the neonate is vulnerable to penetration of harmful luminal macromolecules or their antigenic fragments and, if deprived of the unique immune factors of breast milk (Tables 2.12, 2.13, 2.20–2.22), the condition may become even more critical, and the impact of a retarded gut closure can be striking.

Several factors associated with the physiological immaturity, typical of the neonatal age, can interfere with the protective gastrointestinal barrier function [122] and thus result in an increased antigen entry in both normal and at-risk neonates (Table 2.23). Usually, the enterocytes provide absorption through a process of endocytosis beginning from the microvillous membrane (MVM), which complexes with polypeptide macromolecules to form microvesicles. Instead, during the neonatal age the membrane of such cells shows differences in composition and the MVM protein–phospholipid ratio is dramatically reduced, with a consequent increase in permeability of the intestinal barrier [22, 110]. Age-dependent structural alterations may quickly affect the composition and thickness of the protective mucous blanket, membrane fluidity, activity of membrane-bound enzymes, transport systems, receptor binding events, and protein adhesion to membranes [22], thus enhancing the antigen uptake and its intercellular transport [110].

Table 3.1. Maternal factors active during fetal life that can modulate atopy development

Cigarette smoke
Health state
Immaturity
Possible treatments
Transfers through the placental barrier

Modified from [122].

Factors that may account for mucosal barrier defects during the perinatal period are the following:

- The immaturity of the gastric barrier leading to increased uptake of intact proteins.
- The scarce production of protective mucus, whose glycoprotein molecules ensure that the local defense acts as competitor to the binding of antigens with the microvilli glycoproteins.
- The reduced gastric acidity that reaches levels comparable to those of adults about the 4th week of life.
- The decreased secretion of intestinal and pancreatic enzymes due to immaturity of calyciform cells of the intestinal mucosa and of pancreatic cells is shared with the deficit of natural antibacterial substances (lysozyme, biliary salts), thus explaining why small bowel proteolytic enzymes attain maturity only about the 2nd year of life.
- The reduced carbohydrate/protein ratio of mucin, possibly causing alterations of linking options for proteins, etc.
- The inadequate intestinal motility, following reduced peristaltic activity, delays food progression, which implies a longer contact of luminal macromolecules with gut mucosa, and consequently a higher antigen absorption [11].
- The absence of brush border surface area may allow macromolecules to reach the submucosa. The brush border will start to develop in the first weeks of life, contributing, together with the acquired maturity of the mucosal barrier, to gut closure, a process favored by breast-milk feeding [120].
- An adequate gut microflora (Table 2.11) has no role in preventing or outweighing gastroenteric infections, modulating immune responses to dietary antigens, and balancing the generation of proinflammatory and anti-inflammatory cytokines [99], but the acquisition of an appropriate gut flora may play a role in skewing toward Th1 lymphocytes. Since pregnancy is a Th2 phenomenon and allergy is marked by a Th2 dominance (Chap. 2), the development of a balanced Th1/Th2 immunity is critical [77].

Supplementary Feeding in Maternity Wards

In the complex process of supplementary feeding in the maternity ward, it is believed that the coexistence of physiological immaturity of the mucosal barrier function and the early ingestion of allergenic foods can favor the onset of food sensitization in at-risk babies, who are predisposed to potential IgE-mediated hypersensitivity reactions. In this picture, the role played by the early and occasional exposure to cow's milk (CM) or CM-derived formulas in the first 3 or 4 days of life should be highlighted, a time when the feeding of newborns with CM formulas increases their risk of sensitization. Jarrett's studies reviewed in Chap. 4 confirm that low doses can sensitize the predisposed individual; 49%–100% of babies sensitized to CM [8, 21, 53, 104, 112] were fed supplements of CM or of hydrolysate formulas (HFs) during the first 3 or 4 days of life in maternity wards. Among these babies, allergy to CM (CMA) was more frequent [37], up to 100% of babies, none of whom had symptoms at the first exposure to CM [53]. Our studies demonstrate that immediate reactions (anaphylactic shock, urticaria, etc.) at the subsequent feeding of CM, acting as a booster dose, should draw attention to a delayed effect of the so-called hidden bottle [21], since *in utero sensitization is very uncommon*. CM supplements (40–860 ml) were given to 39 neonates in amounts corresponding to 0.4–7.4 g of β-lactoglobulin (βLG) during the first 3 days of life spent in maternity wards [53]. The amount of βLG in 40 ml of CM formula is equal to the amount provided by ≈19 years of nursing one liter of breast milk daily [53], and according to subsequent measurements [108] 32 years. In a prospective study of 6,209 infants, who received supplementary feeding at the hospital, exposure to CM while in hospital (OR, 3.5; p=0 03) increased the risk of CMA. Of 247 infants who recovered while on an elimination diet, 118 (48%) reacted adversely to the CM challenge test performed at the hospital at a mean (± SD) age of 6.7±2.3 months [104]. However, others disagree. According to a retrospective analysis of record-charts completed by questionnaire data, feeding breast milk supplemented with CM or CM alone in the first 8 days of life seemed to reduce the emergence of atopic symptoms during the first 18 months [35]. In a group of 129 infants randomly assigned at birth to one of three feeding regimens: breast milk, CM, or a casein hydrolysate formula (CHF), during the first 3 days of life, IgE antibodies were equally distributed between the three groups. However, 2 out of 38 CHF-fed infants developed CMA [58]. Early, brief exposure to CM in breast-milk-fed children was not associated with atopic disease or allergic symptoms up to age 5. However, specific IgE (sIgE) to CM (2+ or more) was 5.8% (CM) vs 4.1% (placebo) at age 1 (RR (relative risk), 1.43), and 5.3% vs 3.0% at age 5 (RR, 1.77) [29]. After 7–14 years, some data may have gone unnoticed or neglected, such as the duration of breast-feeding, the timing of weaning, the diagnostic challenge tests and the dropout rates. It is possible that in the final follow-up, cases of CM-induced shock may be disregarded, as well as children who might achieve tolerance by 7 years of age and in an earlier examination would have modified the results. In a cohort of infants randomly assigned to receive at birth either a CM or a HF for 1–4 days, and then all breast milk, supplemented when necessary with HF until day 90 [106], the median titers of total serum IgE were statistically significant at day 5 in comparison with the volume and frequency of supplements received soon after birth and before breast feeding [106], maintaining the statistical significance up to 12 months of life, especially in at-risk babies [114]. In at-risk children, followed up prospectively from birth to 18 months of age and reexamined at age 4–6 years, according to the planned nursing schedule the cumulative prevalence of atopic disease was 18% in the group fed CM in the first days of life or 33% in the exclusively breast-fed group, while in subjects with biparental atopy the incidence was 11% and 61%, respectively [74]. The involved neonates were small for dates, with a gestational age (GA) of 27–42 weeks and 2 SD below the normal median weight, thereby similar to preterm babies who respond in a different manner to sensitization and the onset of atopic manifestations. In the follow-up, the prevalence of atopic disease was almost alike in both groups; however, only in CM-fed infants, there were *3 cases of skin prick tests (SPTs) positive for CM coinciding with RAST* (p=0.0223) [76]. In 118 children with CMA followed until age 8.6 years, IgE-mediated CMA was detected in 86 (73%) children. Among the risk ractors for persistent CMA at age 2.0 years were *CM exposure at the maternity hospital* (OR, 3.2; 95% CI, 1.4–7.8) and early sensitization to egg (OR, 2.8; 95% CI, 1.2–6.6) [105].

It is not surprising that the early administration of dietary antigens to newborn rat pups delays the process of gut closure [3], measured through the intestinal absorption of horseradish peroxidase (HRP), an enzyme employed in immunohistochemistry to disclose CM proteins, although the results of experimental studies cannot be extrapolated directly to human beings. The demonstration that feeding healthy newborns with a CM-protein HF during the first 3 days of life resulted in a delayed gut closure up to the 6th month, based on the observation that serum α-lactalbumin (ALA) absorption at 2 months of age was significantly higher in the HF-fed infants than in the breast- or CM-fed babies [56], suggests that administration of special formulas in neonatal age should be avoided.

Prenatal Sensitization

The likelihood of an *in utero* sensitization has been suggested by several reports of fetal IgE synthesis in infant cord blood (CB) (Table 3.2) [18, 27, 28, 32, 40, 47, 48, 58, 65, 69, 84, 127], including sIgE to penicillin [67] and microfilaria [125]. Such prenatal sensitization is a somewhat infrequent event occurring in 0.5% of newborn

infants, although with a frequency of 0.99%–2.2% for egg, CM and pollens in some babies (Table 3.2). The IgE production begins in the fetal liver and lungs by 11 weeks of intrauterine life [88], in human amniotic fluid by 13 [108] and in the spleen by 21 weeks [88] (Table 2.4). However, IgE-producing cells are rare until 9 months after birth [73]. Numerous IgE^+ cells were detected in the human placenta but had no evidence for local IgE production [115]. Antibodies against maternally ingested foods have been found in the amniotic fluid [82]. The fetus cannot therefore respond with IgE antibodies against food antigens ingested by the mother [82]. Such antigens have crossed the placental barrier, whose permeability is selective: only IgG can be transferred, because arterial CB consistently fails to contain maternal IgE, IgA and IgM [84]. As early as 1902, a placental transfer of egg-white was documented in 29% of rabbits [4]. Regarding the IgE determination in CB for predictive purposes, we should take into account the rather uncommon detection of specific antibodies against known allergens: actually such research in the CB of children who had developed atopy yielded negative results [31, 129]. More probably, high CB IgE levels in at-risk newborns would document the spontaneous synthesis of polyclonal IgE, secondary to the missed suppression of the synthesis of those antibodies [14]. However, recent studies have found memory cells in CB [78, 81] and allergens such as Der p, Lol p, ovalbumin (OVA), egg [52, 86], rye [52], and βLG [86], especially in at-risk neonates [86], thus documenting an evident *in utero* exposure to a critical amount of antigens. That priming of T cells can commence *in utero* is shown by low levels of allergen-induced proliferation in CB [86]. *Allergen exposure in the prenatal period can influence the fetal immune response,* since higher total IgE levels in HR children 3–5 days after birth are related to a larger prenatal exposure to Der p allergens [107]. In the first week of life a high total IgE was also found in 12.2% of boys and 6.2% of girls [59]. For immunological priming to occur, it is insufficient for an allergen to be merely present in the circulation: it must access tissue sites where it can be taken up by dendritic cells for processing and presentation to naive T cells. This does not occur in the circulation but in the secondary lymphoid organs (lymph nodes and spleen) where naive T cells normally reside [116, 117].

Reactions of immediate hypersensitivity have been documented at 5 [126] and 72 h of life [33], SPTs for foods were positive at the 3rd day of life in 1% of neonates [6], a very infrequent event, but possible. Studies done with anti-IgE antibodies have demonstrated that within the first 3 days of life, the skin contained IgE bound to mast cells in 14.7% of neonates and within 39 days in all infants [111]. Moreover, neonates aged 5 h to a few days can fix IgE to dermal mast cells [28]. Consequently, the functional placental barrier withstands the transfer of maternal IgE, thus protecting the fetus first and the neonate later against potential adverse effects of maternal antibodies, since CBIgE antibodies originate in a large portion of newborns, but this is not correlated with the IgE of maternal circulation. As IgE is unlikely to pass the placenta, the presence of elevated CBIgE must be the result of fetal immune response. Therefore an exclusively fetal origin is suggested if a neonate of a grass-sensitive mother has reacted to CM and wheat [126]. Given that IFN-ɣ and IL_4 levels are reduced in the first months of life [60, 102], this reaction cannot be ascribed to a functional immaturity of B lymphocytes, because CB B cells are ready for isotype switching in response to IL_4 stimulation [98] and at least to T-cell stimulation. The nonspecific production of IFN-ɣ by fetal PBMCs (peripheral blood mononuclear cells) from the second trimester of pregnancy onward

could be viewed as an attempt to contrast placental IL_4 and IL_{10} production, and thereby the Th2 phenotype: failure of this machinery may favor the progression of the allergy march [123].

The factors favoring sensitizations in the first years of life are shown in Table 3.3 [20]. The predisposing factors important for the development of an atopic state, which will be discussed in Chap. 4, should stimulate the institution of effective interventions for allergen avoidance even before birth (Chap. 24).

Methods of Predicting the Development of Allergic Disease

The determination of serum IgE levels has been evaluated for several years to establish the diagnosis in the presence of symptoms of allergic disease, as well as to institute pivotal preventative measures. The value considered as normal is between 0.12 and 0.35 kU/l according to the geometric means of several studies, while levels between 0.35 and 1.28 kU/l are regarded as elevated [1]. Many studies have investigated the possible value of such examinations in CB to predict allergic risk early in the neonatal age (Table 3.4) [17, 25, 27, 29–31, 43, 44, 46, 48, 50, 64, 66, 72, 78, 103, 113, 120–122, 129, 130]. Croner et al [27] were the first to demonstrate that high CB IgE concentrations (CBIgE) could be predictive of subsequent atopic disease, observing that 52%–82% of neonates with high levels (and only 5%–30% of neonates with normal concentrations) developed atopic manifestations within the first 18 months of life. So far, we cannot affirm that CBIgE levels, even if specific, are an important predictive marker. Croner et al followed up 1,701–1,651 unselected children from birth to 11 years of age [25, 64], and 82% of subjects with CBIgE levels of 0.9 UI/ml developed an atopic disease, obvious in 68% and probable in 15% of cases. CBIgE sensitivity was 26%, specificity 94%, and effectiveness as a screening method 72%. Corresponding parameters of positive family history of atopy (FHA) were 45%, 74% and 64%, respectively (see Fig. 3.1) [25]. Significant differences among term and preterm neonates have not been noted, whereas newborn infants of atopic parents had significantly higher CBIgE levels. The risk of developing symptoms of allergic disease between 0 and 11 years of age was two- to sixfold higher (for asthma fivefold) in newborn infants with CBIgE levels of 0.9 UI/ml than in neonates with low CBIgE values [24]. In the follow-ups at 12–14 years, even taking into account the FHA positivity, asthma severity failed to have predictive effects [26]. Subsequently, the authors concluded that IgE titers at age 11 years correlated poorly with neonatal IgE concentrations [24]. In 1,123 children, increased CBIgE et the age of 2 was inversely associated with the manifestation and severity of early AD, whereas increased total IgE and sIgE levels showed a strong positive association with early AD, especially with the more severe form [54].

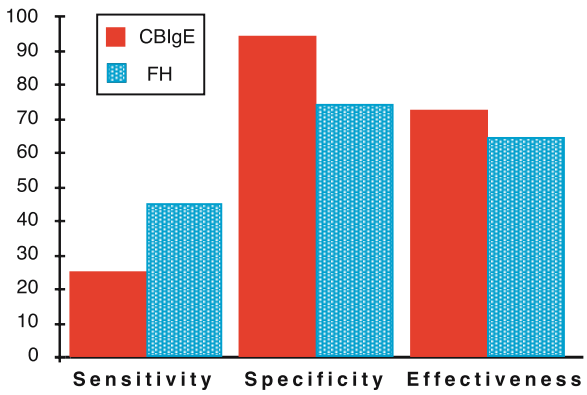

Fig. 3.1. Sensitivity, specificity and efficacy of the two screening methods. *CBIgE* cord blood IgE, *FH* family history. (Modified from [25])

Several studies have found that the CBIgE positive predictive value (PPV) varies between 21% and 42%–46% [50, 72, 120, 128], and others have found that sensitivity is 7%–22% [44, 47, 48, 50, 72, 103, 113, 120]. More precisely, mean sensitivity is 31% and PVV is 42.9%, while most recent works show that the values decrease to 23% and 32.6%, respectively. The mean values of specificity (85%), effectiveness (73%), and negative predictive value (NPV; 80.5%) are more often found to be higher (Table 3.4). A further controversy is that CBIgE is a predictor of neither atopic manifestations up to the age of 2 years [8] nor of atopic disease developed in 76% of infants with elevated CBIgE levels [7]. However, predictivity at age 6 years was significantly associated with aeroallergen sensitization [94].

As regards the *threshold level* (cut-off) to be applied, there is not yet an agreement among all investigators, but it is usually fixed between 0.5 and 0.9 kU/l (Table 3.4); employing a very sensitive PRIST (Paper radioimmunosorbent test), a cut-off value as low as 0.3 kU/l was most reliable [45]. Several investigators have considered cut-off values up to 1.3 kU/l, indicating that the higher the cut-off value, the greater the changes in the sensitivity, specificity and, in some cases, PPV values (Table 3.4).

Alternative Tests to CBIgE Determination

Given such controversial results, FHA positivity should be taken into account, which out of all the available tests has been proven as a much more sensitive marker than CBIgE levels for allergy screening purposes [50]. Furthermore, the positivity of double or single FH associated with CBIgE is sevenfold higher than $CBIgE^+$ alone, whereas FH together with $CBIgE^+$ levels reaches a value of 3.8% (Fig. 3.2) [7]. From Table 3.4 it is clear that the values, calculated by one-fourth of the authors, are of 44% sensitivity and 67% specificity; other authors have suggested that high CBIgE levels associated with FHA positivity, for the time being, are the best predictive methods available [77, 128].

[b] Certain + probable atopy.

[c] Study by Zeiger et al [129].

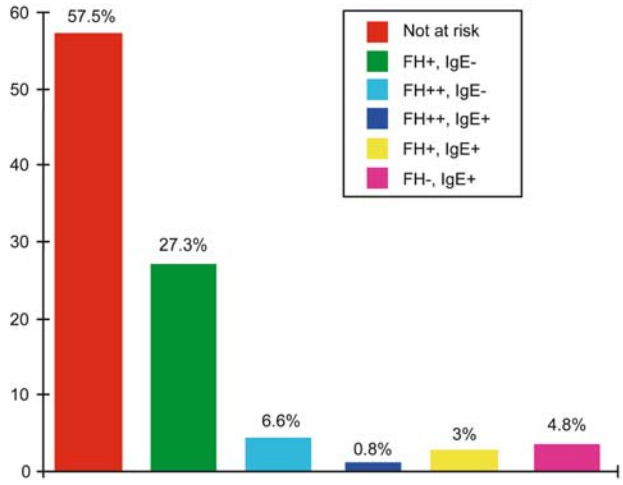

Fig. 3.2. Atopic risk of neonates. Percentage of positivity of FH and elevated IgE concentrations in CB. In this sample 22% of the mothers, 21% of the fathers and 10% of the siblings were atopic; 7.5% of the newborns had at least two atopic relatives. In total, 9% of the CBIgE levels were greater than 0.9 kU/l; therefore 57.5% of the newborn babies were not at risk of atopy. FH+, only one parent atopic, FH++, both parents. (Modified from [7])

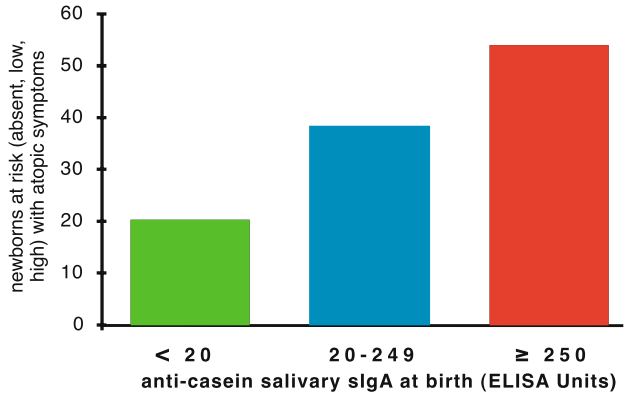

Fig. 3.3. Correlation between cumulative incidence of atopic disease during the 1st year of life and levels of salivary anti-casein sIgA at birth in newborns at risk (absent, low, high) with atopic symptoms ($p<0.05$). (Modified from [100])

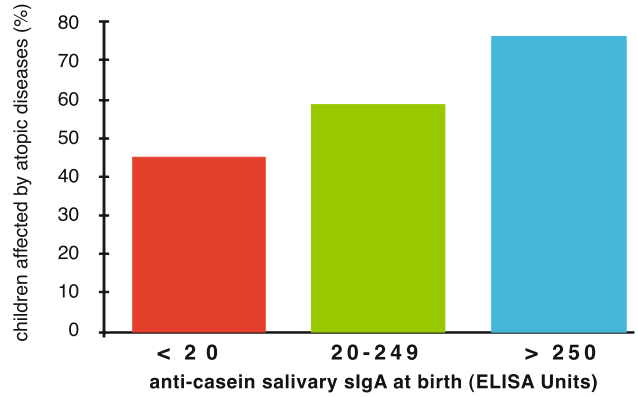

Fig. 3.4. Correlation between prevalence of atopic disease and anti-casein sIgA in high-risk (HR) children at the age of 3 years (p=NS). (Modified from [100])

Hansen et al [45] conclude that CBIgE levels cannot be used as a predictive factor regarding the risk of a baby developing atopic manifestations, assigning a PPV of 44%–48% and a sensitivity of 55%–58% to positive FH vs 15%–17% CBIgE [44]. They suggest evaluating CBIgE as a reliable predictor of atopic disease after the age of 18 months. High CBIgE concentrations are combined with total IgE, also high from 18 months to 5 years of age; however, high levels were also found in 14%–18% to 16%–17% of children aged 18 months with CBIgE under 0.5 kU/l, with and without atopic predisposition, respectively. At age 5 years the levels were 11.6% and 14.6% (with a cut-off value at 0.3 kU/l). Reconsidering their data, Hansen et al [42] highlight that if CBIgE values (with the same cut-off) are examined in parallel with the onset of atopic disease associated with elevated total IgE levels, in contrast with the low PPV of CBIgE alone, specificity is 87%–89%, sensitivity 46%–67%, but PPV remains as low as 22%–24%.

After a wide review of the contention, Croner [23] has concluded that an accurate FHA is adequate, and that routine use of laboratory methods may not be justified, also for financial reasons.

It is now firmly established that CB can be contaminated by maternal blood mixed with fetal blood [27, 39, 71, 103], in up to 4% [39], 7% [103], 14% [71] of cases, or in an insignificant volume, also due to intrapartum surgical procedures [30]. The measurement of IgA levels has less practical value, being of maternal and fetal origin [70, 71].

Many other predictors were proposed as an alternative to CBIgE (Table 3.5) [12, 63, 91]:

- Total IgE levels during the 1st week of life, avoiding possible IgA or sIgE presence [41, 70]. The use of such tests for general screening programs can also be challenging because of the difficulty of drawing enough CB: blood is collected on filter paper on the 4th or 5th day of life using the DELFIA method [34].
- Salivary anti-casein IgA levels, correlated with positive elevated FHA, CBIgE levels [101], and with the development of atopic disease during the first 3 years of life, as outlined by Figs. 3.3 and 3.4 [100], which show the relationship between anti-casein sIgA and the onset of atopic disease at 1 and, respectively, at 3 years. However, although the test has a sensitivity of 34% [100], much higher than the 7%–22% of CBIgE, it cannot be recommended as predictive, and not even associated with CBIgE levels, also due to the striking correlation between elevated sIgA and CBIgE concentrations [100].

Table 3.5. Predictor markers of atopy development assessed in neonates at risk of atopy

	Specificity	Sensitivity
Parents		
1. Family history (2 parents >1 parent >none)	Low	Low

4. Nasal eosinophils	Unconfirmed	
5. Nasal basophils	Unconfirmed	
6. Suppressor CD8	Unconfirmed	
7. CD4/CD8, etc.	Unconfirmed	
8. Skin prick tests	High	Low

Data from [12, 63, 91].

The sIgA increase could suggest a basal lymphocyte hyperresponsiveness in atopic children, or depend on an antigenic stimulation, for example of casein fragments in maternal circulation that modify the baby's immune response.

- CB-soluble FcεRII (CD23) levels in infants who have developed atopic symptoms 5–13 months after birth were significantly higher than those in infants who were free of atopic symptoms [60]; others have found no dif-

ference in CB levels of sCD23 between controls and children with subsequent atopy and AD [97].

- CB eosinophilia has been recently re-examined [19]. However, a high CB total eosinophil count does not seem to be an inherited factor predictive of future development of atopy, nor was there a correlation with maternal counts [50].
- Nasal eosinophils and metachromatic cells at 3 months of life [15]; the peripheral eosinophilia may have a role in prediction, and is also significantly correlated with both CBIgE and total IgE levels [15], because they are associated with the development of atopic disease at 6 years [16]. However, such data have not proven ideal for screening purposes, since they may come too late for instituting primary preventive measures, particularly effective only if started at birth.
- Proliferative response of CB lymphocytes to maternal food antigens (OVA and bovine seralbumin [BSA]) [66], a test that in 37 neonates followed up for 2 years has shown to have very high specificity (93.3%) and sensitivity (85.7%) in predicting not only the onset of allergic diseases in general, but also the particular type of food allergy (FA) within the first 2 years of life. However, significant differences between responses of maternal and HR neonates' CB lymphocytes should not be a significant problem for the contamination of maternal blood. CB PBMC proliferative responses showed highly significant differences vs anti-CD3 in 34 HR infants with atopic dermatitis (AD), whether associated with FA or not, followed up for 1 year. Instead, IFN-γ production was found to be significantly lower than the above parameters. AD children had the highest responses to anti-CD3 and the lowest responses to IFN-γ, while in those with AD associated with FA, the responses after stimulation with βLG and OVA were similar [124].
- CB lymphocyte subsets [72], several deficits of which are reported in Tables 2.5 and 2.6, data not confirmed in HR neonates who had elevated CB total numbers of CD2, CD3 and a CD4/CD8 ratio significantly different among the babies classified as atopic or not at 18 months; however, with wide overlapping values and the ratio normalization at 2 and 6 months of age. Sensitivity, specificity and PPV values were too low for a possible screening [72], a conclusion not confirmed by others [87].
- Platelets with low CB levels [81]; however, subsequent reports have failed to find such levels useful as a test complementary to CBIgE and FHA [91].
- IFN-γ production by CB PBMCs of HR neonates, significantly reduced compared to healthy neonates [68, 102], independently of IgE concentrations [102]. Concordant figures in 21 HR infants at 12 months of age come from the analysis of the correlation between SPT positivity for foods and mRNA expression for IL_4 by CB lymphocytes prestimulated with βLG and OVA: there was a correspondence between mRNA expression for IL_4 and SPT positivity for OVA, but the correlation between IFN-γ expression and SPT positivity for βLG was negative [85]. In two trials, IFN-γ levels were not seen to be useful for the prediction of atopic disease [36, 92].
- Anti-IgE IgG antibodies, associated with a reduced allergy prevalence in infants at risk, a test with a rather poor sensitivity, even if higher levels appear to have a protective effect since they are synonymous with a lesser development of atopic disease at age 18 months: only 9% of infants with high anti-IgE IgG vs 29% with low levels [121].
- Phosphodiesterase (PDE) activity, whose CB increase is controversial since it lacks a significant predictive value. Nor does it seem to be relevant as a screening method without a correlation with CBIgE [90]; the PBMC PDE increase is sometimes not suitable [90], and therefore elevated PDE levels do not represent a primary deficit in atopic subjects [15].

The several tests done in CB, even at an early age (IgE and IgG, SPTs and lymphocyte subsets) have not yielded reliable results [72]. No predictive value has been related to the atopic symptoms recorded at varying ages in 500 babies prospectively followed up over 7 years [83] and in 180 infants evaluated at the age of 18–23 months [30]. Such tests had a 25%–79% sensitivity, a 40%–74% specificity, and 58% efficacy [91].

In the studies reporting CB antigen-specific T-cell responses, it is noteworthy that the study group was modest and the results appear to be near the detection limits employed by the conventional lymphoproliferative assays, but possible alternatives have been studied [66, 121]. In addition, the poor variability of the values of stimulation indices, oscillating within a range varying

Table 3.6. Factors or techniques which can influence the neonatal PRIST determination

1. The neonatal PRIST is influenced by blood sampling technique, depending on whether the blood from the umbilical vein or when the neonate is 4–5 days of age is aspirated or gravity-collected: contamination of maternal IgA should be investigated if the latter technique is employed.
2. IgA levels are significantly lower at days 4–5 of life (hence IgE and IgA samples should be collected at birth at the same time).
3. IgE levels show very good equivalence in cord blood and samples collected at 4–5 days and correlated with maternal levels, but only with that measured at delivery.
4. Consequently, besides an active pre- and postnatal synthesis of IgE antibodies, there is a tangible prenatal maternal influence.

Data from [71].

Table 3.7. Factors reported to be associated or not associated with CBIgE

Factors associated with increased CBIgE levels
Atopy in 1st degree relatives and/or high levels of serum IgE [18, 27, 53, 79]
Gestational age of <38 weeks [30]
Intrauterine exposure to alcohol and/or caffeine [12]
Intrauterine exposure to progesterone and metoprolol [13, 84]
Male sex [10, 12, 27, 38, 43, 61]
Maternal atopy [12, 79, 84, 119]
Maternal smoking during pregnancy [5, 10, 80]
Month of birth [12, 43, 61]
Related to cord blood [70, 71] Contamination by maternal blood Cord blood sampling techniques
Season of birth [12, 38, 43, 61, 119] Higher IgE levels in spring and winter [43]
Factors not influencing CBIgE levels
Intrauterine exposure to albuterol administration [84]
Diet during pregnancy [31, 48, 94]
Male sex [94, 107]
Maternal smoking during pregnancy [12, 31, 53, 93, 95, 107]
Prenatal oral contraceptives [84]
Racial differences [1, 2]
Season of birth [53, 107]

Table 3.8. Genetic/immunological characteristics of neonates and infants at high risk of atopy

Positivity of family history (2 parents >1 parent >none)
High levels of phosphodiesterase in monocytes
High levels of circulating eosinophils
High levels of IgE antibodies in cord blood
High levels of nasal eosinophils/basophils
High levels of specific IgE
High levels of total IgE
Dysregulation of IL_{13} production
Increase of soluble FcεRII (CD23) in cord blood
IgA antibodies deficiency (transient)
C2 deficiency
CD4 deficiency
Opsonization defect
Genetic localization (chromosome *11q*)
Positivity of skin tests for foods or pollens at birth
Presence of specific IgE antibodies to foods in cord blood
Presence of specific HLA alleles
Decreased production of INF-γ
Numerical reduction of T cells and of lymphocyte subsets (CD8)
In vitro lymphocyte proliferative response to food antigens
Thrombocytopenia in cord blood

Data from [63, 92, 127].

between 0.39 and 3.29 [66], is perplexing. As recently stressed (Table 3.6) [71], above all when the IgE levels exceed the normal threshold values, one must keep in mind that CB IgA values between 14.1 [43, 71] and 32 µg/ml [10], with an incidence of 0.7% [94], are indicative of contamination. The mean value of 28.2 µg/ml does not protect from possible contamination [96].

- A useful marker of high-risk neonates may be the increased production of IL_{13} by neonatal CD4 T cells [92, 109], and Il_4, which was detectable in ten of the atopic children (28.6%) and in only two (5.7%) of the control subjects [97].
- Although significant differences were observed in CB-soluble CD14 (sCD14) levels, where children with atopic mothers had the highest levels, the same pattern could not be observed in the same children at 2 years of age [51]. Babies will encounter very high sCD14 levels in breast milk (Table 2.10); however, breast-fed infants with AD were associated with lower sCD14 levels in the breast milk of their mothers [57].

CBIgE levels can also be influenced (mostly as an increase) by several factors summarized in Table 3.7 [1, 2, 5, 10, 12, 13, 18, 27, 30, 31, 38, 43, 48, 61, 70, 71, 79, 80, 84, 93–95, 119]. However, in 2,631 children, male sex was significantly associated with an increase in total IgE and CBIgE (p=0.001). Maternal smoking during pregnancy (even >15 cigarettes) failed to reach significance [12], whereas the maternal intake of caffeine (200–800 mg/day) and alcohol (at least three doses of 12 mg/week) has been included among the harmful factors [12].

It seems logical to attribute such controversial data either to a higher maternal awareness in the last few years of allergy risks, with a consequent reduction in fetal antigenic exposure, or the meaningful criterion of eliminating all sera with elevated IgA levels. Significantly, pollen exposure in atopic mothers confers intauterine stimulation of fetal IgE production [119].

Table 3.8 [63, 92, 127] outlines the immunological and clinical characteristics of neonates and infants at HR of developing atopy. Moreover, the utility of T-cell determination is recommended by some authors [87] and not by

others [72]. In conclusion, we deem it reliable to stress that:

- The CBIgE levels within normal limits cannot definitely exclude the risk of developing an atopic disease, as demonstrated by false-negative results, averaging 21%–37% [127, 128], and 4%–11% of false-positive results, with high titers not always correlated with the development of allergic diseases [7, 120]. Accordingly, 73%–65% of newborn babies with one and, respectively, two atopic parents had CBIgE levels <0.35 kU/l, whereas 13% of neonates not at high risk had CBIgE at 0.35–0.7 kU/l and 10% >0.7 kU/l [10]. More studies [7, 39, 70, 122] confirmed these data.
- Only 0.8% of babies with biparental FHA have elevated CBIgE at birth, which was observed in 4.8% of babies with negative FHA (Fig. 3.2), and according to others 18.2% (only one atopic parent) and 8.3% with two atopic parents [122].
- Only 7 out of 103 (6.8%) neonates with double FHA have levels above the 90th percentile [70].
- Only 28% of neonates of atopic mothers show levels of 0.5 kU/l compared with 26% of control babies [39].
- A low correlation between the IgE levels at birth and later in childhood suggests that different effector mechanisms may be operating at different ages [55].
- We have done a meta-analysis on CBIgE levels determined by various authors in neonates [43], either at risk (8 studies, 468 neonates) or not at risk (10 studies, 9,955 neonates), which showed that the mean level was 0.33 in the first group of studies, range, 0.11–1.1;0.30 in the second group, range, 0.09–0.80. Only 8 of 18 studies also specified the median range: <0.1–0.25. Furthermore, the value of results is not given in all reports by the selection of an adequately representative cohort, compared with an unselected control group.
- When the investigation is not carried out in the general population, but only in a highly selected group, defined, for example, based on FHA positivity, then CBIgE determination, even if by chance valid in 100% of all parameters, serves exclusively to further subdivide and circumscribe a category of HR neonates.

CBIgE concentrations fail to appropriately meet the basic prerequisites and at present cannot be used as a balanced and realistic marker of the risk of developing atopic disease or as a screening instrument for primary prevention [9]. Until definitive strategies become available, we encourage taking a relevant FH for preventive purposes (see Fig. 3.2), an approach recommended by Kjellman [63]. Therefore, even disregarding the economic factors, such drawbacks *fail to justify CBIgE use* as the only validated test within a screening program finalized to select candidates for taking part in studies for allergy prevention [62]. Unfortunately none of all the alternative procedures proposed so far has shown a satisfying level of sensitivity and specificity, in addition to being easily applicable.

We deem that at present the most suitable predictive test is the family atopy score (FAS) (Table 3.9) [63], which may help identify at-risk babies, hoping that in future a potential rational method becomes available that allows the early identification of families where an effective preventive allergen avoidance should be set forth. For pediatricians, the consideration that the association of FHA with skin dryness has a sensitivity of 80% and a specificity of 85% ($p<0.01$) [91] will be decisive for early identification of neonates to be enrolled in prevention programs.

IFN-ɣ reduction, if it could be standardized, could be a predictive marker of the atopic march not secondary to atopic manifestations [102, 117, 124], with reference to the deficit of Th1 lymphocytes observed in CB of at-risk neonates.

Table 3.9. Family atopy score (*FAS*) according to family history

Relatives	Score	
	Obvious	Probable
Father	2	1
Mother	2	1
Siblings	2	1

Paternal and maternal points are added to the highest score in any sibling, a FAS 3 means that there is a statistically increased risk that allergy will develop in that child.
Modified from [63].

Pediatricians and Neonates at Risk

Pediatricians should focus on future trends in prevention because most atopic diseases appear in the very young and sensitization is known to occur early in life. Early intervention strategies to block the atopic march are dependent on identification of neonates at HR for later development of atopic disease. The promotion of allergen tolerance, with resultant atopy prevention, will likely be achieved in the immature neonate's immune system more readily than in the mature immune system. We believe that the future health of the population depends on innovative strategies for preventing the atopic and immunological diseases of infancy and childhood. CBIgE as a predictor of atopic diseases in infants has been discussed in a large number of papers with contradictory results. Even when elevated CBIgE levels are identified as a strong risk factor for sensitization, their poor predictive value may make them useless as a basis for preventive measures. If atopy is indeed a major risk, the ability to measure some markers associated with the atopic trait would be beneficial, especially because atopy has its roots in neonates and toddlers, and interventions aimed at primary prevention can be made a reality. A positive FAS increases the risk of subsequent atopic disease in infancy and childhood.

Genetic and Environmental Predisposing Factors

Genes and Atopy

The atopic state is an individual's augmented and persistent genetic predisposition to produce allergen-specific IgE antibodies after exposure to common allergens, with a significant correlation between IgE-producing B cells and relative total serum IgE levels in the systemic circulation, significantly more elevated than the levels of nonatopic children [201]. We best understand the pathogenesis of the atopic diathesis by analyzing the regulatory mechanisms of IgE synthesis, based on genetic and environmental factors that are not always well known [48]. Genetic control appears to be exercised not only on atopic disease as such and the type of sensitization, but mainly on a predisposition not specifically directed to elicit the onset of atopic disease. Fundamentally, a growing body of evidence emphasizes the role of environmental factors [409, 504] in determining the type of sensitization and form of atopic disease precipitated in genetically at-risk babies in relation to the allergens encountered and the conditions regulating this event [182]. These conditions are linked to genetic predisposition, and specific chromosomal regions appear to be important for linkage of atopic disease-related phenotypes. Heredity regulates the transmission from parent to offspring of the susceptibility to different phenotypes of atopic responsiveness. In this context, the development of atopic disease is dependent on environmental exposure to common aeroallergens, respiratory infections and even pollution. Accordingly, sensitization may occur in different ways: by inhalation, ingestion, contact or puncture. Figure 4.1 exemplifies the sequence of events leading to the development of atopic disease.

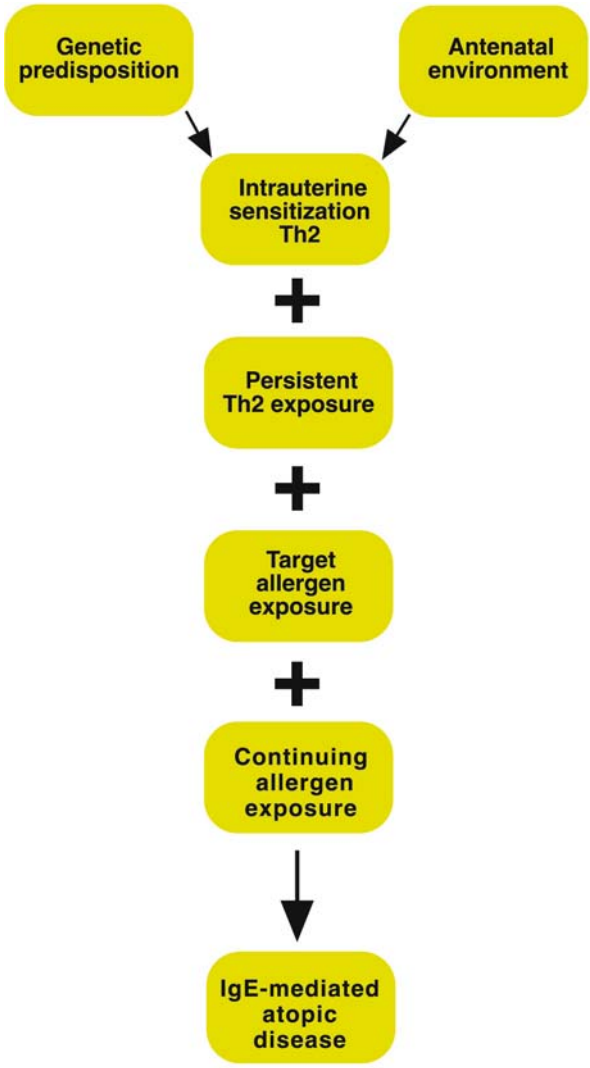

Fig. 4.1. Pathogenetic sequence leading to atopic sensitization

Genetics of Atopy

In 1916, Cooke and Van der Veer convincingly substantiated that atopy runs in families, that family history of atopy (FHA) is linked to genetic factors [76]: inheritance models are first monogenic with a mendelian autosomal dominant trait and then autosomal recessive traits have been proposed [173]. The challenging hypothesis that atopy is genetically determined has gained increasing credibility, based on the following points:

1. A genetic predisposition to atopic disease and an association of atopy with well-identified chromosomes.
2. A preferential maternal heredity of atopy.
3. A genetic HLA-mediated control of the capacity of synthesizing high total IgE and specific IgE levels.

4. Atopy is correlated to a T lymphocyte and pertinent interleukin (IL) dysregulation and to a hereditary maturative defect of immunocompetent cells.
5. Atopy could be conditioned not so much by IgE hyperproduction as by IgA delayed maturation.
6. Atopy could be programmed in the intrauterine life.

1. The existence of a genetic predisposition for atopic disease was first supported by the transfer of atopy to a nonatopic recipient by an asthmatic bone marrow donor [4, 439], conversely clearing of asthma in asthmatic recipients of normal lungs [86]. Transfer of IgE-mediated hypersensitivity can occur after liver transplantation and have serious consequences, such as an anaphylactic reaction to cashew nut that developed in a man with no history of nut allergy 25 days after receiving a liver allograft from a 15-year-old atopic boy who died of anaphylaxis after eating peanut [330].

In Chap. 3 we recorded CB (cord blood) lymphocyte proliferative responses to food allergens [213], thus suggesting an *in utero* sensitization. Moreover, CB $CD4^+$T cells proliferate in response to Der p (*Dermatophagoides pteronyssinus*) with a different IL pattern according to whether there is neonatal atopy: allergen-specific CD4 of neonates from nonatopic parents are Th1, whereas children with an atopic background show a prevalence of Th0 or Th2 clones [98]. As is emphasized by the IFN-ɣ deficit in the neonatal period, Th2 lymphocytes are able, in prospective, to recognize allergens and generate IL_4/IL_{13}, IL_5, IL_6, IL_9, and IL_{10} in virtually all newborn infants [344].

If an increased and persistent production of antibodies to common allergens, already evident at birth, is the main characteristic of atopic subjects, which genetic mechanisms regulate both IgE production and genesis of atopic disease? Immunologists have asserted the IgE hyperproduction as a central feature of atopy and consequently have looked for a possible deficit of immune homeostasis, dependent on T cells: this approach has led to an increasing amount of evidence helping understand the regulation of IgE synthesis [354]. Several investigations have demonstrated that high IgE levels are usually inherited with a recessive mechanism, but – as we observed in Chap. 1 – are not consistently associated with atopy. Studies on the animal model have confirmed the recessive mode of inheritance of high IgE levels via non-H2 genes [182]. According to an attractive hypothesis, the dominant allele of the IgE regulatory *locus* limits the number of clones stimulated in response to allergens with consequent production of low IgE levels: this *locus* is not included in HLA. In mice, the capacity of responding to a given allergen is modulated by immune response (Ir) genes, localized in humans mostly in HLA. In humans, it seems that any HLA-D genetic sequence can be found in subjects responding to particular allergens: certain alleles appear to be more frequent in atopic subjects. The greater frequency of some alleles in a population compared to others could be the expression

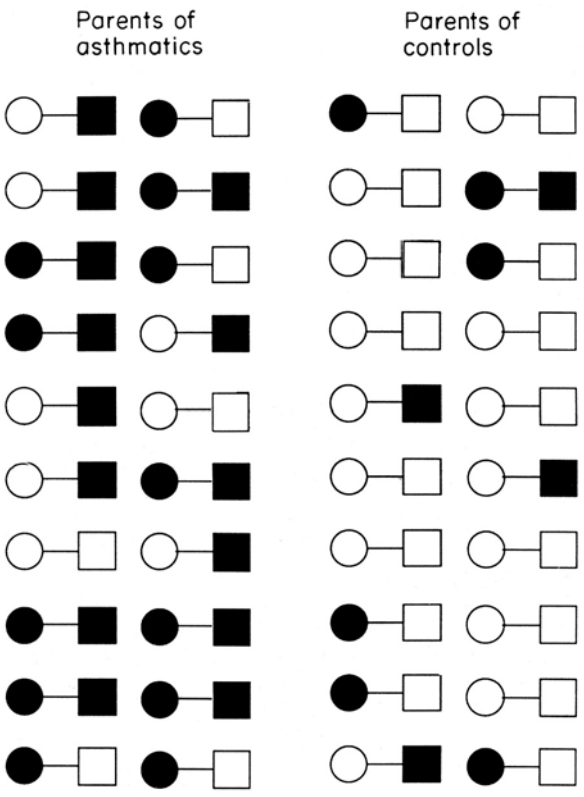

Fig. 4.2. Frequency of atopic IgE responsiveness (*shaded symbols*) in the parents of atopic asthmatics (*left*) and control individuals (*right*)

of a general genetic intervention owing to immune hyperreactivity or, alternatively, could originate from a particular Ir gene selection, while the atopy gene, being proximal to Ir, would be passively dragged along [182].

Family studies may involve twins, helpful in differentiating genetic and environmental factors. Studies on the genetic basis of atopy have found a decisive genetic effect on IgE levels in twins: the IgE variation is significantly lower in pollen-sensitive monozygotic (MZ) than in dizygotic (DZ) twins (0.15 vs 0.51) [37]. The concordance of atopic dermatitis (AD) and asthma was higher in genetically identical MZ twins [114]. MZ twins have a greater concordance ratio for atopy [37, 173], while in DZ twins BHR (bronchial hyperreactivity) and total and specific IgE prevail [37]. A recent twin family study supported a strong genetic component for asthma [227], while in MZ twins, correlation coefficients were significantly higher for IgE levels, since about 50% of variations could be attributed to genetic factors, with a great concordance (71%) for IgE responses to allergens [153]. In a population of unselected twins, a high IgE genetic dependency was shown on the order of 75%–85% [186]. These and other studies in twins [33] show that IgE inheritability (the part of variability attributed to genetic factors) is between 50% and 84%, and that the overrid-

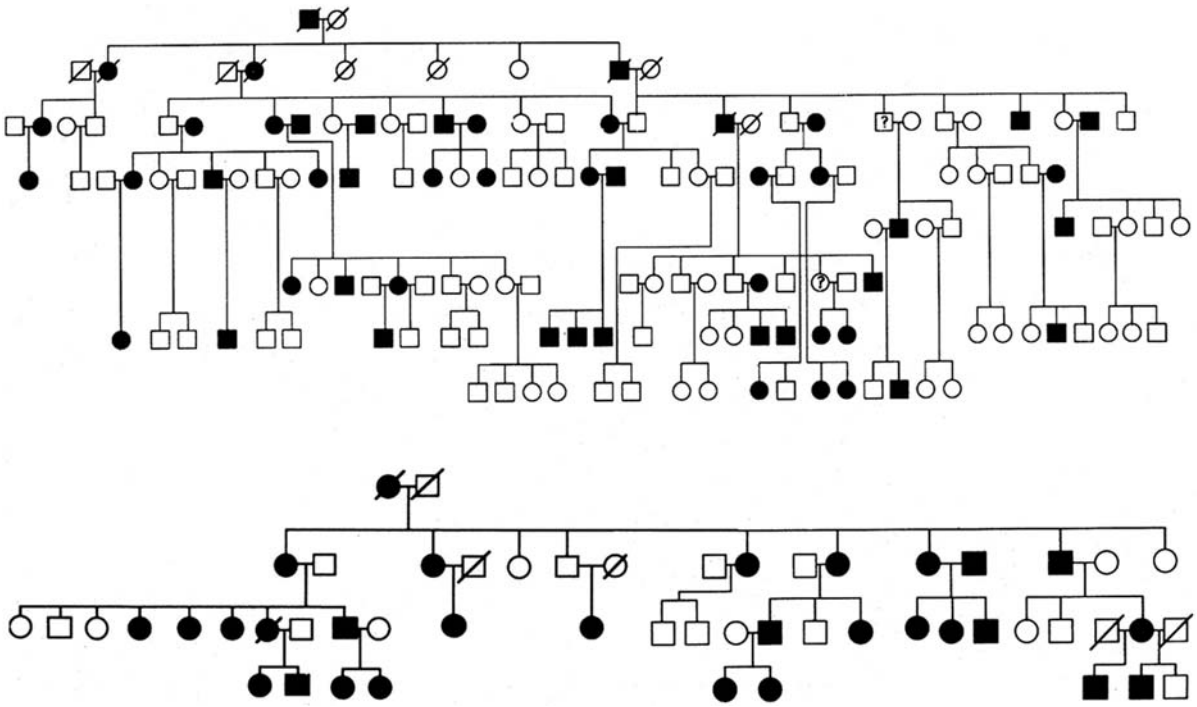

Fig. 4.3. Frequency of atopic IgE responsiveness in two extended families: (*shaded symbols*) atopic, (*open symbols*) normal, (*?*) uncertain phenotype, (*Ø*) dead

ing influence on IgE levels is genetic rather than environmental [153]. A common experience is that the higher the IgE levels the higher the risk of atopy [77]. However, no univocal decision was made on the model of heredity based on IgE levels. In 1916, a positive FHA (FHA^+) was found in 48% of the probands compared with only 14% of the control group, so almost 75% of children with a bilateral FHA were at risk of developing atopic disease vs 50% with a monolateral FHA. The authors concluded that atopy was inherited as a mendelian autosomal dominant trait [76]. By contrast, others conclude that the high IgE state is based on autosomal recessive inheritance [138, 265]. Subsequently, a study on 20 patients and their parents selected according to an FHA positive for IgE-mediated asthma and allergic rhinitis (AR) has demonstrated that atopy is vertically transmitted, since 90% of the 20 atopic subjects had at least one atopic parent compared with 25% of controls (p=0.005), so concluding for a mendelian model of inheritance [77] (Figs. 4.2, 4.3). In these probands and their families, the distribution of specific allergic responses among the members of the same familial nucleus was heterogeneous, thus suggesting the influence of other factors [77]. Several studies have established that atopic disease is multifactorial (Table 4.1) [34, 72, 77, 78, 138, 155, 265, 266, 269, 277, 278, 495, 496]. The terms "polygenic" and "multifactorial" mean that several genes along with a battery of environmental factors influence the clinical expression of atopy; "genetic heterogeneity" means that different genes or combinations of genes determine a disease phenotype, apparently the same or similar to a clinical perspective [262]. A multifactorial pathogenesis is well suited for atopy transmission [114, 205] and is confirmed by the following data: AD and atopy inheritance is not 50%, as required by an autosomal dominant transmission, and atopy incidence is much greater than that of typical monogenic disorders, in which external factors do not play as significant a role as in atopic disease [206].

The interactions between IgE, allergens, HLA-D genes and TcR represent the development of what is called *forward genetics* [173], focussing on the analysis and functional mapping of prospective candidate genes. A further approach of molecular biology is *reverse genetics,* usually termed positional cloning, primarily employing PCR (polymerase chain reaction) to amplify microsatellite regions of genomic DNA or family members [262], which tries to identify the nucleotide markers within the genome for a more effective localization of the genes correlated with the atopy phenotype [32, 182]. In genetic studies the term "linkage" is used, that is, a condition where two genes are both localized on a single chromosome and are usually inherited together, and the lod (logarithm of the odds) score. A lod score of ≥3.0 expresses a significant evidence of association, =1,000:1 [318], but it may be false positive in 1:1,000 cases [263].

Genome-Wide Screens

As yet, several genome-wide screens have successfully identified several chromosomal locations that are likely to contain asthma and atopy genes [18, 73, 92, 105, 144, 215, 228, 234, 272, 306, 307, 489, 494, 497, 498, 501]. In addition, several candidate genes for association with atopy in family studies are outlined in Table 4.2 [17, 18, 21, 26, 73, 74, 77–80, 82, 83, 92, 105, 123, 124, 126, 144, 154, 171, 176, 208, 215, 222, 228, 234, 261, 266, 272, 279, 287, 288, 305–307, 342, 360, 376, 380, 397, 398, 435, 447, 450–452, 457, 463, 487, 489, 496, 498, 501, 502, 503, 506, 511] and in case–control studies (Table 4.3) [26, 78, 109, 165, 166, 178, 201, 361]. Recently, 80 additional genes related to asthma development have been reported [257].

The genome-wide studies have mapped specific chromosomes with high lod scores for asthma or BHR [73, 92, 105, 228, 307, 487, 497], AD [222, 234], seasonal allergic rhinitis (SAR) (lod =1.52–2.01] [502], perennial allergic rhinitis (PAR) [144] (lod =1.04–2.83), IgE [92, 105, 228, 234, 489, 502], specific IgE [234, 489, 497], asthma-related phenotypes, including forced expiratory volume in 1 s (FEV1), forced vital capacity (FVC) [498], SPTs [92, 105, 215, 307], and eosinophils [92, 105, 489].

The CSGA genome-wide screen [73] was done in 266 families and used 323 polymorphic DNA markers that were distributed across the genome. All of the affected family members met the same criteria for asthma as the probands. Evidence for linkage was observed in African-American families for *1lq21*, and a lod score =2.0 (p=0.002). Evidence for linkage to *lp32* was found in Hispanic families, with a lod=2.92 (p=0.0002). Seven other chromosomal regions had lod scores >1.0 (*2q*, *5q*, *1lp*, *12q*, *14q*, *17q*, and *21q*). In Caucasian families, evidence for linkage was found at *6p21*, with a lod score of 1.91 (p=0.003). Lod scores >1.0 were found at *8p23* (lod=1.06), *l9ql3* (lod=1.02), and *20pl3* (lod=1.07). Across the entire population, there were no regions with lod scores >2.0; the highest lod score was found at *14q32* (lod=1.23; p=0.017). Two other regions (*5q31* and *12q22*) had lod scores >1.0, whereas seven other regions (*lq*, *4q*, *8p*, *11q*, *12p*, *13q*, *17q*) had lod scores >0.5 [451].

Candidate Genes for Asthma and Atopy

On *chromosome 2q*, CD28 was found [161], also considered an accessory molecule in the regulation of IgE antibodies.

Among the present multitude of genes that may play a role in elevated IgE levels and atopic disease, the genes on *chromosome 5q31–33* encode for the production of several ILs (IL cluster) (Fig. 4.4) [266] and other candidates, including β_2-adrenoreceptor (ADR) [342]. On chromosome 5q31-q33 specific *loci* contribute to susceptibility to atopy and are linked to the development of asthma in childhood [501]. The corticosteroid (CS) receptor is located in close vicinity in the *5q31-q32* region *6*. In a study of 11 Amish extended families, a significant linkage was found to IgE (sIgE) antibodies, with more significant statistical differences than with the IL_4 gene; however, no significant linkage was found to specific IgE antibody concentrations [266]. The analysis of 170 subjects has shown that polymorphism within the IL_4 promoter region may enhance IgE production and Th2 expression [262]. The most significant linkage of IgE is with the D5S436 marker [279]. Moreover, the genes regulating both BHR and elevated IgE antibodies are coinherited by sibling pairs concordant with asthma and

BHR [257, 342], thus confirming that the region regulating IgE has a *locus* on chromosome *5* [266, 279]. A similar allele association of IgE antibodies is with IL_9 [109]. Clearly, the polymorphism on chromosome *5q* has possible functional consequences: for example, the gene polymorphism of the IL_4 promoter is found in 64% of asthmatic compared to 15% of control patients [41]. Moreover, multiple allelic forms of the IL_4 promoter do exist, associated with an increased transcriptional activity of T IL_4^+ cells [407]. This polymorphism is also

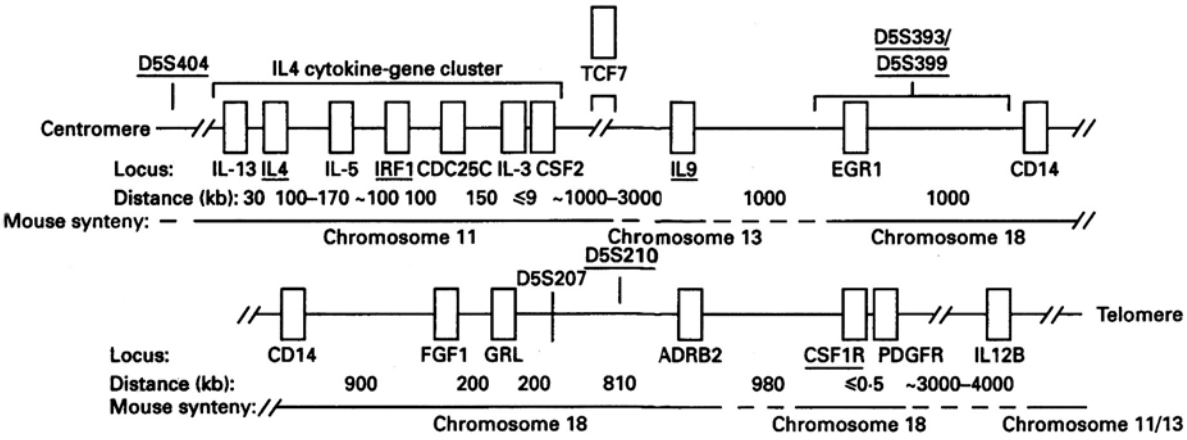

Fig. 4.4. Chart showing genes of known physical location and certain polymorphic markers in and around chromosome *5q31.1–q33*. Band *5q31.1* extends approximately from IL-13 to CD14. linked to the *Arg 16* allele mutations associated with nocturnal asthma and *Gln 27* allele with BHR. Functional studies indicate that a *Gly 16* substitution increases stimulus-related receptor desensitization, thus challenging patients with severe asthma or with a significant nocturnal component associated with an ADR depression [441]. Asthma may be induced by *ADR* gene polymorphism and more precisely by its *Gln 27* form, whereas asthma should be less probable when the *Glu 27* form is prevalent [149]. The candidate genes on chromosome *5* are numerous; thus a clear conclusion is perplexing [31]. A polymorphism in the 5′ flanking region of the gene for the leukocyte antigen CD14, which was mapped to chromosome *5q31–33*, encoding the high affinity receptor for endotoxin, was associated in allergen-sensitized children, with lower serum IgE levels and sensitization to fewer allergens [15]. Interestingly, on chromosome *5q23–35*, a region homologous to human chromosome *5q*, a mendelian trait encoded by T cell and airway phenotype regulator (Tapr) was identified. Tapr is genetically distinct from known IL genes and controls the development of BHR and T cell production of IL_4 and IL_{13} [275]. Positional cloning identified a gene family located at human chromosome *5q23–35* that encodes T cell membrane proteins (TIM, T-cell immunoglobulin and mucin-1). Major sequence variants of this gene family (TIM) were completely co-segregated with Tapr. The human homology of TIM-1 is the hepatitis A virus (HAV) receptor, which may explain the inverse relationship between HAV infection and the development of atopy [275].

The genes encoding the HLA complex are located on *chromosome 6p*, where a strong linkage exists to celiac disease (Chap. 9) and to inflammatory bowel disease (Chap. 18). Since the HLA class II *locus* on chromosome *6* is very polymorphous, especially in the exon corresponding to genes α and β hypervariable regions (HVRs) of each HLA subregion, it is a site of great relevance because it presents allergenic peptides via HLA to effector cells. These HLA genes are also important in allergen-specific IgE responses [123, 261, 503]. Moreover, total IgE shows evidence of linkage to chromosome *6p21* [215, 496]. Linkage has been found for eosinophil count in a genome screen of atopic families [92]. In Caucasian sib pairs, there was evidence for increased allele sharing for markers on *6p21.3.23* [73]. Another linkage is with TNF genes, which is important in mediating inflammatory responses, as is HLA in antigen presentation [78].

Evidence for linkage was found in a 20-cM region of *chromosome 7p14-p15* for three phenotypes: asthma, a high level of IgE and the combination of the phenotypes [228]. In region *q32* is the TcRβ chain (Fig. 1.14).

A gene on the long arm of *chromosome 11* in region *q13* appears to be a key player linked to a specific atopic phenotype (interpreted as a tendency to produce elevated IgE antibodies) and may be correlated to a predisposition to atopy [80]. Significantly, some primary immunodeficiencies, including deficits of IgA, opsonization, C2, IgG_2 and a wide series of functional defects of T lymphocytes, are connected with an increased risk of developing atopic disease (Chap. 22). In particular, the atopic status responsible for asthma and AR seems to be linked to chromosome *11* [80], although such data are questionable and less reproducible [80, 182]. The Oxford group has genotyped parents in several nuclear atopic families related to the transmission of chromosome *11q13* [506], continuing the studies on the mendelian autosomal dominant model and examining >300 sibling pairs [82, 166, 287, 380, 398, 399]. A parallel study on genetic inheritance [505] has demonstrated that in 21 atopic sibling pairs, the concentrations of Der p were

significantly higher in both mattresses and bed linen (but not on the bedroom floor) of a Der p-allergic than in the bed linen of his brother, sensitized to a different allergen [507]. In other 15 perfectly matched pairs (also for bed occupancy since birth) in whom a brother was nonatopic, there were no differences, not even in soil findings. Genetic segregation and related gene analyses, based on IgE antibodies as recruitment criteria to the atopic state, have clarified that heredity was of a dominant type and coded by the *locus 11q* [505]. It was similarly ascertained that sIgE responses to Der p were partly dependent on the allergen load, underlining the key role of the environment [504]. Although the Oxford group results found evidence linking at least one major gene of atopy to chromosome *11*, with a lod score between 10 and 3.38 [174, 287], there has been much dispute over the linking of atopy to this chromosome. Results in the Japanese population demonstrated that the *11q locus* governs IgE responsiveness (lod score =4.88) [397], especially if the atopy is severe [398]. Subsequent studies by Anglo-American and Dutch researchers [5, 72, 92, 167, 258, 251, 355] have found no association with chromosome *11q13*. The discrepancy may also be due to differences in populations, such as ethnicity and how the families studied were recruited, and/or to differences in definition of phenotypes, or different methods used [399], although no definite cause has been ascertained. Studying the patients with AD as probands, the association of atopy with the *11q13* gene disappeared, but the lod scores of these studies were too low (≤0) to direct criticism against the data referred to above [263]. Also localized on chromosome *11q13* is the subunit of the high-affinity IgE receptor FcεRI-β, which could be associated with elevated IgE of atopic patients [380]. Subsequent studies have confirmed the Oxford data [74, 154, 398, 452]. Two of these studies have found replicated linkage between atopy and chromosome *11* by sib-pair analysis [74] and using lod score methods in a set of extended families [398].

The gene encoding for FcεRI-β sequences on chromosome *11q13* is strongly linked to asthma and BHR, regardless of the atopic state: studying the whole population instead of a selected group strengthens the link between *11q13* and BHR [452]. The gene encoding for FcεRI-β, if maternally inherited, has been linked to a potential risk factor demonstrated by the high genetic association observed between polymorphism of *Leu181/Leu183* variants, atopy and BHR [166] (Table 4.3), shown in highly atopic Japanese [398] and English [399] patients. Other studies have not found the same linkage with FcεRI [46, 148, 211, 305]. Subsequent evidence has linked chromosome *11q13* and FcεRI-β to atopy [77, 81, 124, 126, 287, 380, 505], AR [398], BHR and IgE [452], AD [124, 398], and asthma [305]. The FcεRI-β *locus* showed significant allele sharing in affected sib pairs for BHR and for SPT positivity [257].In the region lying between *11q11* and *11q13*, Clara cell protein (CC16, previously CC10) was localized, a polymorphous gene released by nonciliated cells of the proximal airways and usually inhibiting airway inflammation, making this an area requiring further study on the role of Clara cells in asthma pathogenesis [158].

On *chromosome 12q*, the genes of asthma are significantly linked to IgE levels [17, 18, 489] and to AR [18, 144]. This chromosome contains the NO-synthase (NOS), a gene important in the inflammatory response [177]. On chromosomes *11q* and *12q*, either linkage or association of alleles from two markers separated by only a few centimorgans was observed with either log IgE or BHR [17, 109], a finding consistent with the clinical correlation observed between high IgE levels and BHR [176]. In a sibling-pair analysis conducted on 29 Afro-Caribbean families, *12q15–q24.1* with several candidate genes that influence IL regulation and IgE production was linked to asthma and IgE production [17]. Evidence for linkage for atopy was also detected in Hispanic sib pairs aged 11.63±4.95 years [92] and for asthma in Caucasians and Hispanics [73]. Recently, no evidence was found for linkage of the genomic region *12q13–24* to elevated IgE antibodies and related specific sensitization to common inhalant allergens or atopy in a study failing to focus on the asthmatic and inflammatory aspect of atopy [159].

Chromosome 13q maps atopy [92], AD [28], asthma [307], mite-sensitive childhood asthma [501], and SPTs [215].

On *chromosome 14q12*, the α chains of TcRαδ, associated with total and specific IgE [288], and NF-κB are mapped (Chap. 1); several other *loci* related to respiratory allergy have recently been localized [92] (Tables 4.2, 4.3).

Chromosome 20 maps AD [83] and above all asthma [83, 451, 497]. Van Eerdewegh et al conducted a genetic linkage analysis on 460 pairs of siblings from affected families in the US and UK and identified a *locus* on the short arm of chromosome *20* that was linked to asthma (lod, 2.94) and BHR (lod, 3.93). They assessed 135 polymorphisms of 23 genes in this region and identified by positional cloning the *ADAM33* gene, belonging to the ADAM12, ADAM13, and ADAM19 subfamily, which encodes a protein-processing enzyme known as a metalloprotease, significantly associated with asthma [451].

Other Regions of Interest

Novel regions of interest have been described, showing evidence for linkage to several chromosomes:

- *Chromosome 16q*, asthma, atopy, IgE [92], SPTs for molds [307], and IgE antibodies [83].
- *Chromosome 17q,* asthma [73, 105], SPTs [105, 215], AD [83].
- On *chromosome 19q13.3* a suggestive linkage of asthma [73], atopy and positive SPTs [457].
- *Chromosome 20*, asthma [83, 497] and AD [83].
- *Chromosome 21*, asthma [70] and strict asthma [306].
- *Chromosome 22*, specific IgE to Der p 1, SPT to HDM [229], and AR [144].

As regards the preferential *maternal pattern of inheritance,* Cookson et al [82] provided the first evidence for a maternal effect to atopy at the *11q13* marker for the FcεRI. The population under scrutiny [82] had in common an excess of alleles of maternal origin, whereas no excess in sharing paternal alleles was seen, a result different from the expected distribution; 62% of the sibling pairs affected by atopy shared their maternal allele, most likely pointing to a *genomic imprinting,* with activation of the maternal *locus* and parallel suppression of the paternal one [82]. These results show a significant sharing of maternally inherited alleles in region *11q13* in sib pairs with atopic IgE responsiveness. There lies the risk factor of the maternal inheritance of the polymorphism associated with atopy and BHR [166] and with FcεRI-β [398]. Atopic siblings share maternal but not paternal alleles in the chromosome *16p12* region, which increases the risk for enhanced IgE responsiveness. The most obvious candidate gene in this region is the gene for $IL_4RA\alpha$. Further evidence for inheritance through maternally transmitted alleles and atopy at different *loci* has been reported, including chromosomes *4q35.2*, *11q13*, *16q24.1* [96].

2. The genetic association of maternal atopy with chromosome *11* is undoubtedly interesting, although the origins remain for the most part unclear [165]. This is further proof that genomic imprinting [398], or the preferential expression of a paternal or maternal allele, imparts a decisive influence on mammalian development, in addition to the inheritance of polygenic human disease [150]. Several epidemiological studies highlight that inheritance of atopy and asthma is higher through mothers compared to fathers [2, 14, 151, 184, 220, 225, 255]. The evidence accumulated from the reported studies on the one hand points out that atopy is inherited at a given *locus,* and on the other hand provides an explanation for the frequent finding of a *greater risk for the children of atopic mothers.* Several observations suggest a maternal transmission to fetal and neonatal immune systems in evolution or a genomic imprinting by which the paternal gene expression could be abrogated, although it could be reactivated while being transmitted from the mother, thus paving the way for carriers. This hypothesis is in accord with both inheritance patterns, dominant and recessive [150]. Others explain this preference by the *Carter effect* [62]: atopy is a polygenic condition, thus if more predisposing genes are possessed by an individual, atopy expression is more probable. Since the threshold is higher in females, they inherit more genes for a disease expression and consequently their male offspring are more at risk [514].

In conclusion, the genetic mapping of atopy is far from simple, especially when taking into account the increasing prevalence of atopic disease in the past 3 decades (Chap. 5), and it is difficult to explain on the basis of genes alone. Furthermore, linkage of atopy with a gene on *11q13* could not be shown when patients with AD were taken as probands [72]. Thus more than one gene seems to be involved.

3. The interactions among numerous factors, genetic and nongenetic, lead to the disease phenotypic expression of manifold genetic traits that regulate general and specific responses to allergenic epitopes. These should be considered as determinants interacting in atopic disease, correlated with both profile and frequency of allergenic exposure and with the involvement of several HLA-D antigens and TcR as contributors to atopy pathogenesis, and thus of genetic and molecular bases of atopic disease [312]. A predisposing factor for allergic disease could be represented by the particular genetic set of HLA class II antigens, as based on the demonstrated correlation among these molecules and IgE responses to specific allergens. Following this pathogenetic hypothesis, recent studies have suggested that in atopic patients there are three types of *genetic alterations:*

- Increased response to antigens dependent on peculiar genes linked to the HLA haplotype.
- Significantly increased frequency related to some HLA haplotypes.
- Increased IgE production apparently independent of HLA.

Scientists have therefore concentrated their interest on two distinct and interdependent questions: whether a correlation exists between atopic disease, IgE levels, and HLA haplotypes and why there is IgE hyperproduction in atopics.

The possible correlations between atopic disease and/or HLA haplotype and IgE levels have basal mechanisms that are operative since fetal life, because the T-cell repertoire cannot be influenced by HLA haplotypes of a single subject [247]. Studies have speculated on a reciprocal genetic influence between HLA genes controlling specific immune responses and non-HLA genes controlling IgE synthesis. However, there is no IgE response in the absence of Ir genes; therefore the individual has inherited HLA alleles that induce synthesis of antibodies different from IgE in the presentation of allergenic peptides to TcR; yet subjects with an HLA–Ir association can also be sensitized in the absence of IgE responses. In addition, alterations of regulatory mechanisms in atopic subjects are multiple, they have a genetic basis [354] and different associations may lead to the development of an atopic phenotype with a Th2 prevalence [483] (Fig. 4.5).

The role played by HLA molecules in regulating immune response has been an incentive to undertake studies that may link the different disciplines of genetics and immunology; this new and fertile field of research has provided an impetus for the study of the association between particular HLA alleles and IgE responses to specific aeroallergens. In these studies, a product of the *HLA-DRAB3* gene (DRw52a) is a class II molecule assigned to the presentation of HDM allergens to T cells:

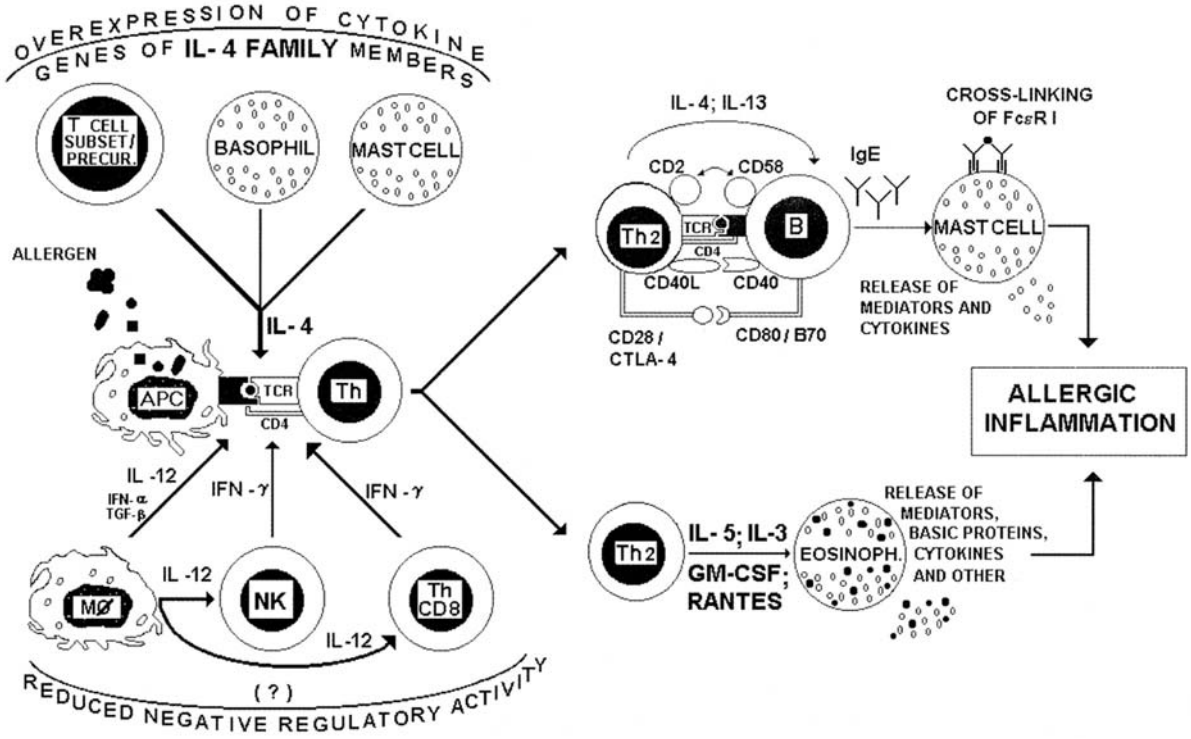

Fig. 4.5. Possible genetic, cellular, and molecular alterations contributing to the expansion of Th2 lymphocytes and to triggering the allergic inflammation in atopic subjects. *APC* antigen presenting cells, *IL* Interleukins, *MØ* Macrophage

following a peptide binding to DRw52b, there was no cell activation [312]. Moreover, an analogic peptide inhibited the proliferation of Der p-specific T-cell clones in vitro, and the HLA-DP recognition restricted T lymphocytes [163], thus opening the way to a possible functional T-cell inactivation by employing these peptides [312] (Chap. 13). Further progress in the research may provide pivotal insights for clinical studies: this approach offers unique opportunities to identify the Der p T-epitope repertoire, that is, the Der p 1 immunodominant regions containing several epitopes activating HLA class II-restricted T cells belonging to various regions [164, 510], or distributed along the primary sequence [510] (Tables 1.76, 1.77). The Der p 2 T-cell epitopes are present in all regions [311]. These epitopes are recognized by allergen-specific T lymphocytes isolated from atopic and nonatopic patients. Taking a more targeted approach to the HLA restriction to HDM allergens, T lymphocytes are directed toward several allergens, and even taking into account only Der p 1 and 2, there are several T-cell epitopes available (Table 1.76) (in addition to B cells). Efforts must focus on defining the Der p allergen presentation to T-cell clones by HLA class II molecules. Consequently, much emphasis has been placed on Der p 1, 2 and 3 allergenic epitope recognition by HLA-controlled T lymphocytes and the ensuing Th2 rather than Th1 T cell production, independently of HLA regulation [311]. One way forward may be the study of additional allergens, thus providing evidence for sIgE responses to Amb a 5, Amb t 5, Amb p 5, Amb a 6 pollen allergens associated with HLA-DR2 (*HLA-DRB1*0102*) alleles, Lol p 1–3 with DR3 (*HLA-DRB1*0103*) and DR5 (*HLA-DRB1*0105*) alleles [177], as well as the Der p family with DRB1 (*HLA-DRB1*0101*), DRB3 and DRB5 alleles [311] (Appendix 1.1). Additional studies have provided convincing evidence for sufficiently defined correlations with IgE antibody increase to other HLA alleles in atopic subjects compared to controls: *HLA-DRB1*0101*, *DPB1*0402* and *DPB1*0501* alleles to Der p 1, and the *HLA-DPB1*0401* allele to Fel d 1, Can f 1, Alt a 1, Phl p 5, Der p 1, and Der p 2 [163]. Significant linkage of HDM-specific IgE response to the *DPB1*0401* allele was found in sib pairs with IgE responsiveness to the HDM allergen [413]. Differences are evident in Japanese subjects, in whom *HLA-DRB1*1502* and *HLA-DRB1*0405* alleles to Der p 2 are common [313]; instead, *HLA-DRB1*1101* is frequent in Caucasians [458]. *HLA-DRB1*0101*, along with *HLA-DQA1*0101* and *HLA-DQB1* 0501* alleles, may be the gene predominant for immune response to the Chi t 1 allergen [435] or it may not [357]. However, several findings were not confirmed. In 83 UK atopic families, Young et al established a strong association with HLA alleles and IgE levels for Alt a 1 and Phl p 5 with the *HLA-DRB1*0104* allele, Der p 2 with the *HLA-DRB1*0103* allele and Fel d 1 with the *HLA-DRB1*0101* allele, which

showed the greatest statistical significance [506], along with that between anti-bet v 1 sIgE and HLA-DR3 in European patients [123]. The correlations of HLA class II and sIgE to Amb a 5 with *DR2*1500*, Amb a 6 with *DR5*, Ole e 1 with *DQ2*, Par o 1 with *DRB1*1101* and Lol 1–3 with *DR3* [32] have been confirmed, as well as associations with high IgE levels to Amb a 5, Amb t 5 and Amb p 5 with *HLA-DR2/Dw2* [520]. Since ragweed-allergic patients have *DR2* and *Dw2* sequences [519], it has been hypothesized that αβ1 heterodimers are the main HLA class II molecules mediating Amb a 5 presentation [520]. Previous data on Der p 1 and the associations with HLA-DR or DP alleles appear to be inadequate [506], while the allergen epitope recognized by HLA-DP and reactive in atopic subjects has been characterized [163]. Furthermore, particular Der p 1 epitopes are probably recognized by multiple HLA-DPB1 alleles provided with a greater heterogeneity in HLA class II-restricted alleles of the same region as the allergens [177]. In highly atopic patients, there is a great proliferative response of T lymphocytes to Der p allergens, HLA-DR-restricted by $CD4^+$ T cells, while in low atopic or nonatopic patients, the response is HLA-DQ-restricted by $CD8^+$ T cells [273].

Several studies show that HLA-D genes are critical for IgE responses [262]. Table 1.77 summarizes a recent investigation on the association of single allergens with HLA alleles and IgE levels, with a different relative risk factor: the HLA-IgE correlation is highest for allergens with a lower MW, which is probably caused by spatial limits; they thus contain only a restricted number of T epitopes compared to other allergens. However, exactly how the *locus* of HLA class II genes regulates the immune response of human beings is unknown [35]. This raises the issue of whether an interdependence between *IgE-regulating genes* and specific HLA molecules is achieved by inducing an immune IgE response [262]; hitherto class I gene products could be implied in the expression of diseases associated with class II antigens [207]. Ir genes, which condition sIgE production, could be localized either in the vicinity of HLA class II genes (in an association disequilibrium with certain alleles), or in the genome. However, their expression depends on specific HLA genes: it appears that positive associations between IgE and HLA class II molecules are correlated with strong $CD4^+$ (Th2) responses to the immunodominant regions of processed allergens, hence regulating IgE-mediated hypersensitivity responses [177].

Genetics of Pediatric Atopic Disease

In *pediatric atopic disease* the *DRB*0100/*0300/*1100* and *DPB*0201/*0401* haplotypes are significantly associated with asthma, AR and atopy (asthma and/or AR and/or AD), but more with Der p, establishing the role played by HLA antigens in atopy development [414]. A linkage between childhood asthma and atopy [305], and HDM-sensitive asthma, is on chromosomes *4p35 5q31–q33* and *13q11* [501], near the $IL_{12\beta}$ *locus,* and on chromosomes *11q22* and *12p13*, which have been found with the phenotype "HDM sensitization" [215] near the IL_{18} *locus*. Further data on the immunogenetic *respiratory allergy* regard significant associations with the HLA-B7 haplotype, DR2 almost exclusively in asthmatics, and with HLA-B8, DR3 more frequent in rhinitis patients, both ragweed-sensitive [35]. In patients with ragweed-induced asthma and rhinitis, IgE concentrations were higher in atopic patients compared to controls and in asthmatic compared to rhinitis patients [35]. A linkage between *HLA-Dw2* and skin reactivity to Ra5, a very purified component of ragweed pollen, cannot be hypothesized [264], because the sensitivity to Ra5 is linked to different HLA haplotypes in different families, in some of them without any link to HLA [33]. In pairs of asthmatic brothers, a recessive gene linked to HLA controlling IgE responses to HDM may confer susceptibility to asthma [59], and in Chinese schoolchildren Der p is associated with *HLA-DQw2* [180]. Instead the association with *DPB*0401* is absent in a mulatto population [58] and in Der p-sensitive patients, either nonatopic or with an SPT diameter <2 mm and with *HLA-DR*, *DP* and *DQ* [237]. In atopic asthmatics, there is a strong association with HLA class II alleles *DR4*, *DR7* [11, 12], *DQA1*0301* and *DQB1*0302* [11] and with atopic disease in general [12]. In Dac g allergic patients and controls, a positive association was found with *DRB1*0301* and *DRB1*0401* and with sIgE to Dac g 1 and Dac g 5, respectively, while TNF-α is encoded by a gene in the HLA class II region on chromosome *6p21.3*, thus playing a crucial role in asthma pathogenesis [78].

The growing literature previously discussed on *asthma genetics* [17, 18, 73, 82, 83, 105, 166, 176, 228, 305–307, 342, 452, 457, 489, 497–499, 501] and so-called loose asthma [306, 307] and on BHR [92, 109, 165, 166, 215, 279, 306, 307, 342, 493] (Tables 4.2, 4.3) has shown striking progress, correlating BHR either to FcεRI (chromosome *11q13*) [166, 452] or to IgE hyperproduction (chromosome *5q31.1*) [342] or not [109]. These trends of genetic research, following the suggestion of an autosomal dominant pattern of inheritance [246], are strengthened by the association with DNA markers on chromosome *5q31–q33* [31, 236] (Fig. 4.6) [236]. Recently, linkage of BHR or atopy was confirmed for markers on chromosomes *5q* [215, 278, 279, 305, 307, 493, 496], *6p* [261, 506], *7q* [92], *11q* [77, 82, 126, 287, 380, 398, 399, 452, 505], *14q* [288], and *17q*, which contain known candidate genes and five new regions (*2q*, *5p*, *11p*, *17p*, and *19q*) [73] (Table 4.2). Although the association of BHR and IgE levels with the same or different genes on this chromosome is still quite uncertain [318], the dependence on atopy may be strengthened by the absence of maternal asthma transmission in patients with BHR not linked to atopy [452]. The heredity factor is materialized in a wheezing risk of 1.7 if only one parent and of 17.9 if both parents suffer from BHR [116], in addition to an asthma risk prevalent in male offspring [514].

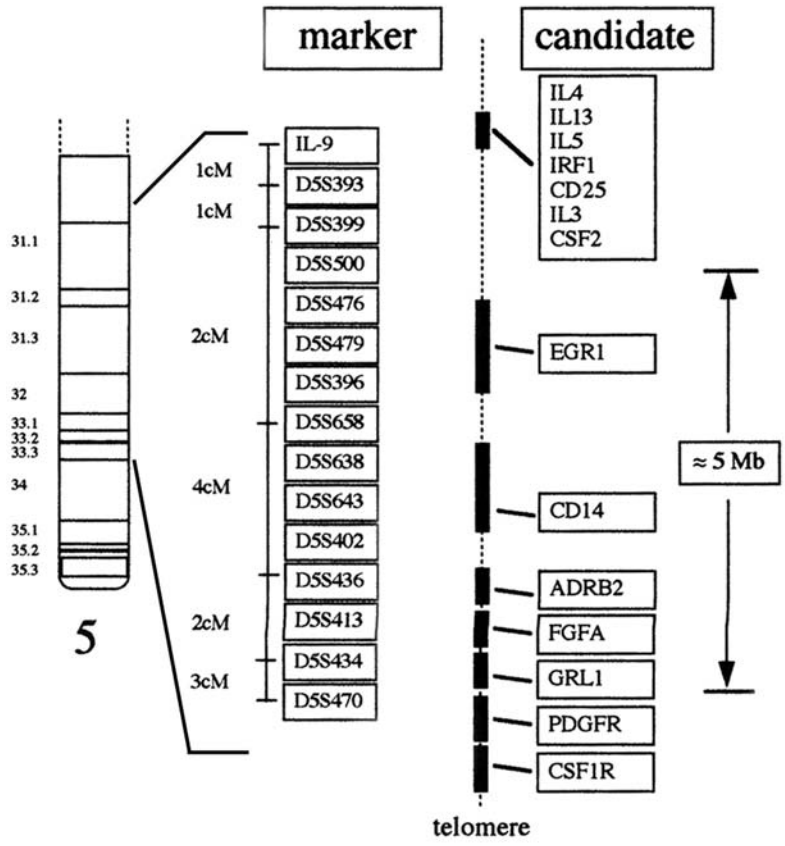

Fig. 4.6. Genetic map of the chromosome *5q31.1–q33* linked to genes providing susceptibility to BHR and atopy

The *AR genetics* has been known since 1916 [76], with positive patient associations with *HLA-DQ3* [136, 373] and negative with *HLA-A2*, as well as an *HLA-A3* and *B7* haplotype increase in those patients manifesting asthma later on [136]. *HLA-DR2* (*HLA-B7*, *SC31*, *DR2*] and *HLA-B8*, *SC01*, *DR3* haplotypes distinguish subjects with asthma from those with rhinitis if ragweed-allergic [35] and *HLA-A* and *B loci* PAR subjects [238]. A linkage between IgE responses underlying AR and chromosome *11q* was found in Japanese families [398]. In 123 children, genotyping data of 400 microsatellite markers suggested linkage of SAR to chromosomes *1p36.2*, *4q13.3*, *9q34.3* [502] and *12q13* [18]. A subsequent study in 79 children revealed one major candidate region on chromosome *4q24–q27* and eight minor candidate regions (Table 4.2) likely to contain susceptibility genes for PAR [144].

In *AD genetics,* positive associations with the HLA system have been thoroughly examined but not fully established [206, 387], and no definite consistent association has been found with HLA-A, -B, -C and -DR antigens [374], neither with a gene on *11q13* [72] nor in children with cow's milk (CM) allergy (CMA) and in their parents with *HLA-A*, *HLA-B* and *HLA-DR* alleles, nor with alleles of the *HLA-D* domain such as *DQ* and *DR52/53* [388]. A recent study in children with AD and CMA found a positive association with *HLA-DQ*, and that DQ^+ children had a prevalence for humoral rather than cellular responses [52]. Evidence for linkage and allelic associations for AD was found in 192 children for markers on chromosomes *13q12–14* and *5q31–33* [26]. A study of 12 families with AD supports the findings of the IgE gene FcεRI-β at *11q13* [124]. A linkage on chromosome *5q31*, a major *locus* that causes a general predisposition to atopy, was found in 50 families with offspring with AD that started at 3–10 months [126]. A significantly preferential transmission to AD offspring of the *T* allele of the –590C/T polymorphism of the IL_4 gene was reported [201] (Table 4.3). Because the *T* allele is associated with increased IL_4 gene promoter activity compared with the *C* allele, the data suggest that genetic differences in transcriptional activity of the IL_4 gene influence AD predisposition [201]. In severe AD, an allele for the $IL_4R\alpha$ subunit that segregates with atopy was found; the *R576* allele of *$IL_4R\alpha$* being strongly associated with AD may predispose persons to allergic diseases by enhancing IL_4R signaling function [162]. On the whole, the data suggest that IL_4 gene expression plays a crucial role in AD pathogenesis. A major susceptibility *locus* for AD was found to map to chromosome *3q21* [222, 234]: this *locus* provided significant evidence for linkage of allergic sensitization by paternal imprinting, further enhancing the presence of an atopy gene in this region [234]. This susceptibility which was not reported for asthma or atopy-related phenotypes, was identified by a genome-wide linkage scan [234]. Addi-

tional positive associations have been established with DPB, DRB [414], HLA-A1 and -B5 in patients with AD, but complicated by asthma and/or AR [444]. Kuwata et al [226] studied the transporter (TAP genes) polymorphism associated with allergen-processing genes in AD and reported a tendency toward an increased frequency of TAP-1 637Asp in subjects with AD, which may contribute to the pathogenesis of AD in combination with *DRB1*1302/DQB1*0604* [207]. An association between AD and genetic variants of mast-cell chymase (MCC) located on chromosome *14q11.2* has been found [259]. Since there is no association of MCC with atopic asthma, AR, or nonatopic asthma, these findings suggest that the genetic basis of AD may involve the interaction of MCC variants (which promote skin inflammation) [259] and FcεRI-β on chromosome *11q* (which promotes enhanced IgE responses and atopy) [399]. Further, AD patients produce IgE antibodies against environmental allergens regulated by HLA-class II-restricted $CD4^+$, although cytotoxic HLA-class I-restricted $CD8^+$ subpopulations may predominate in the infiltrates in AD lesions [343]. The role of atopic heredity in the development of AD is well established and is a significant risk factor (OR >1) [384]. A population-based twin study demonstrated pair wise concordance rates of 0.72 in MZ and 0.23 in DZ twins with AD [387].

Genetic studies on IgE antibodies, whether or not linked to markers localized on several chromosomes, to cytokines IL_3-IL_5, GM-CSF [342] and IL_9 [109], show more or less significant evidence for linkage of high IgE antibodies or atopy on chromosomes *1q* [496], *2pter* [489], *2q* [215], *3q* [234, 496], *4* [272], *4q35* [92], *5q* [31, 36. 109, 215, 266, 279, 280, 342, 496, 502], *6p21* [489, 496], *6p21* and *7q11* [215], *6q* [496], *7p13* [92], *7q* [215, 228], *9q32* [489], *10q* [215], *11p* [79, 92, 105], *11q* [80, 109, 452], *12q* [17, 80, 215, 489, 496, 498], *13q12* [215], *14q* [288], *15q*, *16q-ter* [83] 16q22.1 [92], *17q* [92], *22q* [329] and to two independent *loci* regulating IgE [109, 280, 495]. Each of these regions contains several important genes that are biologically relevant to IgE regulation (Tables 4.1, 4.2). Controversial results [36] may be explained by the heterogeneity of specific determinants of IgE antibodies due to a pleiotropism of pertinent genes [38] in different populations subjected to varying environmental factors, and analytical methodologies [496]. We recall the inheritance of IgE in 50%–84% of cases [33] and family studies suggesting a major *locus* contributing to IgE antibodies [23, 34, 38, 153, 274], apart from elements of complexity deriving from studies on recessive [104, 138, 269, 279] and dominant [269] inheritance of elevated IgE. The results of studies based only upon IgE antibodies are not concordant: parents with low IgE have offspring with elevated sIgE [262] and subjects with $SPTs^+$ and $sIgE^+$ have a low profile of IgE antibodies, so the concordance with SPTs and sIgE is to be found only in 36% of cases with elevated concentrations [211].

A characteristic trait of atopics might be that of inheriting *particular sequences of HLA class II molecules* (mainly in α-1 and β-1 HVRs) expressing preferential bonds to some allergenic peptides more than to others [365]. The incessant presentation of allergenic peptides on the ample surface of *dendritic cells* (DC) with both IgE receptors is unusually able to amplify the recognition by passing $CD4^+$ T cells with an allergen-specific TcR, thus favoring their proliferation, circulation and colonization in different lymphoid sites [354]. The recognition process is specific and genetically restricted [173], even at the clone level: T lymphocytes of atopic patients proliferate in vitro in the presence of very reduced levels of purified allergens [98]. Consequently, allergen-specific T lymphocytes selectively colonize the tissues of target organs where they orchestrate and maintain the aggression of the tissues invaded by allergic inflammation [98, 257, 361, 454].

In the last few years it has become evident that allergen-specific clones of activated $CD4^+$ cells are able to produce high levels of IL_4/IL_{13}, up-regulating IgE production in B cells from healthy donors in the absence of IL_4, thus revealing that the generation of *high levels of serum IgE* is the characteristic of atopic subjects [183, 363]. Progress in the knowledge of transplants gives rise to hypothesizing an epiphenomenon and attention has been focused on a *primitive defect of T cells,* which is strengthened by ascertaining that atopic individuals may have a greater number of circulating clones of $CD4^+$ T lymphocytes (Th2-like), which provide optimal help for antibody responses [354]. Therefore, the quantitative expansion of specific clones of activated T cells increases the probability of peptide recognition from allergen-specific B cells, which capture allergen via their surface Ig (immunoglobulin) molecules and present the peptide bound to class II HLA molecules. This view of the HLA-peptide association for the presentation to T cells offers the key to reconsidering the relation between IgE response and HLA: it appears that different molecules may possess distinct capacities of presentation either of allergens taken up in *minimal amounts* (ng/year) or of epitopes correlated with a given allergen [354]. The signals transmitted during HLA-TcR interactions influence the type of ongoing IgE-mediated reaction. In addition, the epitope immunogenicity, as well as their capacity to drive immune response toward preferential production of IgE rather than of other isotypes, largely depends on the APC recruitment of T lymphocytes [354]. On the one hand, such studies update the mechanisms critical for the allergen penetration into the mucosa and the subsequent atopic sensitization; on the other hand, they contribute to enlightening certain genetic aspects, indicating that atopic subjects undergo:

- An increased number of Th2 lymphocyte clones predisposed preferentially to produce IL_4/IL_{13} compared to normal subjects.
- A decreased number of Th1 lymphocytes producing IFN-ɣ and IFN-α aimed at inhibiting this process [328].

First Hypothesis. *The uncontrolled increased IgE levels in atopic patients might depend on a genetically*

determined defect of T cells: IgE regulation in the animal model and probably also in humans is strictly controlled by T lymphocytes, and especially down-regulation of IgE synthesis is modulated by cytotoxic T cells. In atopic patients, an effective or relative lowering of allergen-specific CD8 T cells has been demonstrated by a rise in the CD4/CD8 rate (Tables 1.35, 2.5) even in BALF (bronchoalveolar lavage fluid) (Tables 1.40, 1.41), therefore inducing a *selective highlighting of the CD4 Th2 phenotype, involved in the generation of* IL_4 *and* IL_5 [365].

Second Hypothesis. In atopic patients, a clue might be offered by *a defect in the regulation of cytokines as well as by an imbalance between* IL_4 *and its antagonists,* emphasizing that ILs, mainly IL_4 and IL_{13}, are major players in IgE synthesis. The reason now arises as to how specific clones of allergen-specific T cells produced by atopics promote a Th2-like profile (Table 1.10) secreting a different pattern of ILs [363]. Research has shown that the overflow of Th2 preferentially delivering IL_4 elicits several mechanisms, including an uncontrolled amplification of both IgE synthesis and eosinophilia characteristic of atopic disease. Coordinate production of IL_4 and IL_5 by Th2 cells results in the Ig gene switching and expressing germline transcripts in B cells and in selective accumulation of eosinophils in the tissues with the working equivalence of IL_{13} and IL_4. The first 6 months of life are a critical time window for the initiation of immunological changes resulting in the development of atopy: an environment favorable to Th2 responses is also orchestrated by IL_6 toward Der p immune responses [450] and IL_4-driven IgE synthesis, where it plays an obligate role (Chap. 1). The selective development of a Th2-like T-cell IL profile in HR (high risk) children who develop atopy is due to increased production of Th2-like T-cell ILs, caused by impaired allergen-induced IFN-γ production in the neonatal period. Furthermore, the decreased allergen-induced IL_{10} levels observed in 12-month-old atopic children may result in a lack of down-regulation of the inflammatory process [450]. Thus, the conclusion evoked *in atopics is the conversion from Th1-like T-cell ILs into Th2-like T-cell ILs.*

An important conclusion of the Melbourne Epidemiological Study of Childhood Asthma that started 40 years ago (Chap. 5) is that patients with persistent and severe atopic asthma have a reduced HDM-induced Th1 response, whereas those with resolved asthma do not. Reduced HDM-induced IFN-γ production was associated with increased severity of asthma, thus implying that a reduced IFN-γ production could be an important factor contributing to ongoing severe asthma. The finding that all subjects with a history of asthma displayed increased HDM-induced Th2 (IL_5 and IL_{13}) responses, irrespective of the presence or absence of asthma, suggests that increased Th2 responses reflect the presence of the atopic state *per se* rather than being specifically linked to asthma [403].

The second hypothesis consequently confirms that the *intrinsic genetic dysregulation of T lymphocytes in atopic subjects* could acquire the *phenotypic aspect of a postnatal delay in their functional maturation,* so driving the overexpression of IL_4 and other IL genes present on chromosome *5* (Table 1.5), of crucial importance for IgE switch recombination and differentiation of precursor T cells into dominant Th2 T cells at the expense of Th1 T cells, evidence stemming from several tissues affected with atopic disorders. Recent data may ultimately provide the immunologic explanation for the postnatal delay in T cell functional maturation. The Th3 cells, termed T regulatory (Tr1), are induced by semi-mature DCs under the influence of regulatory ILs, including IL_{10}, TGF-β and IL_4 Th3 cells, secrete IL_{10} and or TGF-β, but no IL_4 and scarce or no IFN-γ and *are capable of suppressing Th1 and Th2 responses* [283]. $CD4^+$Th2 T cell and IL_{3-5} hyperproduction and low IFN-γ levels [98, 170, 361, 450, 454], a product of IL_4/IL_{13} that results in the preferential differentiation of B cells into plasma cell IgE, thus explaining why IgE synthesis is found to prevail compared to other isotypes. The Th2/IgE predominance may induce the passage from mono- to polysensitization in infants with AD and food allergy (FA), with prevalent respiratory symptoms [143].

What genetic or immune mechanism, at least in atopics, appears to underlie the complex and presently unclear dysregulation affecting T-cell subsets, preferentially interacting with Th2 cells? It is clear that all subjects, regardless of FHA, respond to parasite infections evoking a Th2/IgE response whatever the genetic background, and mycobacteria promote Th1 T-cell generation [363]. Several studies have clarified the grounds for this substantial dichotomy, establishing that allergens preferentially evoke Th2 responses in the atopics, but Th1 responses in nonatopic patients [354]. This finding may reconcile different views on the facilitated and amplified Th2 production and of the specific and decisive role of heredity [262]. Such inheritance may depend on the clonal expansion and rearrangement of the TcR gene β chain, and the production by the T-cell clone of high levels of Th2-like T-cell ILs and of markedly reduced Th1-like T-cell ILs [98]. Additional factors such as the APCs perform variable functions; after the demonstration that in nonatopic donors they were able to skew Th0 T cells to express a Th2 phenotype. It is thus possible that TcR diversity greatly influences the differential compartmentalization into Th1 or Th2 in target organs [313]. IL_4 present in the paracortical zone of lymph nodes, and in the microenvironment where the antigen presentation to Th0 cells takes place, appears to be the most significant factor responsible for CD4 differentiation into Th2 T cells, thus representing the chief threat closing the pathogenetic circle of IgE synthesis [354]. A clue may be that atopic patients are also equipped with Th0 precursors able to interact with IL_4 in basal conditions and in the absence of adequate stimuli and with no difference between allergen-specific Th2 in both FA and respiratory allergy [363].

An additional hypothesis is that the PGE, elevated in atopics and with selectivity for certain APCs, may inhibit the Th2 IL prominence, also considering the blocking effect of IL_4-dependent IgE production by B cells [328]. Several immunoregulatory properties also include the relevant role played by PGE_2 in inhibiting the IL secretion by Th1 cells without affecting IL secretion by Th2 cells. Such action is associated with the rise of cyclic adenosine monophosphate (cAMP) intracellular levels, a relevant effect following the observation that various agents able to elevate cAMP concentrations show similar behavior toward the T-dependent IL production [331]. The PGE-mediated decrease in IL_2 and IFN-γ together with IL_1 production by macrophages inducing PGE synthesis and necessary to Th2 activation and IL_5-production by cAMP may tip the scales to the IgE recombination machinery [134, 331]. In humans, PGE_2 also interacts with B lymphocytes, stimulating their proliferation after IL-independent CD40 activation [134]. The crucial prerequisite needed to verify the outlined hypothesis is the PGE_2 hyperproduction in one or more lymphoid organs, which could underlie the Th2 hegemony in atopics [134]. The scene is complete; however, B and T cells have ample chances of interacting with PGE_2 and/or the cells secreting it, including macrophages, fibroblasts and follicular DCs (FDCs) in the spleen and lymph nodes [331]. For now, the scene of hyperactivity of the cascade of events triggered in atopics stems from indirect observations or extrapolated parallels; it is hypothesized that experimental results concur to explain the apparent contradictions.

Studies on allergen-induced lymphocyte proliferation in children with AD and FA have demonstrated during reactions in an active stage that Th1 T cells produced IL_2 and IFN-γ and expressed FcεRII on B cells in a greater amount compared to controls [213]. Thus in atopic children, the Th1-mediated mechanisms are active near the Th2-mediated mechanisms. Interestingly, CD4 T cells derived from CB showed a different IL profile depending on the newborn's parental atopic status. Der p 1-specific T-cell clones derived from CB of nonatopic parents' newborns showed a prevalent Th1 profile, whereas when both parents were atopic CD4 T-cell clones of at-risk newborns exhibited a Th0 or Th2 profile [333]. CB IL responses specific to the HDM allergen showed a Th2-skewed profile similar to that in atopic adults associated with a slightly detectable IFN-γ, irrespective of atopic risk or later atopic disease [345]. Taken together, these data demonstrate that in addition to the allergen structure and the type of APCs, the genetic abnormalities favor the preferential Th2 response in at-risk neonates. As stated in discussions in Chap. 2, in vivo the fetal immune environment is directed toward a Th2 response as a result of IL_4 and IL_{10} production by the amnion and placenta.

4. The hypothesis that a *genetically determined defect of T lymphocytes in atopic subjects and postnatal delay of functional maturation* appear to be associated in at-risk neonates [333]. In infants divided into at HR and low risk (LR), depending on the presence or absence of at least one atopic parent, symptomatic HR compared to LR infants had decreased levels of CD45RA and CD45RO and increased levels of activated T cells (CD25), with highly significant differences [282]. In CB mononuclear cells (CBMC), CD45ROs were significantly higher in children developing atopy at 12 months compared to those who did not [452]; however, CD45RO levels are scarce in both the fetus and the normal neonate (Table 2.6). So a postnatal maturational delay of T lymphocytes is reflected on the subsequent acquisition of immune memory, which may be delayed in HR children [172]. The CD45RO cell decrease appears to have a greater effect on T-cell activation [282]. A first hypothesis postulates a possible T-cell suppression, either innate or maternally influenced in the uterine environment. The FHA genetic influence was demonstrated by IFN-γ decreased levels [239, 358, 432, 431, 450]. Another hypothesis proposes that if CD45RO cells are a prerequisite of immune tolerance, a reduced presence of memory T cells might result in an altered postnatal exposure to allergens with consequent atopy development [282]. In accordance with a presently more reliable hypothesis, the immune system is more activated and stimulated at birth (Tables 2.5, 2.6, Fig. 2.1) owing to the *in utero* exposure to allergens. Thus the reduced CD45RO titers in HR children imply either a different exposure related to the maternal influence, or a hereditary maturative defect of immunocompetent cells [282], or above all the reduced secretion by CD45RA cells in imbalance with CD45RO cells, of Th1-like T-cell ILs such as IL_2 and IFN-γ [196]. These findings provide a plausible mechanism to the persistence of fetal Th2 responses during early childhood in atopic children [345]. The *first 6 months after birth* may be a pivotal time window for the beginning of immune changes resulting in the atopy expression, associated with skewing of immune responses away from a Th1 to a Th2 IL profile in HR children, caused by impaired IFN-γ production in the neonatal period [345]. These findings provide a plausible mechanism to explain the persistence of fetal Th2 responses during early childhood in atopic children [345]. Moreover, the decreased allergen-induced IL_{10} concentrations in 12-month-old atopic children may result in the lack of down-regulating inflammatory processes [452].

Recent reports on hereditary defects found in HR children who later develop atopic disease confirm that in normal subjects T cells are led to adopt a Th1-like profile depressing IL_4 function with significantly elevated secretion of IFN-γ compared to atopics; on the contrary, in HR children [239, 345, 358, 432] *elevated levels of IL_4 and impaired IFN-γ responsible for switching B cells to produce sIgE are positively demonstrated in atopics* [328]. In neonates, an evident decrease in both cytokines is seen in their levels (Tables 2.1, 2.3). IFN-γ was detectable in human amniotic fluid at 16–17 weeks

Table 4.4. IL_4 and IFN-γ levels in children at high (*HR*) and low (*LR*) risk of atopy compared with adults

Cytokines	LR	HR	Adults
IFN-γ (U/ml)	13.27 ±16.17	20.69 ±26.51	57.65 ±58.64
IL_4 (pg/ml)	2.667 ±4.948	6.328 ±7.379	9.730 ±13.420

Data from [170].
See in comparison the neonatal levels shown in Table 2.3.

Table 4.5. IL_4 and IFN-γ levels in atopic (*A*) and nonatopic (*NA*) children stimulated by $CD3^+$ $CD45RO^+$ and $CD3^+$ $CD45RO^-$

	IFN-γ (U/ml)	IL_4 (pg/ml)
A $CD3^+$ $CD45RO^+$	15.5 (9.4–26.6)	61.9 (<LM–353.2)
NA $CD3^+$ $CD45RO^+$	35.7 (16.8–59)	76.5 (30.2–1180)
A $CD3^+$ $CD45RO^-$	7.7 (2.2–17.4)	<LM
NA $CD3^+$ $CD45RO^-$	21.7 (6.3–36.8)	<LM

Data from [196].

of gestation in only 11 (26%) of 42 samples [194]. How can we justify this deficit in the first few years of life? There is evidence of a post-transcriptional defect [431] resulting from notably deficient IFN-γ secretion compared to controls vs increased mRNA expression [429], or from the poor expression of CD2 and CD11a/CD18 by unstimulated CD45RO lymphocytes [291], or impaired IL_{12} or IL_{18} production (Table 1.5). Impaired IFN-γ production was only observed after allergen-specific stimulation of CBMCs from children developing atopy [452]. Also, neonatal IL_4 impairment appears to decrease as the child ages, so that IL_4 may play a leading role in IgE synthesis [203]. In atopic and nonatopic children, the differences in IL_4 levels are often contradictory, since they are also significantly reduced in nonatopic children (Tables 4.4–4.6) [170, 196, 203, 432], in healthy and HR children with very elevated IgE levels compared to LR children [170] and adults [170], with an additional reduction of IL_2 levels [196]. In healthy subjects aged 1–19 years, $IL_{1\alpha}$, $IL_{1\beta}$, IL_2 TNF-α and IFN-γ levels are reduced compared to adults, and IFN-γ increased only after 10 years of age (Table 4.7) [118]. This is the main difference: IFN-γ values are constantly low in neonates [430] (Table 2.3) and in HR infants [291, 358, 429, 473], to the point of resulting predictive of the subsequent atopy expression [423, 429, 473] and of sensitization to inhalants [270]. *Thus the reduced secretion of IFN-γ at birth is a primitive marker* [430, 473] *and a result of the atopic march* [430], in accordance with the postnatal immunodeficiency [170] rather than an effect of the disease process [430]. Recent studies in animal models demonstrate that selective decrease of IFN-γ gene expression in T cells *in utero* and in early postnatal life may be due to hypermethylation of CpG (cytosine-phosphate guanine) sites in the proximal promoter, which results in reduced capacity to transcribe IFN-γ-

specific mRNA [480], whereas an IFN-ɣ hyperproduction caused by CpG oligodeoxynucleotide (ODN) resulted in the exacerbation of dermatitis in 38.5% of mice [426]. Further mice experiments show that high mobility group A1 (HMGA1)-deficient mice exhibited an IFN-ɣ induction silencing, because IFN-ɣ gene expression requires HMGA1, the architectural transcription factor mediating IFN-ɣ enhanced formation [65]. The greater IL_4 concentrations in atopic polysensitized children compared to monosensitized children, and those 12-fold lower levels of IFN-ɣ compared to controls [429], and even lower levels of IL_2 in infants with double FHA [270], appear to establish a correlation with atopy severity [429]. At birth and *up to the age of 10 years,* the defective IFN-ɣ generation in children by PBMC (peripheral blood mononuclear cell) response to specific stimulation is a predisposing factor to the development of atopic disease, thus causing up-regulation of ILs associated with a Th2 response and the atopic phenotype [430, 431, 473]. Studying the ontogeny of IL production, IFN-ɣ release in atopic children was significantly reduced in the 0–2-year, 2–5-year, and 5–10-year age groups when compared with nonatopic children [402]. Therefore, it is confirmed that the delayed postnatal maturation of this important aspect of cellular immune function is a key determinant of genetic predisposition to atopic disease [170].

In HR atopic-prone babies compared to babies with nonatopic parents, IL_{13} secretion is defective at birth in PHA-stimulated CB MCs, contrasting with IFN-ɣ deficiency. Since IL_{13} is a prototype of Th2-type ILs, this finding may reflect an inherent immaturity or suppression of T-cell IL responses in such babies [486].

The significant reduction in IFN-ɣ and IL_4 levels in atopic children, either with asthma [432] or AD [429], confirms the inverse role of these ILs in the pathogenesis of atopic disease, and that the imbalance is not an epiphenomenon [358, 432], but the expression of a *primitive functional abnormality of T cells* [39] associated with a significant reduction in NK cells in HR compared to LR children [239]. The clinical result is the significant, persistent elevation of IL_4 titers in infants who developed atopic disease during 18 months of observation, compared to healthy controls, parallel to IFN-ɣ levels under detection limits, with *the highest levels of IL_4* at 18 months *in infants with FHA+* [39]. Even if Th2 T cells were not produced, as occurs in mice with the deleted IL_4 gene (or made not functional) [214], it is hypothesized that during early responses a small population of $CD4^+$, $NK1.1^+$ cells may come on the scene [499], or one prematurely migrating from the thymus with double-negative TcR-αβ (DN) [516], or metachromatic cells releasing IL_4 localized after FcεRI stimulation [45]. Mice significantly devoid of mast cells show normal Th2 levels [479].

Other studies indicate that soluble FcεRII (sFcεRII) levels are significantly higher both in infants compared to older children and in atopic infants (aged <1 year) compared to nonatopic infants [203]. These studies emphasize the strict correlation between sFcεRII levels, an increase likely due to IL_4, and IgE antibodies: since IgE-BFs (Chap. 1) have the capacity of modulating IgE synthesis, which suggests that sFcεRII in turn is an IgE-BF, they could indeed be able to increase IgE in atopic infants [203].

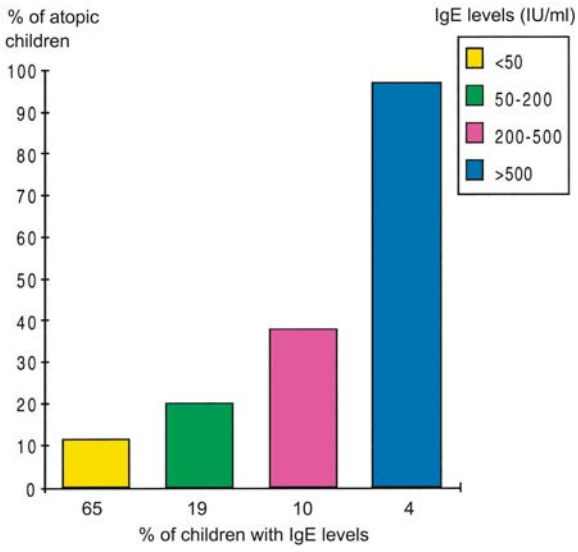

Fig. 4.7. IgE levels and risk of allergy. The higher the IgE concentrations, the greater the likelihood of atopy. (Data from [256])

Also defective is the kinetics of airway DC postnatal maturation, which sequestrates and transports aeroallergens to T lymphocytes from the regional lymph nodes: as seen in the animal model (Fig. 2.24), DCs only develop at the age of weaning. Also in humans, the responses to aeroallergens may develop after the age of 1 year [157].

Evaluating the heredity role in atopy, the role played by IgE molecules in the genesis of atopic disease is remarkable (Fig. 4.7). As outlined in Table 3.4, CBIgE levels in neonates of atopic parents are elevated, and significantly related to atopic inheritance [433], even if there is an evident heterogeneity [180]. Long-term prospective studies have contributed to delineate *the IgE natural history* [157]. Serum IgE antibodies develop in two phases (Table 4.8) [169]: to common food allergens before the 1st year of life in atopic and normal infants, but decline in most babies to undetectable levels by the age of 2 or 3, in healthy children first. IgE antibodies to inhalant allergens have a more markedly biphasic distribution: more often they develop at 1.5–2 years, a peak is attained at about 4 years and takes longer to switch off in normal babies, often not stopping until age 5–7, whereas *IgE responses increase more rapidly in atopic babies, who maintain their serum IgE reactivity to inhalant allergens into later childhood, and about 30% maintain elevated peaks to one or more allergens beyond the age of 12 years* [28, 156, 157, 169, 447, 513]. It was demonstrated that up to age 2 the infants were sensi-

tized to egg (16.4%), CM (13.1%), grass pollen (6.2%), and HDM (3.0%). At age 7, the prevalence of atopic sensitization was inverted: to grass pollen 23.3% (a 3.7% increase) HDM 15.7% (a 5.2% increase), CM 13.6%, and wheat 11.4% [184]. In a parent study, FA at age 2 was a strong predictor for the development of asthma; school age children sensitized to inhalant allergens at age 7, either without (OR, 3.44) or with (OR, 9.43) concurrent FA, had an increased risk of having asthma which was strongest for perennial inhalant allergens compared with seasonal inhalant allergens [184]. HR infants, though residing in allergen-free houses at 9 months of age, exhibited significantly greater antibody levels than FHA-negative infants not protected by environmental measures [156]. In the 817 infants with AD of the ETAC (Early Treatment of the Atopic Child) study from 13 different countries, there was a catalog of factors associated with a larger risk of developing high antibody titers: male sex (62%), exposure to egg (45%), cigarette smoke (41%), kitchen gas (59%) and proximity to plants (44%) [474]. In the first 24 months after birth, the number of children at risk of atopy with sIgE to foods was significantly higher than those with sIgE to Der p 1 (p=0.0006) [48]. In 931 healthy newborns, higher FHA scores and exposure at 18 months of age to egg and to Der p allergen led to a higher incidence of AD at 3 years of age [181]. Similar patterns of IgE responses yielded significant data: only minute doses of allergen are sufficient to drive a primary sensitization, µg for foods and ng for aeroallergens (Table 4.8).

In animal studies, mice exposed to an aerosol of allergens mount an IgE response and divide into two categories: the tolerant mice, with low tendency to produce IgE, which will never again respond to the same allergen with IgE, and those with a marked propensity to IgE production, in whom a repeated exposure to allergens amplifies the antibody response. In the first case, the leaders are Th1 T cells, in the second the pro-IgE Th2 [169]. Thus, feeding low doses (ng) to nonreacting mice produces tolerance, whereas feeding larger doses to highly reactive neonates genetically at risk (mg) does not, since small doses sensitize them [178]. The data we expose in Chap. 9 on the deluge of artificial formulas are a failure for this thesis: given that larger doses truly induce tolerance, millions of neonates and infants, whether or not at risk, have been fed CM and weaned early with solid foods, but on the contrary the atopy prevalence has risen in geometric progression. Early postnatal allergen exposure is a risk factor for development of long-term, primary allergic sensitization, and a recent study suggests that the basis for this risk may be the presence in the newborn of small populations of allergen-specific T cells that are primed during intrauterine life [344].

Holt has been studying the pathogenetic theory on the different genetically determined effects in both GALT and BALT for several years, and Table 4.8 summarizes IgE responses to allergens during early childhood. Holt argues that IgE down-regulation is more rapid and effective in GALT than in BALT: the reason is that the higher concentration of dietary allergen may drive the allergen-specific T-cell selection process much faster and more efficiently in the GALT than the parallel process in the BALT, which is stimulated by intermittent exposure to ng of aeroallergens [169]. More precisely, feeding high food allergen concentrations directly produces T-cell anergy that establishes a functional deletion, whereas continued exposure to low doses produces tolerance, a misnomer for the term "immune deviation" [169], and IgE down-regulation by allergen-specific T cells, with a major component of the suppressor CD8 phenotype [515] stimulated by TGF-β (Fig. 1.40). Studies based on the adoptive transfer show that this form of tolerance is CD8-mediated [515] and in this process prominent roles are played by IFN-γ and TGF-β [178, 515]. IFN-γ production by T cells from lymph nodes draining GALT in response to allergens [179] suggests that most T cells that evade anergy may acquire the Th1 phenotype [169]. Others [171] continue that Th1 cells are tolerated and not the Th2, Th1 hyporesponsiveness being IL_4-mediated. There seems to be a gradient of sensitivity to tolerance induction, with Th1>Th2>B lymphocytes, with a likely outcome in IgE hyperproduction at the systemic and mucosal level [169]. Jarrett stressed that the "very low doses" may stimulate other than suppress IgE responses [187]. We add that at-risk neonates are continually fed low sensitizing doses in the neonatal period: in their CB an effective reduction in CD8,

CD45RO and IFN-γ is reported [291] (Tables 2.5, 2.6), and the gut is physiologically immature. In early life, *the CD8 suppressor deficit* is markedly clear (Tables 1.35–1.39, 2.5), which is the basis of atopic disease. An early Th2 priming is capable of deviating subsequent immune responses toward the selection of potentially pathogenic Th2-polarized memory [344]. In infancy, IgE are synthesized and other factors are conditioned, including intensity and duration of allergen exposure (Table 4.8), diet, maternal smoking and possibly presence or absence of a protective factor that stimulates Th1 responses more than Th2 responses: this is the evidence that asthma has multifactorial causes [175]. A third line of Th (Th3) may be prominent in this context, considering that the induction of experimental autoimmune encephalomyelitis is inhibited by tolerant mice and that the injection of anti-TGF-β blocks the effect [66]. Th3 T cells can be beneficial to the host, since they can function in infection by limiting pathogen-induced immunopathology [286].

The regulation is at the genetic level also for the recognition of varying allergens by the immune system: specific responses of atopic individuals are activated by only certain allergens with which they make contact; the different reactivity makes it possible to distinguish mono- and polysensitized subjects. IgE hyperproduction continues and persists in all atopics, and rises strikingly following an allergen exposure; however, at a certain point it proceeds endlessly from the initial exposure (ongoing production).

5. The phenotypic expression of atopic disease depends not only on IgE hyperproduction and/or both CD8 and IFN-γ defects, but also on IgA hypoproduction. Having observed significantly lower sIgA concentrations in the milk of IgA-deficient mothers affected with atopy [351], we suggest that the maternal deficit of IgA antibodies may play a permissive role in the expression of atopic symptoms, thus appearing to be a more prominent factor than positive predisposition to atopy [253]. As previously outlined, the IgA deficit of a mucosal site is reflected diffusely in other sites, in the first place in the gut. These data have been supported: Fig.4.8 [249] shows that high or intermediate IgA levels combine with low IgE concentrations, and low IgA levels correspond to measurable IgE levels. The results show that low IgA values are correlated with the most severe clinical manifestations and with an increased cumulative incidence of atopic disease [249]. From the demonstration that serum or skin IgA levels are inversely correlated with the expression of clinical atopic disease, we might conclude that *atopy is conditioned by the delayed IgA maturation rather than by IgE hyperproduction.* A prospective study of the association between viral infections and the onset of allergic disease observed in atopic children that serum IgA levels were uniformly in the low range for age during the first 30 months after birth [128]. The sIgA levels are also reduced in the skin of subjects with AD (Chap. 7); low IgA levels may coincide with an increased susceptibility to respiratory infections (Chap. 22).

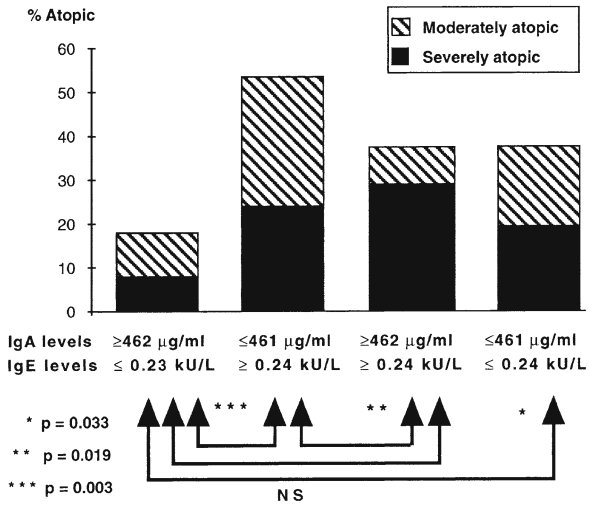

Fig. 4.8. IgE levels and risk of atopy. Percent of atopic subjects. Percent of children with IgE levels. Serum IgE levels (IU/ml). The higher the IgE levels the greater the risk of atopy. (Modified from [249])

In conclusion, the great protagonists of genetic and immunological progress are strictly concatenated: the HLA genes load the gun, so to speak, to *shift the balance of T-cell subsets toward a polarized Th2 dominance*, which along with IL_4/IL_{13} are the builders of IgE synthesis. The expression of atopic disease is the result of a complex interplay between genetic predisposition and environmental exposure. The impact of factors influencing the Th1–Th2 selection during infancy is somewhat modified by the inherent importance of bystander respiratory infections, which may *release strong IFN-α/ IL_{12} signals* in the lymph nodes seat of the Th1–Th2 selective process, *skewing the chair in favor of Th1-type protective immunity* [363], most likely by intervening DCs [252]. Thus, a reduced capacity to produce IL_{12} could lead to aberrant Th2-type responses in atopic children. During the formative period, several changes encourage Th2 allergic responses to allergens, which may otherwise yield Th1 responses in the same baby under dissimilar conditions. Hitherto, allergens are increasingly viewed as the targets of these responses, rather than the primary cause of atopic disease. Additional evidence comes from a study on the spread of pollutants, which found that IgE levels were three times higher in children of the former East Germany, with no correspondence with sIgE to seven different allergens, with the net conclusion that high serum IgE levels do not necessarily correspond to atopic sensitization [20]. However, IgE and atopy map to the same chromosome *4q* [92]. Investigations in atopic children in eastern and western Germany show a high prevalence of sIgE against inhalant and food allergens and atopic sensitiza-

tion [476] and that Th0 lymphocytes prevail in children who grew up in East Germany, regardless of whether they were atopic, whereas children of West Germany, particularly when they are atopic, show a Th2 polarization [352].

Prenatal Genetic Factors and the Fetal Immune System

6. A vast array of factors acting during intrauterine life have been indicated as promoting atopy development in children (Table 3.7). The research on *in utero* sensitization, recently amplified by substantial contributions, has given this factor a salient place among the prenatal factors. CB T lymphocytes proliferate in the presence of Der p 1 and Lol p 1 [333], while when testing CB PBMCs with α-lactalbumin (ALA) [320], β-lactoglobulin (βLG) [332] and bovine seroalbumin (BSA) [213], there was a meaningful proliferative response. Expanding the panel of allergens tested in CB (ALA, βLG, BSA, α, β and κ caseins), a proliferative response was recorded for a broad set of allergens [423]. Moreover, from as early as 22 weeks of gestation onward, the *fetal immune system* (FIS) is active and begins to respond to a similar variety of allergens, including βLG, ovalbumin (OVA), Der p, Fel d 1 and birch pollen [193], and normal-term fetuses showed positive lymphoproliferative responses to one or more common allergens, including whole HDM extract (46%), βLG (44%), OVA (42%), rye allergen (24%) and Fel d 1 (22%). Both an *intrauterine sensitization to foods* [193, 320, 332, 344, 423] *and aeroallergens* [193, 333, 344] was demonstrated, hence supporting the concept that fetal programming by the mother during the second and early third trimester of pregnancy results in FIS T-cell priming [102]. This shows that allergen exposure in the prenatal period can influence the fetal immune response, irrespective of maternal or paternal allergy or asthma [401]. Transplacental transfer has been demonstrated by numerous groups as the likely route of allergen transfer to the fetus, for example, the passage of OVA and bet v1 across the human placenta [424]. Over 11–24 weeks of gestation, HLA class II$^+$ cells, CD68$^+$ and CD40$^+$ cells were present throughout the lamina propria; few CD3-positive cells (T cells) were observed in fetal gut. With the emergence of lymphoid aggregates (14–16 weeks), CD83$^+$ (DCs) and CD20$^+$ cells (B cells) could also be detected (Figs. 2.13, 2.14) [194]. The recent observation of HDM and Fel d1 in amniotic fluid collected during amniocentesis at 16–17 weeks of gestation and in CB provides direct evidence that both transplacental and transamniotic routes of exposure can occur [168]. At 16–18 weeks, human amniotic fluid also contained intact IgE at levels that increased as maternal circulating levels increased, IgE that might bind to CD23$^+$ cells within the lymphoid follicles of the fetal gastrointestinal tract. However, circulating levels are very low, since there is no evidence of IgE production [436]. Prenatal exposure to HDM allergens was associated with total serum IgE at birth [401]. Using fractionation of CBMC CD45 isoforms, it was established that allergen-specific fetal Th cells can be sensitized *in utero* [102]. Expression of the CD45RO by T cells correlated with increased gestational age, indicating that fetal immune memory develops as gestation progresses, but supporting the idea of intrauterine antigen priming [196]. Consequently, the hypothesis that fetal T cells are exposed during gestation to maternally derived allergens is supported by a line of evidence [424]. Studies have demonstrated beyond controversy that CBMCs proliferative responses strongly correlated with an increased risk of subsequent childhood atopic disease development [282, 345, 473], especially when neonatal cells are stimulated with BSA [213]. Such occurrence should be taken into account when an anaphylactic reaction occurs at the first feeding of a given food. However, no sensitization to inhalant allergens *in utero* was found, but responses to tetanus toxoid in the absence of exposure, thus suggesting an additional mechanism of priming for these cells [405]. The anti-allergen lymphoproliferative responses of CB T cells are closely connected, with a peak response to OVA especially in infants aged 6–10 weeks, who in addition had 30% positive CB responses to HDM [171]. At present, these results do not differentiate between atopy-prone and non-atopy-prone children [423]. At 27 weeks gestation, the FIS is capable of IL_{13} secretion, and at birth in atopy-prone babies, but this production is defective [486]. Going back to the Th2/Th1 alternation during pregnancy (Chap. 2), this placental prevalence of Th2-like T-cell ILs may direct Th0-like FIS cells to the Th2 rather than to the Th1 phenotype; moreover, maternal exposure to allergens may prompt the development of fetal T-specific responses [473]. Recent findings suggest that the risk of AD was significantly elevated in children whose mothers had active asthma during pregnancy (RR 1.8) or AD during pregnancy (RR 1.70) [224]. Therefore, we can propose timing of these responses: as seen in Tables 2.4–2.6, the FIS is immunologically active before 16 weeks of gestation, as demonstrated by Jones et al [194]: CBIgE positive to foods (Table 3.2) appear to promote the outcome of an IgE-aspecific synthesis, perhaps due more to an absent suppression rather than to an allergenic stimulation. The above data show why the prospective and randomized studies on diet restrictions to mothers of children who are at risk for atopy during the last trimester of pregnancy had negative results. Several immunodeficiencies benefit from *in utero* transplantation and from *in utero* prenatal diagnosis (Chap. 22).

A study on a birth cohort of 24,690 children suggests that exposure to antibiotics *in utero* is associated with an increased risk of asthma in a dose-related manner (hazard ratio [HR] 1.68), and similar associations are present for AD (HR, 1.17), and AR (HR, 1.56) [276].

Postnatal Genetic Factors and Related Influence

A large body of evidence has accumulated suggesting that asthma and atopy run in families and that family factors play a crucial role (Fig. 4.9) [205]. Epidemiological studies and clinical observations have contributed to quantifying the risk, establishing that when FHA is *negative,* 5%–16% of children are affected by atopic disease, when FHA is *positive,* the percentage rises with the number of atopic first-degree relatives, increasing more when both parents have the same type of atopic disease (Table 4.9) [205]. With an atopic *father*, 33% of siblings may suffer from atopy, vs 45% if the *mother* is atopic. For asthma, the values are 25% and 40%, respectively [205]. The occurrence risk is 40%–45% when in a family two first-degree relatives are affected (one parent and one brother) [360]. FHA was the single most important predictor for atopy in 713 children, and a dual FHA doubled the risk for asthma and quadrupled the risk of rhinitis [433]. FHA is the most vigorous predictor of atopy, BHR and asthma, and this effect is extended until the age of 18 years [392]. A history of asthma in the mother poses a relative risk of 2.3, of 1.6 in the father [16]. In 1,123 MAS children with or without AD, FHA scores in ≥2 atopic family members and was present in 19.4%–36.2%, AD in 9.8%–27.5%, AR in 41.4%–53.7%, and asthma in 21.8%–31.2% of cases [183]. A classic study has demonstrated that 11 out of 13 (85%) children with double FHA were clinically allergic within 5 years vs 2 out of 28 (7%) of the "well-baby" controls [128]. Thus, siblings of asthmatic parents have a significant prevalence of atopic disease compared to those of nonasthmatic parents. The number of affected relatives is not negligible: differentiating CMA prevalence and based on genetic factors, depending on one or two or more first-degree relatives, values of 4.8%–24% are found in healthy, unselected infants and of 19%–54% in infants with CMA, with very significant differences between the two groups [386]. A further demonstration of the studies on genomic imprinting, particularly convincing, is maternal atopy: CB IgE levels are strictly correlated with maternal levels [243]. However, both maternal and paternal allergy increased the risk of an elevated total IgE at birth [202]. The sibling risk is modulated by total IgE positivity [505]. The children of atopic mothers have a higher risk [1, 392] of 26% if correlated with respiratory atopy vs 13% risk if the father is atopic [206], with an OR of 4.4 vs 1.5 (Table 4.10) [108]. Children having an atopic relative are more prone to having asthma, AR, or AD (OR, 2.54–3.81] [290]. The risk of a child being asthmatic was fourfold greater if either the mother or the father had asthma than if the child had been born to nonasthmatic parents [227]. Sibling atopy was a stronger predictor of clinical disease than maternal or paternal atopy [433]. Although some of these effects may be poorly defined, the risk of developing atopic disease is striking even if only one parent is affected, and increases when the disease is AR or AD (Table 4.11). The risk also varies in connection with the disease: children with parental AD have more than a double risk for AD

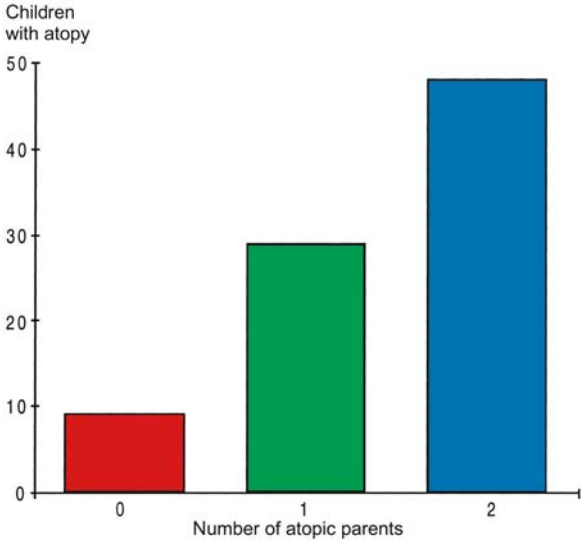

Fig. 4.9. Family history positive for atopy and risk of developing allergic disease. (Data from [205]). *0* No atopy, *1* No. of atopic fathers, *2* No. of atopic mothers

Table 4.9. Risk of developing allergic disease according to family history for atopy

Family history	Risk (%)
Both parents atopic	40–60
Both parents atopic with identical manifestations	50–80
One affected parent	20–40
One affected sibling	25–35
Negativity for atopy	5–16

Data from [205].

Table 4.10. Risk of developing allergic disease according to parental atopic diseases (odds ratio)

Child atopic disease	Asthma	Allergic rhinitis	Atopic dermatitis
Asthma	2.6, 1.5, 4.4	1	1
Allergic rhinitis	2.5	3.6, 4.1, 3	1.7
Atopic dermatitis	1.5	1.4	3.4, 3.9, 2.5

The presence of three figures indicates, in the order shown, the relationship with atopy of one parent (1), of the father (2), of the mother (3).
Data from [108].

Table 4.11. Risk of developing allergic disease according to parental atopic diseases (%)

Child atopic disease	Father (%)	Mother (%)
Asthma	15	13
	2.85 (1.8–4.49)*	2.67 (1.65–4.35)**
Atopic dermatitis	22	17
	2.42 (0.16–3.65)*	2.13 (1.35–3.35)**
Allergic rhinitis	33	49
	2.03 (0.16–2.74)*	2.17 (1.66–2.84)*

The first figures indicate prevalence, the second figures the relative risk and the confidence intervals.
Data from [1].
*$p<0.0001$, ** $p<0.02$.
According to our unpublished data, 289 atopic children had 163 (56.4%) atopic parents and/or brothers and sisters (in 90% of cases with respiratory allergy) vs 49 out of 300 (16.3%) nonasthmatic children ($p=0.0001$).

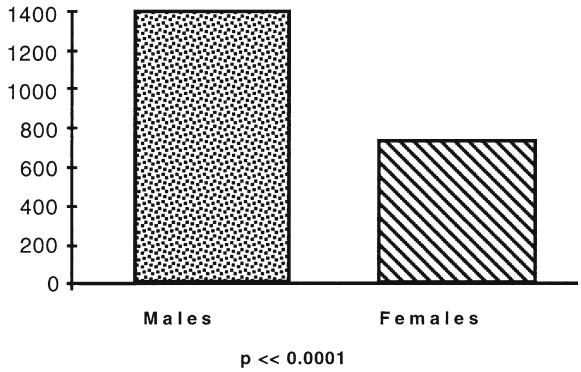

Fig. 4.10. Sex difference in 2,124 children studied

compared to children with parental asthma, while children with parental asthma have an even higher risk for asthma compared to children with parental AD [108]. To confirm the previous data, the statistical analysis reveals very significant differences, with the highest risk with FHA^+ in cases of biparental positivity ($p=0.0028$ vs uniparental, $p=0.0001$ vs double negativity), of atopy in the mother or in her family vs paternal atopy ($p=0.0001$) and of the same or another atopic disease in her son, but doubled if both parents are atopic ($p<0.001$) [3].

The data on 729 children and their parents (Table 4.11) [1] indicate a clear association between respiratory and cutaneous allergies in both parents and their children, again confirming the genetic and multifactorial origin of atopic disease. Two studies should be confirmed by subsequent literature, since they have underlined wholly original occurrences. In one study children have a higher prevalence of atopy, which is lower in children of the former East Germany [465]. In the other study, AD has a higher prevalence in firstborn offspring, unlike previous reports in asthmatic children [485]. In conclusion, on the one hand atopy predisposition is directly proportional to the degree and the number of affected relatives, on the other hand, 23% of children without any FHA also develop allergies [108], thus highlighting the role of environmental factors.

The role of IgE hyperproduction is another mainstay: asthma incidence is significantly more frequent at 12–54 months of age in the offspring of atopics with IgE ≈980–1500 UI/ml [200] and in 36% of 11-year-old children with IgE >1,000 UI/ml [390]. When comparing the total sum of sIgE to allergens, atopic children with current asthma had significantly higher sIgE levels than nonasthmatic atopic children ($p=0.0005$). Similarly, total IgE levels were significantly higher in atopic children with current asthma than in nonasthmatic atopic children ($p=0.018$) [184]. In clinical practice, the *high family concordance between type of disease and sensitization to specific allergens* is frequently observed: there are families in which all components are allergic to grass pollens and others in which all components are sensitized to *Parietaria* pollens; altogether there are families allergic to pets, confirming that immunocompetent cells are activated only by defined allergens [182].

The importance of *sex* has often been clarified: males are more at risk than females, with extremely significant statistical differences (Fig. 4.10) concordant with additional studies [16, 44, 146, 202, 206, 216, 221, 224, 290, 384, 390–392, 420, 432–434, 474, 487, 513, 514] and with total IgE and CBIgE levels (Table 3.7). This risk increases and in the respiratory allergy it may be occasioned by the reduced airway caliber in males, even though lung volume is greater (Chap. 11). This preference can also be explained by the genomic imprinting or the Carter effect [62]. Male children were significantly more likely to have doctor-diagnosed AD than females [224]. Boys with an allergic mother had a higher risk of sensitization at age 4 [202].

Similarly, *the age of symptom onset* (Tabe 5.5) *and the severity* of the clinical manifestations may be correlated with genetic controls: children with FHA^+ present with allergic symptoms more precociously than those with FHA^- [1, 3]. Moreover, DCs are very efficacious APCs [468] and very active in babies only a few months old affected with AD and FA, whereas they are activated in the lung later, as clinically confirmed by extensive experience and a study we have conducted [55], which evidence a lower age of onset for AD than for asthma. CMA onset may occur shortly after CM introduction with immediate reactions [267], and in infants aged <10 weeks T cells are able to respond with proliferative responses to Der p, *Lolium* and OVA [445]. As much as 29% of unselected infants followed from birth to the age of 18 months suffered from ≥2 episodes of asthma, in addition to responses to pet allergens [146]. The data agree with recent reports, stating that in the first few years of life, an active process occurs to recognize environmental allergens, even at levels low enough to elicit negative

SPTs, and the still immune system responds to the first encounter with an undifferentiated production of Th1 and Th2 without provoking sensitizations [28]. During subsequent encounters, the genetic predisposition induces either phenotype to prevail [169]. At 12 months in at-risk children, sIgE to aeroallergens are rare or barely detectable, as in children who later develop high sIgE concentrations to the same allergens [368]; negative SPTs and RAST to a group of aeroallergens at age 9 months turn positive at age 6 years [270].

As for BHR, the rate of Th2-like cells present in the respiratory mucosa of atopics with a specific pattern of responses to aeroallergens and an IL profile driving IgE synthesis is significantly greater than the rate found in nonatopics, hence an acceptable conclusion could likely be that specific Th2 cells appear in the mucosa soon after inhaling aeroallergens and that the Th2 IL-like cells start the allergic cascade of symptoms [98]. Regardless of the significant association between atopy and BPT (bronchial provocation test) to methacholine, BHR and asthma prevalence is greater in atopic children compared to controls [70]. Accordingly, adaption of homes for at-risk children should be planned even before birth, and in the first few months of life they should be fed following particular rules to prevent allergy or at least lessen its course.

Several authors comment that racial factors are strictly linked to genetic factors based on studies demonstrating that asthma prevalence is scarce in autochthonous populations (Chap. 5). However, it is known that African and Caucasian children show the same proclivity to express atopic disease [442].

Environmental Factors

Although molecular studies are in great fervor and may dispose of sophisticated equipment to analyze primary and tertiary structures, it is not yet possible to characterize the physicochemical properties of the molecules participating in allergen–antibody reactions, whereas atopic diseases have a clear distinctive character in children never to be found at subsequent ages. The immune system bewares of especially environmental allergens: the sensitization breakthrough and amplification and the commutation from a genetic predisposition to a true atopic state may be endorsed by a wide spectrum of factors. Association between FHA^+ and IL production at age 9 months and not in the CB suggests that to be loaded, genetic factors need exposure to environmental factors [270]. Indeed, several of them may be committed to the phenotypic expression of atopy, either emphasizing risk, or directly prompting symptom onset, respiratory if triggered by aeroallergens, cutaneous and/or digestive by food allergens. However, clinical manifestations of the respiratory system or of other systems are frequent, provoked by food ingestion or even inhalation when foods are diffused in the environment.

On this matter, the effects of the 1973 energy crisis cannot be underrated, with homes designed to minimize heating costs, fitted with insulating materials, and especially in Nordic countries with double-glazed windows and central heating, resulting in restricted air exchanges between outdoor and indoor environments. Air exchanges in these houses are therefore reduced compared to older houses, sometimes to minimal levels, with an increase in dampness and indoor mold growth because of the tightly sealed building, leading to warm humid habitats for HDMs and a consequent increase in prevalence in infantile sensitization. Appliances with a water reservoir such as humidifiers and vaporizers are a potential reservoir for mold growth as well. In 4,990 children living in homes with dampness problems, all with smoking parents, there was a detectable increase in AR and allergic asthma compared with children not exposed to these risk factors, but also in comparison with children exposed to only one factor. The risk was higher in children with a positive FHA, in whom 22 % had manifest asthma if exposed to both risk factors [7].

Month of Birth

Early infancy seems to be a period of particular susceptibility to sensitization, as indicated by epidemiological and experimental studies. For example, the season of birth may affect the future expression of allergy, particularly in children with a propensity to atopic manifestations. The physiological immaturity of the mucosal barrier has a pivotal influence on subsequent atopy development: several studies have agreed that the month of birth may condition the type of sensitization to pollens or HDM early. Table 4.12 [2, 49, 87, 199, 303, 369, 383, 392, 421, 475] includes 27,536 subjects in 29 different studies, with a convergence of sensitization to grasses of 83.5 % and to Der p of 98.4 %, with highly significant differences (p=0.0001). Our study [49] consisted of 2,124 children and of a control group including all the children born in the same years and the same district of the entrants, born throughout all seasons. We have demonstrated that children born in September and October and in spring express a significantly greater prevalence of allergy related to inhalant Der p and pollens, respectively (in both cases p<0.0001) (Figs. 4.11, 4.12) [49]. To explain the apparent discrepancy of certain studies, a Der p-negative result may depend on taking into account a great number of months (from May to December); others have found differences in winter months for pet danders [303]. The majority of pollen studies are positive, with wide differences, while a prevalence in winter months in English adults may depend on a diagnosis that was only clinical [49]. There is a concordance with CB T-cell proliferation: the neonates studied in the months between May and November show a response positive to Lol p 1, unlike those examined in the subsequent period [333]. A Finnish study

reported that if all neonate entrants were born in July and August, that is, within the season with a more reduced risk (25%) they had later development of allergic manifestations as children and young adults: the confirmation was after the 17-year follow-up [372]. It is therefore tempting to believe that there is of relationship between month of birth and specificity of the allergic sensitization, triggered by minimal doses of allergens.

Geographic and/or Racial Factors

Migration from industrializing to industrialized countries has been identified as an asthma risk factor in black children born in the UK of immigrants, more than in indigenous white children, whereas black children born in West Africa and the West Indies moving to the UK also had a low prevalence of associated atopic diseases, which was credited to a lower allergen bombardment in their home countries [442]. Similarly, Pacific islanders moving to New Zealand had a much higher prevalence than that of their countrymen who remained at home [442]. Another study has shown that the origin of such differences was not geographic, but depends on the age at which the family emigrated: if after the 1st year after birth, the prevalence is related to that of the original population, if before birth, it is related to that of the community where the family now resides [442]. Therefore, we conclude that asthma prevalence is more likely to be influenced by environmental than by racial and genetic factors. Allergy to Der p 1 is likely caused by the introduction of a Western lifestyle to rural peoples, by recent acquisition of mattresses instead of well-aired mats that are not infested by HDMs [442], which prefer the seldom washed cotton blankets encasing the person completely during sleep, and therefore harbor armies of HDMs [443]. This could explain the 70-fold increased asthma prevalence in the adult population over the last decades [442]. For example, a dramatic increase in bronchial asthma has been reported in Kuwait since the mid-1950s, which seems to be attributable to the importation of *Prosopis* trees [117]. The nearly absolute absence of Der p in dry areas such as Tucson, Arizona can be connected with geographic factors [491]. Overall, the data indicate that in "virgin" populations, as well in early in life, an increased exposure to Der p is followed by an increased asthma prevalence.

Residential Influences

Residence in an urban environment constitutes a greater risk of atopy than county life (p=0.000): an OR risk is related to pollens, cat danders, damp and unusu-

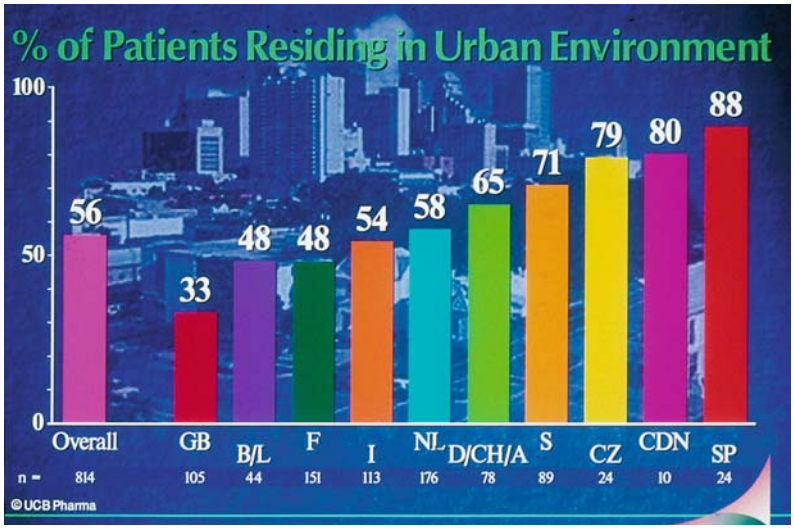

Fig. 4.13. ETAC Study: approximately 56% of children reside in an urban environment, the highest frequency is in Spain (88%), the lowest in Great Britain (33%)

al odors (p=0.03) [42]. A mean of 56% of the ETAC study children live in a city (Fig. 4.13). It is likely that this is the effect of a greater concentration of environmental pollutants in the city compared to the country [40, 42, 43], which could also combine with an increased risk of expressing AD [384]. In the population of Swedish children with asthma (3%–9.5%) 17.8%–71.5% have cats at home, and 36%–66.3% of asthmatic Polish children have dogs, in either country or urban homes [43]. In atopic children aged >2 years, additional, highly significant associations are found between condensation on window panes, either isolated or associated with smoke, and early exposure to dampness and an increase in allergic asthma and BHR [482], which along with favorable temperature (T) facilitate Der p propagation into houses. Other studies have reported no valuable differences on dogs, horses, Der p and tobacco smoke [42], but on the great frequency of furred pets (47%), caged birds (20%) and aquarium fish (23%) [7]. Children living in rural zones and in a damp house with parents who smoke show the greatest frequency of asthma (8.7%) and BHR (19%), both with a RR (relative risk) of 1.3; the damage due to dampness was significantly associated with increased occurrence of asthma, AR, prolonged cough after airway infections, and exercise, more severely in children with FHA^+, thus establishing a significant correlation between dampness and atopic disease [7]. Dampness and molds in the baby's bedroom amplify the risk of allergic asthma [68]. Therefore, it is unclear whether the increased asthma prevalence reflects a direct influence of indoor and outdoor pollutants on airways or an incremented allergic response to aeroallergens due to increasing pollution, of which an adjuvant effect has been supposed [28]. Asthma prevalence increased despite the low local rate of pollution, which was lower in a highly polluted city compared to other less polluted places [43].

Early Exposure to Environmental Hazards

Allergic manifestations develop more easily in children exposed in the first few years of life to an elevated allergenic load [171], thus demonstrating that the prevalent environment during the early formative period is fundamental in predisposing or not to sensitization and to persistent Th2 reactivity, taking into account the precocity and intensity of the exposure. To understand how "sterile" neonates can be sensitized to environmental allergens, foods or inhalants, profound modifications following the exposure to a myriad completely novel substances may overturn routine practices established previously [171]. As noted above, a different procedure regulating the sensitization to foods and inhalants, as well as inhalant sensitization, is carried out more precociously to the perennial allergens HDM and animal epithelia (danders, hairs, feathers) than seasonal allergens, and among these, firstly to allergens with extended or continuous diffusion (grasses, *Parietaria*) and then to allergens with short and circumscribed pollination (*Compositae*, trees). Der p asthma arises at a much earlier onset age than asthma to pollens (p<0.0001) (Fig. 4.14), as demonstrated by high levels of anti-Der p IgG_1 antibody at 3–12 months [370] and an age of ≈3.8 years in Der p-exposed children admitted to hospital with asthma exacerbations [411]. However, during early childhood, even a low-level HDM exposure stimulates T-cell responses [29], which are ultimately shaped by an allergen-driven T-cell selection process during infancy and early childhood [169]. In keeping with this, doctor-diagnosed AR is present during the 1st year after birth [491]. Therefore, a static equation is that not only food but also inhalant sensitization may occur in early life [405]. Der p, Fel d 1 and mold allergens are proteolytic enzymes able to clear a way directly through the bronchial epithelium, deceiving the normal defense barriers: the airway penetration is facilitated by concomi-

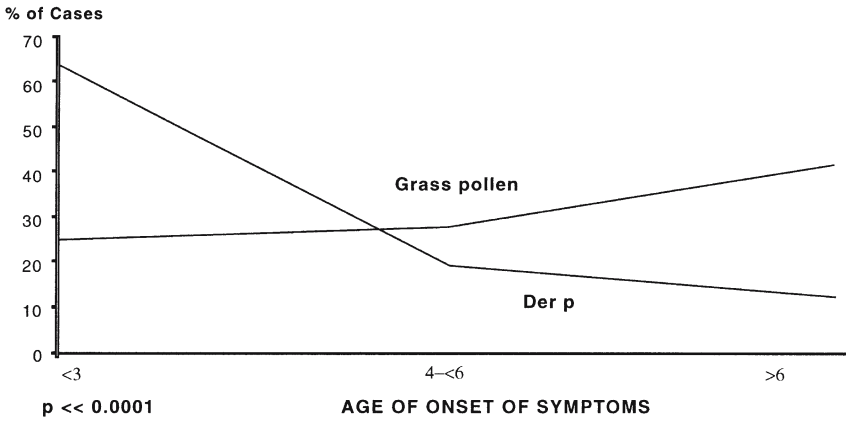

Fig. 4.14. Age of onset of symptoms and type of sensitization in 1,685 children sensitized to Der p and in 439 sensitized to grass pollen

tant viral respiratory infection (VRI), passive inhalation of environmental tobacco smoke (ETS) and pollution exposure. As previously alluded to, another area of increasing interest is the different compositions of the gut flora between infants who will and infants who will not develop allergy, which may be demonstrated before the development of any clinical manifestations of atopy. In comparison with healthy infants, babies who developed allergy had lower bacteria counts during their 1st month to 1st year of life. If the gut microflora drives the maturation of the immune system, negative changes affecting its composition might play a role in the higher prevalence of allergy [30].

Aeroallergens

The *allergen levels* of some inhalants are as follows (g/dust). Der p and Bla g 2, 2 µg; Fel d 1.8 µg. In 4-year-old entrants, the sensitivity to inhalants was significantly associated with FHA^+ [434]. A study on 1812 children living in Munich, 2242 in Dresden and 1222 in Leipzig has shown that the rates of atopic sensitization to inhalants were always *higher in the children aged 9–11* compared with those aged 5–7, with higher figures in children aged 9–11 from Dresden and Leipzig compared with those from Munich. There were no significant differences in the prevalence of SPT reactivity to at least one allergen, and increased sIgE against inhalant allergens between Dresden and Munich. Yet, despite the higher sensitization against cat (see below), tree pollen and HDMs, the prevalence of asthma and BHR in 9–11-year-olds was lower in Dresden than in Munich [476]. As noted by previous investigators, infantile asthma is evoked by aeroallergen allergy, with differences in the clinical manifestations depending on the causal agent: in Der p 1-sensitized children, either asthma or PAR symptoms exacerbate in autumn and often also in spring, whereas in children with pollen sensitization, the symptoms appear typically in the seasonal period of pollination. However, due to the intervention of other triggering factors, the pattern may extend clinical manifestations. In addition, inhalant allergens produce skin lesions by contact and by blood penetration after having been absorbed by the respiratory mucosa and thus through the skin mast cell cycle (Chap. 7). The pollens cross-reacting with foods (Chap. 9) induce symptom worsening in children allergic to the related food during pollination; cases of anaphylaxis after consuming a food containing an inhalant have been recorded (Chap. 24) (see Table 5.18 with the related prevalences).

Mites

Reportedly, Aristotle was the first to observe mites (Fig. 1.80) (350 BC) in some cheeses, but only in the seventeenth century did the first microscopic study appear, credited to van Leeuwenhoeck (1632–1723), followed by Ramazzini in 1713, who also described "farmer lung disease." The first report that mites may be the cause of respiratory problems in humans dates back to Ancona [6], who described cases of asthma driven by *Pediculoides* (now *Pyemotes*) *ventricosus*. We have therefore known the decisive role played by aeroallergens in the sensitization process for 80 years. Although in the 1920s, arguments were put forward about house dust, relating pillows, mats, chairs and bed quilts to AR and asthma onset [416] and anti-mite environmental measures were recommended [97], several decades passed before the relationship between *Dermatophagoides* and what, for lack of a better term, was defined as "dust allergy" was recognized. The scientific basis of allergy received a major boost when Voorhorst documented the source of *Dermatophagoides* allergens with clinical and histological observations reported in a classic paper [466]. His discovery, which was revolutionary at the time, was later confirmed by several reports, the number of which had grown exponentially.

The genus *Dermatophagoides*, species *pteronyssinus* (Der p) (11 allergens), *farinae* (Der f, 13 allergens) (Table 1.74) belongs to the Pyroglyphidae family, such as mites (*Acarus* genus, *Arachnida* class). Cross-reactions are between Der p 1 and Der f 1 and between

Der p 2 and Der f 2; Der p 1 has 85% homology with Eur m 1. Der p 1 and Der f 1 have a sequence homology of 80%. As detailed in Chap. 1, tropomyosin is shared by Der f 10, Der p 10 with Met e 1 and Pen a 1 and with Tod p 1, Lep d 10 and Ani s 2. Mites (Fig. 1.80) have four pairs of articulated legs (and are distinct from insects, which have three pairs), easily discernible buccal appendices and a striated cuticle, the average length of the life cycle is 122.8±14.5 days at 16 °C. The females depend on environmental conditions: within their life span they may produce 2–3 eggs/day during ≈26- and 34-day reproductive periods [336], from which active six-legged larvae appear within the first 5 days, they are then transformed into eight-legged protonymphs for a short time of about 2 days. After about 2 more days, they change into tritonymphs. After about 8 more days, quite mature mites emerge. Male Der p measures about 250 µm and females about 350 µm, with a mean weight of 3.11 µg [336]. Coprophagic HDM *feed* principally *on products of skin desquamation,* so *their ecological niche is concentrated inside, around and under the bed,* because humans enwrapped in bedding lose a host of dead skin cells, a mean of 0.5–1 g of dust/day, which attracts large armies of mite allergens, and may feed several thousands of them for 3 months. Der p levels increase during sleep 10-fold more than in everyday life and 1,000-fold while making the bed [375]. Because indoor humidity is the key factor for Der p growth and development, indoor T is about 20 °C and human body heat brings this T to 25±3 °C in mattresses. Relative humidity exuded from the human body (transpiration) may favor mite development [322]. Recent studies have observed that mites survive at relative humidity of 45%–55% at 15 °C and of 55%–65% at 25 °C, and thrive better at 25 °C and 75%–80% relative humidity, correlated with the maximal number of Der p 1 in mattress dust and on the floor under the bed. The preferred T is 25 °C, but HDMs survive at higher T: at a T of 45 °C HDMs survive 24 h, at 50 °C 4 h and at 60 °C only 1 h; at low T mites become inactive, but can survive at –1 °C for 3 weeks, and at –25 °C are dead after 6 h. Der p 2 are more thermoresistant [322]. Consequently, in temperate dwellings, mites fail to proliferate when indoor relative humidity is <50% and T of 20–22 °C. However, mites also resist sharp variations of such parameters via the regulation of water exchanges made by transpiration through their cuticle; if local humidity falls, HDMs take shelter in the niches offering the perfect habitat, that is 2 mm over the floor [337].

During its life cycle, Der p excretes fecal pellets ≈300-fold its weight, so ≈1,000 each containing 100 pg of Der p 1, particles with a chitinous peritrophic membrane ranging from 10 to 40 µm in diameter, reduced in young mites. In the form of fecal pellets, mites become airborne but fall within 10 min in still air, thus accumulating in house dust with an estimated number of 100,000/g [337]. The particles are surrounded by a viscous substance by which pellets adhere to textile fibers, which are unlikely to be removed by using common cleansing procedures. They are instead split by mechanical action such as walking on carpets and are decomposed when the viscous particle is attacked by molds. When the flat begins to be warmed up, the pellets are dried and pulverized, thus acquiring a diameter equal to that of pollen grains. Unwaxed chitin is not waterproof and allergens elute from fecal particles very rapidly [260]. Mite feces containing Der p allergens have the ideal measures to be airborne and inhaled whenever their support is lifted and shaken. Thus allergens increase in the air during activities that disturb dust, using a vacuum cleaner not provided with the proper microfilter, for example. The particles seen through a light ray contain dead mites and their feces, the most frequent cause of respiratory symptoms. A relatively small number of particles are inhaled per day; however, children who become allergic to HDM in their homes have an increased risk of asthma and continued exposure contributes to morbidity [336].

Much has been learned about Der p 1 noxiousness as resulted from immunohistochemical studies leading in atopic subjects to the isolation of cell lines or Der p 1-specific T-cell clones, demonstrating an in vitro IgE allergen-dependent production driven by IL_4. The association of responses between T cells and HLA-DRB3 (DRw52), and to a lesser degree DRB1, points out that since *DRw52* is in a position of linkage disequilibrium with other HLA alleles, such specific restrictions are expressed in about 40% of the general population. Mite-sensitive childhood asthma is on chromosomes 4q35, 5q31-q33 and 13q11 [501]. Being on an IL cluster (Fig. 4.6) enhances its allergenicity [10]. This impairs proliferation and IFN-ɣ secretion of Th1 T cells, favoring Th2 development, and finally enhancing total IgE production [139], thus clarifying why the prevalence of mite sensitization in humans is so high. While initial studies were focussed on Der p 1, a new chapter was opened up after finding that anti-Der p 2 IgE are present in 40%–88% of patients, with peaks of 92%, leaving in the background both Der p 1 (78%) and Der p 3 (16%); 89% of mite reactivity was to Der p 2 in 9-year-old children (mean) [308]. In HR infants a larger prenatal exposure to HDM allergens was associated with the presence of elevated total serum IgE at day 3–5 after birth [401]. Platts-Mills and his co-workers [336, 337] have convincingly proven *that Der p 1 is one of the principal and more diffused etiologic agents of infantile bronchial asthma.* Therefore, some problems of mite-sensitive asthmatic children can be brilliantly downgraded by providing a substantially dust-free bedroom with a proper degree of humidity [375]. The weight of interventions for allergen avoidance is highlighted by infant conditions: they spend 80% of their time at home (adults spend a mean of 33% of their time) [27], and Der p 1 levels are higher at night [375]. Mites and their feces are preferentially recovered in overcrowded residences and whenever dust is collected and relative humidity rises, in addition to bedding where there is the greatest mite sampling:

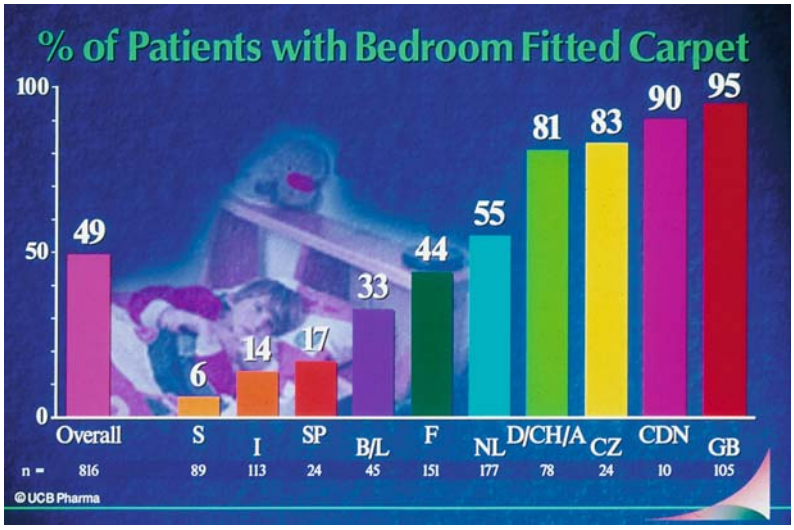

Fig. 4.15. ETAC Study: on average 49% of children have fitted carpets in their bedroom, the highest frequency is in the Czech Republic (95%), the lowest in Sweden (6%)

mattresses, pillows, curtains, carpets, upholstery fabrics, draperies, etc. [222], but also in upholstered seats of public places, in 9% of patients in homes with MDM levels >10 µg/g [88]. Rugs and wall-to-wall carpeting are found in 49% of infant bedrooms (ETAC study) (Fig. 4.15) (see Chap. 24).

When mites die, they disintegrate into a thin dust, which is inhaled by neonates and infants more easily than intact mites [293], a finding related to the greater prevalence of Der p 1 allergy in children born in autumn [49] (Table 4.12). Der p 1 proliferates in summer with a peak in July, declining gradually until October and dying in winter; the Der f 1 peak is in August, with two minor peaks in April and October [244]. The Der p 1 year cycle, as demonstrated graphically by an interesting study, is marked by asthma recrudescence, maximal from the end of summer and the beginning of autumn and minimal in spring, from March to May [449], in parallel with the greater medication requirement in September and October [204], the number of peripheral eosinophils, the response threshold to histamine and the connection between mite levels, humidity rate and BHR variations [449]. In evaluating the impact of Der p 1 and 2 sensitization, SPTs were positive in 33.3% of subjects with no allergic symptoms and/or asthma [460], correlating SPTs to dust samples collected from mattresses. The patients with no treatment had the lowest mite value at home, whereas patients with frequent asthma attacks and daily treatment had the highest values [460]. However, the mite number cannot be related to asthma exacerbations [221], even when exposure is greatest [204].

The values of 10 µg for maximal level equivalent to 500 mites and of 2 µg for the lowest level equivalent to 100 mites can be considered as the threshold [230, 325, 336] for sensitization of genetically predisposed school-aged children and consequent allergic symptoms [221]. The level of 2 µg corresponds to an increased risk of sensitization and BHR, a critical limit for subjects with other sensitizations [221]. In 92 atopic children with sIgE to HDM, mite concentrations above 2 µg/g dust were found on their bedroom floors [357]. In a prospective study on 68 children, exposure to high levels of allergen at age 1 increased the risk of asthma at age 11 and was related to an early asthma onset [409]. Studies on children admitted to hospital showed that as many as 80% were both sensitized and exposed to high levels of allergen at home [336]. A level of 10 µg increases the risk of symptomatic or acute asthma, which increases when mite concentrations run to 1,500 mites/g of dust; in borderline cases concentrations rise to 5,000–6,000 mites/g of dust [336]. High levels of Der p 1 are 10 µg (maximal level); 2 µg (lowest level/g of dust) and expression of clinical manifestations are strongly correlated [337]. In atopic children, the sensitization grows in parallel with exposure to Der p 1 [230, 232]. Worldwide and in the US, the highest mite prevalences in homes are of Der p and Der f. Eur m may also be prevalent in some temperate geographic areas, and at times, their density may even exceed that of Der p and Der f. Blo t is a cardinal source of allergen in homes in the subtropics and tropics, thus confirming the wide Der p diffusion. More or less similar are the concentrations in Great Britain [409], Sweden [293], the US [51, 337] and in schools [115]. Confirmation comes from other pediatric studies done in Brazil [13], France [460], Germany [230, 232], Japan [376], Great Britain [411] and New Zealand [390] on the association of asthma with exposure to >2 mg of Der p 1/g of dust. Very enlightening is the study on 68 children whose parents were affected with asthma or AR. The children were followed up for 11 years: at this date, 52% were atopic and 94% with active asthma had SPTs positive to Der p 1. No child exposed to <2 µg/g of dust was sensitized in the 1st years of life, whereas the children exposed to >10 µg/g of dust had a fourfold risk of asthma. Over the 11 years, 3 of 68 children were admitted to hospital and each of them was allergic to mites and had been exposed to >30 µg Der p 1/g of dust at age 1 year

[409]. It was also found that Der p 1 levels of >5 µg/g of dust in infancy predicted positive SPT results and high IgG levels to Der p by the 5th year of life [368]. The *growing exposure to* mites and other home allergens may critically contribute to the general increase in both morbidity and mortality associated with asthma. Thus, the age of the first wheezing was inversely correlated to the level of exposure at age 1 year [409], demonstrating that 65% of children hospitalized for asthma had been exposed to Der p 1 at a level >10 µg/g of dust [411]. The sensitization to Der p 1, cats and molds is a significant risk factor for asthma expression, with a cumulative risk between 2 and 14 [389]. Such sensitizations arise more frequently in the 1st 18 months [230], even *in infants aged 11 months* [156]. Recently, levels of household HDM allergen at age 6 months were associated with HDM sIgE at age 7 years, but failed to find a relationship with asthma. In our opinion the levels were too low (0.2 µg/g) [232], and justify the failure to find the expected association.

Der p 1 allergen predominates in houses throughout the year [113, 337], with no differences between houses of asthmatics, neighbors and controls [323], and is often associated with cockroach exposure [337], with the lowest levels (<5 ng/m^3) in school [113]. As yet, the number of mites thriving within domestic walls is *much greater than what is commonly reported* in 86% of dwellings and in 25% of those *with neonates* [24]. Der p levels of ≥2 µg/g of dust were found in 55% of cases and levels of 10 µg/g of dust were more frequent in floor dust than in carpets [94]. However, employing more sensitive tests to measure mite numbers, a Der p/g of dust value >1 µg should be considered at risk [337]. At a cut-off of 1–0.5 µg Der p/g of dust, significant differences between atopic children sensitized and not sensitized to Der p 1 were found [346], but the enigma remained unsolved by measuring concentrations per m^2, which was not analogous to results expressed in g/dust [455]. In Tokyo, Sao Paulo and Sydney, mite levels were found of *>10 µg,* reaching even 35.1 [376], *38.4 to 51 µg/g* of dust [260], respectively. It is conceivable that current paradigms have been revolutionized: it is clear above all that only in 22.8% of dwellings of asthmatic children were mite levels ≥2 µg/g; in 51.4% they were between 2 and 10 µg/g, in the remainder 25.7% they were *between 10 and 100 µg/g* and in about the half *between 50 and 100 µg/g* [51]. Der p 1 air levels were between 18 and 89.6 pg/m^2 and Der p 2 from 5.1 to 24.5 pg/m^2 [376]. New aspects of severity come from the discovery that Der f 10 is a tropomyosin highly correlated with sIgE, thus a relevant allergen of the Der family, and that Eur m has 85% homology with Der p 1. We emphasize that mites do not thrive at <1,000–1,500 m only, as was previously believed [461], but flourish even at about 6,000 m, independently of T and of relative humidity, with levels ≫2 µg .

Recently, HD endotoxin (HDE) has been investigated. Exposure to HDE is associated with wheezing in the 1st year of life among infants with a familial predisposition to asthma and allergies [319]. A recent report showed that homes of allergen-sensitized infants had significantly lower levels of HDE compared with homes of nonsensitized infants. Moreover, HDE concentrations correlated with increased proportions of IFN-ɣ-producing CD4 T cells [137] (see also Chap. 24).

Pollens

Pollens (Figs. 1.68–1.73), another well-known cause of atopy, are the male gametophytes of seed plants: a truly impressive number of pollens via aerial transport reach a recipient flower (reproductive destination) to affect fertilization when an ovary is encountered (*anemophilous* pollination). In the *entomophilous* mechanism, the pollination is mediated by specific vectors, most often insects, and pollen allergy in this case occurs only by direct contact with the pollen source (in farmers, florists, etc.) [406]. Flowering plants with anemophilous, wind-borne pollination discharge large numbers of light-weight, buoyant pollens which, due to their small diameter (15–60 µm), can be transported and remain in the air over long periods. One m^3 of grasses produces 1.5×10^9 pollens/year (=1.5 mg of Phl p 5), which during the blooming period pour into the air a maximal amount of 219–250 m^3/day and are dispersed over a distance of several km by wind currents, with the goal of spreading as widely as possible, including on the airway mucosa of the persons nearby, thus accomplishing an outstanding allergenic activity [408]. Few plants with entomophilous pollination and some types of flowers have proven allergenicity: the pollens of most trees, for example, conifers (pine, cedars, etc.), rarely acquire a cardinal role from the allergenic point of view. Several factors foster both pollen diffusion and concentration: season, climate, local flora, 25–30°C T, 60%–90% relative humidity, 5- to 15-km/h wind speed, and rain. The amount of pollen in the air rises on windy and/or sunny days compared to cool and rainy days, is greater in plains, valleys and in the country compared to mountain areas, on the coast and in urban areas [406]. However, starch granules are detected in the atmosphere even on sunny days without rainfall [209]. The pollen effect is manifest in the following cases:

- Allergenicity able to sensitize predisposed or atopic subjects.
- Anemophilous pollination.
- Emission of large amounts of pollen.
- Wind-transport over wide areas.
- Wide territorial distribution of the producing plant.

Respiratory symptoms are provoked by starch micron particles constituting pollen granules. These have a breathable size (<3 µm in diameter) and may therefore penetrate into the lower airways of the respiratory tree, triggering asthmatic symptoms in sensitized patients [209]. The starch granules, copious in air samples taken

during the pollen season, have a highly significant 50-fold increase/m^3 of air on days following significant rainfall [209]. Rain accompanied by atmospheric T inversions tends to concentrate particles close to the ground, thus rupturing the granules by osmotic shock, each of which releases into the environment about ≈700 1- to 2-µm starch granules with allergens ready to enter the damp mucosal environment and to elicit IgE-mediated responses in the lower airways [422]. Consequently, asthmatic patients, generally city dwellers, crowd the emergency departments during thunderstorms inducing air turbulence, or shortly afterwards [209]. When rain is followed by sunny days, the alert decreases due to a rapid water evaporation; thus both spore production and vitality subdue. However, active atmospheric mixing carries pollens aloft, hence diluting levels to which patients are exposed near the ground. During flowering, 10–100 ng of pollen are inhaled daily, so 1 µg is inhaled yearly [110].

Several peculiarities of pollens are well known, but the dose-response rate remains open to conjecture. The priming effect and the minimal amount necessary to trigger asthma attacks are typical (Chap. 12). The allergen load has a greater effect on sIgE development rather than on IgE, skin reactivity and clinical manifestations. Grasses, *P. officinalis and P. judaica, Compositae (Par j),* etc., cause respiratory allergy, so that pollen exposure in the first 4–6 months of life [53], or shortly before the season [372], promotes the sensitization. Single species of anemophilous trees, among which birch and horse chestnut (*Aesculus hippocastanum*), usually shed pollen briefly in given localities, producing symptoms in 5.1% of town children [341]. Finally, pollen grains under humid conditions secrete significant amounts of eicosanoid-like substances able to recruit neutrophils and activate eosinophils. This process of *allergy initiation* precedes the allergen–APC interaction and may be the first step in the process of atopic sensitization [359]. Recent findings suggest that grass pollen sensitivity in childhood is accompanied by a progressive accumulation of allergen-primed T cells and progressive deviation of the allergen-induced IL response toward a Th2 response in atopic subjects throughout childhood [404].

Pollen growth is *accelerated everywhere by ozone depletion*. The resulting increased pollution leads to hyperproduction of carbon dioxide (CO_2), which is associated with pollen overgrowth. For example, ragweed sensitization has actually doubled its pollen production over the last 10 years, not due to an incidence upsurge, but due to the pollen overgrowth [341].

Fungi

Fungi (Figs. 1.77–1.79), also called molds, have long known associations with human disease. Their diffusion into homes is facilitated by the previously alluded to energy crisis, resulting in poorly ventilated interiors: air, T and humidity reduction is optimal for fungal spore proliferation [406].

Two major types of fungi are observed [53]:

- *Fungi outdoors* become more prevalent in summer in temperate areas, but also in the months of May and June as weather becomes warmer (T about 20–30°C). Rain and relative humidity (75%–95%) increase the recovery of anemophilous spores. Air currents, as in the case of pollens, may transport the spores even hundreds of km from their source; they spread copiously during dry weather subsequent to rainy days especially when humidity rises. A high atmospheric load of fungi often takes place once snow covers the ground or the ground is frozen, because devitalized vegetables represent a favorable culture medium for saprophyte mold growth.
- *Fungi indoors* dominate samples taken throughout the year in ordinarily ventilated interiors. We emphasize that indoor, humid places can be frequent sources of allergy, from 33% to 86% of cases [54].

Fungi may also behave as *parasites:* various yeasts are employed in the preparation of wine, milk, baked foods and some cheeses. Parasites are veritably facultative when they grow on living plants or plant foods, which are used after the decay of parasite organisms, thus closing the circle because they turn again to saprophytes [406]. However, yeast-sensitive children should follow a more or less restricted diet (Chap. 24).

The best-known fungi belong to the *Deuteromyces* group (fungi imperfecti), and their recovery is dominated by spores of *Alternaria alternata* (*Alt a*), 9 allergens (cigar-shaped, 18 µm long, 5 µm in diameter) and *Cladosporium* (*Cla h*) species, seven allergens, both belonging to *Hyphomycete* class and the *Hyphomycetal* order and grow on leaf surfaces. *Asp f* (*Aspergillus fumigatus*): 19 allergens are implicated in children with allergic bronchopulmonary aspergillosis or chronic granulomatous disease (Chaps. 11 and 22). Alt a 1 allergen is correlated with the onset of symptoms in sensitive patients [207]. Allergic sensitization with SPT reactivity and clinical signs of sensitivity to inhaled fungal spores is generally not correlated with the seasonal patterns of presence of the spore molds in the atmosphere [91]. Both *Alt a 1* and *Cla h* frequently trigger asthma, with 100–3,000 spores/m^3 of air risk levels, respectively. *Alt a* is the *third most common cause of sensitization* after Der p and grass pollens at 4 years of age [434]. Fungi sensitization may be low, although in the atmosphere and in confined settings they are in concentrations remarkably higher than that of pollens (1,000:1 for *Cla h*): evaluation of mold allergy is difficult because of their poor propensity to release allergens when close to the respiratory mucosa [91]. The spores achieve their highest levels mostly in very moist and slightly windy weather and are recovered on the skin and airway mucosa. Measuring less than pollens (*Penicillium* <5 µm), this exposure to fungal spores can adversely affect the daily respiratory status of some asthmatics [91]. Such exposure to the

spores can be aggravated because *Alt a* can release mycelia more rapidly than other molds, potent allergens that worsen respiratory symptoms in allergic patients more than the spores [54]. The spores also provoke AR, but are encountered in the lowest airways where the ciliary function does not operate, so that spore clearance from respiratory mucosa requires a rather long period [91]. Eating mold-containing foods may provoke allergic (Chap. 24) or toxic reactions, especially if aflatoxins are involved [362].

SPT positivity to molds in 5.5% of children with asthma and in 19.5% of those with AR points to molds as critical indoor allergens [85]. *Alt a* spores are diffused according to the geographic position, the season, the prevalent atmospheric conditions, the time of the day and in all seasons of the year, but above all in summer [326]. The spores are more prominent in internal regions with a dry climate than in humid and warm sea resorts (15.2% vs 4%, $p<0.001$), while sensitizations depend on the exposure duration in addition to place of residence, thus representing a very potent allergen [326], also liberating spores and mycelia. A dry climate favors spore detachment and the consequent potential to trigger sensitization [53] *Alt a* may be associated with *Cla h* in 14.3% of dwellings [434]. Clinically, multiple sensitizations to *Alt a* are harmful, as highlighted by 6.4%–17.7% of children presenting with SPT positive for *Alt a* (mean, 13%) [85, 346], which we have found in 15.5% of 6,040 children [53]. Further, in the three studies, only 0.2%–2% of children were monosensitized (mean, 1.3%), a discrepancy of 4.8% (2.1% to *Cla h*) [434], and the significantly reduced monopositivity we observed was also related to the extracts in use (1.3%) [53]. The children aged 9–11 had SPTs + for *A. tenuis* in 0.3%–1.4% of cases [476]. With respect to the diagnosis and concordance between SPT and RAST, SPT positivity included all cases, RAST positivity only 63% [53]; no correlation between the two methods was noted [55]. In subjects suffering from asthma and perennial AR, often very severe and difficult to treat, a sensitization to molds should always be suspected and readily identified in the indoor setting, owing to a substantial association with asthma severity, hospital admissions, AD and FA [53]. In young adults, mold sensitization (and sensitization to Der p 1) implies an elevated BHR risk, reduced by half in patients sensitized to pollen and pet allergens [81].

Pets

The relative allergens are much more diffused compared to Der p 1 allergens: Fel d 1 and Can f 1 air levels are 160- and 110-fold higher than Der p 1, on the ground they are 59- and tenfold higher, respectively, in the homes of at-risk children [293]. The progression of cat allergy is proved by the high proportion (≈20%) of babies aged <2 years with positive RAST to Fel d 1 [111] and the association of the early Fel d 1 exposure with high antibody titers (RAST ≥1) in ETAC babies followed up for 36 months, 36% of whom had a pet at home [474]. Both families and children try to minimize and even resist recognizing pet-related symptoms, fearing that the beloved animal will be banished from the home. It was not a surprise to find that 70 French subjects who were advised to remove the cat became asthmatic before age 20: only 11% of them accepted, 39% preferred to take the pet, but 50% who first accepted cat avoidance *bought another cat* before the age of 20 [100]. Cat hair is much more sensitizing than dog hair. However, the soluble allergens induce symptoms in atopic children and more easily than mite and pollen allergens. The easily airborne particles bearing cat allergens are smaller, thus allowing penetration into the airways in higher numbers and consequently diffusing everywhere. Thus symptoms are experienced soon after the contact [65, 293].

There are three *cat* allergens: Fel d 1–3. Both dander and hair allergenic content is similar; all the three allergens can bind to human IgE antibodies. The primary allergen (Fel d 1) originates from lacrimal, sublingual and anal glands [453], urine, epithelial and squamous cells, but mainly from cat sebaceous glands, with a gradient from 10 to 1 from the hair base to the point [65] and the apex in the areas rich in these glands, such as the tail. From the tail, Fel d 1 is scattered in the dander; either with its saliva, or as a result of habitual hair licking or tail wagging, the cat spreads Fel d 1 to the whole environment [65], so allergens also are found in male urine, environmental air, furniture, mattresses, sofas and the ground, especially the carpets, unlike the Der p 1 allergen [94].

Thirty minutes after a cat enters a 30-m^3 room are sufficient to increase Fel d 1 concentrations up to 30–90 ng/m^3, or 127 ng/m^3 [94], rising up to 3,120 ng/g of carpet dust [293], 16,840 ng/m^2 in school carpets, with a tenfold increase in dwellings [113] and up to 100 ng/m^3 in homes with cats [376]. In cat-allergic children, Fel d 1 allergen inhaled through the nose and absorbed may exacerbate asthma. The threshold level is 8 µg/g, but within 20 min Fel d 1 levels rise up to 20 ng/m^2. Characteristically, 15% of Fel d 1 (vs <0.3%–1.0% of Der p 1 and 2, respectively) remains easily airborne after turbulence of environmental air; by adhering to particles <2.5 µm in diameter it is able to penetrate the lungs deeply, and 6 min are enough to inhale 8 ng of allergen [94]. Therefore, a sensitized subject often develops acute symptoms within minutes of entering a home with a cat and a highly sensitive subject could inhale the quantity used in BPTs within 20 min, even when the cat is absent [337]. In an apartment, both cat and dog allergens are significantly more concentrated in living rooms than in bedrooms or in mattresses [292], in dust, where concentrations vary from 0.8 and 1.6 µg/g of dust (homes without cats) up to maximal levels of 642–948 µg/g of dust [376] and 100 µg/g of dust in carpets (homes with cats) [94], and are very low in

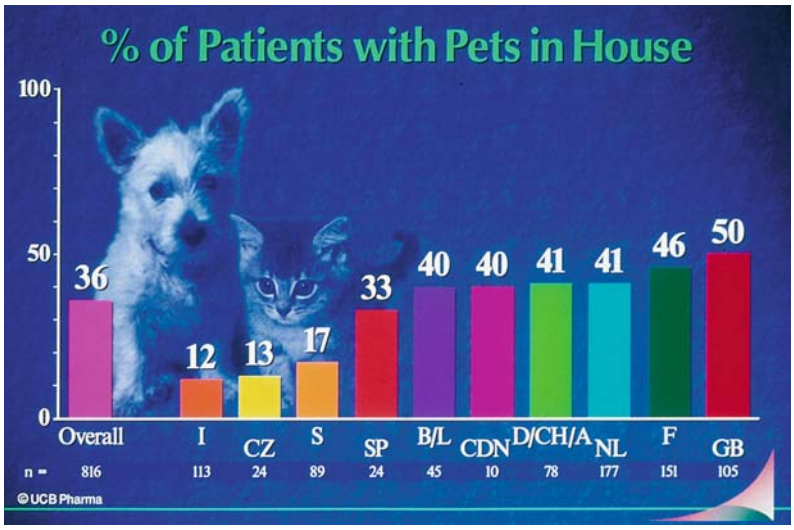

Fig. 4.16. ETAC Study: on average 36% of children have pets in the home, the highest frequency is in Great Britain (50%), the lowest in Italy (12%)

kitchens and bathrooms [339]. The children aged 5–7 had SPT+ for cat in 2.7%–3.3% of cases, and children aged 9–11 had SPT+ for cat in 8.6%–9.1% of cases [476]. Airborne levels are between 1,100 and 23,000 pg/m^2 [376]. Following repeated reports of elevated Fel d 1 levels in homes constantly without cats and in normally cat-free private or public buildings such as subways, department stores, schools, offices, hospitals [119, 293, 294], upholstered seats of cinemas and other public places, where measurable airborne concentrations were present [88], it was hypothesized that the cause was Fel d 1 ubiquity. As a consequence, exposure to cat allergens may occur in a variety of settings, transported by clothes and shoes of cat owners [10], and highly dependent on the activity taking place, including cotton operatives [88, 119], and ventilation systems [448]. Fel d 1 allergen levels were found in the mattress dust of *families without cats:* second-hand exposure to cat allergen is detrimental in terms of allergy development in infants [160]. The proof of passive transfer is likely in the significantly high levels of Fel d 1 and Can f 1 on school benches compared to floors [294]. There, the levels of cat allergen are high enough to induce sensitization and cause perennial symptoms in cat-sensitized asthmatic children [294]. In the end, children living in cat-free houses may be exposed to Fel d 1 at school, in houses of cat-owning schoolmates and in their own home due to passive transfer: levels as high as 8 µg of Fel d 1/g of dust in cat-free houses shows that unlike outdoor allergens, sensitization to indoor allergens is more often associated with asthma [10]. Occult sources of animal dander allergen are found in homes without these animals [10], but animal dander sensitization commonly occurs in children born in settings with nearly undetectable allergen exposure and who have never had contact with pets [375].

Can f 1 allergens have been purified; about 5%–30% of nonasthmatic atopic subjects and 30%–50% of those with asthma produce SPTs positive for Can f 1. Sensitizing levels are >10 µg/g of dust [376]. Can f 1 allergen may constitute a marker for studying dog allergy, since it reacts with sIgE antibodies of about 70% of dog-allergic patients. Cat allergens are found in dander, urine and mainly in dog hair and saliva; however, in assessing Can f diffusion in homes, we find that studies on the dimensions of particles to which Can f 1 binds are rare. A marked cross-reactivity between Can f 3 with albumin of Fel d 1 has been found (Table 1.73). Cat allergen levels can vary from 60 ng and 866 µg/g of dust and airborne up to 10,500 pg/m^2 [376]; they are higher in living rooms compared to bedrooms and other rooms [10], especially with rugs or wall-to-wall carpeting and, similarly to Fel d 1, stuck to the seats of public places more often than inside private homes [88]. Significant levels have been detected in dog-free houses [10, 456], a finding explained by frequent contact with the animal in the houses of grandparents (22%), friends and neighbors (14%) [456], with subsequent transfer to the child's own house. The earlier the exposure in life, the higher the chances of sensitization: at birth domestic pets are found in 31% [24] and in 25%–27% of homes with babies aged <12 months [100]. In infants of the ETAC study aged 17 months (mean), a pet was present in 36% of cases (Fig. 4.16) and a cat in 16% of cases (Fig. 4.17). In our study on pet allergy, we have found that 54 cats and 30 dogs were in the homes of 289 HR children since birth, with an incidence of allergy of 18.7% for cats and 10.4% for dogs, but 16 cats and six dogs were in the home of 300 healthy controls with a total incidence of 7.6% (p=0.0001) [54]. The negative effects of early exposure to pet allergens is demonstrated by an increased cat presence during the first 3 months [421] or of a dog during the 1st year of life [456] and is associated with BPT positivity. As much as 51.5% of English asthmatic children with cat allergy had housed a cat since birth, vs 11.4% of nonallergic children (p=0.0003), and the association between SPTs positive to Fel d 1 and cat presence in the environment

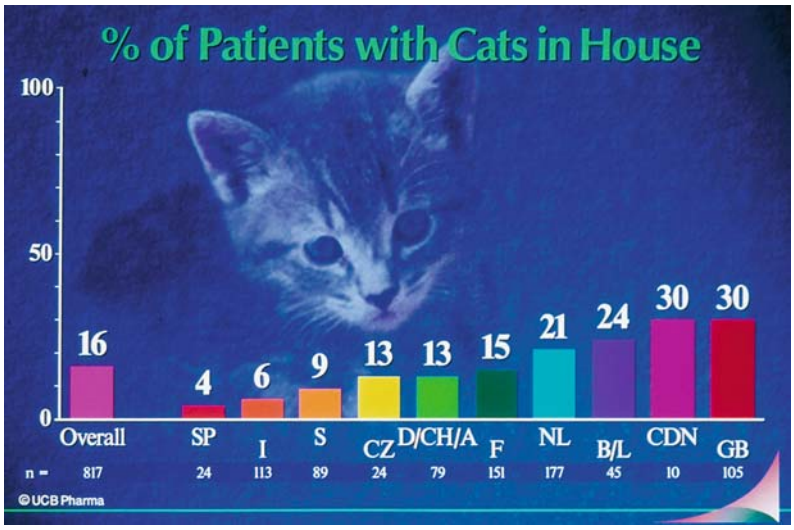

Fig. 4.17. ETAC Study: on average 16% of children have a cat in the home, the highest frequency is in Great Britain and in Canada (30%), the lowest in Spain (4%)

was more significant at the age of 2–7 years ($p<0.007$) [472]. After 1 year, more BPTs are positive in children housing a dog since birth than in children not housing a dog [456]. In atopic children with or without Der p 1 allergy, the direct exposure to domestic pets for at least 1 month in the first few years of life was statistically significant compared to controls, and high in children <2 years [482]. With continuing cat exposure in the adolescent period, clinical symptoms worsen and positive SPT prevalence increases compared to controls [421]. Such differences might go back to the different intimacy with which both animals are handled because most families of atopic children keep cats compared to controls [471], many dogs are often kept outside or at least out of bedrooms, and the proposed thresholds of exposure that have been associated in children <18 years with an increased risk of sensitization are >2 µg/g for Can f 1 and >1 µg/g for Fel d 1, and with asthma symptoms in allergic children are >10 µg/g for Can f 1 and >8 µg/g for Fel d 1 [10]. Houses completely without cats or dogs have consistent Fel d 1 or Can f 1 levels [10, 472], equal to >8 µg/g of Fel d [337], or <16 pg/m^2 or <0.02 pg inhaled/min by a child, and in homes with these animals, levels are 1–100 ng/m^2 [376], the sensitizing dose for an infant being of 3–300 ng/daily or 1–100 µg/year [110]. Importantly, for the Can f 1 and for the Fel d 1 house index, 55.7% (SE=2.2) and 66.0% (SE=1.6) of US homes, respectively, exceeded the sensitization threshold and 34.9% (SE=2.1) and 34.7% (SE=1.5) of US homes, respectively, exceeded the asthma symptom threshold [10]. Domestic pet sensitization is active even if the exposure started and continued after babyhood [100], indicating a prolonged sensitization. Appropriate investigations are necessary to re-evaluate pet allergy compared to the Der p 1 lower prevalence [376].

Epidemiological studies show that Fel d 1 sensitization attains highly significant levels in children followed up to the age of 11 years [410]; SPT positivity to Fel d 1 and/or Der p 1 increases 5-fold the risk of developing asthma, even 10-fold if associated with grass sensitivity. Over 50% of children with SPTs of >8 mm in diameter were asthmatic at age 13 years [391]; 12 children of 12–45 months with severe asthma had a more frequently ongoing contact with domestic pets than the 12 non-allergic children [382]. Contact was daily in 61% of 276 asthmatic infants [146]. In 174 neonates aged 3–5 days the median levels of exposure were 484 ng/g dust for cat, and 270 ng/g dust for dog [401]. In young asthmatic children, early exposure to cat increased the risk of allergic sensitization and further development of more severe asthma later in childhood. Such children should not live in homes with pets during their first few years, above all if the pet is a cat and a parent a smoker [281]. For pet-allergic children allergen avoidance may not be possible: although a dog or cat had lived in only 49.1% of US homes in the previous 6 month, Can f 1 and Fel d 1 were detected in 100% and 99.9% of these homes, respectively [10].

A common characteristic of dogs, cats, horses, sheep, etc. is having interspecies cross-reacting epitopes (Table 1.73).

Birds and Feathers

Avian allergens are connected with allergic alveolitis (Chap. 11) and in forms possibly complicated by FA (Chap. 9). Aged feathers, including those contained in down pillows and comforters, often offer excellent refuge for dust mites (Chap. 6), thus fostering mite sensitization.

Horse

Horse allergy is in a phase of recrudescence: hair, dander, serum and urine are immunogen, the allergens are detected also in certain houses, there transported by

subjects in contact with horses (79% of cases) [339]. Riding a horse is widespread in Sweden (21.3% in cities and 31.4% in country) and in Poland [43].

Rabbits and Rodents

Ory c 1 is a saliva constituent contaminating rabbit fur and is recovered in the environmental dust due to progressive dehydration. In guinea pigs two allergens have been found, mainly in urine, less in saliva, but also in the hair and pelt, and is diffused in elevated concentrations as recovered in the environmental dust. Mice have two major allergens found on hair follicles: Mus m 1 resides, also found in urine, Mus m II, also on the skin surface. Rat allergens are cross-reacting; Rat n 2 is mostly a male-derived allergen.

Cockroaches

In house dust, cockroaches (*Blatta orientalis*, *Periplaneta americana*, *Blattella germanica*) are a fundamental source of indoor allergens, especially in multi-unit housing and in urban areas [51] and are key allergens for infants and children [99, 133]. Bla g 1 and 2 levels in kitchens and bathrooms are 50-fold higher than those detected in other household places, unlike Der p/f 1 and Fel d 1 levels [339]. Cr-PI, perhaps a major allergen, is so hidden but so potent as to induce lymphocyte proliferation with production of IL_4 [190]. sIgE are in 69% of children positive to Der p 1 and/or to cockroach and/or to cat, vs 27% of control children [339]; 60% (21/35) of children have a double sensitization vs 13.6% [3/22] of control children [51]. Children with allergies had positive SPTs to cockroach in 12.7% of cases, including those with AD, asthma, rhinitis and urticaria [329]. Atopic adolescents sensitized to Bla g have a more severe asthma than the general population, with sIgE more elevated and high steroid-dependence [174]. Cockroaches are found in places and houses with prevalent humidity and poor air exchanges, but rarely in cool places with dry winters [292]. In 20% of homes with no visual evidence of cockroach infestation, significant levels of Bla g 2 were found in at least one dust sample, but uniformly distributed in all the rooms, unlike Der p 1 and Fel d 1 [339]. Bla g 2 levels >2 U/g have been detected in 65% of schools and in the air of other rooms [88]. The association of sensitization and exposure to cockroach allergens (Table 5.20) is a major risk for children with asthma exposed to high levels of cockroach allergen in their bedrooms, resulting in more clinical symptoms and a greater degree of morbidity [367]. Studies have raised the possibility that tropomyosin may be the basis for cross-reactivity among cockroaches, mites, shrimp, and squid (Table 1.73) , thus again linking respiratory allergy to FA. Asthmatic children may have sIgE to not yet classified insects, which are also detected in apparently free houses [242].

Insects

Several genera of insects, including butterflies, moths, midges, and mosquitoes, contain species that may induce inhalant allergy, as cockroaches do in asthmatic children [367], thus causing worldwide allergy. The sensitization may be more frequent because of widespread home aquariums [7, 492]. Pollen-sensitive patients are more exposed. Allergic symptoms are provoked by fish fodder containing Hb of *Chironomus thummi thummi* larva (13 allergens), or of *Tubifex*, muddy red worms. Relevant information comes from a report on 2,119 Chi t 1-sensitized patients with 33% of children: in patients polysensitized with asthma, conjunctivitis and urticaria, an expression inducible after HLA-DR antigen-specific stimulation on $CD3^+$, CD23 and CD25 was shown, while that on TcR α/β was decreased [241]. Association of HLA class II sequences encoding *DR1* and *DQ5* specificities with hypersensitivity to *Chironomus* allergen Chi t I has been reported [435].

Cage Baits

Allergy to baits of larvae and worms, with SPT and sIgE positivity of subjects with asthma and rhinoconjunctivitis is similar [492].

Environmental Pollutants

The worldwide rising public concern in the last years concerns the noxious effects of air pollution on children's respiratory health: children the world over are the greatest victims of environmental degradation, despite the great strides made over the past 10 years in improving both children's well-being and the environment (Tables 4.13, 4.14) [21, 481]. The pervasive problem of automotive emissions is the chief source. Experimental data suggest a correlation between the modifications of the surrounding ecosystem and the increased risk factors for the respiratory system, which is naturally exposed to

Table 4.13. Main outdoor air pollutants

the consequences of air pollution owing to its particular structure and direct contacts with the outside; several air-polluting agents facilitate both sensitization and IgE production by enhancing or aggravating asthma in subjects with BHR [19, 20, 23, 121, 205, 216, 217, 471, 488]: cigarette smoke, gas exhaust (GE) particles, atmospheric dust, smog (smoke + fog), combustion products, building materials, volatile substances with a strong and pungent smell, including perfumes, toilet products, deodorant and insecticide sprays, cooking smells, damp, thermal stimuli, chemical agents derived from combustion of industrial residues such as CO, CO_2, SO_2 (sulfur dioxide), or due to an ultraviolet (UV) light-induced photochemical change on GE such as NO (nitric oxide), NO_2 (nitric dioxide), O_3 (ozone), formaldehyde, detergents, solvents, paints, etc, and in children with AD the T variations. Among unforeseeable events, we include the asthma outbreaks that occurred in Barcelona and Naples caused by the unloading of soybeans from ships in the harbor: installing filters on silos in Barcelona prompted a significant decrease in asthmatic symptoms [9]. Air pollutants bound to pollen may enhance allergic sensitization [20].

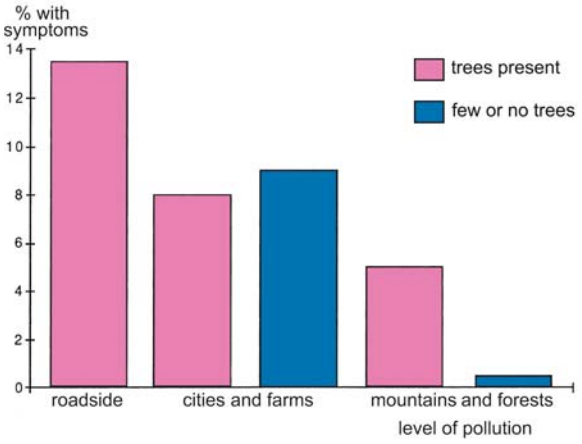

Fig. 4.18. Prevalence of rhinitis due to cedar pollen. *Pink bars* indicate trees present, *blue bars* indicate few or no trees. (Data from [185])

A Japanese study in mice immunized with cedar pollen-bound diesel exhaust particles (DEPs) (20- to 100-fold more numerous than in gasoline motors) showed that DEPs have a more adjuvant effect on IgE immune responses in mice than in control animals, thus facilitating the onset of atopic disease. As shown in Fig. 4.18 [185], sensitization to red cedar pollen is related to air pollution from cars, as it was found that the closer the people lived to a motorway, the more they suffered from AR [185]. In the least or most polluted quarters of Tokyo, the AR prevalence has attained rates of 1%–2% in children aged 0–14 years [285]. Additional evidence comes from DEPs, 0.01–10 µm in width, with <10 µm mean diameter (particulate matters <10 µm, PM_{10}), made of quartz, $CaSO_4$ and rock salt, which can bind to pollen grains, thus increasing their allergenicity [135]. Animal experiments have shown that mice were sensitized only when they inhaled pollen allergen mixed with DEPs, and that sIgE concentrations were correlated with the amount of inhaled DEPs [285]. Further, DEPs exert a direct effect on in vivo B-cell IgE production by acting on the ε germline [427]. In Australia and New Zealand there was a 6.0% increase in asthma admissions in 5–14 year-olds in relation to a 5.1-ppb (parts per billion) increase in 24-h NO_2 [19] and in Brazil there was a 31.4% increase in asthma or bronchiolitis admissions also due to NO_2 [121]. In Oslo, Norway, the asthma admission rate over 10 years has more than doubled; however, the higher admission rates were located along the main motor roads through Oslo [60]. In industrialized areas, the increased pollinosis prevalence is correlated to the duration of exposure [476]. There is also evidence of the different NO_2 and SO_2 diffusion in polluted townships and in the rural environment in two countries: NO_2 was equally prevalent in both Polish and Swedish cities and reduced by half in a rural zone; SO_2 was 7.5-fold more frequent in Polish than in Swedish

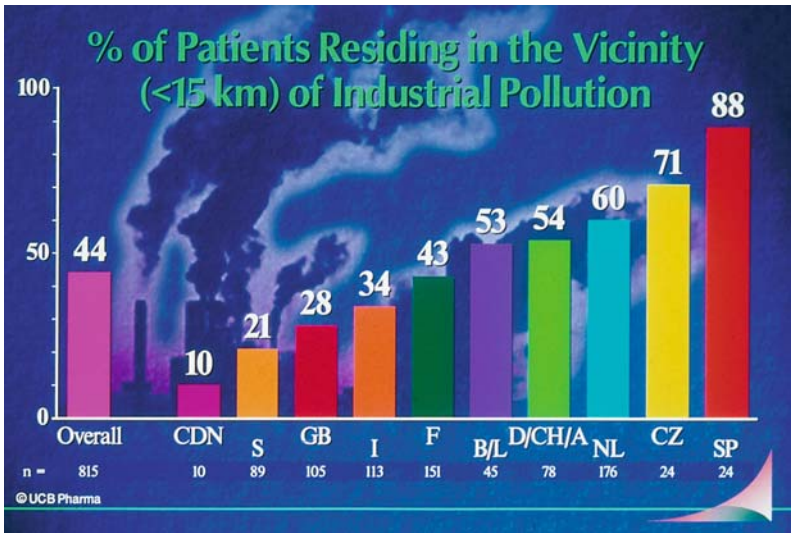

Fig. 4.19. ETAC Study: on average 44% of children reside in the vicinity (<15 km) of industrial pollution, the highest frequency is in Spain (88%), the lowest in Canada (10%)

localities [43]. In two industrial towns located 30 km apart (Upper Silesia, Poland), the children exposed to pollution (PM_{10}, NO_2, SO_2) suffered from wheezing and asthma, although with differences between the two towns [514].

The data above confirm that allergic sensitization is more probable in an urban environment, in parallel with industrialized areas, compared to areas with less traffic and other country areas [40]. Thereby, the atmospheric pollution increase is an emerging environmental plague related to the interaction between chemical substances foreign to the body (xenobiotics) and the immune system [22], which may lead to increased medical examinations and hospital admissions for asthmatic crises in younger children [361] and additional respiratory manifestations [106]. Significant is [304] the clear coincidence between a >100% increase in allergy prevalence that occurred 25 years apart and the increased fuel consumption, thus of traffic fumes that have replaced coal fire smoke as the major atmospheric pollutant. The greater prevalence of respiratory allergy in children living in Munich is probably related to the NO_2 [464] and GE [487] predominance. A significant correlation between GE and PEF (peak expiratory flow) and of MEF_{50-75} (maximal expiratory flow at 25–75% VC) reduction, in addition to recurrent dyspnea, correlated with the volume of car traffic in children aged 9–11 years [487]. Residing on a road with frequent motor traffic is a risk factor for AD [384], asthma and rhinitis [290], and if in one lives on a road open to heavy traffic, the risk of bronchiolitis in the first 2 years of life increases up to 41% [68]. The ETAC study children with AD in 44% of cases live <15 km away from sources of industrial pollution (Fig. 4.19). An unusual prevalence of BHR in schoolchildren living in the vicinity of power stations [161] was congruent with increased IgE levels significantly correlated to the degree of air pollution [23]. Atopic stigmata (OR 3.7) and AD (OR 1.4) rose depending on the lesser or greater pollution load [21]. Consequently, hospital admissions for asthma in an area with particulate air pollution mainly affect children aged 1–4 years [438] or <3 years, increasing 2.5-fold in 10 years [60]. Up to 35% of children residing in areas with high pollution reacted to BPT vs only one of the control children [469].

Another area of increasing interest is that the effects on humans depend on age, airway size, pre-existing illness, and pollutant characteristics: hydrosoluble gases such as ammonia, chlorine, formaldehyde, H fluoride, H_2SO_4 (sulfuric acid) and SO_2 dissolve in the upper airways, and can reach the lower airways only when their concentration is high. However, phosgene, NO_2, O_3 are less hydrosoluble and dissolve slowly, thus reaching the lower airways where they increase airway inflammation [60]. NO_2 and O_3 exert their noxious effects upon the airways, as a source of free radicals (FR) of O_2 mediators of inflammation [60]. The total impact of pollution on the asthmatic manifestations in children may be of 10%; no correlations with asthma have been subsequently ascertained [63]. The study in children living in three German cities has shown that the concentrations of SO_2 in ambient air were mostly due to emissions from power plants, heavy industry, and private heating, which were increased by a higher sulfur content of the coal burned in winter. Moreover, annual mean NO_2 concentrations certainly grew due to increased automobile traffic. In conclusion, the children had current asthma in 5.8%–10.3%, wheeze in 6.9%–9%, waking with cough in 16.4%–20.4%, morning cough in 10%–12.4%, runny nose with itchy eyes in 4.4%–15%, and AD in 13.5%–17.5% of cases [467]. Both figures of alert and warning states are in Appendix 4.1 and the equivalents of the parts per million (ppm) of atmospheric pollutants:

- *O_3* is very polluting from a clinical point of view (>180–>361 µg/m^3, mean per hour), a reactive allotrope of O_2 originating in the stratosphere by photochemical processes and UV rays, which convert diatomic molecules into triatomic molecules [189]. The wide damag-

ing effects of these rays, the UV-B rays, are only partly absorbed by the O_3 layer [245]. Ambient UV-B rays have the potential to decrease host resistance and immunity to some infectious diseases, thus leading to their increased incidence, severity, and duration [189]. The thick O_3 layer in the lower stratosphere between 15 and 25 km in altitude absorbs UV rays, thus forming a protective shield (ozonosphere) [245]. Yet the primary consequence of O_3 loss observed over the past 2 decades (ozone depletion or ozone hole) generated by human activity, particularly NO_2 release and photodegradation products of anthropogenic CFCs (chlorofluorocarbons) [245], is a global warming of the atmosphere, which advances pollination and promotes pollinosis. Its extension is equal to threefold the US surface. The parallel result is the thermal expansion of the oceans and the melting of the Svalbard Islands and the Greenland ice complex over the last century equivalent to –0.6 mm/year of sea-level rise [284], and the palm trees possibly growing on the Alps (Reuters). CO_2 is increasing in the atmosphere: its concentration, estimated at 280 ppm before the industrial revolution, has risen from 317 ppm in 1960 to 368 ppm in 1999. O_3 levels tend to be highest in warm and sunny weather and peak in the mid-afternoon hours, when children playing outside are more at risk [350]. The primary effects of O_3 and acidic sulfate exposure are exacerbations of asthmatic symptoms requiring hospital admissions and reducing pulmonary function tests (PFT) [63]. Studies indicate that symptoms are always more severe in the asthmatic group, with a significant correlation between admissions and increased O_3 levels [327].

The results are not less toxic when O_3 is formed by sun ray action on SO_2 and reactive hydrocarbons, both released by motor vehicles and industrial wastes. The ensuing chemical reactions usually lead to mixtures of pollutant gases in the lower layers, processes by which oxidative pollution is integrated and strengthened by photochemical pollution [245]. The ambient air standard for O_3 is ≤0.12 ppm over 1 h of the year [327] (1 ppm=2,000 µg/m^2). At a concentration of 0.08 ppm of O_3, this agent provokes epithelial damage, increased centroacinar inflammation in the airways, and structural alterations of the lower airways, as indicated by leakage of lactate dehydrogenase, albumin and total protein, and an increase in neutrophils, eosinophils, mononucleated cells, IL_6, IL_8, GM-CSF and PGE_2 is observed in BALF [101]; at 0.15 ppm, there is cilia shortening and necrosis in monkeys [350]. In vitro exposure of human epithelial cells to 400–800 ppb O_3 induced significant release of GM-CSF, TNF-α and CD54, which was blocked by cell treatment with 10^{-5} M nedocromil sodium [101]. UV-B exposure alters the patterns of IL secretion from keratinocytes in culture, and alters the morphology, decreases the number, and modifies the activity of Langerhans' cells [189]. Asthmatic adults exposed to 0.12 ppm O_3 at rest for 1 h and subsequent allergen challenge experienced a bronchial response and nonrespiratory manifestations, including nausea, malaise, headache and decreased ability to carry out sustained exercise; the patients required significantly less inhaled allergen to induce a 15% decrease in FEV_1 after an O_3 exposure than after a clean air exposure [289], hence O_3 interacting with common allergens could potentiate the host capacity of producing bronchoconstriction. In children exposed to 0.02 ppm O_3, a consistent drop of PEF values persistent up to 1 week has been found, suggesting damage in the respiratory tract such as a reduced ciliary clearance and an increased epithelial permeability; repeated exposures may result in persistent BHR [518]. Prolonged exposure is irritant and toxic for pulmonary cells and magnifies the bronchospastic response to allergens, thus impairing exercise performance and PFT in elite cyclists [210]. The PFT changes suggest that the effect of O_3 exposure on allergen-induced bronchoconstriction may be more significant than the effect of O_3 alone in asthma [327]. In children exposed to O_3, a deficit of CD4 and an increase in CD8 T cells with their ratio inversion have been observed compared to control children [518]. In another pediatric cohort [130], increases in environmental O_3 exposure were related to an increased nasal inflammatory response, similarly to Der p-sensitive asthmatics exposed to 0.4 ppm O_3 for 2 h, thus concluding that eosinophil inflammation is also transmitted to the airways [327]. Pollution catalyzes O_3 depletion, thus more UV-B rays, no longer absorbed by O_3 layer, reach the surface, potentially decreasing host resistance and immunity to infections [189], especially in atopic children [60]. The results relating both allergic sensitization to pollens and growing AR prevalence to the increased traffic rates and the coincident interaction with photo-oxidant agents are by no means insignificant [135]. Possibly, the long CFC atmospheric lifetime (up to two centuries) foreshadows that human beings will still have to deal with the repercussions of O_3 depletion for several generations, until the Cl level approaches pre-1970s levels [245]. The O_3 hole continues to widen, despite CFC decreases; possibly CO_2 increases CFC levels.

- *CO_2* is a polluting and toxic compound, with concentrations increased from 250 ppm at the beginning of the industrial era to 350–400 ppm currently (+66.6%), as noted previously, but in 2020, 92% of its emissions will be due to the car gases [481]. Consequently, the CO_2 ability to absorb the heat of the earth's surface has proportionally increased, and is a third cause of O_3 depletion. Another reason is Amazonian deforestation, which reduces CO_2 absorption by trees (–60%). The Rio Summit in 1992 has not stopped this devastation: today an area as wide as a soccer field disappears every 12 s (Johannesburg Summit 2002).
- *SO_2* emitted from diesel engines, refineries, coal-fired power plants, etc. is a source of important problems [381] (<125–>250 µg/m^3, mean per day): at 8–12 ppm, throat soreness appears, at 20 ppm eye irritation and immediate cough, corresponding to the highest tolerated dose in prolonged exposures; 50–100 ppm SO_2

(1 ppm=2,860 μg/m^2) are tolerated even for 30 min, but after a short exposure to 400–500 ppm, PFTs may deteriorate, and at 1,000 ppm lung resistance may increase >100% [101]. SO_2 may act as an aspecific bronchoconstrictor agent, similar to inhaled histamine or methacholine: the rapid onset of bronchoconstriction after exposure suggests a neural mechanism of action for SO_2 in asthma [327], but airway inflammation may result from short-term SO_2 exposure [381]. SO_2 enhances acute bronchoconstriction and lowers the threshold of aspecific BHR [334], because it causes airway inflammation of remarkable severity [381], effects that are exaggerated by cold air [334]. SO_2 decreases mucociliary clearance in both normal and atopic subjects at 0.02 ppm (urban level often common over long periods of time), especially with exercise-induced bronchospasm and/or mouth breathing, and BHR at 0.5 ppm [437]. In the BALF of healthy nonsmoking adults 4 h after exposure to 8 ppm SO_2, a significant increase was found in the number of lymphocytes, macrophages and mast cells, their number increased to peak values 24 h after exposure, and after 72 h returned to normal [381]. The SO_2 effect has been demonstrated in an epidemiological survey by a significant increase in BHR prevalence in children living near a paper pulp plant discharging 0.5 tons of SO_2 and 0.08 tons of hydrogen sulfide (H_2S)/day, as compared to children living in a less heavily polluted area [7]. Children living in a community where a steel mill was located also had increased respiratory symptoms [340]. Drawing conclusions from correlations between two pollutants, namely SO_2 and NO_2, may be justified since the association significantly emphasizes the bronchoconstrictor response to sensitizing allergens [440]. However, the hazard of similar associations is illustrated by an inverse correlation between SO_2 levels and *hospitalizations for severe asthma in 0–14-year-old children* [437]. Moreover, in children aged 6–15 years, asthma prevalence was highest and most significant in children living in the zone with the highest O_3 levels compared to those living in the vicinity of a highway with high SO_2 and NO_2 levels or in a zone with intermediate characteristics [385].

- *NO_2* (1 ppm=1,880 μg/m^2) is a precursor to photochemical smog derived from reactive hydrocarbons and is generated by the burning of fossil fuels in outdoor air in urban and industrial regions [90] and the use of unvented gas cooking stoves [210]. Outdoors, the most significant NO_2 source is GE fumes, although power plants and other industrial sources that burn fossil fuels also release NO_2 into the environment [90, 381]. The increased indoor exposure to combustion products of gas cooking stoves, fireplaces and space heaters, such as NO_2, acrolein, particulate material, formaldehyde and hydrocarbons, is significantly correlated with asthma exacerbations [315] and BHR worsening, also in nonasthmatic subjects [379]. The previous results have not been confirmed in a cohort of 1,205 healthy infants during the first 18 months of life [379], but such pollution may increase IgE levels in 6–12-year-old children [216, 488]. NO_2 reduces the efficacy of lung defense mechanisms, and exposure to 400–800 ppb caused *dysfunction of ciliary beat frequency of bronchial epithelial cells*. This may reduce either the threshold for allergen exposure [101] or the permeability of bronchial mucosa to allergens, but allergens remaining longer on the cells increase the chances of contact with immunoreactive cells, thus producing sensitization and increasing asthma prevalence [101]. Prolonged exposure induces the generation of mediators such as LTC_4 and influx of proinflammatory ILs (GM-CSF, TNF-α and IL_8) in the respiratory tract, with significant differences between cells produced by atopic and nonatopic subjects [101]. In vivo exposure to 0.01–0.06 ppm of NO_2 (>200–>400 μg/m^3, mean per hour) provokes BHR in exposed subjects, notably the asthmatic, with differences between exposure and symptoms of 24 h for NO and of 7 days for NO_2 and increase in lymphocytes, macrophages and mast cells of BALF [101]. The reduced mucociliary clearance and the increased production of inflammatory ILs by epithelial cells exposed to NO_2 in vitro [334] uncover the NO_2 capability to alter airway function, to the point of playing a significant role in wheezing development in children, and particularly in girls [371].
- *NO* (>15–>30 mg/m^3, mean per hour) is a reactive gas found in nerve, endothelial, epithelial and vascular smooth cells, macrophages, neutrophils, mast cells and lymphocytes, induced by $IL_1\beta$, IFN-γ and TNF-α. NO has a short half-life (<5 s) and may act as an intracellular messenger or a paracrine substance; leading to vasodilation and bronchodilation, NO production contributes to self-defense but is a *double-edged sword* in that it induces inflammatory and auto-oxidative damage [517]. NOS, a class of enzymes collectively known by this name, appears to fulfill a powerful homeostatic regulation of microcirculation permeability, to modulate the local perfusion and host defense mechanisms. NOS types are the enzyme catalyzing NO formation (endothelial, neuronal) known as cNOS (constitutive) and iNOS (inducible) formed in activated immune cells and vascular smooth cells with a Ca^{++} independent activity [302]. However, the NO hyperproduction up-regulated by iNOS expression, initiated by ILs and/or endotoxin, may suppress the enzyme activity with a decrease in cGMP and an increase in Ca^{++}, thus leading to bronchoconstriction [302]. Both IL_4 and IL_{10} inhibit NO production by macrophages, but not the production by endothelial cells, thereby expanding Th2 activation [219]. Inhaled CSs suppress iNOS [302]. Interestingly, NO has been identified as the main neurotransmitter of the nonadrenergic noncholinergic (NANC) pathway [208] and as such may contribute to a constant vasodilator tone [394], but it may play a role in the *early onset of asthma in children* [517].
- *PM_{10}* daily levels of the standard limits (Appendix 4.1) are correlated with a 3%–6% PEF decrease, increased reports of respiratory symptoms, and increased use of

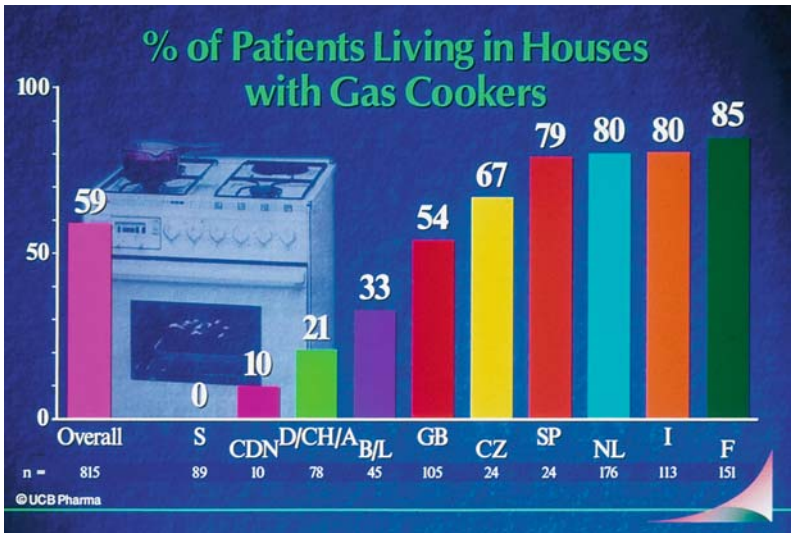

Fig. 4.20. ETAC Study: on average 59% of children live in houses with gas cookers, the highest frequency is in France (85%), the lowest (0%) in Sweden

medications in American asthmatic children [340]. Significantly increased were hospital admissions in asthmatic children associated with PM_{10} [19]. The Six Cities study found that chronic cough and chest illness in children were especially associated with total suspended particles (TSP) <15 µm in diameter, but not with flow measurements (FVC, FEV_1, MMEF) [106]. In Italy air pollutants appear to aggravate symptoms in already sensitized subjects [84]. TSP of 0.02–10 µm (>90–>180 µg/m^3, mean per day) have been correlated in children and adolescents with PFT decreases and symptom exacerbations, since these particles have been shown to be readily inhaled and deposited into the lungs where some remain indefinitely [210]. In a cohort of 4,400 children aged 1–5 who were surveyed in 1998 and in 2001, exposure to primary PM_{10} from fossil-fuel combustion as it is found in most cities was associated with an increased prevalence of cough with ORs of 1.21 and 1.56, respectively, and of current wheeze with ORs of 0.99 and 1.28 respectively. The ORs for incident symptoms were 1.62 for cough, and 1.42 for wheeze. These data confirm the association between locally generated primary PM_{10} and new-onset symtpoms with a consistent association with primary PM_{10} and incidence of wheeze [334].

- *VOCs* such as ammonia derivatives (NH_4), also found in household products such as paints and hair sprays, are of concern to public health because of their diameter, between 0.1 and 1.0 µm. They are readily inhaled and deposited into the alveoli, with a latency time of 5 days. Signs and symptoms may include eye and upper respiratory irritation, dyspnea, rash, itching, headache, nausea, and vomiting [40].
- *Indoor pollutants* (Tables 4.13, 4.14) include kerosene, gas, coal, wood cookers or stoves and fireplaces, which emit NO_2, CO, formaldehyde, aromatic polycyclic hydrocarbons and particulate substances <2.5 mm in diameter: unvented gas cooking stoves add 25 ppb NO_2 to the background level in a home, which increases NO_2 to 200–400 ppb during cooking, a major cause of unsuspected pollution [210]. A meta-analysis of eight studies investigating 40,269 children aged 0–15 years found a significant FVC and FEV_1 reduction in three studies involving a total of 85.7% of these children [378]: this is a significant risk factor for children with AD if the devices are unvented [384]. In Polish homes, gas cooking stoves and heating are very widespread, with a resulting production of smoke up to levels of 32.3 µg/m^3 (mean), with a threefold increase in respiratory symptoms [43]. In the ETAC study (Fig. 4.20), 59% of homes have gas cooking stoves.
- At least 2.7 kg of *formaldehyde* is produced during the combustion of 450 kg of gasoline: US car and airplane discharge is >300×10^6 kg/year of this relevant environmental pollutant found in foam insulation, chipboard, and carbonless copy paper. The minimal dose needed to provoke a reaction is 0.3 ppm. However, no effects are reported in 50%–70% of cases at an exposure of 0.05–1.5 ppm; 0.05–1 ppm is the odor threshold, 0.01–2 ppm provokes eye irritation, 0.1–25 ppm upper airway irritation, 5–30 ppm lower airway and pulmonary effects, 50–100 ppm pulmonary edema, inflammation, pneumonia, and >100 ppm leads to death [412]. Formaldehyde volatilizing from particle board and pressed wood products commonly used in the construction of new homes may also be found in carpet adhesives [412]. Its high content in the chipboard used in children's rooms may be responsible for IgE development [488]. In a particle board-paneled school, >0.075 ppm have been detected, able to cause *IgE-mediated sensitization* in 40% of schoolchildren [471], that is, the upper limits of values considered as inoffensive by WHO (0.050–0.080 ppm) [481]. Children are more susceptible than adults to toxic substances leading to IgE-mediated sensitizations [471], besides *hidden sources* such as cosmetics and cigarettes: a smoker of five cigarettes in a poorly ventilated room is exposed to concentrations three times the upper WHO limit of 1 Bq.

CFC				±	+

CFC chlorofluorocarbons.
Internet data.

- The use of *asbestos* has recently been drastically curtailed: when buildings become cracked and broken, they may liberate microscopic fibers that are pathogenetic when inhaled, such as fiberglass, used for acoustical and thermal insulation [229].
- *Radon* is a gas coming from radioactive decay products of ubiquitous uranium deposits in the soil. It enters houses through cracks in the foundations, porous cinder blocks, and granite walls, but easily volatilizes when water is in contact with air, at concentrations of 10×10^6 Bq/m^3 [229].

Table 4.15 summarizes the effects of atmospheric trace gases. Great attention has focused not only on the increase in CFCs chiefly used as propellants in pressurized metered-dose inhalers (pMDI), refrigerators, air conditioners, lighters, and Styrofoam insulation [245], but also on CO_2 and N_2O. The transition from CFC to non-CFC pMDIs has taken much longer than expected and has been far more costly than anticipated. However, alternatives based on hydrofluoroalkane (HFA) are currently being studied, also taking into account patient compliance [112].

Consequently, the convincing evidence that pollution increases atopy prevalence is clearer and clearer, as verified in Chap. 5. The results may be controversial: the children of highly polluted Leipzig and those of much less polluted Munich suffered from asthma and BHR in an insignificantly different way [464]. The Six Cities study in the US has found no connection between asthma, SO_2 and NO_2 [106].

In a positive light, there are the sources of renewable energy, including wind, sun rays, geothermal energy, hydroelectric energy, wave-motion, and tides.

Immunotoxicology

Immunotoxicology is the discipline concerned with the study of the immunotoxic potential of environmental xenobiotics on the human immune system components [22]. *Xenobiotics* (from Greek "ξενος," foreign) may be defined as the grouping of harmful components of the external environment, from the simplest chemical compound to the most sophisticated microbial agent. Most external agents confronting and eventually activating the host's immune system may evoke, in a variable way depending on the nature of the agent and the host's genetic disposition, antigen elimination or persistence with consequent perturbation of immune homeostasis or immunomodulating effects: both Fig. 4.21 and Table 4.16 summarize some of these effects [22]. Although immunotoxicology has become a prominent and respected discipline with global recognition since its inception nearly 30 years ago and has significantly contributed to the advancement of biomedical sciences, only relatively recently has the participation of investigators, clinicians, immunologists and allergists (but only occasionally and partly that of law-makers) been emphasized. Several of these approaches have been borrowed and utilized by clinical ecology, but they can have serious effects on the immune system of children, thus rendering them susceptible to infections or other disease conditions.

The immunotoxicity effects at the immune level stem from immune modulation and may be depicted as follows:

- Immune potentiating, which corresponds to an up-regulated or exaggerated immune response, to be expressed potentially in hypersensitivity and/or autoimmunity.
- Immunosuppression (or immune depression), underlying the generalized down-regulation of immune responses and may be materialized by an increased susceptibility to infections or sometimes irreversible forms of carcinogenicity [57].

Among the immunotoxic substances, some are ingested at low doses for a long time, such as those included in foods, either deliberately (additives), or inadvertently (contaminators), with potential risks for the immune system [57]. The salient characteristics of xenobiotics are otherwise unimaginable: immunotoxic substances exert their effects at remarkably lower doses than those normally expected. In particular, Ni and other metals may act as haptens, thus binding to host

Smooth muscles	Increased contraction	Bronchospasm
Glandular cells	Increased secretion	Increased mucus production
Formed elements	Red cell destruction	Anemia
Skin	Disruption of epidermal cells	Dermatitis

Data from [22].

proteins, inducing symptoms and signs suggestive of either immediate or delayed immunoreactivity. Metabisulfites excite *an irritant action on the bronchial epithelium,* thus activating a vagal reflex. Na nitrite inhibits monoamine oxidase, *eliciting cellular anoxia,* and erythrosine by *altering the neuron membrane permeability* could provide support for behavioral modifications. Also in this context, there is a *toxic action at the epithelial level* of substance P (SP) and the risk of neuropeptides, but the involved mechanisms are poorly understood, in addition to certain mycotoxins, which putatively suppress both humoral and cell-mediated immune (CMI) responses [250]. It was not a surprise to find studies that have reiterated the old adagio *post hoc ergo propter hoc* (after the fact, therefore a corollary). There is the case of children with recurrent respiratory infections (RRI) ascribed to drinking water contaminated by industrial solvents, accompanied by numerous immune alterations also in their relatives: the factors should be understandably reversed to make the diagnosis [377]. According to Bellanti, who proposed a stimulating working hypothesis, the study of the immune modulation induced by pollutant chemical compounds allows a proper assessment of immune system alterations clinically induced by those agents, thus providing sound knowledge of the mechanisms altering the immune surveillance [22].

The following list delineates a few relationships between immunotoxicology and epidemiology of atopic disease:

- The *aerodispersed pollutants* of chemical origin may either directly sensitize the organism by targeting

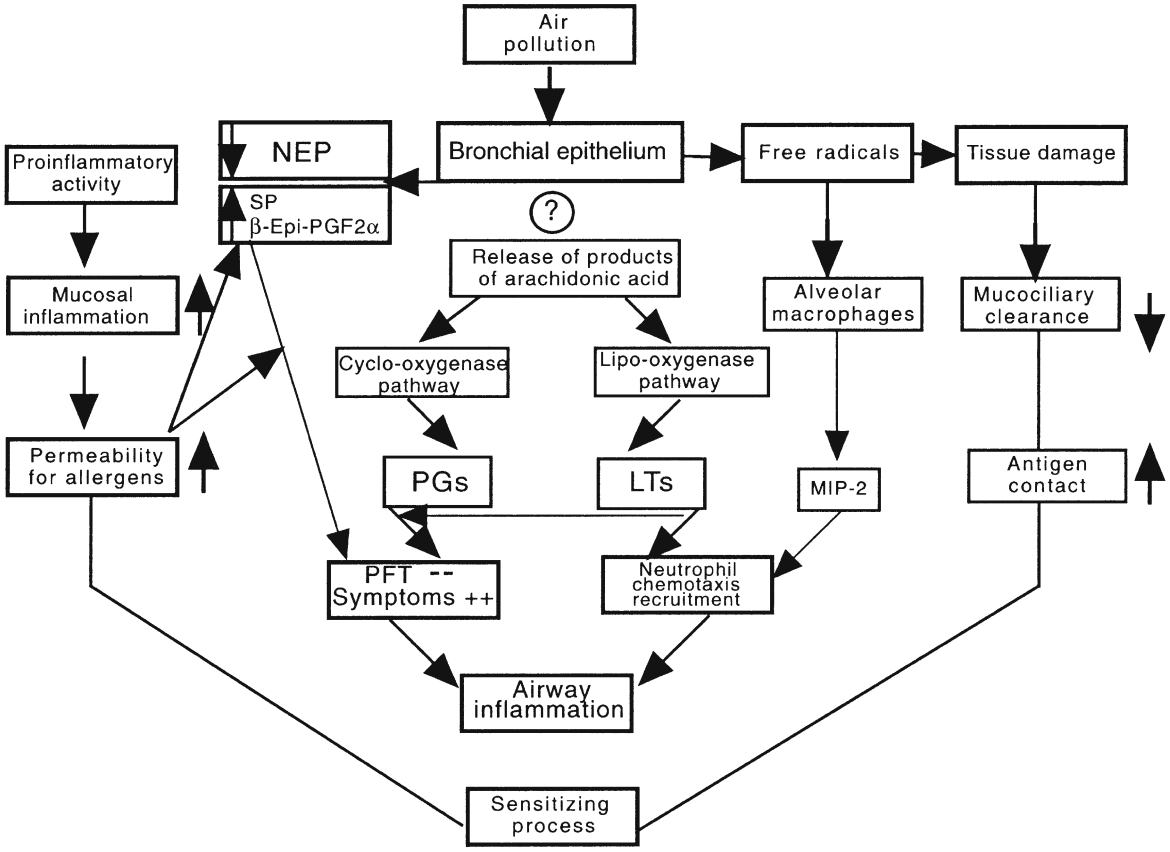

Fig. 4.22. Pathogenic hypothesis of sensitization enhancement by environmental pollution. The exposure to air pollutants can influence the development of the atopic march and clinical manifestations. Pollutants, in particular ozone, cause epithelial injury and diminish NEP activity, with a resultant increase in the neuropeptide concentration, such as substance P (SP). SP induces bronchoconstriction, increases airway permeability and activates neutrophils, while β-epi-PGF2α, marker of oxidative stress, induces pulmonary vasoconstriction. Alveolar macrophages through MIP-2 contribute to further stimulate neutrophils. *MIP* macrophage inflammatory protein, *NEP* neutral endopeptidase, *PFT* pulmonary function tests. (Modified from [219, 356])

immune reactions, or indirectly influence the host immune responses (by a potentiating or suppressing effect).

- Some *particulate pollutants* may act as adjuvants by potentiating IgE response to common allergens [22].
- *Atmospheric pollution may act as a precipitant factor of clinical manifestations* in subjects sensitized though still asymptomatic, or facilitating sensitization in nonatopic subjects [219, 356]. Figure 4.22 [219, 356] synthesizes the effects of pollution, in particular those supported by NO and O_3.

A wealth of chemical agents may play a central role in causing *immunodepression* in humans, such as *DEP-emitted SO_2*, which provokes an increased frequency of acute bronchoconstriction in asthmatic subjects, in addition to lowering the aspecific bronchial reactivity threshold. C powder (emitted by diesel engines) in contact with SO_2 plays a crucial role in the production of activated O_2, which by combining with unsaturated fatty acids, sets off a series of reactions damaging the bronchial mucosa: neoformed lipid peroxides prejudice the vessels, decreasing their functionality [377]. It is to be hoped that this further health offense may help establish safety levels with biodiesel, a product of natural origin deriving from vegetable oils (of rape, soy and sunflower). Above all it is S-free and consequently does not occasion SO_2 formation. Tables 4.17 and 4.18 [250] list a number of xenobiotic immunotoxicants, including gases, vapors, and particulates, and the results of several studies exemplifying the complexity of this issue. Table 4.19 [57] shows the experimental effects exerted by toxins potentially present in foods such as the aflatoxins and Table 4.20 [377] the environmental agents that compromise the immune system in the animal model. Moreover, bacterial exotoxins may target immune organs such as GALT by an immunostimulant effect, with a virtual rise in FA sensitization [57]. The intestinal mucosa may also establish long-term contact with elevated concentrations of immunotoxins during absorptive processes: such substances are able to

Table 4.17. Classification of immunotoxic xenobiotics associated with immunological changes

Class	Examples
Abused drugs	Ethanol cannabinoids, cocaine, opioids
Aromatic amines	Acetyl aminofluorene, benzidine
Aromatic hydrocarbons (solvents)	Benzene, hexachlorobenzene, toluene, xylene
Drugs	Diphenylhydantoin, lithium
Metals	As, Cd, Cr, Hg, methylmercury, Ni, Pb
Natural products	Selected antibiotics, estrogenic and fungal products, plant alkaloids, Vinca alkaloids, vitamins
Organic tin	TBTO
Others	Butylated hydroxyanisole, nitrosamine
Oxidant gases	CO, NO/NO_2, O_3, SO_2
Particulates	Asbestos, beryllium, cadmium, coal dust, silica
Particulate substances	PM_{10}, PM_{25}, TSP
Pesticides	Carbofuran, chlordane, trimethylphosphorothioate
Polyhalogenated aromatic hydrocarbons	Polybromurate polyphenyls, polychlorinated diphenyl compounds (PCB), polychlorinated dibenzofurans, tetrachlorodibenzo-*p*-dioxin (TCDD)
Polycyclic aromatic hydrocarbons	Benzopyrene, dimethylbenzanthracene, methylcholanthrene
Vapors (in addition to solvents)	Carbon tetrachloride, styrene, sulfuric acid, trichloroethylene

Data from [250].
PM_{10}, *PM_{25}* particulate material <10/25 µm, *TBTO* bis(tri-*n*-butyltin)oxides, *TSP* total suspended particles.

Table 4.18. Potential immunological changes of immunotoxic xenobiotics

Xenobiotics	Potential effects
Halogenated aromatic hydrocarbons	Thymic epithelium B-cell differentiation T-cell regulation
Polycyclic aromatic hydrocarbons	
Benzopyrene	T helper cells
Dimethylbenzanthracene	Macrophage function and proliferation
Benzene	Microtubule assembly
Dimethylnitrosamine	B-cell function
Mycotoxin	Protein synthesis
Organic metals	Immunotoxicity, immunosuppression, cell depletion, inhibition of glucose metabolism
Trimethylphosphorothioate	Macrophage function

Data from [250].

alter the local immune response, thus promoting the appearance of allergic responses or a greater susceptibility to infections [57].

The effects provoked by *dioxin* (tetrachlorodibenzo-*p*-dioxin, TCDD) stem from studies on the animal model, which appears to be very sensitive, while statistical increases in IgG levels, absolute and percent number of CD8, $CD4^+CD45RO^+CD45RA^-$, have been demonstrated in volunteers [300] as well as $IL_1\beta$ expression in response to epidermal keratinocytes with a potential role in the modulation of immune and inflammatory responses [500]. The effect on ILs is caused by the TCDD properties of mimicking the ligand of the Ah (aromatic hydrocarbon) receptor, the transcription factor inducing a gene battery including the ILs [131]. The explosion of a plant that manufactured the herbicide trichloro-

Table 4.19. Experimental immunotoxic effects induced by toxins potentially present in foods

Aflatoxins	Decrease in antibody responses and lymphocyte proliferation, suppression of phagocytic function, increase in mortality from infections
Citrinin[a]	Activation of B-cell- and T-cell-dependent immune responses
Ochratoxin A	Suppression/decrease in phagocytic function
Rubratoxin B	Decrease in antibody proliferation
Staphylococcal enterotoxin[b]	Suppression in vitro of immune responses
T2 Toxin from *Fusarium*	Decrease in antibody responses and lymphocyte proliferation, depression of B-cell- and T-cell-dependent immune responses, increase in viral reactivation and susceptibility to infections

Modified from [57].
[a] Isolated from *Penicillium citrinum*; note the opposing effects of citrinin and T2 toxin.
[b] See Chap. 7.

Table 4.20. Environmental pollution (chemicals and related substances) reported to affect the immune system of experimental animals

Substance and source	Immune system alterations
Benzopyrene Incomplete combustion of coal and other fossil fuels, cigarette smoke	Decreased antibody production by pulmonary lymph node cells
Beryllium (salts) Alloy production, aerospace, electronic and nuclear industries	Delayed cell-mediated hypersensitivity, lymphocyte transformation and cytokine production
Cadmium Paint and battery manufacturing, electroplating, smelting	Altered T- and B-cell function, antinuclear antibody formation immunosuppression, antiglomerular basement membrane antibody, amyloidosis
Carbofuran, Dizainon Pesticides	Alteration of serum immunoglobulin levels
Chlordane Pesticides, insecticides	Depression of contact hypersensitivity
Cigarette smoke	Decreased mitogen response, increase in either serum IgE levels (see text) or IgE production, enhancement of bronchial hyperreactivity; anaphylaxis after albumin aerosol
Diesel exhausts	Alteration of alveolar macrophages and leukocytes, reduced IFN-γ production, increased serum IgE levels
Demethylbenzanthracene Incomplete combustion of fossil fuels	Decreased splenic antibody production, decreased resistance to bacterial infection and tumor challenge
Fly ash Coal combustion	Decreased splenic antibody production
Formaldehyde Auto exhaust, smog, incinerators, biomedical research, insulation, industrial processes, cigarette smoke	Enhanced resistance to bacterial challenge
Lead Paints, gasoline combustion, battery production, welding, smelting	Decreased serum immunoglobulin and complement levels, depressed salivary IgA levels and ADCC
Mercury Organic and inorganic products, such as natural and industrial contaminants, pesticides, fungicides, jewelry, paints, foods, drugs	Autoimmune disease, hypergammaglobulinemia, decreased neutrophil chemotaxis

Table 4.20. (Continued)

Substance and source	Immune system alterations
Nitrogen dioxide Oxidant air pollutant, cigarette smoke	Alteration of antibody production in lung-associated lymph node cells, negative effects on mucociliary clearance and macrophages
Ozone Oxidant air pollutant	Increased susceptibility to infections, increased production of IgA antibodies in secretions and in lymphoid tissue
Pentachlorophenol Pesticide	Increased tumor susceptibility, reduced susceptibility to viral challenge suppression, increased macrophage phagocytosis
Silica Sand blasting, mining, glass industry	Altered T- and B-cell function, macrophage toxic effects, autoantibody formation and autoimmune-like disease
Sulfur dioxide Oxidant air pollutant	Depressed resistance to bacterial infections, increased immune response, enhanced synergism among pollutants, inflammation and alteration of fibrous septa
Tetrachloroazoxybenzene Herbicide manufacture and degradation	Decreased thymic weight, decreased splenic antibody production, inhibition of macrophage function, depression of bone marrow cellularity
Tin Canning processing of foods	Decreased splenic antibody production
Titanium dioxide Paints, cigars	Macrophage morphology and enzyme production abnormalities
Toxaphene Insecticide in agriculture	Reduced antibody production, suppressed delayed hypersensitivity responses, decreased macrophage phagocytosis
Trichloroethylene Industrial solvent	Decreased antibody and cell-mediated immune responses, inhibition of bone marrow stem cell colonization

Data from [377].
ADCC Antibody-dependent cell-mediated cytotoxicity, *IFN* interferon.

phenol in Seveso, Italy, on July 19, 1976, probably released >30 kg of TCDD into the environment. The net result is that human exposure to TCDD is linked to a lowered male/female sex ratio in their offspring, which may persist for years after exposure [286]. WHO experts (Press Release WHO/45, 3 June 1998) lowered the TCDD tolerable daily intake to 1–4 pg toxic equivalents/kg bw, and recommended that every effort be made to reduce exposure to the lowest possible level. Subtle effects may occur in the general population in developed countries at current background levels of 2 to 6 pg/kg bw. A preventive action limit for TCDD in feed for chickens and pigs was set to 2 pg toxic equivalents/g feed. This limit was effective in the detection of feed contamination and in the prevention of food contamination according to WHO tolerable daily intake. The adoption of the WHO level would have detected and prevented the 1999 crisis in Belgium, which followed the TCDD contamination of foodstuffs, and TCDD was subsequently discovered in the animal mash used to feed cattle instead of the usual forage, and finally to be a cause of *mad cow disease* (MCD) or *bovine spongiform encephalopathy* (BSE). The main cause was probably by feeding cattle with feed originally made from the carcass of an antelope infected with a similar form of BSE. The antelope was rendered for use as protein-rich animal feed after it died. The infected batch was then given to about 1,000 local cows between 1975 and 1977, passing the prions on to the cattle [Times 12. 3. 1990]. Cattle carcasses and carcass wastes were recycled through the rendering plants, increasing the levels of the now cattle-adapted pathogen in the protein supplement and eventually causing a full-scale BSE epidemic. The press reports that thousands of tons of BSE-infected cattle feed were exported from Britain to other nations over the past decade have set off the largest food scare in history. About 100 Europeans have thus far officially died since 1996 from the new variant of Creutzfeldt-Jakob disease (CJD), the human equivalent of BSE. There are many parallels with scrapie in sheep, also included in the recent definition of prion disease (Chap. 24). Unfortunately, the long chain of infected cattle continues: on May 20, 2003 the FDA learned that a cow has tested positive for BSE in Canada. On December 23, 2003, the US Department of Agriculture (USDA) made a preliminary diagnosis of BSE in a dairy cow in Washington state. On December 25, this diagnosis was confirmed. A preventive sampling strategy and regulations ensuring non-stop traceability of contamination to the raw materials utilized to produce cattle feed and human food are therefore mandatory.

Moreover, dietary antioxidants, polyunsaturated fats, and modern contaminants including phthalates, polychlorinated biphenyls (PCB), and organochlorine pesticides [349] are ubiquitous and persistent in the environment and may alter the intrinsic propensity for Th2 responses. The effects of these and other environmental

Table 4.21. Main pesticides

Class	Examples
Insecticides	
Carbamates	Aldicarb, carbaril
Organochlorines	DDT[a], lindane, aldrin[a], dieldrin[a]
Organophosphates	Parathion, malathion, diazinon
Vegetables	Pyrethrin, nicotine, permethrin
Anticryptogamics	Dithiocarbamates, sulfur, Cu salts
Acaricides	Acetyl bromide, ethylene oxide, paradichlorobenzene
Nematocides	Dichlorodibromopropane, trichloronitromethane
Herbicides	Chlorates, atrazine, carbamates
Molluscacidas	Metaldehyde, mercaptodimethur
Rodenticides	Phosphorus and derivatives, warfarin
Other pesticides	Chlordane[a], endrin[a], heptachlor[a], mirex[a], toxaphene[a]

Data from [141, 353].

[a] With β-hexachlorobenzene(β-HCB), polychlorinated biphenyl, dioxin and furans, belongs to the 12 POPs (persistent organic pollutants).

DDT dichlorodiphenyltrichloroethane.

changes are poorly understood, but are the focus of recent research. Undoubtedly, in addition to the introduction of many new chemicals into the environment, there have been many changes in the alimentation in industrialized countries over the past decades [101]. A recent study has, however, found that *in utero* exposure to background PCB levels is associated with *poorer cognitive functioning in preschool children* [321].

Pesticides (Table 4.21) [141, 353], a real plethora, are widely used also as herbicides, insecticides, fungicides, etc. The first of them, DDT, was banned in the US in 1972, but continues to be used in developing countries, so hundreds of millions of people are significantly exposed to pesticides each year. A number of insects develop a specific resistance to pesticides and their elevated stability provokes an environmental capillary diffusion, since ≈80%–90% of pesticides disperse through the air, soil and water. Vegetable and animal organisms gather DDT and other pesticides in their tissues up to 20 parts/10^9, more often in lipids, thus causing a progressive bioaccumulation along the food chain. Seventy-eight percent of countries report pesticide contamination as a threat to health [446]. Pesticides may pose serious risks to birds and human beings eating fish exposed to organochlorine pesticides in the paddles for only 6 months [353]. Pesticides depress immune system functions: for example, CD4/CD8 T-cell ratios and cell counts have been found significantly altered and lymphocyte proliferative responses suppressed, indicating severe dysfunctions in CMI. Clearly shown are the effects on B-cell function, macrophage phagocytosis, NK cell numbers and host resistance. Negative repercussions particularly affect *infants and children,* whose immune systems have not yet fully matured. In the more exposed areas, children are threefold more likely to have infectious diseases of the gastrointestinal tract and two- to threefold more likely to have infections of the respiratory tract than children living in areas of lower pesticide use [353]. WHO experts have grouped 12 pesticides not broken down naturally by light or other chemical substances, called POPs (persistent organic pollutants), which inevitably accumulate in the environment and because of their liposolubility target the tissues of living organisms. In children, exposure to pesticides may be magnified if they crawl or play on freshly sprayed surfaces. An infant's breathing is close to the ground where pesticides are at very high concentrations. Exposure may also result from dermal absorption. Most of these exposures do not cause poisoning, but severe symptoms may occur by overexposure [350]. However, pesticides added to crops enter the food chain and can have further damaging effects on metabolic functions. Data from a sample of US emergency rooms show that children <5 years of age were involved in 55% of 20,480 cases of *pesticide poisoning*, and 10% of children were later hospitalized. Insecticides and rodenticides accounted for 87% of these cases, and ingestion occurred in 76% of the cases [141].

The chemical substances outlined in Tables 4.20, 4.21, present in environmental air and other pollutants, in various ways carry on noxious actions on the immune system of human beings following involuntary exposures, thus calling attention to a much-needed examination of the mechanisms involved in immune surveillance alterations subsequent to such exposures, to prevent the severe complications of environmental immunotoxic plethora. These substances could be eliminated with a concerted action of international bodies and replaced with less toxic products.

Free Radicals

In the last few years, growing evidence states that *free radicals* (FRs), so called in that they carry a supplementary electron, can be of importance in immunology [338]. Approximately 1%–3% of inspired O_2 is used for the synthesis of $O_2^{\bullet -}$ (superoxide anion), the most reactive FR, which has a role in diverse fields, particularly in various lung diseases. The superoxide dismutase (SOD) then dismutates superoxide to H_2O_2. We should consider that FR oxidative changes deliver a large amount of O_2, and that we produce >2 kg/year on average. O_2 is not toxic as such, but due to products of reactions with H_2O,

which involve a series of extremely reactive substances, including H_2O_2 and hydroxyl radicals (OH). The production of these highly toxic molecules starts within 30 s of the target binding to the cell surface. When metabolic reactions dismantle an O_2 atom of an electron, FR tries to replace the missing electron by removing one from a molecule of cell membrane: thus a new FR is formed and a chain reaction begins [338]. FRs have a short half-life, measured in milliseconds, and react with other molecules found in the immediate environment. Usually, phagocytic cells use FR produced in small quantities in the mitochondria to kill microbes, and both neutrophils and macrophages protect themselves from FRs escaping from the phagosome, while FRs that have left the cell exert a toxic activity on nearby cells. On the other hand, FR release from phagocytes activates membrane phospholipase A_2, generating arachidonic acid (AA) and other lipid mediators, resulting in an amplified production of proinflammatory factors of lipid origin. FRs concur indirectly to neutrophil stimulation: IgG antibodies in FR presence show a characteristic fluorescence and form aggregates able to stimulate FR release.

An imbalance in superoxide production may activate a vicious cycle marked by contributions to the pathogenesis of many diseases. FRs can be involved in lymphocyte accumulation in inflammatory sites: in this situation the human phagocyte response to LTB_4 is inhibited by SOD and/or catalase, which reduces H_2O_2 to H_2O and O_2. Similar results have been obtained employing other chemotactic factors. SOD and/or catalase activation in varying types of inflammation shows that FRs play a crucial role in inflammatory processes, even if elaborate interactions surely occur and concur to the final cascade. Human beings in physiological conditions have the ability to cope with FR toxicity, by a series of defense mechanisms of various types, including the enzymes so far analyzed, in addition to glutathione peroxidase, but we can be exposed to an increased risk of cellular injury when the production is increased. Stress proteins have a potential defensive effect against oxidative stress, by playing an important role in protecting cells and tissues from injury. However, tissue sufferance oxidative stress may either contribute to or be the background of the tissular damage caused by the disease; moreover, FRs may worsen tissue damage in a more or less significant way. Mast cells and basophils have the ability to generate superoxide. In turn, reactive FRs activate histamine release from basophils, and activated neutrophils evoke histamine release from mast cells, thus creating a further amplification loop between immediate reaction and asthmatic inflammation [338]. Tachykinins (SP in particular) provide one more proof of the connection between FRs and asthma: SP is normally degraded by neutral endopeptidases, highly sensitive to oxidative damage and in turn can be degraded, for example, by ETS. In this occurrence, laboratory animals develop BHR to SP. BHR observed in cigarette smokers or in subjects exposed to O_3 may recognize a similar mechanism. A further class of FRs is elicited, in addition to normal metabolic challenges, by external causes, such as, for example, atmospheric agents, drugs, smoke, pesticides, radiation, cigarettes, etc. *Several antioxidant factors* such as natural vitamins, flavonoids, glutathione, uric acid in the epithelial lining fluid, and foods confer protection to neutralize excess FRs so that the bronchial epithelium escapes tissue injury (Table 4.22). Antioxidants normally bestow protection, but if the balance with oxidants is disturbed, the epithelium may undergo an oxidative stress, thus up-regulating eicosanoid metabolism, which contributes to early symptom development and PFT decrement and to arachidonate oxidative products chemotactic for neutrophils [219] (Chap. 22). Stress proteins could represent a self-protective mechanism that could promising-

ly be manipulated so as to provide a more effective shield against oxidative stress [338].

O_2 FRs and antioxidant defenses were evaluated in 210 asthmatic children aged 5–18 who had a 3-fold higher FH of asthma and a 4-fold IgE increase than in the healthy controls. Excessive production of superoxide, OHs and antioxidant enzymes was noted in the blood cells in asthmatic children, whereas SOD and FR scavengers in blood cells were significantly lower in asthma, thus stressing the correlation between asthma severity and O_2 FR production in asthmatic children [394].

Environmental Tobacco Smoke

ETS passively inhaled is the commonest respiratory irritant, especially in the home, where infants spend most time and older children more [27], considering that modern homes allow air exchanges in only 50% of cases vs 100% of older houses [28]. The role played by ETS is incontrovertible in exacerbating respiratory allergy and increasing its prevalence: in all likelihood the age of the child is a significant factor, thus younger babies are particularly at risk, also taking into account that 75% of smoke released in the environment is sidestream smoke, with greater T making it more toxic [132]. Hence ETS is the greatest factor in causing early asthma in children, correlated with the number of smokers [68], especially in children with a genetic predisposition for allergy [232]. It has been demonstrated that offsprings of smokers show an increased prevalence either of SPT positive to inhalant allergens or of BHR and suffer earlier and more frequently from atopic disease than the offsprings of nonsmoking parents [366, 425], as well as from AD and asthma (p=0.0001) [348].

The bulk of studies that have examined the relationship of parental smoking to wheezing and asthma in children have found a positive association [298, 425, 477]. The OR can be 2.1 between maternal smoking and childhood asthma [477], and an increased severity of the disease was seen in asthmatic children with smoking mothers compared to asthmatic children of nonsmoking mothers [298]. A clear connection with atopic sensitization has been established by other studies [7, 42, 146, 366, 482] and in particular with increased total IgE levels [488]. In children of atopic parents, total IgE levels are significantly higher and respiratory infections are more frequent compared to children of nonsmokers; consequently ETS occasions or worsens asthma in a high rate of children [484]. A synergy between pollutants, ETS and allergy has also been reported [7, 371, 385]. In 74% of infants aged <2 with bronchiolitis or asthma, the determination of salivary cotinine was positive, the main metabolite of nicotine, with a long half-life in body fluids with levels of 10 ng/ml, pointing to a high exposure to ETS vs 14% of children aged >2 [111]. An aspect to be evaluated is the detectable cotinine levels found even more often in children unexposed to any ETS source [75], thus implying an ETS community exposure. Dosing urinary cotinine has shown increments of passive ETS inhalation parallel to increased exacerbations of infantile asthma and decreases in the FEV_1/FVC rate and FEF_{25-75} (forced expiratory flow) levels [67]. Epidemiological studies document that ETS *passively inhaled* by children favors the onset and persistence of asthma; the association between parental smoke and symptoms such as cough, wheezing and airway inflammation is well demonstrated in children [147]. In children allergic or not to Der p 1, early exposure to ETS is a risk factor (41.5% of children) correlated with dampness of windows and/or of the home [7, 42]. Allergic infants with severe asthma are exposed to ETS more than nonallergic infants [382] and even FHA^+ is a hindrance for ETS [216]: it is significant to note that 65% of 210 asthmatic children had a smoking parent while in the control group it was ≈25% (p=0.0001) [394]. In the ETAC study, 41% of children were exposed to daily smoking indoors (Fig. 4.23); in

Poland, 59% of fathers and 51% of mothers smoke, and in Sweden the mothers are more often smokers (37%) than the fathers (30%) [43]. However, paternal smoke could not be associated with respiratory symptoms [44], perhaps because fathers are less present at home. Another threat is that of the older brothers possibly smoking at home: the current smokers aged <16 were 22.5%, the atopics 27.6%, a fivefold increase [396]. In a cross-sectional study on 770 children aged 7, which collected data with salivary cotinine determinations, *72.5% of children from nonsmoking households had detectable cotinine levels,* 10.1% of which was in the upper levels [419]. In an epidemiological investigation on 3,040 children aged 10–14, also based on salivary cotinine determinations, both parents smoked in 51% of cases, only mothers in 19%, only fathers in 17%, another household member or regular visitors in 3% of cases. However, 7%–11% of children had positive levels although not exposed to ETS [75]. The rising problem of finding *critical levels of cotinine in unexposed children,* logically *reached by ETS coming from anywhere, still awaits basic answers.* In children aged 7 with a HR of atopy, the levels were 24.3±20.7 and 6.5±6.4 ng/mg of creatinine depending on whether there were smokers in the house [512]. In a cohort of 199 asthmatics of 8 months to 13 years, mean urine cotinine was 5.6 ng/ml in those not exposed to smoke, 13.1 ng/ml in those exposed to maternal smoke or smoke in other households and 55.8 ng/ml considering all active smokers [67]. Often such results depend on smoking in parents of both asthmatic and control children, with no testing for the exposed offspring [317]. According to the parents of 19 asthmatic children, only 31% were exposed to ETS; when measuring salivary cotinine with high selectivity liquid chromatography, the rate rose to 69% [69]. The definitive proof was obtained using a method similar to that of Talbot (see Chap. 9): if the mother smoked immediately before breast feeding, a tenfold increased *nicotine concentration was dosed in the baby* [89].

The main toxic substances are summarized in Table 4.23 [132]: the levels of such substances are broadly dependent on the release of *sidestream smoke produced by the slow combustion of cigarettes* (without aspiration), often released in greater amount per cigarette than those of mainstream smoke exhaled back into the air by smokers [132]. The numerous and not completely known mechanisms by which ETS could act on the immune system are outlined in Table 4.24 [20, 47, 56, 67, 75, 107, 129, 132, 140, 145, 146, 191, 206, 268, 298, 366, 396, 425, 462, 490] and Table 4.25 [103], which quantifies the positive risk as related to pertinent parameters. Children exposed to ETS undergo a greater number of airway infections and suffer from changes in respiratory epithelium [145], with consequent facilitated allergen access to immunoreactive cells. These children experience a number of infections 16-fold higher than unexposed children, and the risk of respiratory infections increases 3.5-fold [15]. The ensuing restoration of infection-induced inflammatory alterations may be incomplete due to unending exposure to ETS [147]. Since these infections are asthmogenic, a vicious circle is started, especially in winter months when a greater virus transmission is facilitated: parents' smoking → VRI → asthma in the child. As a result, only a drastic inhibition of smoking can interrupt this circle. Consequently, children develop asthma (Chap. 11), infections of the lower airways (Chaps. 9 and 22) and more easily and prolonged secretory otitis media (Chap. 15). The effects produced on the offspring by ETS of 20 cigarettes consist in significant mean reductions of PEF (5%–6%), MEF_{75} (5.7%), MEF_{50} (4.9%) [107], FEV_1 (0.0008 l) and FEF_{25-75} (0.003 l/s) per cigarette with greater reductions and more significant statistical differences in children with active asthma [145]. More precisely, in asthmatic children aged 10 of average weight and height, FEF_{25-75} will be reduced by 6.8% if >1 cigarette/day is smoked in the home, plus a further reduction of 3.3% for a current respiratory infection, and 2.4% if >20 cigarettes/day are smoked in the house [145]. From the clinical point of view, ETS is associated with ongoing cough, effort-induced, nocturnal and recurrent wheezing, with highly significant differences based on the number of cigarettes smoked in the house daily [107]. ETS not only causes respiratory allergy in children at risk of atopy, but especially *an additional genetic factor,* because asthma is most likely occasioned when one atopic parent smokes and chiefly when both parents smoke [56].

The substances contained in ETS may variously influence Ig synthesis and stimulate the IgE system *in utero,* thus predisposing infants to atopic sensitization, since maternal smoke causes a significant increase in CB IgE

Table 4.23. Main toxic and/or noxious substances present in central tobacco smoke (quantity/filter-tipped cigarette)

Toxic substances	Amount
Nicotine	1–2.5 mg
Ammonia	50–130 µg
Carbon monoxide	10–23 mg
Carbonyl sulfide	18–42 µg
Cyanhydric acid	400–500 µg
Nitrogen oxide	100–600 µg
Toxic substances for the alveolar and/or ciliary epithelium	**Amount**
Acetone	100–250 µg
Acrolein	60–100 µg
Cyanhydric acid	400–500 µg
Formaldehyde	70–100 µg
Formic acid	210–490 µg

Data from [132].

Table 4.24. Mechanisms by which tobacco smoke could act on the immune system

General effects
Acts by irritating the respiratory mucosa
Predisposes to an increased susceptibility to respiratory viral infections
Adult smokers contract influenza more frequently
The incidence of influenza and of recurrent respiratory infections is higher in the offsprings of smoking parents
Potential mechanisms effective on the immune system
Direct action on mast cells, independently of IgE-mediated mechanisms, inducing mast cell degranulation
Increase in $CD4^+$ cells and changes in $CD4^+/CD8^+$ ratio
Dose-dependent increase in IL_4-producing Th2 cells
Increase in IgE antibody concentrations
Presence of specific IgE antibodies
Capability to impair both bronchial mucosa and epithelium, thus promoting the penetration of antigens, which in turn can sensitize the child, and stimulating IgE antibody synthesis
Hyperplasia of calyciform cells
Mucus hypersecretion
Alteration of ciliogenesis, so provoking the disappearance of cilia, which need months or even years to be re-formed
Damage of intercellular junctions integrity and of epithelium permeability:
The increase in bronchial epithelium permeability facilitates the allergen penetration into the sub-epithelial lymphoid tissue
The epithelial damage, especially the loss of cilia, could favor the persistence on mucosal surface of antigens and infectious agents and hence their penetration
The effect on alveolar macrophages inducing their increase in respiratory spaces, also critically altering their functions and metabolism, in particular as regards the arachidonic acid derivatives
Fulfills a potential up-regulation on T lymphocytes
Relationships with IgE levels and atopy
Neonates born to smoking mothers have increased CBIgE levels, independently of the family history of allergy
IgE concentrations are higher in smoking adults in the offspring of smoking atopic parents
In adult smokers the levels of serum and specific IgE antibodies are higher than in nonsmokers and in adults with airway infections are also higher compared to healthy individuals
A similar relationship is found in atopic smokers compared to nonatopic individuals
Even ex-smokers have high levels of serum IgE antibodies
There is a significant correlation between the number of smoked cigarettes and IgE levels
Infants and children of smokers affected with atopic disease present levels of serum IgE antibodies significantly higher than controls
Cigarette smoke favors the development of atopic manifestations in at-risk babies
The onset of atopic manifestations is earlier in children of smoking parents
Clinical data
Asthma and its exacerbations are more frequent in the offspring of smoking atopic parents
Passive smoking is responsible for 8% of all episodes of otitis media, prolonging the total duration of the affection
Wheezing is more frequent and has an earlier onset in the babies of smoking mothers
Asthma due to Der p is more frequent in children with a mother smoking during and after pregnancy
Children with a mother smoking during pregnancy develop bronchial hyperreactivity during the very 1st month of life
Maternal smoking during pregnancy may impair in utero airway development and/or alter lung elastic properties
Daily exposure to parental tobacco smoke is associated with an earlier and more frequent development of atopic disease compared to infants and toddlers of nonsmoking parents
Adult smokers manifest a higher frequency of infectious episodes of upper airways, therefore their babies have a higher risk of developing viral infections
Male children are more at risk than female children
Passive smoking in infants and toddlers is directly correlated to
Exacerbations of asthma attacks in children previously asymptomatic
Increase in number and severity of asthma exacerbations
Alterations of pulmonary function
Increase in number and severity of upper and lower airway infections

Data from [20, 47, 56, 67, 75, 107, 129, 132, 140, 145, 146, 191, 206, 268, 298, 366, 396, 425, 462, 490].

Table 4.25. Pediatric morbidity associated with household smoking

Condition	Pooled risk	At-risk children (%)
Asthma	1.43–1.46	8–13
Respiratory hospitalization	1.55–2.41	15–23
Lower respiratory tract infections	1.46–2.50	12–20
Cough	1.36	10–16
Middle-ear disease	1.19–1.58	2–13
Tympanostomy	1.60	1–26
Adenoidectomy tonsillectomy	1.20–2.06	16–24

Pooled risk is a relative risk for cohort studies (first figure) and an odds ratio for case–control studies (second figure when present); a value >1 shows a high risk of disease.
All the results show a statistical significance between 0.01 and 0.0001.
Data from [103].

and IgD levels, with a higher prevalence of atopic disease in the first 18 months after birth (Fig. 4.24) [256]. These data have not been confirmed by other studies of CB IgE [314, 316] and IgD [316]. Recently, late gestational smoke exposure was found to be associated with an increased risk for wheezing but not with asthma, yet data showed a tendency towards a protective effect of smoking on AR, and AD [254], or no significant relation to AD [183, 224]. Passive smoking was also protective at 12 months in children of allergic mothers, but not at age 4.

Several studies have certified a strong association of maternal smoke with the onset of the atopic march: *maternal smoke increases in utero IgE levels, provokes hypoplasia of fetal lungs and reduces the number of alveoli and/or alters passive respiratory mechanics* [14, 47, 152, 415, 425, 477], resulting after birth in PFT reduction, even more if linked to a hereditary basis for asthma [415]. It is well established that substances derived from the maternal environment can be found in the gestation-associated environment. Cotinine has been found in placental tissue, celomic and amniotic fluid and fetal serum from the first trimester when mothers have been exposed to cigarette smoke [188]. Prenatal maternal smoking was associated with reduced FEF rates in infants tested shortly after birth, thus smoking during pregnancy might *impair in utero airway development and/or alter lung elastic properties* [152], also suggesting an obstruction of small airways in dysmature lungs, which contain few alveoli and are smaller at birth, more marked than in the lungs of unexposed infants [47]. A precise conclusion is that *the fetus* is *the first victim of ETS,* although only one study [152] has clearly separated prenatal from postnatal maternal cigarette smoking, as completed by the PFT study at birth [415]. Further objective data underscore ETS effects in the first few years of life: 27% of neonates had cotinine CB levels higher than 5 ng/ml [24]; already in the 1st month of life, at-risk babies of mothers smoking during pregnancy had BHR [508] and symptom-free infants had PFT alterations in 8% of cases [507], and significant FEF reductions may actively predispose infants to the later occurrence of wheezing illness [152]. A strong association links maternal smoking with the development of asthma during the 1st year of life [14, 268, 477], placing the estimated risk at about twofold [268, 477], or fourfold [14] of nonsmoking mothers. Therefore ETS represents the main environmental factor hitherto identified in the etiology of early infantile asthma,

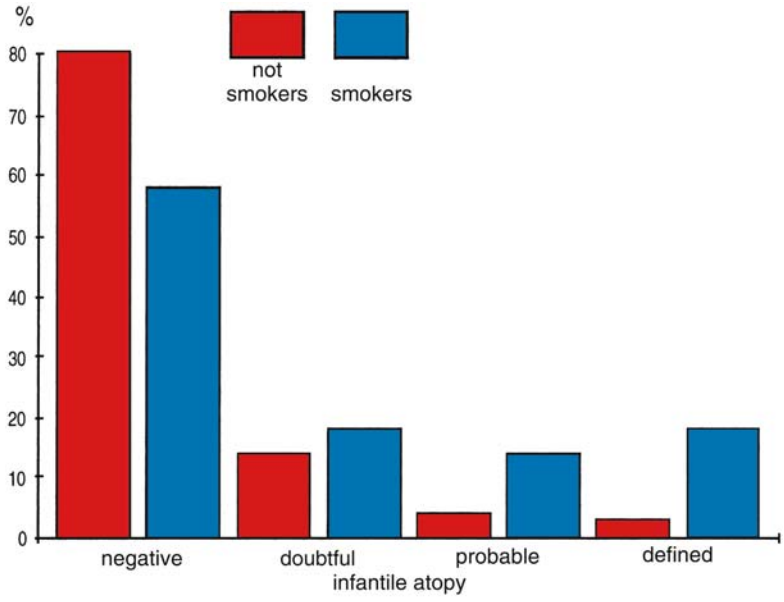

Fig. 4.24. Incidence of atopic disease among the children of smoking mothers. (Data from [256])

Data from [56].

[a] Compared with the mothers of atopic children.

to the point that about 40% of cases are related to chiefly maternal ETS [147].

Maternal smoke, even of only 10 cigarettes/day, is responsible for the earlier wheezing onset [490] even in the 1st year of life [129, 146], and is significantly predictive of asthma development in children [268], at school age [184], or after age 16 [420]. The mothers of atopic children with asthma and SPT and RAST positive to Der p 1 have smoked during and after pregnancy more than the mothers of nonatopic children (Tables 4.26, 4.27) [56]. We can therefore conclude that the principal source of ETS is maternal smoke during and after pregnancy and that the effect of maternal smoke of >20 cigarettes daily is significantly associated with asthma onset in children and that males are more significantly at risk than females [56, 268]. Smoking only during pregnancy or after delivery fails to modify the results [116]: the risk of developing BHR is positively associated with maternal smoke during pregnancy and/or in the 1st year of life [129]. In 276 unselected infants [146], the risk was extended at least up to 18 months of life. The association with ETS is statistically significant in Der p 1-sensitive children and of maternal smoke with the prevalence of atopic sensitization [465]. In 98.8% of 1461 asthmatic children of smoking mothers, the free running test increased heart rate to >170 beats/min, an effect sufficient to elicit bronchoconstriction in sensitized subjects [129]. The risk factor was quantified in 744 subjects aged <5: *children with mothers smoking at least 10 cigarettes daily were 2.55-fold more likely to develop asthma* and 15.7% lower MEF than children of nonsmoking mothers or those smoking <10 cigarettes daily [268]. *An OR of 2.1 was reported for asthma in children with mothers smoking even only 10 cigarettes daily compared with children of nonsmokers;* also highlighted were use of asthma medications (OR 4.6), asthma developing in the 1st year of life (OR 2.6) and increased numbers of hospitalizations [477], possibly leading to a greater risk of asthma in children with PFT anomalies [296] and to permanent PFT changes in children exposed *in utero* [470]. These studies suggest that maternal smoking during pregnancy may influence mechanical factors that are important throughout the whole life of the child. A consequence is that maternal smoke may implicate bronchial reactivity: symptoms were 47% more frequent in children of smoking mothers and a fourfold greater BHR to the histamine test than in children of nonsmoking mothers was reported [298]. After a longer exposure to maternal smoke, PFT abnormalities were more consistent [296]. Both obstruction and malformation of the lower airways, resulting from the exposure of the unborn child may predispose to a precocity of longer and more severe obstructive episodes, potentially worsened by poor effects of medications.

The true smokers were 52% of males and 49% of females: the mother smokes 20 cigarettes daily, but girls seem to be more susceptible considering that they spend more time at home and are more exposed [125]. Negative effects should be more pronounced in males for anatomical reasons; instead the picture has been reversed at the expense of females, with an elevated OR for smoking of either parent [125, 425]. This finding may be explained by the increased levels of dehydroepiandrosterone, an androgen of the metabolic pathway of testosterone and cortisol that has been demonstrated in the amniotic fluid of pregnant smoking mothers [240], *leading to a possible masculinization of the female fetal lung,* with effects similar to the male lung. A large body of epidemiological evidence has stressed the risks connected with ETS and suggested the urgency of firmly advising against maternal smoke in pregnancy and after [56]. This crusade is made more crucial by the observation that women who stop smoking in pregnancy often restart in the immediate postnatal period [56, 116] and that prolonged breast feeding in infants of heavy smokers ensures a protective effect against wheezing development [116]. However, ETS reduces EGF (epidermal growth factor) levels also in breast milk. The widespread nature of ETS is documented in Table 4.28 [43, 44, 75, 84, 125, 146, 198, 233, 335, 514]. Smoking as a serious problem for young girls is emerging in many countries. Figure 4.25 [140] shows the difference between active smokers aged 10–14 and 15–18 years in the US: the younger ones totaled 20% of smoked cigarettes and the only difference was the higher rate of females of

15–18 years smoking 1/2–4 cigarettes daily; in the younger group the prevalence was 17% for males and 19% for females, and at their age mild airway obstruction and slowed growth of lung function are already present [140]. A decline of FEV_1 and FEF_{25-75} was evident in the girls of 17–18 years who smoked. Perhaps youngsters are influenced by 67%–69% of smoking mothers [116, 140].

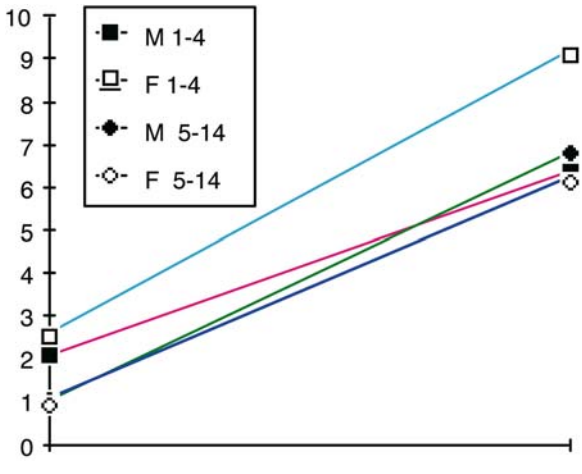

Fig. 4.25. Proportion of smoking children and adolescents (see text). *F* females, *M* males. (Data from [140])

The postulated links between the increase in atopic disease prevalence and smoking are proved by the significantly increased number of smoking girls aged 16–24 (9%) [467] paralleled over the same time span by the increased asthma frequency (6%) [304]. In an epidemiological study, the asthma prevalence is increased sixfold in those aged 16–33, especially in a period highly associated with active cigarette smoking [420]. It is needless to comment that in 1988 US cigarette manufacturers spent (or invested?) the equivalent of $100/s for cigarette advertising and promotion, and it appears that magazines that depend on advertising revenues are less likely than others to publish articles dealing with the hazards of smoking for fear of losing these revenues. The evidence on the dangers of smoking (Table 4.25) suggests that adopting adequate measures to warn smoking boys and girls, as well as women in their reproductive years, and mothers against smoking at all, particularly during and after pregnancy, can help ensure a normal development of infant airways in the generations to come. The parents of asthmatic children studied by Murray et al have reduced their children's exposure to smoke, so that the prevalence of asthma in their children has reached the levels of the normal population [297]. Although several countries have strengthened smoking regulations in public places, they are often hard to enforce [446].

Infections

Further insights into respiratory infections show strong epidemiological and pathophysiological evidence to link viral infections to exacerbations in childhood wheezing and asthma and to susceptibility to atopic sensitization: in 11 of 13 children, an upper respiratory infection occurred 1–2 months prior to allergic sensitization [128]. Based mostly on animal experiments, pups previously virus-infected, for example, by the respiratory syncytial virus (RSV), have supplied evidence that viral infections can promote IgE sensitization. Infection-induced release of potent mediator peptides, made by stimulated immunocompetent macrophages and monocytes, may result in the activation of immune responses. Host metabolism is altered in a way that may be debilitating and lead to malnutrition if continued for too long. Matching the changes produced in the intestinal mucosa, VRI may increase aeroallergen absorption via the respiratory mucosa, and epithelial permeability to a greater extent because of inflammation [127, 235]. Table 4.29 [50] recapitulates the numerous hypotheses increasingly proposed to elucidate the intriguing relationship between viral infections and their interference on IgE immunoregulation, thereby influencing development of atopic sensitization in experimental models [50].

Table 4.29. Possible mechanisms by which viral infections promote atopic sensitization in experimental models

Increase in total IgE levels by inducing clones of virus-specific IgE
Promotion of a direct epithelial damage
Epithelial damage + alteration of mucociliary clearance favor greater penetration of inspired viral allergens
Alteration of the allergen process at the mucosal level
Preferential reduction of IgE-specific T-suppressor cells
Increased release of histamine induced by IFN-γ and consequent increase of mucosal permeability
Increase in mucosal permeability may favor allergen absorption

Data from [50].

Intranasally RSV-inoculated mice and exposed to OVA with or without adjuvant developed higher OVA-specific serum titers of IgG and sIgA antibodies. OVA serum concentrations were significantly higher in RSV-infected animals compared to uninfected animals or those exposed to OVA with the adjuvant (Fig. 4.26) [127]. The same team of investigators has demonstrated that RSV infection in mice may also significantly enhance IgG and IgE antibodies to ragweed administered by aerosol (Figs. 4.27, 4.28) [235]. These observations may explain why mucosa-restricted VRI may enhance the development of sensitization in children with viral-induced bronchopulmonary disease [127, 235]. RSV

may induce a consistent IgE response in the respiratory mucosa of infants with bronchiolitis, in whom cell-bound IgE persist longer compared to infants with other forms of respiratory illness due to RSV infection [478]. RSV is also capable of activating and stimulating eosinophils to release cationic proteins, thus amplifying its action in the pathogenesis of bronchiolitis and provoking persistent BHR after its infection.

Rhinoviruses have the ability to stimulate mast cells to release histamine, with foreseeable effects on older children, while RSV is the causative agent for wheezing in younger children. In an epidemiological investigation on schoolchildren, asthmatic episodes were accompanied by viral infections in 80% of cases and in 65% of cases *Rhinovirus* was detected [192]. *Rhinovirus* infections are prevalent mainly in April and September–December, in correspondence with the peak of asthmatic exacerbations [192]. In this outlook, the effect of viral infections on adhesion molecules regulating eosinophil and neutrophil migration is particularly interesting [50]. CD54-stimulating eosinophils migration is the main *Rhinovirus* receptor; this suggests that these viruses play a pivotal role in determining BHR. Recently, *Chlamydia pneumoniae* has been included in the asthma pathogenesis (Chap. 11). Interesting studies in infants and children have reported that airway viral infections are associated with respiratory allergy in children suffering from their first episodes of wheezing after 2 years of age, chiefly if they are at risk for atopy, while others continue to wheeze for years [509]. Moreover, a greater number of infections were found in babies in their first 2 years of life than in controls [50].

As both children and their airways grow, atopy exerts an ever greater impact on recurrent airway obstructive infections [61], so that while its influence is scarce in the first 2–3 years of life, as noted previously, it has a crucial role in provoking recurrent wheezing in schoolchildren [410]. In this context, studies done in Germany have revolutionized traditional concepts, leading to a critical re-examination of the role played by viral infections in facilitating allergic sensitization. The attendance in daycare facilities has increased the risk of early infections and of sensitization; however, *early infections may protect from atopy,* since 62.5% more babies in the former East Germany than in the former West Germany had access to daycare settings [464], and they are less atopic than the children attending daycare settings in the former West Germany [464, 465]. However, it appears that more children of former East Europe suffer from respiratory infections, and fewer SPTs are positive to inhalants [43]. The less ventilated modern homes with a wide use of rugs and wall-to-wall carpeting, and a scarce use of daycare facilities, might have protected children from exposure to infections, which when acquired in the first few years of life, could have protected from atopy onset [28]. The mechanism is far from being understood but revisiting other studies, the role played by infectious agents could be the inverse of current theories, that is, measles infection may protect children by significantly lowering the prevalence of allergy [393]. Evidence in support of the Th1/Th2 paradigm (a postulate of the "Hygiene Hypothesis") came from a large cross-sectional study of Japanese schoolchildren first immunized with BCG (Bacillus Calmette-Guérin) and then tested with tuberculin, thus showing *an inverse relationship between tuberculin response* (a Th1-mediated delayed hypersensitivity reaction) *and both allergic disease and a Th2-like T-cell IL profile* [400].

First, the initial observations on the protective effect of measles [393] and mycobacterial infections [400] have not been replicated in larger studies in Western communities. Second, the results of a recent study do not support the hypothesis that BCG vaccination in early infancy is associated with a subsequently decreased risk of atopic sensitization or of clinical manifestations of atopic disease in general [142]. Third, a study on 20,690 atopic children who had had measles has shown a positive association between measles and atopy, which was evident at all ages, in both urban and rural dwellers, and among subjects with many or few contacts at home or in daycare facilities [324]. An alliance between virus and mycobacteria may downregulate Th2 by inhibiting their ability to respond with IgE production due to a decline in Th2-like T-cell ILs: it is likely that PBMCs in response to a microbial challenge produce IL_{12}, IL_{18} and TNF-α by supplying a valid signal to inhibit Th2 proliferation directly or priming NK cells to generate IFN-γ, with ensuing Th1 preferential activation [363]. This hypothesis is substantiated by the observation that infections may indeed result as protective, especially if in concomitance with low socioeconomic status and domestic crowding [44], thus inducing frequent infections (Fig. 4.29) [79]. Thus, a declining number of infections in the first years after birth may occasion respiratory allergy [79]. However, the exposure to a range of infections *in utero* was associated with a small increased risk of developing allergic disease [276].

These data are in line with the revisitation of those theories binding atopy to viral infections [50, 356], which may be able to tip the scales toward Th2 [79]. From this point of view, the pertussis toxin is an adjuvant for IgE generation vs previously encountered antigens in a dose-dependent way; in humans pertussis is associated with BHR, which extends for several months, and in atopic children there is correlation between IgE and IgG response to pertussis toxins after booster immunization [309]. Viral infections cannot be underestimated: mainly in the first few years of life, they may damage the special mechanisms of the mucosal barrier, thus facilitating penetration of allergenic molecules and consequently B lymphocyte activation, isotype switching to IgE antibodies and the pertinent inflammatory cascade [50, 356]. At the same time, ETS fosters the increase in IgE concentrations (Table 4.24): *the pairing of virus and smoke modulates atopy genesis.* As we report in Chap. 22, children with RRI and with the tran-

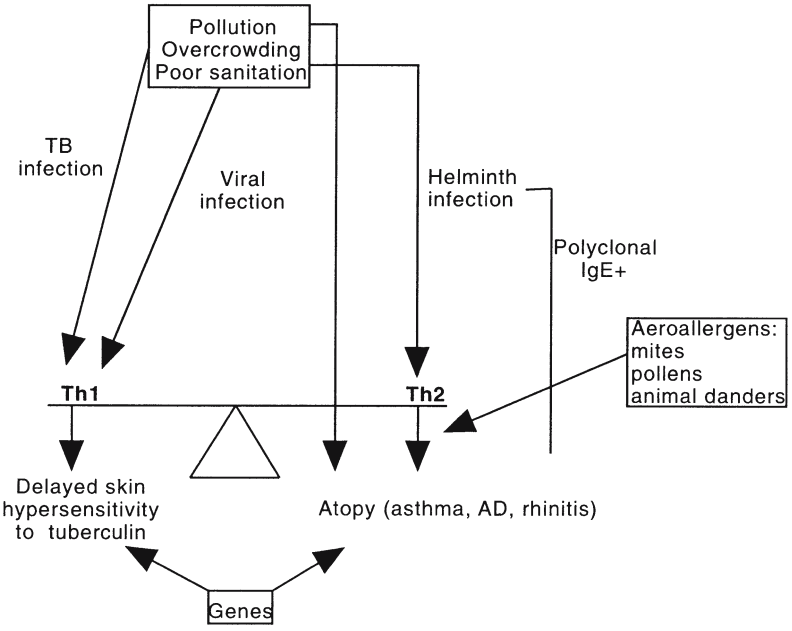

Fig. 4.29. Effect of infections. Atopy is reciprocally related to immunity to tuberculosis (*TB*). If a subject has predominantly Th2 cells, the Th2 phenotype interacts with environmental allergens to produce atopic dermatitis (*AD*). Infections may alter the Th1/Th2 balance, shifting it toward the Th1 phenotype. The clean living conditions of Western society, by reducing the incidence of infection, may tip the balance toward the Th2 phenotype and predispose individuals to the atopic march. (Modified from [79])

sient deficit in CMI are susceptible to undergoing the inactivation of normal mechanisms of antiviral defense.

Considering that several patients without a genetic predisposition suffer from atopic disease, it is obvious that the underlying source of asthma and atopy is not yet fully known. Viral infections often precede asthma onset, but more convincing is the frequent occurrence of unidentified viral agents, in line with certain epidemiological characteristics of asthma; therefore, the identification of causative agents may be the first step to define preventive strategies. The intervention is feasible when viewing an early vaccination as highly efficient in directing immune defenses toward host protection [169]. The original sin is that while the type of virus and the timing of exposure may play a critical role in both the initiation and induction of atopy and asthma, the immune system is no longer engaged in reacting to infections, tuberculosis, etc. Rarefied by vaccinations and effective treatments, it fails to produce Th1 and IFN-γ and becomes hyperactive to allergens, thus skewing to Th2 and IL_4 and contributing to the *unprecedented rising severity and prevalence of allergic disease*. Linked to Gram- infections is the polymorphism of the CD14 gene, encoding the high affinity receptor for endotoxin [15].

Dietetic Factors

Food allergens are the most frequent cause of atopic sensitization in the first few years of life, when the intestinal barrier is more permeable to protein macromolecules. The first 4 weeks of life appear to be particularly at risk because sIgA antibodies are absent at birth, since sIgA are able to limit the absorption of food macromolecules and play a protective role against viral infections. This absence is overcome by the very important immune protection ensured to neonates by receiving *colostrum and breast milk* rich in sIgA and other protective factors (Tables 2.14, 2.17). The first unequivocal demonstration of the role played by foods in FA dates back to Talbot, who reported AD development in a 3-week-old girl breast-fed from birth after the mother had eaten a pound (454 g) of *milk chocolate*. The symptoms cleared when the mother avoided chocolate and recurred when she ate it again [428]. A look at studies on atopy prevention suggests that dietetic restrictions in mothers breast-feeding children genetically predisposed to atopy development have yielded convincing results. Associating exclusive and prolonged breast-feeding with detailed dietetic measures and allergen avoidance, the prevalence of atopic disease and the severity of symptoms were reduced even in children already suffering from atopic disease (Chap. 24).

There is little doubt that *early weaning* inversely affects atopy development. A prospective study demonstrated a direct linear relationship between the number of solid foods introduced into the diet by 4 months of age and the subsequent development of AD, with a threefold increase in chronic or recurrent eczema at 10 years of age in infants who had received four or more solid foods before 4 months of age compared to those who received no solid foods by the same age (Table 4.30) [122], thus confirming the results of a classic study [197]. Introduction of other milk before age 4 months increases the risk of both asthma and wheezing [310].

Recent studies support the theory indicating that *anomalies of essential fatty acids* (EFAs), especially long-chain polyunsaturated EFA LC-PUFA, may negatively influence immunoregulation: according to the type and pathway of introduction, both T and B immune responses could be either amplified or suppressed. Breast milk LC-PUFAs suppress OX40 levels and de-

crease Bcl-L and Bcl-2 expression, thus protecting against atopy, asthma, autoimmune diseases and diabetes mellitus [94]. EFAs consist of monocarboxyl side chains; their classification is based on the number of C atoms and double bonds, which reflect the main determinants of their specific biochemical and functional characteristics. Figure 4.30 outlines EFA, long-chain fatty acids (LCFA): the first two lines show polyunsaturated EFAs, the third line monounsaturated EFAs. EFAs derive from linoleic (ω6 series) and α-linolenic (ω-3 series) acids: ω-3 series acids are found in high concentrations in diverse fish varieties and, along with ω6 series acids, are the main constituents of the cell membranes of all tissues. From the linoleic acid supplied with food, via δ5- and δ6-desaturase and elongase enzymes, humans form a family of derivatives including, in order, γ-linolenic, dihomo-γ-linolenic and arachidonic acids. However, mammalian cells are devoid of desaturase enzymes that introduce double bonds into the ω-6 and ω-3 positions, so an insufficient energy intake may cause deficiency symptoms. The deficit could be the effect of an as-yet undemonstrated deficit of δ6-desaturase, due to deficiency of prostaglandin and leukotriene precursors. EFAs are acquired via placental transfer: the fetal daily requirement is 400 and 50 mg/kg of ω-6 and ω-3 series, respectively, but the immaturity of both desaturase and elongase enzymes determining their synthesis is destined to persist if infants are not breast-fed or do not receive opportune integrations (Chaps. 2 and 7). During the last trimester of pregnancy, the fetal brain accretes the necessary EFA rapidly, in contrast with solely small amounts of the precursors linoleic and α-linolenic acids [212]. We believe that only a few topics have aroused as much interest and debates in immunology as EFA levels. Koletzko et al [212] have produced a worthy review on breast milk variations of EFA levels in several countries. In particular, their meta-analysis of 14 European and 10 African studies [212] provides mean values that are well suited as a point of reference to evaluate the indications of these integrative treatment in atopic children. In persistent Epstein-Barr virus and human ID virus (HIV) infections, as well as in AD (in AIDS) there is a high incidence. As a consequence, atopic and nonatopic children may differ with respect to the proportion of various LC-PUFA received through breast-feeding or perinatal supplementation which promotes the Th1 phenotype and thereby *protects infants against atopic respiratory disease* [93].

In food, not only additives, pesticides (Table 4.21) and different pollutants are found, but also *genetically modified organisms* (GMO) are now part of food intake, and we are not aware of the extent of the impact they may have on the development of infantile allergy, not to mention the use of unspecified chemicals and the notable prolongation of preservation time [57]. Such a concern is intensified by observing that, either for the introduction of new compounds and additives or techniques devised for the genetic manipulation, even fresh food items differ in many respects from those available only a few decades ago [28]. The type of foods eaten has changed dramatically with the introduction of the GMOs (Tables 1.78–1.79), available everywhere (Table 4.31). Virtually nothing is known regarding the possible influences on childhood allergy of such changes in their diet [28]. The original sin of GMOs is fully debated in Chapter 9.

Figure 4.31 [71] illustrates the factors influencing atopic disease development from the fetus to the adolescent [71].

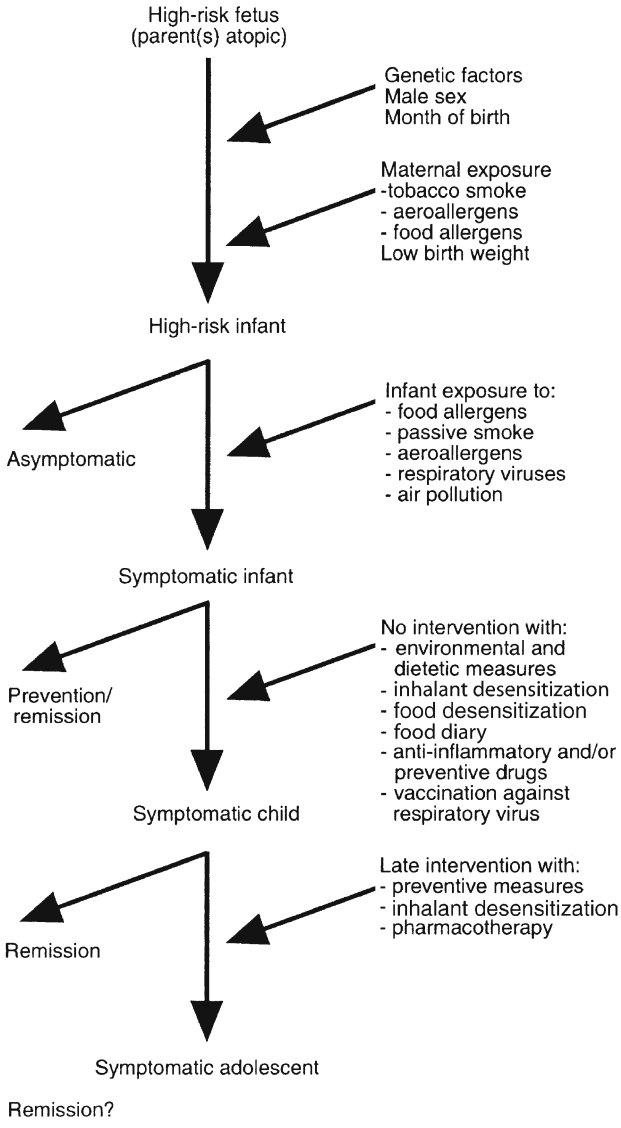

Fig. 4.31. Factors known to influence the development of atopy, from the fetus to the adolescent (see also Table 4.16). (Modified from [71])

Additional Factors of Importance for Atopy Development

Besides the factors incrementing IgE concentrations (Table 3.8), those arising more or less frequently as favoring the appearance of allergic disease are the following:

- Low birth weight (LBW) was not associated with asthma at 6 years of age [346] or at 13 years of age, while greater birth length was associated with an increased prevalence of reported asthma [233]: low (≤38.5 wk) or normal gestational age was an important determinant of asthma at 6 years of age in a birth cohort with FHA, significantly greater among boys (OR: 8.15) than among girls (OR: 1.90) [346].
- In premature babies, the incidence of asthma or wheezing is higher in those subjected to ventilatory assistance compared to unassisted babies [248]; specific risk factors for preterm babies are parental history of asthma, maternal smoking, siblings at home and neonatal O_2 supplements [116].
- In 8,088 children, infections in pregnancy and contraceptive use before pregnancy increased the risk of allergic disorders. Infections in the first term increased significantly the risk of AR and AD in the offspring [493].

- Complications and/or surgery either of the mother or neonate, including prematurity, delivery-related stress, delivery by Caesarean section, especially when complicated for medical reasons, prolonged O_2 treatment, anesthesia and surgery in the neonatal period, trisomy 21, infectious gastroenteritis, Hirschsprung's disease, prior intra-abdominal surgery in the clinical history of infants with CMA [459] and the number of hospital admissions in the first months after birth [116].
- Asthmatic children with recurrent early infections and antibiotic courses were at a lower risk of being symptomatic at school age, since the number of fever episodes and antibiotic courses were strongly inversely related to the prevalence of atopic sensitization [463]. A subsequent study in children from Belarus did not support the hypothesis that infection protects from recurrent wheezing or AD in the first year of life [216].

An analysis on 4,065 children has shown that early or threatened labor and malposition or malpresentation of the fetus were significantly related to a higher risk of developing asthma later in life (10.1%) [8], as well as neonatal illness in the 1st week of life [299]. Caesarean section had a strong effect on current doctor-diagnosed asthma in adulthood, with an adjusted OR of 3.23 (95% CI, 1.53, 6.80). However, no substantial effects were observed for atopy, AR, and AD [494].

Concerning latex and plants, see Chap. 8. In 16-year-olds a study has reported 167 cases of inhalant allergy caused by quilts due to raw silk employed in the fabrication; diagnosis was done by prick + prick test and RAST [120]. Jute, hemp, kapok and cotton widely used for carpets, underwear, etc. are irritants through contact, inhalation of the dust diffused, or as a possible substrate for growth of mites and molds.

Hygiene Hypothesis

The Th1/Th2 paradigm has been proposed as an explanation for the hygiene hypothesis; namely, the risk of allergic diseases is reduced by infection in early childhood [395]. An immunity skewed toward the Th2-type cytokine pattern at the cost of Th1-like ILs is a characteristic of being atopic [142]. Moreover, the results of a national cross-sectional survey (NHANES III) show a strong positive association between a history of Th2-mediated allergic disorders and Th1-mediated autoimmune disorders, and no epidemiological evidence to support the Th1/Th2 paradigm as conventionally understood [395]. The findings in a group of Estonian children do not support the hypothesis of an immune deviation with decreased Th1 and increased Th2 responses leading to atopic disease [195]. Therefore a mechanism of immune modulation throughout life, whereby both Th1 and Th2 responses are enhanced or suppressed in concert, provides a better way in which to view the effect of microbial agents on the development of atopic disease [395].

Originally, Strachan [417, 418] demonstrated an inverse relationship between birth order in families and the prevalence of wheezing, AR and AD [417], thus implying a different lifestyle. He suggested that the risk of allergic diseases is reduced by infection early in life. Moreover, several factors such as household size, infant dietary habits, vaccination status, antibiotic use, and migration history may alter immunoregulation. In a further comparison between East and West German schoolchildren [20], parasitic infections were significantly higher and atopic sensitization lower in the former than in the latter. Recent epidemiological studies have shown that children with siblings have a lower prevalence of allergies and asthma than do children without siblings. This association has been attributed to a preventive effect of cross-infections from older siblings in large families (the socalled *sibling effect*) and start daycare attendance at a younger age. This hypothesis is supported by a plausible biological mechanism, according to which early-life infections stimulate Th1 lymphocytes that may inhibit the expansion of allergen-specific Th2 lymphocytes, thus limiting the development of allergic diseases [359]. According to the hygiene hypothesis, widespread vaccination practices, and *increased use of antibiotics* in childhood, have led to a lower cumulative exposure to microbial pathogens, and as a consequence, to a prolonged propensity toward Th2-skewed immune responses, which prevail in atopic children who grow up in West Germany [352]. These results demonstrate differences in the Th1/Th2 response in two regions of Germany [352]. The atopic children from western Germany showed Th2 polarization; in eastern Germany, as in Estonian children [195], atopy was associated with Th0 responsiveness and production of IFN-γ in >60% of cases [352]. At birth there is a shift to Th2 T cells, which then prevail in FHA^+ neonates, whereas FHA^- neonates evolve toward a Th1-dominated pattern, as we stressed in Chap. 2. Subsequent studies have continued to explore the arguments for and against this hypothesis [395]. According to the postulates of the hygiene hypothesis:

- The number of siblings: the decreased prevalence of atopy is related to an increased number of older siblings [16, 465] or the presence of siblings did not have a significant association with sensitization at 12 month and 4 years [202].
- Daycare attendance started before the age of 1 year assured a lower prevalence of asthma, AR, and atopy compared to the children who started after the age of 1 year in a cross-sectional German study of schoolchildren [218]; at 2 years there was a lower RR of developing asthma [16].
- The type of dwelling (poorly ventilated homes, domestic crowding, furnishing, dampness, etc.) is often associated with atopy [28], which contrasts with increased prevalence in advantaged children [485] and the reduced prevalence [473] or not [146, 392] in connection with economic factors [464].

• In particular, domestic crowding is controversial [44, 488], because strikingly high IgE concentrations are dependent on the number of people living in one apartment [20], or because of a highly significant inverse relationship with atopic sensitization [44].

Recently, in a study of 2,531 children followed from birth to 4 years of age, early respiratory infections increased rather than decreased the risk of developing bronchial obstruction during the first 2 years of life and of having asthma at 4 years of age [299]. However, if a reduced microbial turnover at mucosal surfaces may be responsible for the association between hygiene and atopic disease among populations adopting a Western lifestyle, the sites involved may be those where APCs take up, process and present microbial and nonmicrobial antigens to specific T cells. The quality and intensity of bacterial stimulation would dictate the state of activation and the kind of accessory signals transmitted by APCs to surrounding cells of the innate and acquired immune system [271]. If a high microbial turnover educates our immune system, mimicking this education could safely revert the epidemic trend of atopy in a kind of early life immuno-education [271].

We conclude that the hygiene hypothesis is no explanation for the increasing prevalence of atopic diseases in the developed world (Chap. 5).

Interactions Between Genetic and Environmental Factors

Several factors that when isolated fail to influence atopy have the potential ability of reciprocal stimulation and provoke atopic disease in the first years of life, such as CD3, CD4, CD8 CB levels and parental smoking, becoming significant factors when associated [71]. In two-thirds of children with CMA (hospitalized at the mean age of 13.6±1.2 weeks of life), at least one of the following conditions was noted: parental atopy, no breastfeeding and one of the conditions pointed out above, with a significantly greater prevalence than in the average population [459]. Several genetic and environmental factors, alone or associated, condition raised IgE and CBIgE concentrations: male sex, cigarette smoke [513], parental asthma, SPT positive to egg at 4 months, and to CM, egg, peanuts at 1 year after birth, as well as nasal eosinophilia and basophilia [512]. We summarize in Table 4.32 [71] the most important genetic–environmental factors in HR infants and children.

Pediatricians, Genotype, Phenotype and Early Predisposing Factors

I would like to take a further step in my comments, by stressing the unique function of pediatricians, traditional advocates of children's health and above all a front-line source of information and guidance for parents, who live atopic disease with understandable anxiety and worry. Since intervention on the genotype is not achievable, it is more realistic to aim at modifying deleterious environmental factors but, apart from allergen prevention, a particular factor to be taken into consideration is the *quality of life of young patients* who, as previously seen, are the victims of pollutant aggression from the very day of their birth (Table 2.26). Even if there exists a substantial gap between what is likely and what we can put into practice, limiting the pollution impact is certainly achievable. Pediatricians should be a champion of no smoking, especially in homes with children, also suggesting that children stay away from homes with smokers. The introduction of CO_2 and other gases in the atmosphere cannot be influenced, yet one should stay away from places and moments with increased concentration of motor exhaust fumes. The ozone depletion leads to a T rise in thereby pollens begin damage earlier. Transgenic vegetables are another aspect of so-called progress that will be dealt with in Chap. 24. We stress that *children* are more at risk because they breathe more rapidly given that their airways are narrower than those of adults, so they have markedly increased needs for O_2 relative to their size, and *inhale more pollutant per kg/bw* than do adults and spend more time in outdoor activity [229]. Children are especially exposed to environmental toxins because kg for kg/bw they drink more water and eat more food. Moreover, their hand-to-mouth behavior increases the ingestion of any toxin that toddlers may find in dust or soil, and playing close to the ground may increase the exposure to toxins in dust, soil, and carpets. Much is still unknown about the long-term effects of exposure to pesticides, and children may be more vulnerable than adults. However, pediatricians should suggest that parents encourage children to eat a variety of fruits and vegetables: the health benefits outweigh the risks of pesticide residue consumption [229, 350]. According to the legend of Romulus and Remus, the twins were abandoned by their mother on the Tiber rivers and were suckled by a wolf. The twins survived in such a hostile environment as the Tiber river although they were fed with milk as different as wolf's milk. However, they grew so strong as to enable them to build Rome. This fascinating legend teaches us that *human newborns are able to overcome great difficulties*. However, there is no doubt that the twins would have failed to react in this way if pollution had been as widespread as in our times. Children in the New Millennium: Environmental Impact on Health, a new study released by three United Nations agencies, shows that every day 5,500 children die from diseases caused by consuming water and food polluted with bacteria [481].

Table 4.32. Main genetic–environmental factors responsible for or contributing to the development of atopic disease in high-risk infants and children

Genetic/immunological/perinatal factors
Positive family history of atopy
Altered IL_4/IFN-γ ratio
Altered CD4/CD8 ratio
Intake of alcohol and/or caffeine during pregnancy
Intrauterine exposure to drugs
Male sex
Maternal smoking during pregnancy
Month of birth
Prematurity, perinatal stress, surgery in the neonatal period
RFLP atopy in general
Markers with a probable genetic basis contributing to the atopy phenotypic expression
Number of mast cells/basophils and their releasability
Number of IgE receptors and affinity for IgE antibodies
Relationships with the autonomic nervous system (α-adrenergic hyperresponsiveness, β-adrenergic hyporesponsiveness, cholinergic hyperresponsiveness)
Target organ sensitivity
Clinical and environmental markers
Alimentation during the first days/months of life Absent or reduced breast-feeding Cow's milk allergens Egg allergens Additional food allergens Early introduction of solid foods Weaning period and procedure Food additives
Positivity of skin tests for foods and inhalant allergens
Presence of IgE antibodies specific for foods and inhalant allergens
Exposure to allergens during the first months of life, especially at birth Foods Inhalants
Early exposure to specific or nonspecific factors Antibiotic therapy ETS at home Home crowding Home dampness Presence of pets at home Urban air pollution (as adjuvant) Viral and/or bacterial infections
Range of allergen concentration
High prevalence of atopic disease
Severity of clinical manifestations
Multiple atopic disease

The hygiene hypothesis considers crowded living conditions, early exposure to pets and to group daycare as factors decreasing the risk of atopy: the truth may be also the opposite.
Data from [71].
RFLP restriction fragment length polymorphism.

Epidemiology and Natural History of Atopic Disease

Epidemiology

In this chapter we analyze the unending worldwide increase of pediatric allergic diseases and their natural history. Of concern is the early age at which atopy starts its march in these defenseless children.

Definitions. Epidemiology, literally a study on the population, is the correlation existing between diseases and certain factors regulating the appearance, diffusion, and outcome of these diseases in a human community. During the last 3 years, the study of both frequency and distribution of atopic disease has been particularly intensified to better identify the factors triggering atopy onset.

The *natural history* of atopic disease usually establishes a sound scientific basis to arrange measures able to modify the phenotype, thus improving both the course and prognosis of these diseases.

We hereby add a number of definitions to calculate the pertinent titers [303]:

- *Incidence* of a disease is the frequency, that is, the number of new cases of a particular disease in a defined population identified during a given time (usually 1 year, or the last year), also called 12-month prevalence.
- *Prevalence* of a disease is the diffusion, that is, the number of cases of a disease in a given population at a specific period of time.
- *Point prevalence* is used at a particular point of enquiry, expressed as a proportion of the total population.
- *Period prevalence* expresses, over a specific period of time, the relation between the number of cases at a defined observation period and the total population.
- *Cumulative prevalence*, that is, the number of cases in a given population who have had a given disease [290].

The terms *lifetime prevalence*, the existence of a disease at any time in an individual's life, and the *current prevalence*, the existence of a disease at the present time of the individual's life, also-called *12-month prevalence*, have been recently added.

In the many tables of this chapter, we have tried to use a unifying method to link different data characterized by their non-homogeneity. The result is a high, unexpected prevalence/incidence of atopic diseases.

Lack of Uniformity of Diagnostic Parameters

Several parameters can invalidate the indispensable prerequisites of epidemiological data (Table 5.1) [20, 31, 33, 100, 112, 232, 294, 341] such as the lack of uniformity of terminology in establishing definitions and of criteria employed for the diagnosis [232]. Apart from most prospective studies, some are retrospective and bedeviled by problems of subject memory, such as the frequent reports affected by parents' recall bias, and liable to variations ranging from 25% [69, 127, 193] to 44% [142]. In a prospective study conducted on 480 newborns followed in a general pediatric practice through their third birthday, 28% were thought to have had an adverse food reaction [33]. Of the 133 children identified, only 38 (8%) had their symptoms confirmed by an oral food challenge (OFC). In a retrospective study, up to 25% of the conditions diagnosed in a child from birth to the age of 1 year were forgotten or not reported by the parents of 11-year-old children [69]. Only 37% of parents knew that their children suffered from asthma, and even fewer (32%) knew that their children had rhinitis [289]. Use of information obtained from both parents induces important bias. Such bias is reduced when the cases, for example of atopic dermatitis (AD) and asthma are diagnosed by doctors [268, 322]. Parents are less worried about respiratory problems, forget the wheezing episodes of their grown-up children, which were instead reported regularly in early infancy [193, 222], whereas only 68% of fathers and 72% of mothers recollected the feeding procedures [346]. Parents reported recurrent wheeze in 19.4%–25.9% of children, the doctor diagnosed even asthma in 6.9% of their offspring [332]. Over the years, 40% of the children failed to confirm the data originally elicited by their parents [142] and more than one-third of young adults did not remember that they had wheezing episodes during their infancy [303]. Parents with many children may not recall a relatively mild disease such as AR (allergic rhinitis) as accurately as parents with one or two children [330]. Some trials are based on objective measurements, others on responses to questionnaires, which when not standardized can be a catalogue of different definitions of disease and significant variations on prevalence data [232, 330]. Differences in diagnostic criteria may be due to relative-

Table 5.1. Parameters accounting for the discrepancy of data

1. Variable diagnostic criteria
2. Terminology used to establish a precise definition of disease
3. Lack of supportive allergic/immunological data
4. Heterogeneity in terms of age, sex and socioeconomic status
5. Criteria of selection (atopy of children, of parents)
6. Evaluation of family history
7. Evaluation of exogenous factors
8. Small number of children, hence more random fluctuation
9. Randomization, control groups, so the development of new diagnostic criteria, or the differing definitions of clinical cases
10. Representative criteria (general population or selected) of the samples studied
11. Diagnosis of atopic disease (doctor, clinical, laboratory, pediatricians, allergists, etc.)
12. Diagnosis of atopic disease (skin tests, sIgE study, provocation tests, blinded evaluation)
13. Statistical analysis of data
14. Prospective vs retrospective design
15. Possibly confounding factors
15. Drop-out rate
16. Compliance
17. Duration of follow-up: monthly, trimester, yearly controls, or start-end
Additional guidelines for studies on atopy prevention:
18. Environmental controls (smoking, mites, pets, chemicals)
19. Duration of breast-feeding or with special formulas
20. Dietary restrictions of the nursing mothers (diet duration, foods eliminated)
21. Time solid foods introduced
22. Type of foods introduced
23. Qualification and experience of study clinicians, definition of study population

Data from [20, 31, 33, 80, 112, 232, 294, 341].
sIgE specific IgE.

Table 5.2. Factors underlying the increased incidence and prevalence of atopic disease

Increased exposure to allergens
Environmental pollutants
Improvements in personal sanitation
Lower cumulative exposure to infections
Increased use of antibiotics in childhood
Increase in mobility in general and in social relationships
Decreasing numbers of siblings

Data from [171, 176, 330].

ly few studies involving clinical examinations [317]. In a trial on patients affected with AR, two-thirds were rejected at the military check-up because they did not respond to fixed parameters [334], while an observer found in children a 1.4-fold increased prevalence [3]. However, groups from medical practices tend to represent the more severe cases [155]. The sample variability has selection bias, but by selecting >400 patients, a type II error is avoided [290]. In the field of statistics, more and more frequently papers are committed only to χ^2; however, odds ratio (OR) confidence intervals and other specific tests should be employed [290]. A related crucial parameter is whether the trial has been carried out by using the double-blind placebo-controlled food challenge (DBPCFC). A DBPCFC study in subjects declaring a 7% allergy to food additives indicated a prevalence of only 0.023% [356]. In the field of food allergy (FA), the comparison between clinical response to elimination diet or food challenge test (FCT) and SPT or sIgE (specific IgE) results may invalidate the conclusion: SPTs may individuate as offending only the food that has provoked a type I immune reaction, but they do not identify the frequent late reactions (Chap. 6). The ISAAC (International Study of Asthma and Allergy in Children) has proposed a standard written questionnaire. Recently, the written questionnaires have been developed as video questionnaires obtaining a 78% concordance [231] with an ISAAC protocol. In Turkish children aged 8–11 the ISAAC found a prevalence of current wheeze of *11.5%* and of physician diagnosed asthma in *6.9%* [266].

In the tables showing epidemiological results, although we have preferred doctor-diagnosed or questionnaire data (such as ISAAC "has your child ever had asthma, eczema, rhinitis?"), methodological differences in several studies make it difficult to compare the magnitude of the difference in prevalence/incidence between countries, and among populations in countries of widely differing lifestyle and ethnic groups. Even when differences in methodology are allowed for, atopic diseases are alarmingly frequent and their prevalence has substantially and progressively increased in industrialized countries over the past 30 years. Undoubtedly, a wide spectrum of factors, both genetic and environmental, are mainly responsible for this; however, several recently appreciated features emphasize the multifactorial mechanisms behind any such disease (Chap. 4). Table 5.2 summarizes the factors that explain such an increase [171, 176, 330].

Age at Onset [51]

Table 5.3 [29, 33, 40, 72, 87, 130, 143. 148, 149, 167, 172, 177, 268, 359] shows the mean prevalence of FA, Table 5.4 [33, 68, 72, 86 , 88, 103, 108, 124, 133, 136, 142, 146, 192, 239, 249, 269, 270, 273, 299, 320, 326] of cow's milk (CM) allergy (CMA) and Table 5.5 [22, 29, 32, 33, 38, 48, 53, 68, 69, 71, 93, 96, 107, 118, 120, 140, 144, 148, 153, 163, 179, 187, 198, 208, 211, 241, 242, 273, 281, 291, 355, 358] the onset age of atopic disease; the onset of peanut allergy is as high as 91.5% within the 7th year [93]. In some studies, we find a quite accurate pattern of the onset age of AD [51], asthma and AR: Table 5.5 shows that 90%–95% of cases begin within 1 and 5 years. As shown by several investigators in different countries, asthma, AR, AD and FA are among the commonest childhood illnesses worldwide, and their prevalence may be progressively increasing in the pediatric population [63, 138, 343]. The Aberdeen colleagues report high figures: in over 25 years the asthma prevalence has increased from 4.1% to 10.2% and has more than doubled in 1992–1996 [215, 221], but above all the onset age has lowered (Fig. 5.1) [291]. Recently, an increased incidence has been

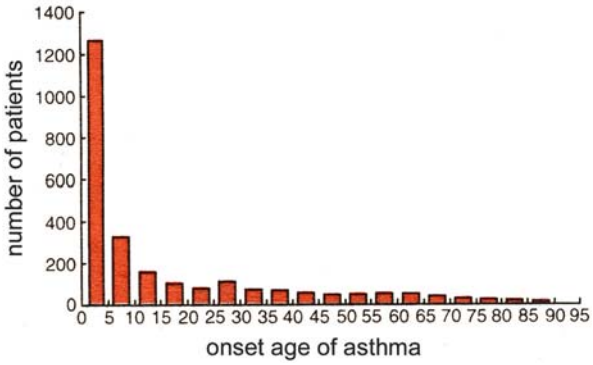

Fig. 5.1. Age of asthma onset vs number of patients

reported in the first 18 months, which was as high as 8% [39, 123], 15% [126] and 18% [29] for AD, 10% to 15% [29] for asthma, and a cumulative incidence of atopic disease of 19% in the first 18 months [127], and 34% during the 2nd year of life [29]. At variance, FA reaches a frequency of 2%–3% in the first 2 years [29, 127]. Moreover, several studies report infants with recurrent wheezing [30, 78, 122, 193, 257, 267], also with early symptom

onset in numerous cases [32, 48, 163, 193, 257, 355], 57% within 5 months [257] and 53%–59% within 12 months [163, 355] (Table 5.5). This is critical for males: 69% [193] or 66% of cases [145] with severe forms and bronchial hyperreactivity (BHR) [267] requiring hospital admission [257]. The highest figures in the asthma and AR onset were found in boys aged 0–5 [97]. In many babies, AR also begins in the 1st year of life [349].

Atopic March

What is called the *atopic march* is more evident in the earliest years of life (Fig. 5.2, Table 5.5): it is estimated that in the first 10 years of life, 10% of children suffer from AD, 20% from asthma, and 15% from AR [43, 69, 340, 341], while CMA prevalence (Table 5.4) is very different from that of FA. In adolescents, the cumulative

[a] The first figure indicates the males and the second the females.

[b] In Spain [242] in a study with 189 babies with food allergy, 93 had an onset before 12 months of age.

[c] In Spain [65] a study of 416 babies aged <1 year showed 617 immediate reactions to the pertinent foods.

[d] In Italy [22] 92 babies were studied, 49 males and 43 females, with a mean age of onset of 2.8±2.1 months, SPTs and specific IgE (RAST).

[e] An English study [93] on 60 children established the prevalence.

[f] In a preventative study done in the USA [358], 20% of 103 prophylactic-treated and 60% of 185 control infants were exposed to peanuts within their 1st year of life.

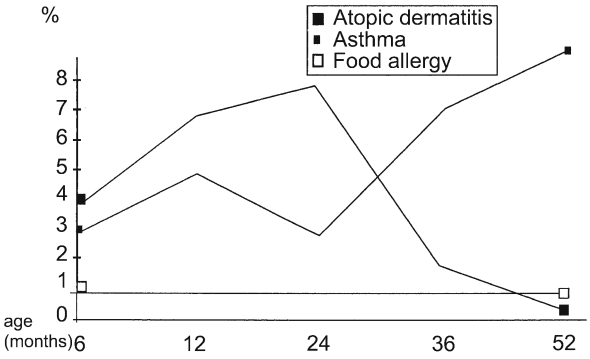

Fig. 5.3. Prevalence of atopic disease in 174 children at high risk of atopy according to their age. (Data from [39])

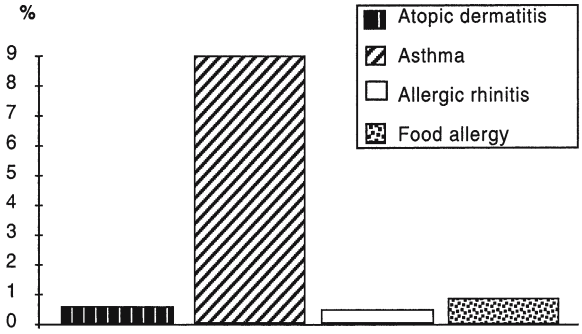

Fig. 5.4. Percentage of the 174 children with atopic disease at the 52-month follow-up. (Data from [40])

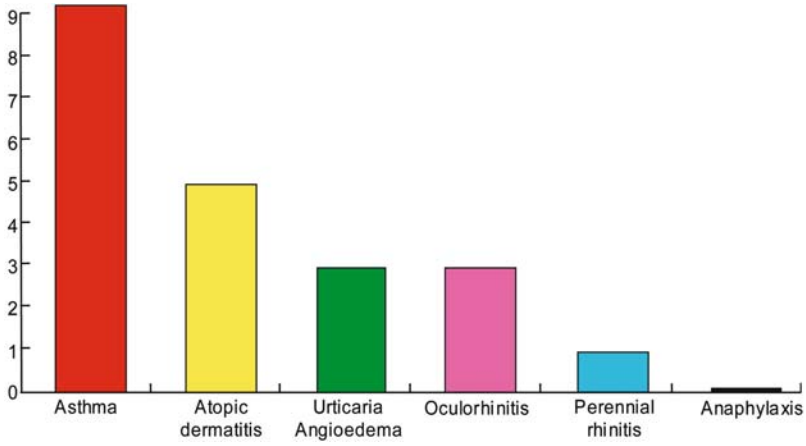

Fig. 5.5. Prevalence of atopic disease in children (for details, see text). (Data from [48])

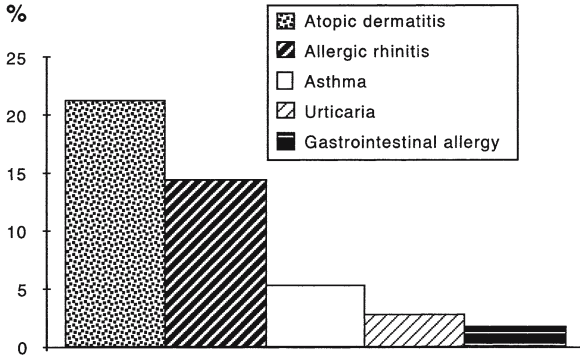

Fig. 5.6. Cumulative incidence of atopic disease in 1,654 children between 0 and 11 years of age. (Modified from [69])

incidence of atopic disease has a sensitivity frequency, between 25% and 31% and the prevalence is 21% [70, 321]. However, in different countries lower values are found, so that a dichotomy is observed: in Finnish children and adolescents the prevalences are 1.7% for AD, 6% for asthma and 4.3% for AR [240], evidently due to favorable environmental conditions. Therefore no univocal values are detected, except an increased prevalence in several countries or categories such as in preterm babies [192]. In 174 at-risk children followed-up for 52 months (Figs. 5.3, 5.4) [39, 40], the cumulative incidence of atopy was 18.5% [39], and 22.1% in the multicenter study (Fig. 5.5) [48]. These results should not be considered as timelessly invariable: for example, a considerable increase in asthma prevalence has been found in Australia [252] compared to 1969 [340] and between 1982 and 1992 [233]. Moreover, in Swedish children followed up for 11 years, the cumulative incidence of atopy was as high as 18.2% at 7 years and 32.5% at age 11 with a 23.7% prevalence [69]: Fig. 5.6 [69] shows the cumulative incidence of atopy between 0 and 11 years and Fig. 5.7 [70] the prevalence at age 11. Figures 5.8 and 5.9 depict the trend of atopic disease prevalence at distinct ages [53, 268]; in Fig. 5.9 [268], urticaria angioedema and oral allergy syndrome (OAS) are added. In the former East and West Germany [27, 329–331], AD prevalence is greater in the former East, the other atopic diseases in the former West. There is a substantial worldwide increase in the incidence of symptoms of asthma, AR, and AD in children aged 12–14 from 56 countries [311], including Arctic countries [166, 306].

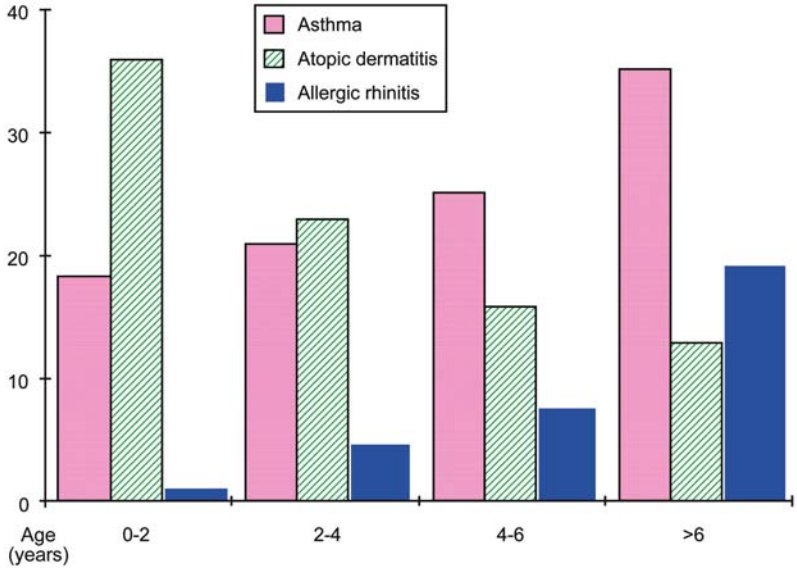

Fig. 5.8. Prevalence of the atopic march among 220 children divided into four groups according to their age. The slow decrease of AD prevalence, asthma progression and to a lesser degree AR should be noted. (Data from [53])

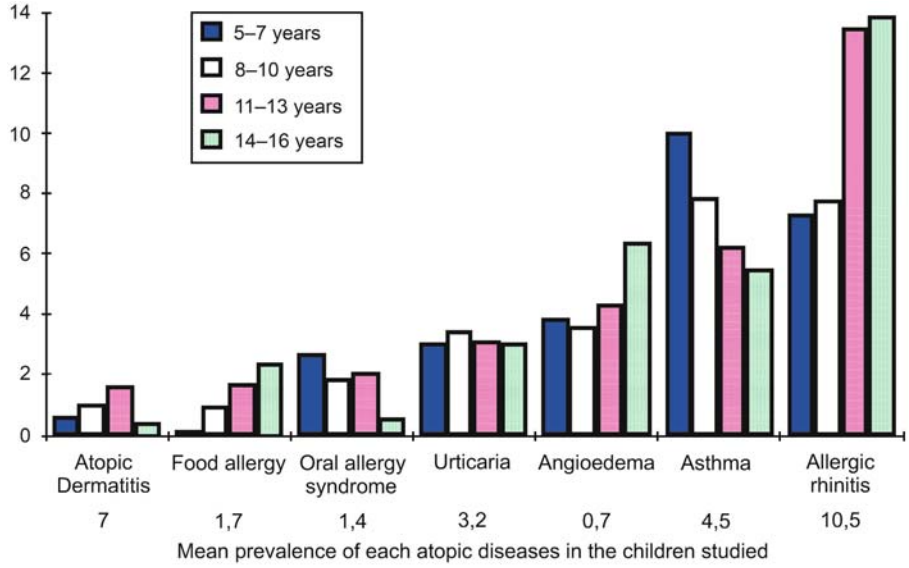

Fig. 5.9. Mean incidence of atopic disease in 1,052 children divided into four age groups; mean for males and females. (Data from [268])

Atopic Dermatitis

AD is very frequent in the offspring of atopic parents [271]. FHA (family history of atopy) rose up to 72.8 [128] – 83% of cases [239] and is an important risk factor for AD [81]. If only one parent is atopic the incidence is 9.5% at the age of 12–18 months; if both are atopic it rises to 12.8% (Fig. 5.10) [29]. In 0–4-year-old children with no FHA, 27.1% developed AD; of those with single or double FH, 37.9% and 50.0% developed AD, respectively [34]. AD rarely appears before 6 weeks of life (Fig. 5.11) and males are more involved than females (rate, 1.3:1) (Table 5.5). It is more frequent in children of high social classes and/or with a high education level [271, 306], in preterm babies [192], in twins [192, 276] and living in a detached house [306]. A greater incidence in females is found in Sweden in the first 2 years (1:1.8) [2], in Denmark from 5 to 16 years (1:1.9) [268] and at 8.1 years (1:1.2) [85], in Germany at 5–7 years in two out of four cities (1:2.5) [271] and at 8–33 years (1:1.5) [173], and in Hungary at 6–14 years (1:1.12) [128]. Additional risk factors are documented in Chap. 4 [271].

Table 5.6 [3, 6, 7, 15, 17–19, 23, 27, 29, 44, 45, 48, 52, 69, 72, 76, 79, 81, 83, 85, 94, 95, 113, 114, 116, 128, 129, 148, 153, 155, 158, 172, 177, 179, 183, 184, 187, 192, 193, 207, 209, 214, 232, 240, 241, 244, 254, 268, 271, 279, 286, 298, 307, 310, 315, 317, 323, 324, 329, 336, 337, 342, 351, 354, 362] outlines the values of prevalence and incidence of AD.

Data by Taylor et al [309] have shown that AD prevalence increased between 1945 and 1975 from 5.1% to 12.2% in England and between 3.1% in Bristol in 1945 and 17% in New Zealand in 1982 [95]. In Danish twins the prevalence significantly increased from 3.2% to 11.5% in 20 years or from 2.9% to 10.9% between 1939 and 1991 [276]. In 777 preterm infants with birthweight under 1,850 g, followed up to the age 18 months, AD incidence was 19.4% in general and 30% in twins [192]; in another 80 preterm infants, it was 7.5% compared to 5% of controls [76]. In a 3-year follow-up study [39], the prevalence rose to 8% at 24 months, decreasing to 2% at 36 and then fading (Fig. 5.3): the incidence was 4% at 6 months, 2% at 24 and 0% thereafter, and the cumulative incidence was 7.5% [39]. Likewise Sporik et al observed an analogous decline when children grow [296]. In 143 Greenland children followed up from birth to age 2, 16.78% of children developed AD. The incidence rate of AD was 177 cases per 1,000 child-years at risk, corresponding to a cumulative risk of 16% per year [306]. A recent worldwide ISAAC study on AD has found a 14.7% prevalence in 64,460 children aged 6–7, and a 14.6% prevalence in 135,559 children aged 13–14. In this group of children, the prevalence rates were as high as 46.9%–49.3% in Sweden, whereas the highest rate was 57.2% in Japanese children aged 6–7. Higher incidence values (≥15%) were found in 458,623 children aged 13–14 in northern Europe (Great Britain, Sweden) and especially in Japan and New Zealand in the younger group [339].

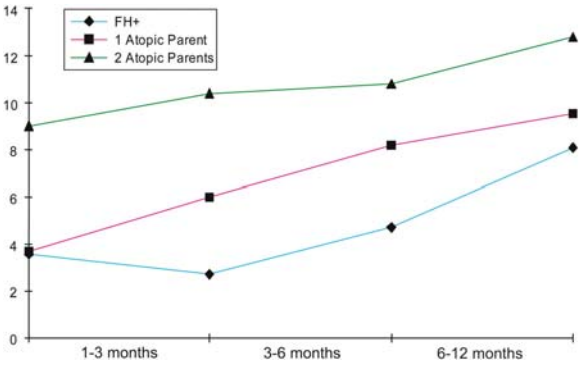

Fig. 5.10. AD in offspring of atopic parents: the more the parents are affected, the more AD incidence increases. For details see text. *FH* family history. (Data from [29])

Fig. 5.11. A baby with atopic dermatitis

The *natural history of AD* in children is poorly known due to the few studies that have been conducted; however, it can be in part re-established on the available data indicating a significant increase in prevalence in recent years (Table 5.7) [3, 5, 10, 12, 43, 55, 69, 72, 92, 137, 174, 178, 215, 221, 233, 253, 282, 294, 309, 323], for example, up to 12.6-fold in England between 1946 and 1994. In a study of 1,654 children, it was 7%–25% at 11 years depending on low or high CBIgE [69]. Prevalence was the same among subjects irrespective of whether they had symptoms at examination as adults [109]. In twins it was 2.3% before 1960, 5.6% in 1960–1970, 10.7% in 1970–1986 and 11.5% in 1991 [276].

The rates of remission observed by various investigators are widely variable: between 17% and 90% of cases at 6 years of life. Only a study conducted on 2,000 children followed up in some cases for 20 years was more optimistic, over 84%, but the results are controversial because most patients suffered from seborrheic dermatitis [327]. Rudzki et al [261] reported that 41.8%–50.8% of cases of respiratory allergy in children with AD was associated with one or both atopic parents, re-

[b] With peaks of 25%–40% in children with severe AD.

[c] Median age.

[d] See Fig. 5.6.

[e] See Fig. 5.4.

[f] In some Swedish studies the cumulative incidence was calculated: 12% [1], 4% in children aged 1.5 years and 13.1% in those aged 7 years [69]. In the Chinese children, those of Beijing reported more asthma than the children from Urumqi; we report the Hong Kong children separately [362].

spectively, and in 25.2% of children with no FHA. Alarmingly, a high proportion of children with AD develop respiratory allergy: 46.9%–53.3%, with 48.7% in remission (Table 5.8) [2, 22, 49, 100, 104, 118, 137, 140, 156, 157, 160, 188, 208, 220, 241, 229, 258, 263, 264, 322, 327, 328, 332, 352, 353], but with peaks of 79% for asthma [118] and of 79% for AR [118]. The association with asthma occurs in 14% of children before 2 years of age and in 40% before 5–6 years, with AR in 25% of cases at 5–8 years [173, 353]. In comparison with the results of a recent analysis, in eight studies conducted in 1953–1966 all results were decidedly more favorable [275], either due to parental data or due to a lesser consideration of respiratory symptoms. The progression to respiratory allergy was evident in 18 atopic children followed up from the age of 6 months to 5 years: at 6 months all suffered only from AD, at 18 months 23.5% also suffered from asthma, at age 5, 38.9% still had AD, 50% asthma, and 44.4% allergic rhinoconjunctivitis (more diagnoses in the same child) [213]. Moreover, children may have pollinosis in 27% and urticaria in 40% of cases [14]. The more severe forms of asthma are a feature of children with unremitting AD [31]: infantile AD is therefore characterized by long-lasting morbidity [156, 157].

Rystedt [263] has suggested some unfavorable prognostic factors in order of importance:

- Severe AD or with atypical or widespread distribution of skin lesions in infancy
- FH positive for AD
- Association with AR and/or asthma
- Female sex and early onset

[a] The first study in the last 50 years documenting this rise.
[b] See Fig. 5.6.
[c] Study conducted in regions with two different climates (see Tables 5.12 and 5.22).

AD persisted in adulthood in 80% or 15% of subjects according to the persistence or not of these factors [263].

In 56 children followed up for 5 years, we reported that the following factors were significantly associated with persisting skin lesions [34]:

- AD onset after the 6th month of life
- Atypical or widespread distribution of skin lesions
- Persistence of food intolerance
- Elevated levels of serum total IgE and of sIgE for foods
- Positivity of SPT and/or sIgE for inhalant allergens at the first visit, with a predictive value for the development of respiratory allergy [49]

The remission of symptoms may be significantly lower in females, 29% vs 42% of males [2]. Furthermore:

- In Swedish children, 41%–47% were affected with AD before the onset of asthma [2, 71] and at follow-up 38%–41% suffered from both diseases [2, 69]. Early onset and positive FHA predisposed to respiratory allergy [2] and the risk was doubled if CBIgE were elevated [69].
- Among 1,052 Danish schoolchildren, 10% had asthma, 15% rhinitis, 26% angioedema and 20% OAS [268].
- In 55 asthmatic children prospectively followed up to 24 years of age [160], the cumulative incidence of AD was 54%; the persistence was 30% in infancy, 19% in adolescence and 28% in adulthood. Onset in adult age was only 7.45%.
- Wüthrich et al [156, 157, 352, 353] (Table 5.8) showed that patients followed from infancy and controlled at the age of 23 had a rate of persistence as high as 63.1%: in

NS not shown.
[a] Study including adults.
[b] Adults suffering from AD in their childhood.
[c] High prevalence of seborrheic dermatitis.
[d] The first figure refers to in-patients, the second to out-patients.
[e] Thirty-eight percent if AD is isolated.
[f] Thirty-four percent up to 6 years and 48% from 6 to 15 years.
[g] The first figure refers to asthma and the second to AR.

11.3% of cases there was a remission during infancy, 26.4% of patients were free of symptoms for a mean of 9 years, followed by a relapse in 19.1% of cases. In conclusion, 32.1% suffered from persistent AD from their infancy, >50% suffered from concurrent respiratory allergy, 71% were sensible to a season effect and 59.5% to stress. Respiratory allergy relapsed during infancy in 19.8% of patients.

- A greater rate of remission was present in 1,050 medical students followed during a 10-year period [101]: only 3% of them were affected with AD at the age of 24–>40.

In 46 children, full recovery was seen by the age of 8 years in 16 (34.8%), 8 of whom recovered within 3.3 years from the date of presentation (17 months) [258].

However, the main association of AD is with FA (Table 5.8), as has long been known, even if the role of IgE-mediated FA in AD is quite controversial, because of the scarcity of studies conducted using DBPCFCs, and not always based on Hanifin and Raika diagnostic criteria. FA could be responsible for AD in 67%–93% of cases, with an elevated risk of developing respiratory allergy [118]. When both diseases are associated, tolerance is acquired later and with unfavorable complications. Data on natural resolution of the condition are variable:

- In a classic study on 25 children with AD and hypersensitivity to egg demonstrated by DBFCs, at the follow-up at 2.5 years only 11 of 25 children (44%) had a spontaneous clearance of symptoms [99].

- In the 56 children of our study, a significant relationship was found between the outcome of AD and the development of food tolerance: 82% of the children who recovered achieved a complete or partial tolerance to the offending food. The offending foods were CM and egg in 69% of cases; tolerance to such foods was achieved at the age of 4; however, 50% of children had bronchial asthma and/or AR during the follow-up [49].
- After 8 years of follow-up, only 22 of 88 children (28%) with AD that developed in the first year of life, associated with high IgE levels and early sensitization, tolerated the sensitizing food, and 33 of 88 (38%) developed respiratory allergic disease [52]. Of the Der p-sensitized children with AD, 55.26% developed respiratory symptoms compared with 22.58% of the nonsensitized children ($p<0.001$). In these children, the OR of developing respiratory allergy was 4.23 [328].
- In 19 of 75 (25%) patients with AD and FA diagnosed by DBPCFC, tolerance was acquired after 1 year of elimination, in 4 of 44 (9%) after 2 years, and 20 patients after 3 years were not yet tolerant. The sensitizing foods in these 75 patients were CM in 81%, peanuts in 80%, egg in 76%, and wheat in 67% of cases. In the DBPCFC in 44 subjects the involved foods after 2 and 3 years were CM in 100% and egg in 90% of cases, other sensitizations were between 30% and 50% of cases. The high median age (7.9 years) and total IgE levels over 2 SD are, as previously discussed, unfavorable prognostic factors [265].
- In 250 children aged <2 years to 16 years, after 3 years of follow-up food sensitization was present in 93% of subjects, persisting in 73% of those aged <7 years and in 67% of those aged <16 years. The incidence of respiratory allergy was 19% at <2 years, 40% at 2–7 years and 86% at 7–18 years: 79% of children with severe AD suffered from respiratory symptoms within 3 years [118].
- In Italian children at the follow-up at 5 years of age, 31% of intolerant subjects were sensitive to CM, 25% to egg, 100% to fish and dried fruits [22].
- In 66 Spanish children the mean follow-up for 21 (32%) nontolerant infants was 58 months. The sIgE levels grew as the age of the infants increased, and *sIgE levels to case-in predicted clinical reactivity* [104].
- In the 1,749 children with AD, sensitization to food allergens was most prevalent in early infancy, replaced by sensitization to inhalant allergens later in childhood [137].

Oral Allergic Syndrome

A 1.4% incidence has been reported, associated with angioedema in 16%, with AD in 4%, with asthma in 11%, and with AR in 10% of cases (Fig. 5.9) . Moreover, 36% of asthmatics and 80% of pollinosis children with AR had OAS [268].

Fig. 5.12. A child showig a marked angioedema of the eyes, lips, and cheeks, following cow's milk ingestion to which the baby was allergic

Urticaria and Angioedema

Angioedema is more frequently associated with urticaria: in 10% of cases it can occur alone. In childhood, a self-limited form of this syndrome may have a 2%–5% prevalence [360]. Up to 7 years of age, the incidence is 1%–2.5% [124, 268], 2.2% in children aged <16 years [342]. Saval et al [268] found a prevalence of 3.2% for urticaria and 0.7% for angioedema (Fig. 5.9). Moreover, 23% of cases of urticaria are associated with angioedema [268], but in selected children aged 7–12, peaks may be as high as 8.8% in males and 17.7% in females [83]. When angioedema is provoked by foods (Fig. 5.12), higher levels have been described. Prevalence of urticaria is 3.2% in the first 3 years of life [33] (Fig. 5.5) and 1% at 5 years [148]. In Sweden it decreased from 5% to 4.5% between 1981 and 1993 and is significantly more frequent in females [294]. In Swiss children aged 4–6, it increased from 0.4% to 0.9% between 1968 and 1981, decreasing in adolescents (0.7% vs 0.5%) [323]. The coexistence of urticaria and AD has been studied [160] (18.9% in 10-year-old children with AD [172]), and in particular the positivity of FHA: the associated prevalence was 30% when only one parent was atopic and 34.8% when both were atopic (32%), while in nonatopic children with no FH, it reduced only to 21.3. After 15 years of follow-up, urticaria persisted in 8.2% of subjects who suffered from AD in infancy [352].

Allergic Contact Dermatitis

Childhood allergic contact dermatitis (ACD) is a much more widespread condition than commonly estimated: both sexes are equally involved at all ages [14, 243].

Table 5.9. Prevalence of ACD in children with AD (%) reported from studies conducted in different countries

Even if children are in contact from birth with potentially sensitizing objects (identification bracelets, necklaces, etc.), in children it is an uncommon finding in the 1st year of life, less frequent between 1 and 3 years of age [14, 115, 223], after which ACD becomes less rare, until the prevalence reaches values comparable to those of adults. Data on the prevalence of reactions summarized in Table 5.9 [14, 38, 110, 111, 115, 124, 152, 209, 223, 243, 254, 260, 338] modify appreciably this panorama. In two large samples, 2.1% [243] or 3.7% of children were tested and 57.8% of them were positive [14]. In those admitted to a pediatric clinic, levels of about 8%–10% are found. However in children with at least one positive patch-test, the prevalence was as high as 70% [64], or 88.2% in children aged 1–3 [260]. Several ACD infants aged between 1 week and 12 months have been reported. The 1-week-old infant developed ACD to the epoxy resin in his *vinyl identification band,* and a 7-month-old infant nickel dermatitis to the *snaps in his sleepwear* [96]. Two 6- and 12-month-old infants were allergic to nickel and a 12-month-old child to *para-phenylenediamine* [281]. Two more infants aged 6–9 months were positive to nickel [38]. Children aged 6.5±2.4 years may be positive to disperse dyes in their clothing [111].

Food Allergy

Adverse reactions to foods are commonplace in childhood allergy. Prevalence is subject to variations depending on certain parameters:

1. No unique marker of FA polymorphous image
2. Scarcity of reliable diagnostic tests that are easy to administer
3. Lack of studies on sufficiently wide samples
4. Patient selection only based on SPTs, RAST, or FCTs results

Additional shortcomings hold true for the often improperly used terms (Chap. 10) and the axiom of three FCTs (Chap. 9).

FA prevalence is generally identified with that of CMA, the more studied form of FA. FA prevalence is between 1% and 18%, with a mean of 5.8% (Table 5.3), that of CMA is between 0.00013% and 7.5%, with a mean of 2.25% in healthy babies (Table 5.4). In a group of children at high risk not receiving any prevention, FA prevalence increased up to 20%, and in selected young patients, as those affected with AD, the values may be higher [213]. In 777 preterm babies, the incidence was 10%–11% up to 19% in the sons of multi-

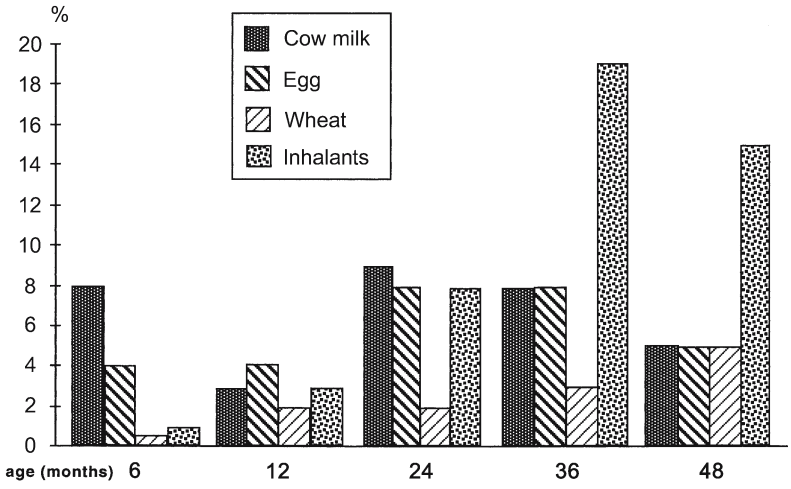

Fig. 5.13. Prevalence of IgE specific to foods and inhalant allergens in 174 children, which increases with age. Cow's milk, p=0.335; egg, p=0.362; inhalants, p=0.0001. (Data from [39])

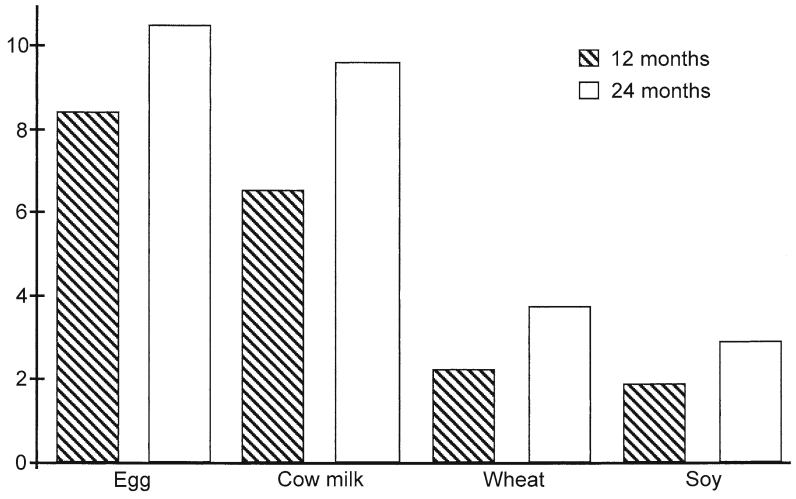

Fig. 5.14. Prevalence of food sensitization. (Modified from [29])

parous mothers [192], and in other cases it was 16.2% vs 13.7% of controls [76]. In a study on at-risk children, the prevalence was continuously 1% (Figs. 5.3, 5.4) and the incidence 1% at the age of 6 months [39] or 0% at 5 years [148]. In a multicentric study it was 6% (Fig. 5.5). CMA incidence is followed, in order of frequency, by allergies to egg and wheat, the foods most frequently provoking allergic reactions in children [39, 40, 264] (Fig. 5.13) [39] showing an upsurge of inhalant allergy. In the German multicenter study (Fig. 5.14), prevalence increased from 12 to 24 months [29].

The onset age of symptoms in IgE-mediated FA is a very significant factor: both allergies to CM and egg develop within the 1st year of life [29, 130], without any subsequent sensitization [131], or the symptoms appear in the 1st year in 80% of cases, and in 20% between 2 and 3 years [33] (Table 5.5). The onset may be biphasic: 69% of cases in the first 2 years, 8% in the 3rd year, then decreasing gradually until 7 years, rising to 10.5% in the subsequent period [68] (Table 5.5). CMA is alone in the first 3 months of life and provokes 30% of cases occurring in the 2nd month, and egg allergy follows (Fig. 5.15) [68]. The total impact in the first 4 years is for CM 97.5%, for egg 65%, for fish 35%, for other unspecified foods 8%. Such types of FA may also develop subsequently [68]. In the children of the ETAC study (mean age 17 months), CMA incidence was 53% (Fig. 5.16) and egg allergy was as high as 49% (Fig. 5.17). In particular, children with cod allergy had a high prevalence of asthma (60%), greater than in other atopic children studied, inhalant allergy in general (55%) and allergy to other foods (20%) (Chap. 9). In a study investigating children aged ≈3 years, the parents reported a prevalence of ≈25% during the first 4 years of life, but only 8% of such diagnoses have been confirmed by OFC [33]. These results confirm the suspicion that more elevated rates of incidence reported elsewhere referred in certain cases to highly selected children, and in other cases to very high rates, reduced by FCTs to the prevalences shown above.

The *natural history of FA* is not yet fully understood because most authors quote 40%–70% improvement at 3 years of age, whereas according to other authors, above all ourselves, a complete clearance of symptoms in this

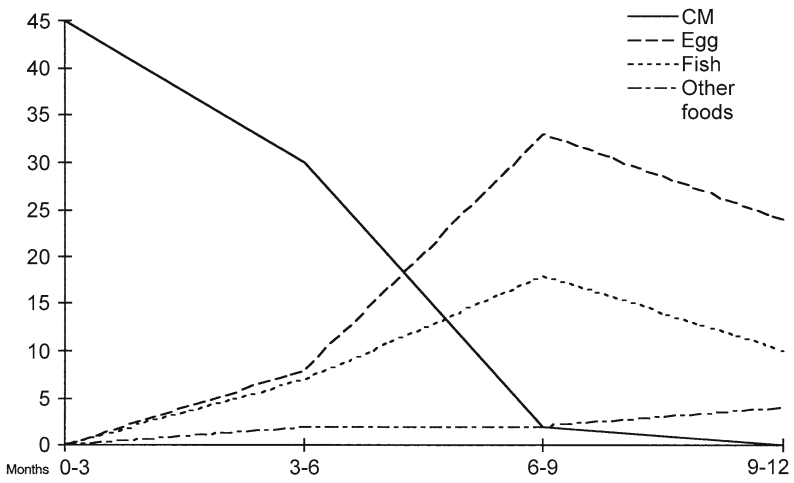

Fig. 5.15. Percentage in the 1st year of age of children with food allergy caused by foods correlated to the onset of symptoms. (Data from [68])

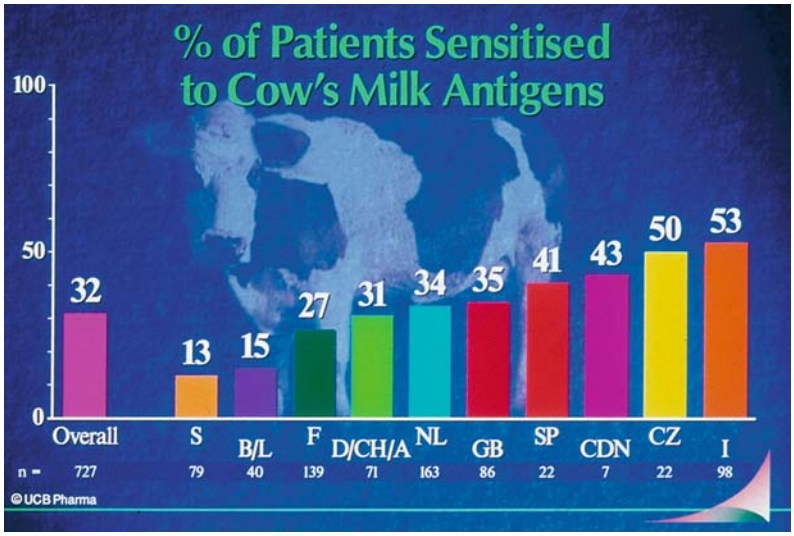

Fig. 5.16. ETAC Study. On average 32% of children are sensitized to cow's milk antigens, the highest frequency is in Italy (53%), the lowest in Sweden (13%)

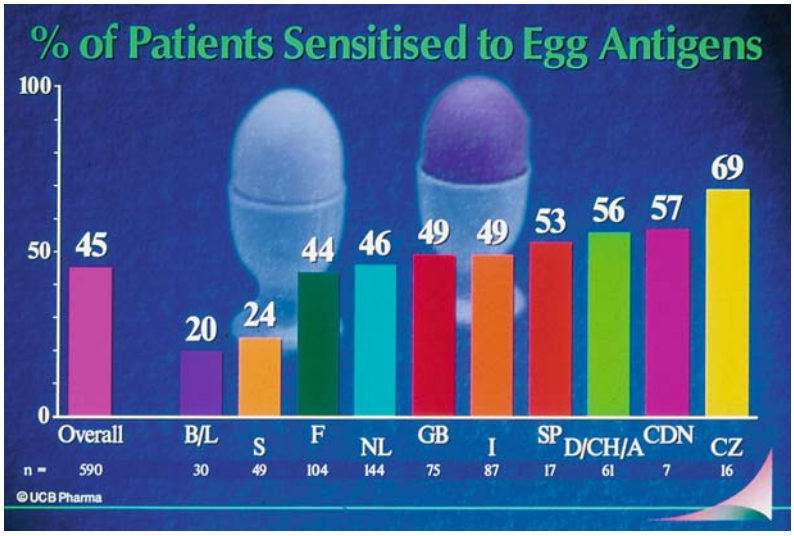

Fig. 5.17. ETAC Study. On average 45% of children are sensitized to egg antigens, the highest frequency is in the Czech Republic (69%), the lowest in Benelux (20%)

time span is uncommon, because of the frequent development of additional allergies. In particular, sIgE elevated levels for egg in infants are predictive of the subsequent appearance of respiratory allergy [130]. There is concordance with a computerized study showing a mean persistence after the initial diagnosis: in 71% of cases, CM intolerance persists after 3 years, in 50% after 6 years and in 28% after 9 years [199]. According to the initial level of serum IgE (<or >10 kU/l) at the age of 4 years, 90% or 47% of children, respectively, became tolerant to CM [272].

Few studies have investigated this aspect of FA:

- High rates of children are tolerant within a wide span of years: 67.6% [46] or 77% [136] at the age of 2 and 87% at 3 [136], but 32.4% were intolerant at the median age of 6–7 [46] and 72% at the age of 9 [52].
- Many children show additional sensitizations during follow-up: 73% [46], 67% of children with CMA and 27% of children with egg allergy, 54% had adverse reactions to other foods and 28% to inhalant allergens [52].

Remission therefore depends very much on the foods responsible for FA. When fish, shrimps and mollusks, peanuts and nuts are the offending foods, the symptoms will require a longer time to clear up: the children should undergo differentiated FCTs to check whether FA persists (Chap. 9). Probably, an early sensitization to inhalants is established in children with CMA including Der p, grasses and cat epithelium, even <2 years of age [134]; tolerance may be reached beyond childhood, and in several cases these diseases may persist into adulthood.

Asthma

Asthma, the most common chronic disease of childhood, now affects >15 million individuals in the USA and involves direct treatment costs exceeding US $6 billion for medications, hospitalizations and work absences. In children, the disproportionate increase in asthma prevalence, as measured by ambulatory visits, hospitalizations [262], and mortality was for those *younger than 5 years, for whom accurate diagnosis may be more difficult* [4]. Asthma accounts for 1.01 million lost school days, 1.21 million ambulatory care visits, 200,000 admissions with 1.9 million days in the hospital annually more than nonasthmatic children, 5% of whom complain of activity restrictions vs 30% of asthmatics [324]. In 1985 the prevalence of asthma in eight South Fore villages of the Eastern Highlands of Papua New Guinea was reported to have risen dramatically over the past decade and was 6‰ in those aged <20 [84], but the international ISAAC study has shown very contrasting and dramatic data [311]. Also, in many published studies different results are found, as shown in Table 5.10 [3, 6, 7, 11, 13, 15–18, 27, 35, 44, 48, 50, 53, 54, 56, 59, 61–63, 65, 66, 69, 79–81, 83, 84, 98, 105, 113, 151, 157, 169–172, 175, 182, 183, 184, 192, 193, 195, 196, 203, 204, 207, 209, 210, 212, 214, 217, 219, 225, 231–234, 240, 250, 251, 258, 261, 266, 268, 271, 277, 279, 283, 286, 289, 295, 297, 298, 301, 302, 307, 310, 315–318, 323–325, 329, 331, 344, 345, 351, 361, 363] showing prevalence, incidence, and wheezing rates. To these data we add personal findings. During the period October 2001–December 2003, we consecutively enrolled 592 children aged 4–11 years attending our division because they were affected with severe asthma (SPTs, sIgE and spirometry). There were 135 children during 2001 and 215 during 2002, with a 62.8% increase. During 2003, there were 242 children, *with an 88.8% increase compared to 2001.* We found 18.9 asthmatic children each month. The prevalence of childhood asthma has been described in high-risk cohorts, but not in randomized children. In a worldwide ISAAC study, 463,801 13- to 14-year-olds were studied in 56 countries and 257,800 6- to 7-year-olds in 38 countries. The variations in the prevalence of asthma symptoms were marked with a global total of 10.2% in the younger ones and 13.0% in the older ones. The prevalence of wheeze in the last 12 months was 13.8% in the older age group and 11.8% in the younger age group [16]. Table 5.11 [10, 119, 163, 210, 214, 218, 230, 251, 252, 286, 295, 298, 302, 361] details the prevalence or incidence of precipitating factors and asthmatic symptoms. The influence of environmental factors is confirmed, asthma being scarcely known in autochthonous populations residing in rural areas [318, 325], whereas in mixed populations the asthma incidence is more elevated compared with European countries [287]. In Canada the incidence is minimal [196], most likely because of a scarcity of allergens and/or pollutants, as demonstrated by studies in Gambia, New Guinea and among Eskimo children [65, 318, 344]. Asthma is 1.9-fold more frequent in European compared with Asian children, contrary to previous reports [225]; in black children it is instead 2.2-fold more frequent, a statistically significant risk of asthma [277]. Several studies have reported *an earlier age of onset, up to 59.3% of cases in infants aged <1 year* [357] *and 76% within 2–3 years* [163] (Table 5.5, Fig. 5.18) [302]. The figures are confirmed by a greater prevalence of asthmatic attacks in 5- to 10- vs 11- to 17-year-old boys [221]. More data confirm this trend.

In a Swedish study, the cumulative incidence was 5.3% and prevalence 3% between 3 and 11 years of age.

In a study on the month of birth in a selected cohort of 4,030 children aged 1–17 years with symptomatic allergy by inhalant allergens, asthma incidence was as high as 54% and AR as 30.7%. The prevalence of monosensitization to Der p was 79.3%, to grasses 20.6%, and to Parietaria 3.5% [47].

Sporik et al extend these data and conclude that wheezing and BHR prevalence does not decline until 11 years of age in 65% of children who wheezed after their second birthday [296].

The prevalence of atopic disorders differed significantly between children with asthma (60–81%: AR 20%–60%, allergic conjunctivitis 10%–45%, AD 20%–21%, FA 13% [119, 245], any allergic disorder 33%),

Studies are arranged according to the age of the children studied. In the study of asthma symptoms in Latin America, if several cities of the same country were studied, we report the data of the related capital or most important city.

M Males, *F* females, *E* Europeans, *A* Asian (see text), *I* incidence of wheezing, *P* prevalence of wheezing (a single figure shows the incidence), *U* urban, *R* rural, *NS* not specified.

[a] Median age.
[b] See Fig. 5.6.
[c] Preterm.
[d] Two cities (Linköping and Östersund).
[e] The first figure shows the more polluted city, the second the less polluted city.
[f] In a Chilean city defined as pollution-free, the incidence of wheezing in children aged 7 and 15 years was 18.5% and 27.5%, respectively [251].
[g] Mean of two cities.
[h] The highest figures usually belong to children living in Munich, a city certainly more polluted than Leipzig and Halle [331] or to a more polluted area of Rio de Janeiro [195]. In an Italian study [261], the first figure shows the parental reports, the second that of their siblings; in different studies the cumulative incidence has been calculated: 18.2% in 7-year-olds, 21.8% in 11-year-olds and 24.5% in 16-year-olds [11], 5.3% in 11-year-old children [69] and 14.3% (11.3% at 0–4 years, 16.4% at 5–11 years, 15.3% at 12–17 years) [66].

Fig. 5.18. Early asthma onset: a young child using a peak flow meter

and children with other symptoms from lower airways (62%), thus concluding that atopic diseases have a notable prevalence independent of diagnosis [245].

The prevalence increases over 20 years (Table 5.12) [1, 3, 4, 5, 12, 37, 42, 43, 84, 90, 92, 105, 121, 137, 141, 165, 166, 168, 174, 190, 196, 203, 215, 216, 221, 224, 233, 234, 251, 252, 255, 219, 282, 287, 294, 295, 305, 312, 323, 333, 335], is modest in Canada with an increase of 0.01% in 0- to 14-year-old children [196], and in Finland with an incidence of new cases of 0.0015% [240]. In the USA, an increased incidence of asthma (definite + probable) from 183×10^5 in 1964 to 264×10^5 in 1983, in males more than in females, has been documented in the entire pediatric population of Rochester, USA [357]. An Australian study demonstrated a reduction in the 12-month period prevalence of reported wheeze, from 27.2% in 1993 to 20.0% in 2002, whereas the current wheeze *increased from 63.3% to 66.2% in the 1- to 3-year-olds* [253]. An ISAAC study has found in Australian 13- to 14-year-olds, a 28.2% prevalence of ever having asthma and a 29.4% prevalence of wheeze [16]. In northern Sweden, the prevalence of ever having asthma increased in only 1 year from 6.4% to 7.7% in 3,525 children aged 7–8 years [255]. In London in 13 years (1973–1986), there has been a remarkable increase in asthma, higher in females [42], with a parallel increase in school absences and hospital admissions [135], similarly in Canada from 1980 to 1985 [141]. In 1989, Anderson suggested that the prevalence of wheezing illness might have reached a plateau [8], or even a decline in admission rates [139], associated with a significant fall in school absences [10, 301] with no interference in normal

[a] Parental reports.
[b] The lower numbers were reported in Switzerland. In 13- to 15-year-old Maltese children, there is 20.6% of effort asthma and 31.8% of nocturnal cough [206].

activities [10]. Instead, a 27% increase in asthma prevalence was found in Australia compared to a 1964 survey [252], and although a 7.3% decrease in the asthma prevalence was noted in 2002, a 31% prevalence is quite alarming [314]. Recently reductions were reported between 1993 and 2002 in the proportion of children attending an emergency department for asthma in the previous year (3.6%–2.3%), in children admitted to hospital (1.7%–1.1%) and in children taking asthma medication (18.5%–13.4%) [253]. The high proportion of children aged 1–3 with current wheeze increased from 63.3% to 66.2% [253]. Even if there was an 18% drop over 5 years in hospital emergency visits for asthma in children aged 2–14 years, a decline in the number of annual episodes per child and in the number of children needing further hospital treatment for the same episode, *the hospital admission rates rose by 35.9%* (28). In two Norwegian studies in 3,538 children admitted to an Oslo hospital for acute asthma from 1980 through 1995, the admittance rate *increased significantly among children aged 0-3 years* [145], *3.3-fold in children aged 1–2 years* [91] *or in the 1- to 47-month age group* [194],

The time span refers to data of the first and second follow-ups, usually collected on the same cohort and using the same methods.

[a] The two figures refer to data collected in two study towns, the first coastal and humid and the second inland and dry.

[b] In Maori children the wheezing increase is significantly higher, from 27.1% to 36.2%. In Polish children [190], we first report the children from Krakow and then the children from Poznan, a more industrialized city.

and wheezing illness continues to increase in Aberdeen [221]. In other English children the admission for wheeze increased from 6% to 10% during 9 years, in parallel with the treatment for wheeze (15% to 26%). However, from 1977 to 1986 hospital admissions increased more in children aged 0–4 than in children aged 5–14 [8]. In Honolulu these rates more than doubled from 1986 to 1989, and the *0–2 age group* was the largest [257]. In asthmatic children aged <14, there was a 98% rise in 10 years (vs 15% of all other illness) in accordance with a doubling of hospital admissions over 13 years [301]. In a French study, school absences reached a rate of 21% and the number of urgent hospital admissions 20.4% [176], clear proof of the increased prevalence and severity of asthma [252] . The data are at variance with the decrease observed in Sweden, up to 4.9-fold between 1973 and 1993 [305] and in the USA, which was caused by lower hospital admission rates among children aged 5–17. Younger babies had a fourfold risk of a significant number of readmissions [313], and in infants, especially of low birth weight (LBW), the hospitalizations were affected by increasing exposure to urban pollutants [202]. Recently, the Nordic country incidence of first hospital admission in 1999 was 2.17 per 1,000 children, readmission was noted in 16% of children, mean length of hospital stay was 2.64 days. *Hospitalization rate and BHR* were significantly higher in children <5 years old compared with 6- to 14-year-olds [162]. In Israel from 1990 to 1999 there were 1,584 admissions, 76.3% were first-time admissions, significantly increased over time, and 23.7% were re-admissions, significantly decreased, a finding was more significant in children aged <8. These data reflect the increase in the prevalence of asthma and changes in its treatment [259]. The overall asthma hospitalization rate remained relatively stable from 1991 (1.90) to 1995 (2.31), per 1,000 child-years [262], or rose from 38.0 to 59.7 $\times 10^5$ in 0- to 4-year-olds between 1980 and 1996 (decreasing, so to say, to 51.4 $\times 10^5$ in 1998–1999 [4]), but it was important that *the hospitalization rates for severe asthma rose 270% – from 0.57 to 1.55 – during this period*, while the hospitalization rates for mild asthma decreased from 0.26 to 0.12 per 1,000 child-years [262]. However, the rise in asthma hospitalizations was *24-fold higher among black children* from 1960 to 1997 [67], and in 1998–1999 they were more than threefold as likely to be hospitalized compared with white children [4]. The frequency of asthmatic symptoms seems to be related to unexpected causes (Table 5.11). Between 1985 and 1995 the severity of symptoms was unchanged, despite a large community-based asthma campaign and a *tenfold increase in the number of children receiving inhaled steroids* [36]. Data from Table 5.10 show that lower values are found in studies based on scientifically controlled parameters and definitions of disease (Table 5.1), as well as in countries with less pollution, and that higher levels may be directly related to atmospheric pollution [35, 119, 195]. Pollution may add to the very high prevalence of asthma and related respiratory symptoms [202].

The *natural history of asthma* includes an abundance of studies conducted in several countries, which cover the adult age, sometimes with contrasting results. A study on children living in two different Australian towns, the first coastal and humid and the second inland and dry [233], after 10 years observed an increase in wheezing incidence in both groups. Peat et al evaluated not only the questionnaire results, but also that BHR to histamine (not synonymous of asthma) increased above all in atopic children, as did Der p 1 levels [233]. This rise may match the rise in symptoms. The only positive study seems to be one done in Sweden on a wide and representative group of children, in 55% of whom asth-

ma stopped <14 years, in particular when the onset was in the first 2 years of life (74% of cases). We can presume that this group contained cases of wheezing with a more favorable outcome [2]: an early onset is a negative prognostic factor [53, 340]. In contrast, 11.5- to 14.5-year-old children with severe chronic asthma had an earlier onset of asthma symptoms, a higher incidence of other allergies, and SPTs especially positive for Der p and domestic pets, more frequent thorax deformities, elevated serum and sIgE and BHR in response to both the treadmill test and bronchial provocation test (BPT) with histamine [71]. Also taking into account heredity, 66% [119] to 87% of asthmatics have a positive FH [203] (see Tables 4.10, 4.11). A study from Singapore has found an asthma prevalence decrease in 6- to 7-year-olds, but it increased 2% in 12- to 15-year-olds [333], and from 8.7% to 9.6% in Swiss 13- to 14-year-olds [37] (Table 5.12).

We separately examined the prospective *Melbourne study* with the aim of determining the prevalence and natural history of asthma and wheezing bronchitis in children for as long as 42 years. The study started in 1963 [340] on 295 randomly selected 7-year-old asthmatic children, 74 with <5 episodes of wheezing with VRIs (viral respiratory infections) and 104 with five episodes of wheezing with VRIs, 113 with recurrent wheezing unassociated with VRI, and 105 second graders who had never wheezed to serve as controls. They had a medical examination at school that included a short questionnaire and interview and were followed-up with repeated evaluations until the age of 42.

- At the second follow-up at the age of 10, it was significant that only five children (1.7%) manifested severe wheezing, thus an additional 83 children from the same population were enrolled, who had a history of onset before age 3 with persistent symptoms at age 10, to make the group more representative [197].
- At the follow-up at the age of 14, ≈50% of subjects were still wheezing who, in the more severe cases, started before the age of 2. Bronchial obstruction was often present in the intervals between the attacks associated with PEF and FEV_1 anomalies and frequent thorax deformities. AR prevalence was significantly higher than in the controls and asthma was often associated with severe forms of AD [341].
- At the age of 21 years, the association with AR was frequent, not correlated to wheezing severity. The patients with more severe disease also suffered from urticaria and AD had started before their second birthday; compared with the previous follow-up, the cases of AD and AR had increased. In this review, 50% of subjects had minor wheeze, 25% had frequent symptoms, and only 5% of patients with persistent asthma in childhood were wheeze-free [197].
- In the subjects restudied at 28 years, a significant correlation between asthma severity, IgE levels and atopic disease was seen, with RAST significantly correlated with the classes of subjects at 21 and 28 years (p=0.0001). AR increased to 67% in subjects with more severe asthma and AD cases were significantly fewer. Compared with the follow-up at 14 years, only 32% of subjects were wheeze-free, 41% had less frequent wheezing and in 27% asthma persisted at 28 years: in 21% of subjects with symptoms that were less severe at age of 14, asthma was more persistent, and 39% of asthmatics were smoking [110]; IgE levels were very high in the severe forms (436.1±491.9 IU/ml) and high also in the controls (213.2±246.6) [154].
- In the follow-up at 35 years, in comparison with the previous review, *60% of subjects with persistent asthma at 28 years were unchanged*. Compared with the original diagnosis, 35% of subjects with mild wheezy bronchitis, 70% of asthmatics and 90% of those with severe asthma had persistent asthma, with a mounting progression. Current smokers amounted to 24%–34% of these subjects and AR occurred in 85% of subjects with severe asthma and in 43% of controls. The cause of the high rate of severe asthma was always that the group was "enriched" with children with more severe asthma at the age of 10 so that they had the greatest rate of persistence (63%) at 35 years [222].
- In the last follow-up at 42 years, most who had continued symptoms were little troubled by them, whereas most of those with asthma as children continued with significant wheezing into adult life, *and the more troubled they were in childhood, the more likely it was that symptoms continued*. The risk for AD or AR in later life increased with the severity of asthma in childhood. Subjects with mild disease *who had not taken inhaled steroids had no evidence of pulmonary function testing (PFT) deficit as adults* [236].
- In the people born on 3–9 March 1958 followed-up to age 33, the incidence of asthma or wheezing (42.9%) was associated with atopy, AD and AR. The high risk factor of active smoking is demonstrated by the great consistence of symptomatic groups at 16 years (33.3% were atopic and current smokers) and the relapses after prolonged remissions of childhood wheezing (13% before 33 years and 15% after), *which was more common among current smokers and atopic subjects* [303].
- Blair reported a 20-year follow-up of 267 children treated for asthma before the age of 12. In this study, 52% of patients were wholly or in a great part asthma-free, 21% were never asymptomatic, and 27% went into remission and then asthma caused a 3-year relapse. Blair concluded that *most children with asthma did not outgrow their disease* [31].
- In wheezing children reviewed after 13 years, AD incidence increased by 80% (from 21.7% to 39.2%) [10].

The study by Jenkins et al [144] is interesting because of the debate on clinical history reliability: in a follow-up after >25 years of a cohort of 8,700 schoolchildren recruited at the age of 7, only 59.9% confirmed the data given by parents in their infancy, with substantial underestimation based on the onset age: in 34.3% the onset was before and 20.9% after 7 years. Moreover,

16.9% of children defined as not asthmatic at age 7 suffered from asthma at the last follow-up. At this follow-up including a cohort of 1,494 subjects, 25.6% of those who were asthmatic at 7 years and 10.8% of those qualified as not asthmatic at the first check-up had current asthma (the prevalence of atopic asthma was 21.1% and 8.2%, respectively).

Moreover, 43% of 101 children reinvestigated after 16 years were still affected with asthma. It is striking that the prevalence of SPTs positive to pets increased by 26%, to molds by 16% and to pollens by 46% compared with the first visit at age 6–14, with no differences between current smokers and nonsmokers [109].

In 76% of 406 asthmatic children aged 8–12, 62% with positive FH suffered from asthma at 21–29 years, with an increase in FEV_1 mean percentile predicted values and in inspiratory vital capacity [256].

In a cohort of asthmatic children re-examined after 25 years, the proportion of subjects with BHR was statistically higher in the asthmatics studied, either symptomatic (88%) or not (42%), than in the group of controls (12.8%) [112].

In children followed-up to adulthood, *only 16% were symptom-free* in the year prior to the last follow-up, even if asthma severity was significantly decreased (compared to controls at 13 years), with FEV% and FEV_1 normalization and reduction in the sensitivity to aeroallergens [160].

To these data, which extend asthma natural history to the 3rd or 4th decade and contribute to clarifying that a long-term prognosis can be made for a substantial spectrum of patients, the study by questionnaires of 117 adults hospitalized for asthma at the age of 5–15 years provided a valid and original contribution: 47% were still affected while for the other 53%, who claimed to be free from specific symptoms, the results of spirometry and BPT showed BHR in 23% and rhinoconjunctivitis in 61% of cases [147].

In subjects followed from birth to age 22, the annual prevalence of both wheeze and atopy increased with age: 25% of adults showed both wheeze and BHR (asthma). The prevalence of BHR was *29% at 11 and 40% at 22 years.* Remission of wheeze was common in subjects <5 years of age and likely if wheezing occurred on < two occasions, but *wheeze at 11 years was likely to persist.* Sixty percent of the adult subjects with asthma developed sensitivity to common allergens *by the age of 2 years* and were showing BHR by mid-childhood. There was a steady increase in the *annual prevalence of atopy* over the 22 years, reaching 70% for the whole cohort by adult life [246].

In a cohort of 18,873 subjects involved in a large, nationally representative, cross-sectional study carried out in Italy from 1998 through 2000, asthmatic patients in remission had an earlier age at onset (7.8 vs 15.9 years, $p<001$) and a shorter duration of the disease (5.6 vs 16.1 years, $p<001$) than patients with current asthma. The probability of remission was strongly ($p<001$) and inversely related to the age at onset (62.8% in the <10 years age-at-onset group [74]). In a subsequent paper on 18,156 subjects, the *FH of asthma and allergy* was associated with a higher risk of developing asthma throughout life and worsened the prognosis of both childhood and adult asthma, and *early respiratory infections* were a strong risk factor for asthma starting at any time during a person's life. However, asthma onset at 0–10 years was associated in adulthood with a remission rate of 44% in males and 42% in females, which was reduced to 31% and 27%, respectively, when the onset was at 10–20 years [75].

In an unselected birth cohort of >1000 children, 14.5% had wheezing that persisted from childhood to 26 years of age. Moreover, 27.4% had remission, but 76 (12.4%) subsequently relapsed by the age of 26, together with persistently low PFT results. It was found that *the earlier the age at onset, the greater the risk of relapse* (OR, 0.89 per year of increase in the age at onset). The factors predicting persistence or relapse were *sensitization to Der p, BHR, female sex, smoking, and early age at onset.* Those with persistent or relapsing asthma had substantially impaired lung function at each assessment during childhood, adolescence, and adulthood. Most importantly, the findings suggested that outcomes in adult asthma may be determined *primarily in early childhood* [280].

It is not a surprise that the atopy score during infancy was high in 15 children who had severe atopic asthma at seven, and low in 15 who developed mild disease: 9.2 vs 5.9 [319].

Probably, some previous studies with discordant results have included subjects with a more severe form of asthma, without performing BPT and/or spirometry for diagnosis. Moreover, comparisons between children and adults do not take into account different indoor environments or lifestyles.

Examining the studies on pediatric asthma, three important points should be addressed:

1. Prevalence comparisons after decades, on the same terms, place and age distribution of the patients.
2. Evaluation by certain studies of patients of different ages, usually 15–16 or 21–25 years, in whom the prevalence might also decrease, but other asthmatic forms may arise, including daily shortness of breath or exercise-induced asthma. Moreover, the association with another atopic disorder is frequent, often respiratory such as rhinoconjunctivitis.
3. As Blair [31] has underlined, several studies reported a high proportion of remissions at puberty, but the restricted time span considered made it impossible to uncover the numerous cases of relapses after 3 years. In studies that have documented these relapses with long-term follow-ups of patients undergoing remissions of at least 3 years, a relapse in 27%–38% of subjects was noted.

We deem it necessary that prospective longitudinal studies be extended more often to 18 years and over, even better to 42 years such as the Melbourne study

[222], to better delineate either possible grow-outs or relapses, in order to provide an image that is not false-positive of the natural history.

The variability of prevalence may interact with genetic or environmental factors, but most often depends on the population selected for the study and the diverse prerequisites and parameters related to the diagnosis of childhood asthma. For example, in the first 2 years of life a substantial recurrence of terms such as "asthmatic bronchitis" and "recurrent wheezing" is recorded [141], plausibly caused by the lack of a precise coding of the disease labeled "asthma" [43]. The prevalence increase cannot be explained simply by nomenclature differences [8], since the prevalence of "wheezing" diagnosed separately has remained constant [43]. Some studies based on the differences between asthma and wheezing are interesting: wheezing has an incidence/prevalence at all ages that is almost always higher (and even much higher) than that of persistent asthma (Table 9.10). Moreover, it causes the same number of school absences in the first 5 days, while for longer periods up to >20 days, the total is 18% vs 35% for asthma [135]. The separation between the two conditions is challenging because the diagnostic method varies in several studies. In addition, many parents may forget minor episodes of wheezing in their babies with the passing years, thus underestimating their percentage: this may explain why 49% of such children elude diagnosis [158]. There are children with a transient early wheeze aged <3, likely in connection with a reduced airway development at this time and with VRIs, persistently wheezing children aged <3 and between 3 and 6, and others with a late wheezing aged between 3 and 6, associated with atopy and development of BHR heralding asthma onset [200, 296, 321, 347] and aeroallergen sensitization [308] over age 11 (Table 5.11). Thus the difference is between transient vs persistent wheezers, while we underline that "asthmatic bronchitis" and "asthma" are different labels for the same disease [222, 340]. The term "asthmatic bronchitis" included in the International Classification of Diseases (ICD) has only contributed to underdiagnosis and undertreatment of childhood asthma and to an increase in antibiotic usage [278] in >95% of children [60]. To confirm previous indications [97], the significant decrease in the diagnosis of "bronchitis" (34%–63%) and of "asthmatic bronchitis" (3–31%) [42] leads to concluding that "asthmatic bronchitis" and "asthma" are really two terms applied to the same disease. Increasing knowledge and progress in the diagnostic field have certainly led to an earlier diagnosis of infantile asthma, even if its underdiagnosis continues to be confirmed [283].

When considering the age of onset of asthma (Table 5.5), in the cohort of Anderson et al [10], all cases occurred within the first 3 years of life; in the Rochester study asthma developed in 93.5% of cases in children aged <1 to 14 years and in 59.3% of those aged <1 year [357]. Asthma caused by Der p 1 has an age of onset at <3 years, with a frequency of 3:1 compared to that of pollens ($p<0.0001$) and definitely at ≤3 years ($p=0.0001$) (Fig. 4.14) and rises to an even higher prevalence in several countries, also because serious environmental controls are not always adopted. As regards sex, as discussed in Chap. 4, males are always more affected than females [25, 48, 61, 66, 105, 113, 119, 129, 158, 161, 193, 196, 213,

Table 5.13. Prevalence of atopic disease based on sex

	Males (%)	Females (%)	Total (%)
Food allergy	75	25	1
Asthma	65	35	9
Atopic dermatitis	60	40	5
Urticaria and angioedema	56	44	3
Allergic rhinitis	59	41	4

Data from [48].
p (males vs females)=0.0000.

Table 5.14. Factors predicting the onset of asthma or wheezing in children

Prenatal factors
FH positive for atopy and/or asthma
Male sex of the child[a]
Type of feeding
Smoking in pregnancy
Mother's age <20 years at birth of the child[a]
Postnatal factors
Atopic dermatitis (AD) and allergic rhinitis (AR) (present or past)[a]
Especially early exposure to unfavorable environmental factors
Cigarette smoke
History of pertussis or pneumonia[a]
Infections of upper airways
Adenoidectomy or tonsillectomy[a]
Periodic vomiting or abdominal pain[a]
Factors not associated with statistical significance
Birth order
Low birthweight or premature birth
Social class
Number of children in household
Crowding in household
Smoking of parents
Separation from mother
Previous measles

Modified from [9].
[a] Factors more specifically predicting the subsequent onset of asthma. The highest relative risk is for AD in the 1st year, after the 1st year and in the past year and AR ever and in the past year, both at age 0–7 and later.

Table 5.15. Prospective studies on the natural history of asthma in different countries

Author(s) and reference	Year	No. of patients	Follow-up (years)	Remissions (%)	Notes

Mean remission varies between 41.3% and 47.5% according to the more or less favorable values considered in the Australian study.
AD atopic dermatitis, *AR* allergic rhinitis.

225, 257, 283, 286, 295, 297, 310, 323, 332, 351], beginning at age <12 months [158] and decreasing later until the difference practically disappears. There are exceptions at 0–2 years [2], 4–8 [141, 323], at 14 years [92, 217] in Norwegian children [83, 298] and less so in teenagers [312, 323], until a reversal of prevalence is found at 15 [196] and 23 years [11]. In the USA, male prevalence is at least threefold greater in the 12–17-year-olds [66]. In our cohort of 4,030 children, the male:female ratio was 2:1 (p=0.0000) (Fig. 4.10); in the Rochester series, the ratio was 1.8:1 for the ages of <1 year to 14 years and in the 1st year of life 1.9:1 [3571], in Papua New Guinea 0.9:0.2 [84], until the same rate is found in all atopic diseases (Table 5.13) [48] (p=0.0000). Additional factors predictive of asthma development are summarized in Table 5.14 [9] and widely confirmed [303]. Further details concern the negative significance of bottle-feeding compared to breast-feeding [175], of LBW babies and smoking in pregnancy, even of 1–4 cigarettes, and at 5 years [185]. A crucial factor that should be investigated is the mother's age (<20 years at) childbirth [9, 185], while social factors may attain a statistical significance according to some authors [185, 323], but not others [9]. As regards birth order, firstborns are at risk in 36.3%–39.7% of cases [141]; additional studies have shown no relationship with the number of children in households [185].

The natural history of childhood asthma appears to be favorable: 22 prospective studies (Table 5.15) [31, 69, 71, 73, 109, 112, 144, 154, 155, 159, 160, 164, 187, 197, 222, 226, 255, 256, 296, 303, 340, 341] confirm that 41%–47.5% of children undergo a remission of symptoms at the start of their adult life [252], considering that unlike in adults, specific immunotherapy is able to positively

Table 5.16. Unfavorable prognostic factors of childhood asthma

1.	FH of asthma
2.	Male sex
3.	No breast-feeding, or breast feeding ≤3 months
4.	Mother smoker
5.	Chronic and persistent asthma and severe asthma arising during or before the 2nd or 3rd year of life
6.	Repeated wheezing in the 1st year of life
7.	Presence or persistence of AD, especially severe AD
8.	Coexisting AR
9.	Periodic vomiting or recurrent abdominal pain
10.	SPT positivity
11.	House dampness
12.	Pneumonia, respiratory infections or pertussis
13.	Adenoidectomy and/or tonsillectomy
14.	Delay in the diagnosis and/or inefficient treatment and/or prevention

Having or having had pets at home was associated with an increased risk for incidence of wheezing (OR: 2.9) [255].
Data from [5, 31, 255].
AD atopic dermatitis, *AR* allergic rhinitis, *SPT* skin prick test.

influence the natural history (Chap. 13). However, in children with severe asthma the remission rate is as low as 5% [197]. Yet some studies report a consistent association with other atopic diseases, with a firm persistence of both AR (56%–89%) and AD (29%–54%). In subjects studied over 14–21 years, the less troublesome their asthma was the more likely they were to grow out of it by the age of 21 [197]. Examining the influence of FH on asthma persistence in adulthood, some studies confirm the association [9, 73, 154, 155, 160, 232, 233, 303] and others do not [109, 112, 197, 222, 256, 280].

The unfavorable prognostic factors of childhood asthma are summed up in Table 5.16 [9, 31, 255], to which we add early-onset atopy, an important predictive factor of BHR [232]. Asthma onset before age 3 implies the occurrence of moderate or severe forms in 52% of adults vs 16% if the onset is afterward [160]. Additional factors include wheezing starting after 3 years [296, 321], Der p 1 [280, 321] and/or pollen [141] sensitization, air pollution [232] and BHR [280] at an early age at onset. Several unfavorable predictive factors mark missed remissions in adults: either childhood FEV_1 [256] or a wide panel of factors [144] such as female sex, AD, FEF_{50} decrease, positivity of an intercritical spirometry, positive FH for asthma and asthma in infancy, onset at an age <2 years or having suffered from <10 asthma attacks, symptom duration or severity, passive smoke, pets, soft furnishings, and living next door to busy roads [207, 256].

Although childhood asthma deaths are rare, mortality varied according to international comparisons. In pediatric patients in England, the rates are lessening in children 0–4 to 5–14 years of age [3]. In the USA, 100

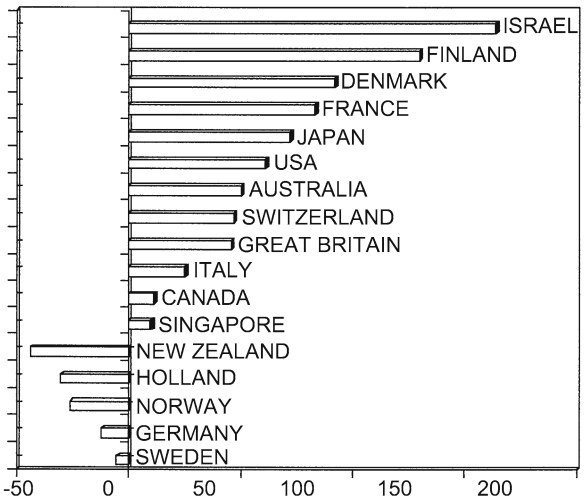

Fig. 5.19. Asthma mortality in 17 countries in 1987, calculated as rate of increase compared to 1980 rate among subjects aged 5–34 years. (Data from [218])

deaths per year are recorded in children, especially in the last decade there has been an annual increase in fatal cases, more likely in children 5–14 years than in the 15- to 34-year-old age-groups [357], with a time-trend of increase involving mostly the younger part of the population. US children aged 0–4 had the largest increase in prevalence, but adolescents had the highest mortality, and black children compared with white children were > fourfold as likely to die from asthma in 1997–1998 [4]. In 1988 (data $\times 10^5$), the year prevalence was 0.1×10^5 in 0–4 years, 0.3×10^5 in 5–14 years,

Table 5.17. Asthma mortality rate in 1990–1993 in persons aged 5–34 years

Country	Rate × 10^5 residents
Australia	1.13
Singapore	1.05
New Zealand	0.79
England	0.74

USA	0.43
Israel	0.40
Canada	0.37
France	0.37
Italy	0.23
Austria	0.32
Finland	0.21
Sweden	0.12

Data from [24, 191, 278].

and 0.4 × 10^5 in 15- to 24-year-old individuals but could rise yearly to 1–2 cases × 10^5 [357]. In a survey of children aged 12–19, death rates per year were highest in New Zealand (1.75 × 10^5), intermediate in England and Wales (0.66 × 10^5) and South African Caucasians (0.67 × 10^5), and lowest in Sweden (0.38 × 10^5) [44]. Data from the USA show a rate 0 until 10 years, 0.04 % for 10- to 15-year-olds and 0.1 % for 15- to 20-year-old patients: if the total rate is 4 %, with a general total of 2.4 cases × 10^5, this increase is more pronounced for older subjects [291]. Asthma mortality in Israel is higher in the 5- to 34-year-old subjects, especially males [191], but remained stable between 1980 and 1997, with a mean rate of 0.226 × 10^5 [237]. However, it is not known whether these deaths attributed to asthma [291, 357] are also due to associated factors [348]. Figure 5.19 [278] outlines the increased rates between 1980 and 1987 relating to subjects aged 5–34; the 1990–1993 data are shown in Table 5.17 [24, 191, 278].

Allergy to Inhalants

The increased prevalence of specific allergens, especially that of pollens, due to an increase in environmental pollution and ozone depletion has been documented in Chap. 4; however, the reported different rates appear to depend on many factors [26, 42]. The results of various studies are summarized in Tables 5.18 [30, 35, 78, 84, 106, 120, 148, 150, 163, 235, 245–247, 289, 308, 331, 361] and 5.19 [271], showing that a very high proportion of infants develop multiple sensitizations [78, 292], a rate that is higher in small groups, but diffused through the entire pediatric age range, with rates significantly greater than in monosensitized children (Fig. 5.20) [292]. The ETAC study has established that 20 % of babies are sensitized to Fel d 1 and 17 % to Der p 1 (Figs. 5.21, 5.22). In Sweden, allergy to pets and pollen is prevalent [35], and is increased by 2.4 % in 12 years [294], the rates in Finland are higher [245]. Der p sensitization is more frequent in heavily polluted places [35, 247], with meaningful rates in Munich [331] and in other German cities [271]. It is

[a] Evaluations done on 61 out of 981 children.
[b] The percentage was calculated on the whole sample since the controls had more SPT+ than the asthmatics, extended polysensitizations were present.
[c] The first figure is related to urban, the second to suburban children.

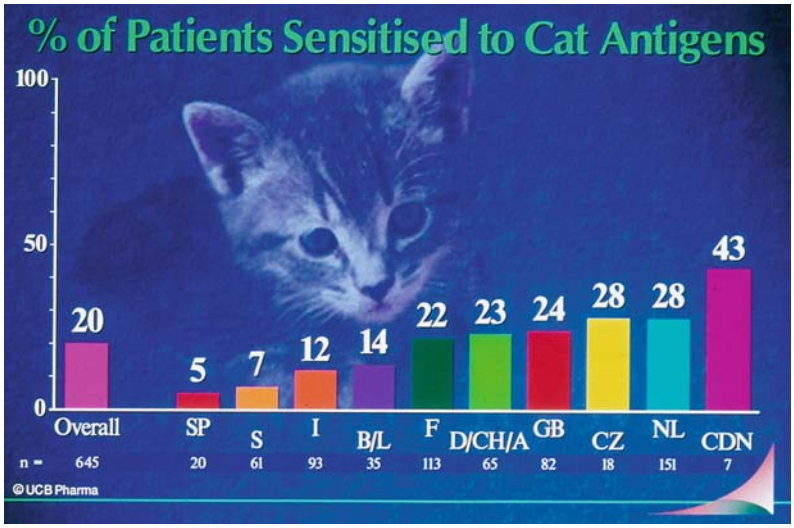

Fig. 5.21. ETAC Study. On average 20% of children are sensitized to cat antigen (Fel d 1), the highest frequency is in Canada (43%), the lowest in Spain (5%)

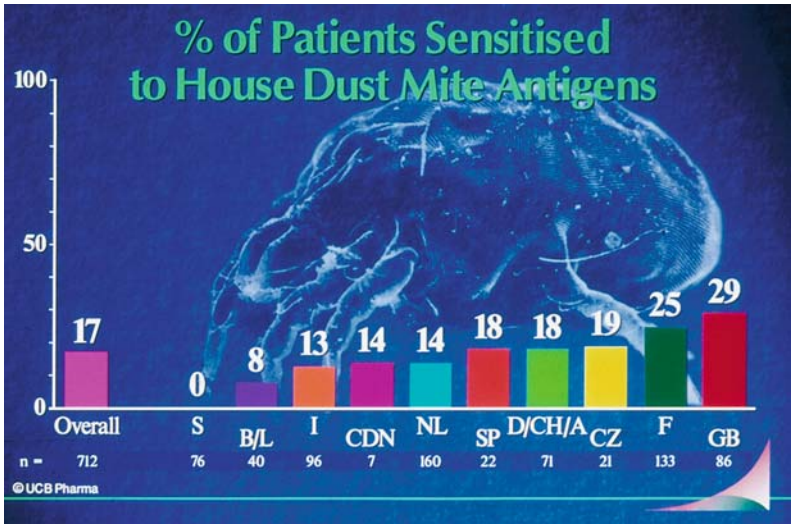

Fig. 5.22. ETAC Study. On average 17% of children are sensitized to dust mite antigen (Der p), the highest frequency is in Great Britain (29%), the lowest is 0% in Sweden

higher in France [205], in New Zealand [280], in Italy [235] and Wight Island [308], four- to fivefold higher after 10 years of age in Australia [233], reaches elevated levels in Hong Kong even in nonasthmatic children [182] and is often associated with mold allergy [245, 295]. Not only asthmatic children are Der p-sensitized (11.1%), but also those with AR (8.8%) and AD (6%) [307]. In Australia the prevalence of pet allergy reaches unexpected rates in the same time span with a 4.5- to 5.5-fold increase [233], contrary to Wales [296], and is lower (1.2%) in Sweden [294]. *Cat allergy* reaches high levels, which at 1 year of age are responsible for 70% of positive SPTs [78]. In a school, positive RAST and CAP increased from 8.5% in 1983 to 9.5% in 1992 [41]. Among 4- to 8-year-old children, prevalence is as high as 28%–34.5% [20, 169, 176, 225], in 9- to 12-year-old children it is 2.5%–7.3%, with no notable differences between polluted and unpolluted areas [35, 247, 331], with peaks from 21.1% [35] to 53% in Sweden [71], 28% in Wales [297], 63% in New Zealand [14], decreasing to 5% in former students [101]. This picture was remarkably complicated by the incredibly ubiquitous Fel d 1. The prevalence of *dog allergy* in Mexican infants is as high as 65% of SPT+ [78]; in children 4–8 years of age, it is lower, with 15%–16% titers [235, 245, 308]. In Sweden there is a peak as high as 49% [71], in Wales 35% [297] and in former students there is a 10% rate of allergy, documented with SPT positivity [101]. In New Zealand the figure is 48%, with high titers even for other mammals, from 11% to 23%, and birds from 11% to 17% [23], highest in South Africa with 76% (dog), 42% (cat) and 26% (birds) [44], the lowest apparently in Sweden, 17%, 23% and 21%, respectively [44], with the lowest rates in Poland [35] and Estonia [247]. Estonian children aged 5 had the highest SPT positivity to cat and dog [148] (Tables 5.18, 5.19). *In 13 studies comprising 16,638 allergic children, the incidence of pet allergy was 18.4% for cat and 12.7% for dog.* In France, 46.2% of asthmatic children live with at least one pet [176], as do 1.9% of students in China [184].

Horse Allergy

Horse allergy is present in 2% of unselected children at age 5, 5% at age 7–16, 7.8% at age 7–12 [180, 245], in 16% of atopic children of equal age and in 21%–35% of asthmatic children aged 7–15 [245]. Increased prevalence in the later years is due chiefly to extrafamilial contacts (79% of cases) [180]. It causes conjunctivitis in 64%, asthma in 54%, rhinitis in 43% and skin symptoms in 18% of cases, and is associated with allergy to mites (79%), grasses (68%) and cat (64%) [180].

Cockroach Allergy

Cockroach allergy is increasing: 38 US children, 22 asthmatic and 16 controls, had sIgE for cockroach and in 71% of their houses the dust contained Bla g 1, especially in the kitchen, surprisingly also in 20% of unaffected houses [238]. In China, the prevalence is high in students [184]. In Israel cockroaches are present in the majority of houses, independently of the socioeconomic level of residents [158]. The prevalence of asthma to *Blattidae* is still higher, rising from 16.9% to 42%, with onset in the 1st year of life (Table 5.20) [30, 50, 77, 78, 102, 125, 184, 235, 238, 361]; thus it is necessary to look for multiple sensitizations [297]. In 50 asthmatic and not asthmatic children, several other insects have been reported such as ants, crickets, flies, grasshoppers, moths, some cross-reacting between themselves at the RAST inhibition, moths also cross-reacting with Der p 1, Bla g, Fel d and CM [186]. The prevalence of allergy to rodents and domestic birds is not very common.

Allergic Rhinitis

AR is very frequent: some authors state that AR onset occurs by the age of 5 years in 94% of cases [163] (Fig. 5.23) and in 21%–35% in the 1st year [163, 349], or in 36%–46% of cases from 4 to 10 years and in 35%–54% from 10 to 20 years (Table 5.5). The male:female ratio is 2.3:1 up to 10 years, then equal [32], or it is reversed from 5 to 14 years [350]. The prevalence variation in different countries is noteworthy (Table 5.21) [2, 3, 6,

Fig. 5.23. Early onset of AR. Note the marked suborbital edema, the prominent suborbital folds (Dennie-Morgan folds) and other symptoms of multiple allergies

S seasonal, *P* perennial.

[a] Study conducted in two cities (see Tables 5.7 and 5.12).

7, 13, 15, 17–19, 23, 27, 44, 48, 53, 56, 69, 79, 81, 83, 85, 94, 113, 116, 129, 171, 172, 177, 183, 184, 205, 207, 209, 214, 217, 232, 240, 244, 268, 271, 279, 286, 289, 298, 304, 310, 315, 317, 323, 324, 329, 331, 332, 349, 350, 351] as well as the significant increase with age change [268]. The top rate was attained by a US prospective study where in 747 children followed up from birth to 6 years of age, the prevalence was 42%, which in Sweden has fallen in the last 12 years [294]. AR is often underdiagnosed, mainly in asthmatic children, probably because rhinitis symptoms are in proportion less apparent, or because they are of minor importance compared with a more severe allergy [334]. These data are strengthened by the suggestion that up to 75% of asthmatic children and 53% of those with AD risk are affected with AR in the future (Table 5.8); other studies report that AR is a precursor of asthma in 3%–24% of cases [189]. The rate of SPTs positive to aeroallergens is high in 6- to 24-year-olds. Only for dog allergens is it <20%; for other allergens it ranges from 20% to 30% [106]. Two studies disclose no variations between urban and rural populations [300, 350], but one study has found AR more frequent in villages (10.5%) than in cities (8%) [350]. The low incidence of AR and allergic sensitization, for example, the highly polluted Leipzig [329] indicates that the decreasing prevalence of atopic diseases is indirectly caused by the increased exposure to environmental pollutants [132]; however, the greater incidence in firstborns is confirmed [300]. In parallel with Table 5.10, Table 5.22 sums up the prevalence/incidence of provoking factors [288].

We have analyzed the most significant studies in addition to those outlined in Table 5.21. In one study (Fig. 5.3), at the last follow-up the prevalence and incidence were 0%. Sporik et al [296] recorded a gradual increase with age.

The data for *natural history* are summarized in Table 5.23 [1, 3, 4, 10, 12, 14, 37, 43, 92, 137, 174, 178, 215, 221, 233, 253, 279, 282, 294, 323]:

- AR usually persists up to adulthood, complicating with asthma in 50% of cases. Prognosis is more favor-

Olive	38
Mesquite	31
Mulberry	29

Data from [349].

able in the monosensitized subjects who follow reliable preventative measures [101].

- In Sweden, AR incidence is fairly constant without remissions [2]. Prevalence increased from 4% to 14.5%, that of asthma from 3.8% to 5.3% (Fig. 5.6).
- In Japan, the prevalence (cedar pollinosis) increased from 8% to 12% from 1950 to 1987 [350].
- In studies done in Finland, 38% of adolescents also manifested AD [237]. In children aged 3–17 years checked after 8–11 years, only 9.7% were symptom-free at the last control; 23% of those with seasonal AR manifested a perennial AR and 19% had asthma, 34% of them with perennial AR vs 12.7% with seasonal AR [189].
- There were more children SPT positive for pollens after a mean of 26 years and 19 out of 36 (52.7%) adults with positive history were still affected [109].
- In a group followed-up from birth in 1953, the prevalence was 16.5% at 23 years [300].

The risk factors included in the US study are summarized in Tables 5.24 and 5.25 [349].

Allergic Conjunctivitis

Allergic conjunctivitis is frequent in children, although less than in adults. However, its prevalence is unknown because of the lack of epidemiological studies and the frequent association with several cases of AR, especially when the sensitizing lung allergen is a pollen. In the study on the month of birth, 12.7% of children were-affected [47], corresponding to 10% of another cohort [245]. In 154 children, eye symptoms disappeared or were effectively controlled by topical treatment [189], whereas in subjects with other allergies, the prevalence is over 60% [180, 245], and in patients controlled at 17 and 24 years of age, it persists in 80% of cases [160]. In 7632 children aged 5–14 between 1992 and 1999 the impact varied between 6% and 7.5% [132]. Between 1995 and 2001, the impact of itchy eyes/conjunctivitis increased from 11.8% to 24.1% [92] and from 13.6% to 17.2% [178].

Insect Allergy

Insect allergy syndrome, whose diagnosis and treatment were established >10 years ago, after recognition of the venom as the responsible agent, is a problem not so much for the number of involved patients as for the extent and severity of reactions, potentially fatal. Some 15%–24% of the general population appears to be sensitized to Hymenoptera venom following a medical diagnosis and SPT or RAST [57, 58], and every year thousands of reactions are reported. It is prevalent among the children of beekeepers (about 65%–70% are involved), with a small number of other children residing in the country [228]. At pediatric ages, this allergy has a prevalence of 10%–20% [117, 228, 274, 284] up to 32%–54% [21]; otherwise there are minimal levels, ranging from 1×10^6 to 0.15% [227, 285, 293]. Clinical evolution in children is more favorable than in adults. Mortality is also lower [228], which in adults varies from 0.45×10^5 in Switzerland to 0.09×10^5 in England (Chap. 17).

Prevalence of Atopic Disease at Various Ages

Figures 5.3, 5.4 and 5.13 show the differentiated prevalence according to age. In particular, Fig. 5.13 shows sIgE prevalence to foods and inhalants as a function of age. We have commented on the sIgE prevalence to foods; the increasing prevalence of inhalant allergy from 14 to 36 months can be seen in Fig. 5.20. Children

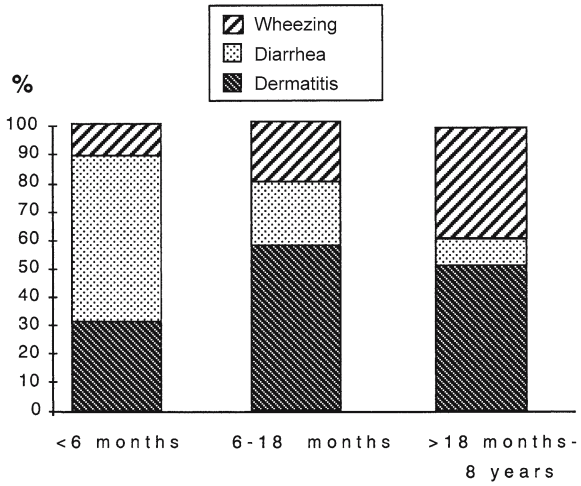

Fig. 5.24. Reasons for medical consultations according to age group

sensitized only to food allergens have an elevated incidence of AD. If the allergy to inhalants is exclusive the incidence of respiratory allergy clearly prevails over skin allergy [317]. The Hattevig et al study [131] confirms that sIgE to foods and the subsequent tolerance are evident from an early stage, while sIgE to aeroallergens appear later but do not disappear with age. Figure 5.8 from a study on 220 children [53] shows the ascending prevalence of atopic disease: a progressive increase of asthma and the fall of AD cases with age (whereas in the Hattevig et al study they increased >30 % at the last follow-up) [131]. Similar data in Fig. 5.9 show the prevalence of almost all the atopic disease in four age groups of 1,052 schoolchildren. Interestingly also urticaria angioedema and OAS prevalences are shown. The rate of 11- to 16-year-olds affected with AR is noteworthy [268]. Figure 5.24 [53] shows the most common reasons for consultations for children in the first years of life (>6 months–8 years): in babies diarrhea is by far the most frequent (Fisher = 0.008), in older children it is bronchopathy (Fisher = 0.013).

Prevalence of Immunodeficiencies

Very high is the relative incidence of primary immunodeficiencies (Chap. 22). Figure 5.25 is a world map reporting the estimated number of children (<15 years) newly infected with HIV in 2003 (total, 590,000–810,000) (Chap. 23).

Pediatricians and Epidemiology

Epidemiology is the study of the relationships existing between disease and certain factors intervening in the onset, distribution and evolution of these diseases, whether such diseases depend on the individual or on the surrounding environment. Allergic reactions and the diagnostic process are somewhat similar to a loaded gun. A great deal of knowledge is being obtained about a great variety of triggers that fire the charge: but why is the gun loaded? And what constitutes the load? We continue to focus on the triggers, and we have learned a lot about the load, but we do not know why children are hyperreactive to so many varied stimuli. While we are discussing the hygiene hypothesis, the prevalence of atopic disease such as AD, FA, AR and asthma is on the upsurge. These disorders have become a major health problem in industrialized countries, especially in infants and young children, because their prevalence has increased worldwide in the past several decades. Consequently, if the factors responsible for the increasing prevalence can be identified (Chap. 4), then there will be an opportunity to develop strategies to reverse these trends. The pediatrician is challenged to provide therapeutical and preventative interventions that achieve optimal health from infancy through adolescence. Regarding the natural history of atopic disease, it would also be helpful to identify infants who are at risk of developing allergy, so that these preventative measures could be started and used most effectively. An immense information campaign, which should benefit young children, adolescents, and their parents, is needed to make these

Fig. 5.25. Estimated number of children (<15 years) newly infected with HIV during 2003. UNAIDS. AIDS epidemic update. December 2003

measures more effective. Future progress will decisively depend on a better understating of the rising epidemiology of atopic disease.

Diagnosis of Pediatric Allergy

From History to Clinical–Functional Examination

The diagnosis of atopic disease has particular characteristics, since *pediatric allergy is significantly different from adult allergy*. It is essentially based on a *detailed family and personal history*. The purpose of the history is not only to confirm or exclude a clinical pattern of suspected allergic disease, but also to identify and demonstrate the pertinent etiological factors. Diagnostic tests can help the physician if they are considered in connection to symptoms, but not if evaluated individually: infants and boys are too often labeled as atopic only because skin prick tests (SPTs) or RAST (radioallergosorbent tests) are positive. We cannot continue without underlining the special prudence that must be reserved for the possible inappropriateness of parent declarations, mainly when symptoms are not reported in a simple and objective way. However, to facilitate information exchange, it is necessary to take advantage of what parents report, listen to them, encouraging them to talk: a keen and accurate patiently gathered history concretely helps the pediatrician to individuate the direct causal relationship. Adler et al [2] have shown that if on the one hand SPTs, RAST and MAST-CLA tests were positive in 6.7% of asthmatic children but their parents declared they were affected with food allergy (FA), on the other *at least one test was positive in 23.3% of children declared healthy* [2]. In several cases we shall find a notable discrepancy between data referred to by families and data ascertained during the medical visit (Table 6.1).

Although in the last few decades the very great and multiform technological progress has in various ways changed the approach to children with atopic disease, diagnosis is very important, since both prophylaxis and the early institution of specific treatments are able to positively modify the natural history of atopic disease (Fig. 6.1) [179]. Therefore, diagnosis covers several points:

1. History
2. Medical examination
3. Diagnostic testing (in vivo and in vitro)
4. Specific provocation tests
5. Pulmonary function testing (PFT)

Table 6.1. Factors provoking asthma according to parents

Factors	%
Infections	70
Weather changes	49
Passive smoke	22
Physical exercise	17
Strong odors	7
Emotions	4
Food allergy	2

Data from personal results of a polycentric epidemiological study in Italian allergic children (unpublished data).

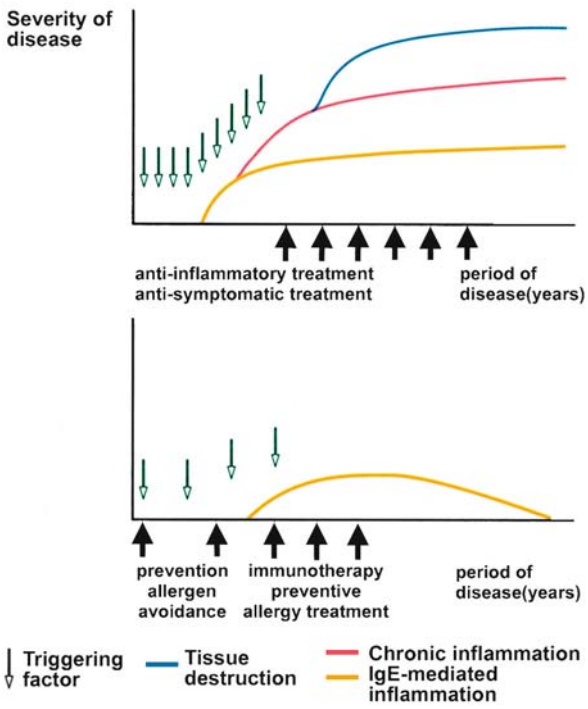

Fig. 6.1. The value of early diagnosis. The specific diagnosis of IgE-mediated allergic disease is very important in the early phase of the disease. By environmental prophylaxis and early treatment, it is conceivable to modify the natural history of allergy. Nevertheless, when the disease is already well-established, an antisymptomatic and/or anti-inflammatory treatment will become necessary. (Modified from [179])

The diagnosis of atopic disease in children, and above all the identification of pathogenic factors, needs the cooperation of a specialist center.

Allergy History

An accurate history is of *paramount* importance, because it is the key to gathering relevant information. After collecting a complete and accurate record, the nature, characteristics, frequency, as well as the possible severity of allergic symptoms will be defined [175]. As the interview continues, it is possible to exclude different conditions that present similar patterns. Subsequently, the clinical manifestations are explored: from the combined examination, specifically medical and with the possible help of diagnostic testing, the diagnosis is established [127]. To facilitate information exchange, listen patiently to the parent describing the history of the present illness as he (or she) deems appropriate, making the parent(s), who are generally unprepared and anxious, comfortable. If the baby weeps or screams or is naughty, the doctor may suggest entrusting the child to a parent until the moment of the visit, also to assure a greater concentration for both physician and parent(s).

Experience shows that:

1. History, although accurate, can be *silent,* thus complicating the diagnosis.
2. To ensure that the history is careful and detailed, the doctor should be friendly and unhurried, repeating if necessary the same question, even if only in a different form.
3. Nothing should be neglected, yet all data should be well investigated and properly arranged.
4. It is better to ask more questions or note more data, rather than to overlook them in the belief that the issues have been focused.
5. To continue methodically it is convenient to have a mental checklist at hand.
6. A record-chart or a computerized program with prearranged questions will make the task easier, but no issue should be neglected: with time, the opportunity of adding new questions or better detailing the already present ones can be evaluated.

The utility of *well-organized and drafted record-charts* is also underlined by the likelihood (or necessity) of updating them, considering second thoughts and unceasingly updating the written records with further data, which may often be recalled or provided in subsequent visits. Therefore, depending on his/her mood, the interviewer should decide whether or not to return to the history at a later time. A meaningful history therefore represents a diagnostic moment of great significance, even if it can be stressful, because history taking requires patience, listening and synthesis and abstraction abilities, as well as a great availability.

Family Allergy History

When the family history is positive, the chance that the patient is predisposed or sensitized and that some or all of his/her symptoms have an atopic origin increases: in this case it is helpful to recall the risk rates indicated in Tables 4.9–4.11. The immediate history of each family member is of the utmost relevance and should include both the mother and father of the child, as well as any information regarding other relatives, based on the family atopy score (FAS), as shown in Table 3.9. Moreover, because of the growing exposure to different cultures, medico-therapeutical trends not necessarily a part of our training, and our increasingly frequent encounters with citizens of other countries or continents, it is timely to investigate probable adhesions to homeopathic therapy and/or clinical ecology, as well as the family's cultural or religious eating habits.

Starting an *immunological diagnosis,* several questions must be answered, including unexplained miscarriages, cases of early death, morbilliform rashes during the neonatal period, early candidiasis or subsequent severe and recurrent infections, etc., leading to a PID (primary immunodeficiency), or whether addict parents have a child with ID, of as yet unexplained causes, as shown by infections from opportunistic germs, etc., suggesting a possible HIV infection.

Personal Allergy History

Following the protocol established by our division, we first investigate the mother's previous pregnancies, the related pregnancy and delivery, the neonatal period, alimentation, growth and subsequent development. If the mother smokes, ask whether she continued during or after the pregnancy and how many cigarettes she smoked or smokes daily. Regarding the type of delivery and the neonatal period, inquire whether there was any complication and/or the newborn was hospitalized for any disorder. Then accurately examine the type of feeding during the very first days, including the administration of colostrum and/or formulas different from breast milk in the maternity ward as supplements (Chap. 3). Also determine the month of birth, because there are potential implications for respiratory allergy (Figs. 4.10, 4.11). Table 5.5 shows, according to the child's age, which atopic disease will most probably affect him (her).

Inquire into the type of feeding (based on the record-chart or mental checklist) with more or less detailed questions (depending on the child's age). When feeding difficulties play a crucial role, it is timely to determine the onset of the problem with all the essential episodes, evaluating the child's growth in terms of weight and height.

Past and Present Allergy History

The *past allergy history* can give information directly related to the presenting symptoms such as episodes of anaphylactic shock, dermatitis, urticaria, vomiting, rhinitis, otitis, conjunctivitis, bronchitis, food allergy (FA), apparent multiple sensitizations, etc. In young children, episodes of vomiting and/or diarrhea, colic, and itching can be significant complaints. Itching is a common finding in AD (atopic dermatitis) and could be the first sign of an underlying disease. The purpose is now to define allergic symptoms, their onset, seat, intensity, duration, remissions or recurrence, etc. There may be a potential association with related allergy problems, viral or bacterial infections of the respiratory or gastrointestinal tracts. It is essential to collect information on temporal relationships and precipitating events, frequency of bettering or worsening, possible complications and/or relapses, treatments given and their responses. Then go on with the *present allergy history* to gather data on the age of onset and chronological sequence of symptoms: perennial or seasonal, or a daily, weekly, monthly, yearly occurrence. At this level, the decision is directed to what is most appropriate: selecting a diversified allergy history based on the prominent symptom's group, either AD–FA or asthma rhinoconjunctivitis.

Present Allergy History for Atopic Dermatitis and Food Allergy

When FA is suspected, the related history should be centered above all on the alimentation in the very first days of life and the type of feeding: exclusively maternal or supplemented and for how long, the diet prescribed to the nursing mother or, in case of bottle feeding, whether cow's milk (CM) or special formulas were used (Tables 6.2, 6.3) [32, 175].

Questions now explore at what age solid foods were introduced and which ones, verifying if necessary the data in Table 4.30, the age of onset and nature of symptoms, whether *general symptoms* were or are present such as shock, urticaria, skin rashes, wheezing, swellings, anemia, etc., and *intestinal symptoms* such as vomiting, diarrhea, colic, intercurrent infections, etc.

Starting with skin manifestations, note their morphology, time of onset, localization and timing of the lesions, also in view of the possible differential diagnosis with the seborrheic dermatitis or other skin affections. Note the relatively common contact urticaria associated with food antigens (Chap. 8).

Begin with a detailed description of symptoms, including the food suspected of provoking reactions, the time elapsed between food ingestion and symptom onset, the type of suspected food, whether it was fresh, raw, or cooked, conserved or lyophilized, the quantity of food that was necessary to produce the development of symptoms and their extent, whether similar symptoms occurred on other occasions when the food was consumed and the relative management, the response to diets and/or treatment, the chronology of occasional relapses or multiple sensitizations and the symptom outcome [34]. A "virgin" case is not always seen: diets of varying types have often been arranged, recommended by several specialists, or prepared directly at home even before consultation (Chap. 9).

Regarding medications, include vitamin and mineral supplements.

When the history indicates immediate symptoms, a *cause–effect relation* is easily suspected. Diagnosis will be more demanding in the following cases:

1. Late reactions (even up to 15 days).

Table 6.2. History pitfalls to be evaluated with attention when food allergy is suspected

Family history
Growth and development progression
Parents giving misleading indications
Dietetic, cultural or religious practices (vegetarians, Hebrews, Muslims, etc.)
Suspected food Freshness and/or cooking method Ingested amount Interval between ingestion and reaction Digestion and absorption Possible contaminations Possible cumulative effects
Relapses after ingestion of the same food
Probable dietetic or therapeutic measures

Data from [32].

Table 6.3. Frequent causes of confusion due to parents' misleading interpretations

Inclination to attribute all the clinical manifestations of the child to the last ingested food and to describe clinical findings similarly to one's own food allergy or that of a family member
Belief that a previously eliminated food is the responsible one, even if its exclusion was not productive
Probable confusion between aversion for a food and a true allergy
Tendency to interpret as an allergy the simple aversion for a food
Propensity to introduce arbitrary modifications to the diet or treatment
Propensity to set up inappropriate diets with consequent nutritive deficits

Data from [175].

2. Interferences of additional foods.
3. Multiple sensitizations.
4. A presumed sensitization is related to breast milk priming, for example AD in exclusively breast-fed children.
5. Severe manifestations (anaphylaxis) occurring at the first introduction of a food, apparently without a previous direct sensitization (supplements in the neonatal nursery), especially when *the history is silent*.

When a clear correlation cannot be established, particular attention should be focused on possible temporal or environmental relationships, including infant's age, the year, season, residence at home or in other people's home, households, relatives, baby sitters, etc.

Two different occurrences can be delineated in this approach: FA in its strict sense, characterized by hypersensitivity of the IgE-mediated type, documented by specific positive tests, or food intolerance, not sustained by IgE-mediated mechanisms (Chaps. 9 and 10).

Present Allergy History for Urticaria and Angioedema and Additional Skin Allergies

Clarify whether urticaria and angioedema are isolated or associated, or whether there are hereditary forms (hereditary angioedema) or acquired forms (apparently primary, associated with other affections, or physical forms). Although it is important to consider the main pathogenic causes, it is also critical to select them based on a single clinical history, especially when urticaria is induced by medications, food and/or contact. However, if a physical form is prevalent, Chap. 8 should be consulted for the diagnosis, as for the allergic contact dermatitis (ACD) allergic vasculitis, and urticaria caused by additives.

Present Allergy History for Asthma Rhinoconjunctivitis

The key question is whether symptoms mostly of a respiratory type refer to past episodes of wheezing, bronchiolitis, relapsing cough or bronchitis, recurrent respiratory infections, pertussis, bronchopneumonia, with special emphasis on the time or seasonal vs perennial appearance, course, intensity and therapeutic interventions. In older babies, also investigate a possible exposure of the upper airway: rhinitis (rhinorrhea, cough, sneezing, etc.), otitis (serous, recurrent, chronic), maxillary sinusitis, feasible intervention of (adeno)tonsillectomy, and the related causes and outcome. The chance that pneumonia and/or pertussis and/or persisting cough may underlie an unidentified asthma case should not be neglected, also because the trend of interchangeably employing the terms of asthma and bronchitis in children aged <5 years seems to be widespread: several young asthmatics were admitted to hospital with diagnosis of pneumonia or bronchitis [144].

If the child has suffered from asthmatic attacks, additional specific questions aim at determining what age the first episode took place, if respiratory symptoms are seasonal or perennial, then the yearly number of episodes, their severity and duration (dyspnea, shortness of breath), onset modalities, chronological sequence of breakthroughs, visits to emergency wards, hospitalizations, time course of symptoms and selective triggering factors (Table 5.11). Inquiry about seasons, climate, barometer and/or altimeter variations, places, indoors or outdoors, food, day or night, exercise-induced asthma (EIA), pets, pollens, passive smoke, odors, emotions, drugs, etc. is necessary. One may then be able to ask questions of the child beginning at ≈7 years of age such as night/day worsening, upon waking, during cleaning, in meadows or in the country, improvements, outdoors or in dry areas, yearly periods highlighted by more evident or attenuated symptoms.

As far as medication is concerned, the following must be recorded: intermittent or continuing treatment, routes of administration, daily or alternate-day dosage, whether or not asthma has provoked a reduction of physical activity, sleep, and school attendance, participation in social events, limitation in the use of public means of transportation and the capacity of going up or down stairs, etc. [29].

When rhinoconjunctivitis is suspected, one should check whether or not there are watery or purulent rhinorrhea, sneezing even upon waking, nasal obstruction and itching, oral respiration, postnasal drip, and mucus; eye findings such as tearing, itching and/or burning, eye redness, photophobia, edema, secretions; or allergic symptoms often associated with and related to otitis, including itching, otalgia, frequent infections, or general manifestations such as migraine, fatigue and possible secondary complications, including chronic nasal obstruction (CNO), sinusitis, disturbances of both smell and hearing, or sleeping, nasal hemorrhage, superinfections, etc. Similarly, we suggest thoroughly investigating whether parents report recurrent colds and bronchitis, chronic rhinitis and the like. All possible differential diagnoses should likewise be taken into account.

Environmental History

The allergy history should be completed by collecting information on the child's environment and living habits.

This includes the subject's home, the parents' or relatives' homes, as well as a possible vacation home:

- Location: urban, rural, in the mountains, at the sea. If urban, evaluate the degree of environmental pollution (severe, moderate, slight).
- Plants: type and location (indoor, outdoor); trees, weeds, grasses in the vicinity.

- Dampness, localized or generalized, air conditioning, humidifiers or fans, type of heating, air-heating, type of filters and frequency of cleaning and changes, fuel oil/gas/coal/wood heating, existence of fireplace, stoves, etc.

Bedrooms

- Location: basement or which floor
- Mattresses and pillows, type of filling (wool/down/hair/foam rubber or box-springs), encasing and purchase date
- Carpets and rugs, wall-to-wall carpeting, bedside rugs; wallpaper, curtains: if present, which material (cotton, nylon, etc.), whether washable and frequency of washing
- Furniture (upholstered furniture, etc.). If there is a closet containing household linen/clothes in the room where the child sleeps or studies, ask whether closet doors are open or closed, or rarely opened (at the change of season, etc.);

Child's Bedroom

- Other occupants, bed characteristics: when the beds have the same characteristics, return to the previous point
- Stuffed, plush toys, and whether kept in bed
- Pets (past, present and future, how long in household), which species, and whether kept in bed
- Indoor smoking: parents, relatives, regular visitors, locations allowed
- Stress: inquire whether or not there are causes for it
- Day-care facilities, baby-sitters: inquire about the location and environmental characteristics of daycare facility or child's schools, whether child consumes meals, snacks, etc., prepared locally there

Taking into consideration the pros and cons of the history, we suggest that the pros such as maximal convenience, absolutely low cost, direct contact with the child and his/her parents, and 100% noninvasiveness are immediately appreciated. If accurately done it may reduce the costs of further testing; the contras are represented by an evident subjectivity, the time required and the necessity of ensuring the child's (and parents') compliance [179].

Medical Examination

Some characteristic aspects can suggest the diagnosis such as allergic salute, infraorbital edema, nasal congestion, cough, Hertoghe's sign, etc.

In a child with *suspected dermatitis with FA* and skin manifestations, we observe the nutritional state, the type, localization and extension of lesions, usually corresponding to the child's age and the lesion severity. Body diagrams can be used (Figs. 6.2, 6.3), which arbitrarily divide the body surface into 20 areas. For each area the eczema is assessed in terms of:

- Redness (R)
- Vesicles, oozing/crusting (V)
- Excoriations (E)
- Lichenification (L)

Each type of lesion is given a score on a scale of 0 (none) to 3 (severe). The use of a scoring system quantifies possible improvement (or worsening) of skin lesions at subsequent visits. Note the data on the diagram to compare this with the next one.

Another method is based on different scores [20]:

0: Healthy child, no lesions

1: Mild, with scarce erythematous areas, with or without occasional scratching

2: Moderate, with areas of erythema, macule and scaly lesions, with or without obvious scratching, lasting >2 min each time

3: Severe, with marked and diffused erythema (>50%), scaly lesions also diffused (>25%), vesicles and/or pilary erection and incessant and conscientious scratching

The European Task Force on Atopic Dermatitis [161] has devised a composite index, applied in our division, the SCORAD (scoring of AD), which also takes into account lesion severity and subjective symptoms (Figs. 6.4–6.18) [161]. It is divided into three scores:

A Extent, according to the indications shown in Fig. 6.19 [161], which proposes a different evaluation of lesions for children <2

B Intensity, regarding the different symptoms, equally scored 0–3

C Pruritus and sleep loss (mean of the last 3 days or nights), each graded 0–10

Once A, B and C are calculated, the formula (A:5) + (B×3.5) + C is applied; the highest score in an infant <2 is (103:5)+(18×3.5)+20, thus A 20 + B 63 + C 20=103. In children aged >2, the calculation is equal because the total of A is 102. This way great emphasis is given to the symptom intensity: A (extent) and C (symptoms) are each equal to 19.4% and extent to 61.2%. Definitions of commonly used skin descriptive terms are summarized in Table 6.4.

In all children, the *medical examination* should include the auscultation of the chest, the examination of the abdomen and, depending on the circumstances, of ears, nose, and eyes. Also necessary is the accurate determination of heart (HR) and respiratory rates (RR), as well as the anthropometric evaluation with percentiles (Appendices 6.1–6.4), also considering growth and nutritional state. In asthmatic children, the medical examination should include spirometry and the peak expiratory flow rate (PEF or PEFR) (see "Additional Tests").

Table 6.5 [175] outlines the clinical symptoms that can be helpful in *differential diagnosis* [175] and Table 6.6 [104] concludes with *risk factors* for wheezing <3 and childhood asthma in children <3 years [104].

Table 6.4. Descriptive terms useful for reporting skin lesions

Type of lesions	
Erythema: diffuse or localized redness (due to active or passive capillary hyperemia), disappearing with vitropression	
Macule: circumscribed color change, not palpable, of different form, color and dimensions, not disappearing with vitropression	
Patch: macule larger than 1 cm in diameter	
Papule: firm skin elevation (following hyperemia or phlogosis), 1 cm or less, colored or not, localized and persistent	
Wheal: evanescent elevation (due to edema), localized, consistent, pink-red or porcelaneous-white, surrounded by an erythematous flare; it is characteristic of urticaria	
Vesicle: small, clear fluid-filled elevation within the epiderm or between epiderm and derma	
Bulla: localized, clear fluid-filled elevation of varying dimensions, subepidermic or between epiderm and derma, elevated on the skin plain	
Scale: small agglomeration of horny cells, mono- or polystratified, easily detachable assuming the aspect of a thin lamella	
Characteristics of the lesions	
Number: one, some, several, many	Surface: smooth or rough
Location	Limits: net or faded
Distribution: disseminated, confluent, linear, figured	Consistency: soft, stiff
Extension: localized, regional, disseminated	Pain: to the touch
Shape: regular or irregular, roundish, annular, etc.	Aspect: mono- or polymorphous
Color: normal or abnormal pigmentation	

Table 6.5. Differential diagnosis according to clinical manifestations

Symptoms	Diagnosis to be evaluated
Airways	Asthma from inhalant allergens, foreign bodies, otitis media with effusion (OME), cystic fibrosis, IgA deficit, primary ciliary dyskinesia, dysgammaglobulinemia, anatomical defects (tracheoesophageal fistula, etc.)
Skin	Several diagnoses are possible (see Chaps. 7, 8)
Gastroenteric	
(diarrhea, failure to thrive, malabsorption)	
0–30 days	Food allergy, food errors, viral disease, galactosemia, disaccharidase secondary deficit, congenital lactase deficit, short bowel syndrome, intestinal lymphangiectasia, Wiskott-Aldrich syndrome
30 days–2 years	All the above-mentioned disorders, plus intestinal parasitosis, celiac disease, abetalipoproteinemia
>2 years	All the above-mentioned disorders, plus cystic fibrosis, ulcerative colitis, Crohn's disease
(Vomiting, diarrhea, abdominal distension/pain, melena)	
	Surgical causes (congenital megacolon, hiatal herniae, pyloric stenosis, tracheoesophageal fistula), infections, metabolic diseases (galactosemia, phenylketonuria, disaccharidase deficit), organ-specific diseases
Blood	Sideropenic anemia: several causes are possible
Central nervous system	Headache, hyperactivity, irritability, tiredness, behavioral and sleeping troubles

Data from [175].

Diagnosis Type

Before utilizing SPTs and other diagnostic tests, it is necessary to define disease [121]. In our division we use the following operational definitions of disease:

- AD diagnosis follows the appearance of erythematous or vesicular itching skin eruptions, involving typical seats (cheeks, extensor aspects of the extremities in infants, retroauricular sulcus), and a severity score as described in the previous section.
- For the diagnosis of urticaria defined as allergic, if appearing on at least two occasions within 1 h after exposure to a particular allergen and later to additives.
- For the diagnosis of asthma, we define the wheezing without asthma as a wheezing in the past 12 months without lifetime asthma; the wheezing with asthma as a

Table 6.6. Differentiation between wheezing and asthma in babies aged <3 years

	Wheezing <3 years	Asthma
Exogenous causes		
Allergen exposure	–	+++
Bottle-feeding	++	–
Passive smoke exposure	++	+++
Airway exposure to viral infections	++++	++
Endogenous causes		
Family history of asthma	–	++++
Atopy	+	++++
Male sex	++	+++
Immune response to infections	+++	?
Initial airway reactivity	–	++
Initial lung function	++++	?

Data from [104].

lifetime asthma with wheezing in the past 12 months; the severe wheezing as having >4 attacks of wheezing, or >1 nocturnal awakening/week due to wheezing, or speech limiting wheeze, in the past 12 months, the severe asthma as lifetime asthma with severe wheezing in the past 12 months. The wheezing is nearly always associated with upper respiratory tract infection (URTI).

- For the diagnosis of rhinitis, nasal discharge and/or blockage occurring continuously for at least 4 weeks plus the typical pale aspect of allergic mucosa on rhinoscopy, without any sign of infective rhinitis in other relatives, is required.
- For the diagnosis of gastrointestinal symptoms, recurrent colic, vomiting, and/or diarrhea after excluding ordinary eating problems, coincidental infections, and lactose intolerance.
- For the diagnosis of FA, skin, gastrointestinal, and respiratory symptoms occurring after the definite disappearance of symptoms after each of two dietary eliminations of the food in question and recurrence of identical symptoms after DBPCFC (double-blind, placebo-controlled food challenge) with the offending food, or after intake of a specific food on at least two occasions.

Results of both history and medical examination are helpful to determine which SPT is the most appropriate [127].

Immunoallergic Diagnosis

Among immunoallergic tests, in vivo tests, SPTs and provocation tests and in vitro tests are included as well as serum total and food-specific IgE (sIgE), eosinophil count and other tests. In this chapter we do not discuss elimination diets and FCTs (food challenge tests) and tests with drugs, which are to be found in Chaps. 9 and 19. The diagnosis of autoimmune disorders, PIDs and pediatric AIDS is covered in Chaps. 18, 22 and 23, respectively.

In vivo Immunoallergic Tests

The diagnosis of allergic disease in children requires a careful and critical evaluation of laboratory test results. Serum total IgE levels and sIgE are not always correlated with history, and all different tests employed may lack specificity and/or sensitivity.

Skin Prick Tests

SPTs were devised by Blackley [18], who was allergic, by putting grass pollen on a skin scratch done on the forearm volar face, where an itching wheal surrounded by a flare developed. This method was substituted in 1912 by intradermal testing, followed by SPTs in 1924 and by prick + prick (P+P) tests in 1978. In Chap. 1 we underlined the necessity of standardization, hence the allergen concentration in the extract should be dosed in BU (biologic units) [49]. We follow the indications of the European Academy of Allergy and Clinical Immunology (EAACI) [49].

Choice of Method

The best-known method that we prefer is SPTs, although intradermal skin testing, except for specific cases (Hymenoptera, drugs), is not recommended in children, because it has an increased risk of inducing a systemic reaction and a great number of false-positive results [41]. It has been revived by the AAP (American Association of Pediatrics) as an integral part of the ritual preceding anti-measles vaccination (Chap. 9); the so-called scratch test has been largely discontinued because of its lack of precision.

Indications

SPTs consist in allergen percutaneous administration. If correctly done and with standardized extracts the advantages are: rapidity, certainty, low-cost results, ease of performance, high sensitivity and is thus reliable and reproducible [176], because it has been widely experimented. As a consequence, SPTs are the most frequently used methods for a diagnosis of IgE-mediated allergic disease where skin-sensitizing antibodies are present. When skin mast cells have surface sIgE for intruding allergens, mast cells degranulate, releasing their media-

tors, thus producing a cutaneous wheal-and-flare reaction, a type I immune reaction [49].

SPTs are more sensitive and specific in respiratory allergies, thereby representing the first-choice investigation when an IgE-mediated allergic disease elicited by aeroallergens is suspected and in asthma epidemiological studies [45]. In FA diagnosis, SPTs are less reliable, because of different factors, including the instability of some allergens, cross-reactivity between allergens belonging to different plant species or to the same species, antigenicity loss during extraction and inadequacy of allergenic extracts (see "Prick + Prick Testing").

Age

SPTs can be done at any age, although infants can manifest less evident skin reactions than older children, since skin mast cells exhibit a lower number and express fewer IgE receptors and less mediator release, and total or sIgE values are reduced; this also applies to histamine tests. SPTs can yield reliable results even in neonates and in infants, aged even 1 [99] or 3 months [163], as we habitually practice SPTs. However, if these disturbances persist regardless of negative results, SPTs are repeated in a subsequent visit. We generally do not advise doing a large number of SPTs [37].

Seasonal Variations in SPT Reactions

No seasonal variations were disclosed other than the report of monthly influences (February and October +, July and August –) [118]. Selection of a season to perform SPTs may be important for pollen-sensitive children, who are more reactive during the pollen season since enhanced allergens by grass pollens increase wheal reactions to such allergens.

Allergens to Be Tested

In the commercial diagnostic collections, a large variety of allergens are found; nonetheless, the majority of them have no clinical significance, because either some allergens rarely cause sensitization or the child is rarely in contact with such allergens. As discussed above, we find it convenient to use mostly those allergens commonly responsible for atopic disease, taking into account the results of both history and clinical manifestations of each child. For the diagnosis of respiratory allergy, in most cases a limited group of aeroallergens are sufficient [19] (Table 1.74):

- *Mites: Dermatophagoides pteronyssinus* (Der p) (Fig. 1.80), *Dermatophagoides farinae* (Der f). It is not necessary to asses the value of *Euroglyphus maynei* (Eur m 1), since it cross-reacts with Der p.
- *Pet* allergens such as cats (Fel d 1) and dogs (Can f 1); bird feathers, horse hairs, etc., when requested.
- *Hymenoptera* venoms: when suspecting a related allergy, perform the tests in hospital employing all venoms of the most widely spread insects: *Apis mellifera* (honeybee), *Vespula* spp (yellow jacket), *Polistes* spp (wasp).
- *Pollens:* grasses (Figs. 1.69–1.73) including *Lolium perenne* (Lol p), *Cynodon dactylon* (Cyn d), *Parietaria* (P) (Fig. 1.75–1.77), *Compositae* (Fig. 1.67, 1.74), and possibly also Mercurialis annua [7], *Platanus acerifolia*, *Betulaceae*, *Cupressaceae* [193], two or three trees that are more frequent in the related geographic area, in addition to emergent pollens (Chap. 12). In children positive to Lol p and Cyn d, we also test *Phleum pratense* (Phl p), *Poa pratensis* (Poa p), *Dactylis glomerata* (Dac g) and *Festuca elatior* (Fes e). When a crossed sensitization between different types of a single pollen species exists, it is often sufficient to test only one for each species. We stress that the so-called ozone hole has caused an anticipation of pollination, favoring pollen spread in geographic areas where temperature (T) is increased. Therefore, certain species, for instance P, can be detected in regions that have become climatically more favorable.
- *Molds: Alternaria alternata* (Alt a) (Fig. 1.79), *Cladosporium* (Fig. 1.78).

In the great majority of children, the likelihood of respiratory allergy can be established utilizing extracts of grasses, Der p, P, Alt a, Fel d 1, Can f 1 [189]. Employing a panel as shown above, independently of history data, provides a complete skin testing, with possible disclosure of nonapparent sensitizations, which could be subsequently highlighted. Indeed skin positivity to different allergens can be ascertained about 2–3 years before the specific symptoms. The inclusion of Fel d 1 is imperative because it is found throughout the world, even when no contact is manifest (Chap. 5). The clinically important pollens vary according to location, so it is best to refer to the pollens prevalent in the region or country: some patients have been classified as affected with an intrinsic asthma, whereas they could be sensitive to unknown allergens and/or those not included in the common battery of allergens [7]. Another poorly defined aspect is the frequent cross-reaction among pollens, fruits and vegetables, namely, grasses, mugwort and birch with certain antigens in common with apple, wheat, spices, celery, carrot, etc. [111] (Table 1.73), partly explained by profilins and various related plant proteins that may function as cross-reacting allergenic components and therefore could explain that certain allergic patients display IgE-mediated reactions to other pollens as well as distantly related plants. (Table 1.72). A discrepancy may be provoked by certain Fel d 1 extracts that, due to cross-reactivity with Der p, give false-positive tests in cat-allergic patients [8]. In another study, Der p contamination of dog dander

extracts was shown to be the cause of false-positive SPT responses in patients sensitized only to Der p [171]. Such drawbacks can be prevented by using recombinant allergens (RAs) [117, 126, 151] (Tables 1.70, 1.71). Bird allergy is uncommon, often SPTs are positive to Der p contained in the feather bedding material [70], therefore extracts obtained from old feathers may be used.

The ISAAC (International Study of Asthma and Allergy in Children) protocol phase 2 module 3.2 includes the following aeroallergens: Der p and Der f, cat hair, mixed grasses [*Dac g*, *Lol p*, *Festuca pratensis (Fes p)*, *Poa p*, *Phl p*, and *Avena elatior*], *Alt a*, mixed trees (*Alnus glutinosa*, *Betula verrucosa* and *Corylus avellana*). This protocol is specifically intended to allow comparisons between centers [143].

For the diagnosis of FA, one should proceed on the basis of (1) epidemiological data (foods more regularly consumed in a typical Mediterranean diet for infants are CM, egg, wheat); (2) age: in an infant aged ≤6 months on an exclusive CM diet, the related proteins should be tested (Table 1.75), subsequently egg (two allergens), cereals, wheat, cod, peanuts, nuts, etc., adding bovine seroalbumin (BSA) if meat allergy is suspected; (3) history, recalling that alimentary customs influence the frequency of allergic sensitizations. In addition, children who are monosensitive to grass pollens may show an unusual prevalence of positive SPTs to food allergens (Chap. 9). We always perform SPTs to foods and inhalants in the same session; for fruits and vegetables see "Prick + Prick Testing."

Extracts to Be Employed

The principal obstacle is the inadequacy of extract characterization, purification and standardization, from which both qualitative and quantitative differences often originate, since the extracts produced vary considerably as extraction techniques are generally different, thus affecting SPT optimal potency and reproducibility (Chap. 1). A basic prerequisite of SPT reliability is biological extract standardization [128]. Although the number of RAs continues to increase (Table 1.70), at present several RAs related to food allergens are available. In addition, the digestion role in modifying food antigenic properties should be better defined. Gad c 1 is the most purified food allergen and hence the most reliable (Table 1.74), followed by peanuts, CM and egg. SPT sensitivity for codfish is 100%, for egg 70%, and for peanut it ranges from 45% to 100% [121]. Cereals yield highly specific responses from a biochemical point of view. However, there is no clinical correspondence, as we have demonstrated for chocolate, thus explaining why when employing commercial extracts from different producers to investigate the same group of patients, results can be very divergent and yield unexpected (false) negative results. Several of the above problems will be obviously unraveled using RAs: use of a single RA can play an effective role as a marker of severe atopy, delivering a useful means to individuate child sensitivity to a given allergen [117, 126]. The concentration usually utilized in conventional extracts (1,500–10,000 BU/ml) was shown as the most fitting to elicit a specific response without aspecific irritating reactions, being effective even when falling to 3,000 BU/ml [107].

Choice of Lancets

Presently, utilizing single-use lancets has gained popularity, especially if allergenic extracts coat the point (Prilotest): they are easy to use, prevent excessive traumas and provide homogeneous and reproducible results, in addition to assuring a more accurate standardization, but they are expensive. Table 6.7 [47, 105] summarizes the features of different devices in use: the Morrow-Brown needle has a new version [47] and the Duo Tip Test has a bifurcated needle [105]. Commonly used lancets such as the ALK lancet (module 3.2) are manufactured in such a way as to allow a small point to penetrate 1 mm into the skin with a collar or flare on the

Table 6.7. Characteristics of the different lancets available for skin prick tests

Data from [47, 105].

instrument to prevent further penetration of the point, also producing more consistent results. Shorter points are problematic in that they produce false-positive tests, while longer points are discouraged in infancy because they induce visible bleeding. In practice, either insulin needles or single-use 25- to 26-gauge hypodermic needles can also be used, both to be discarded after each test [120].

The present version of the MultiTest (MultiTest II) is a multipuncture applicator with eight heads loaded with seven antigens and glycerin as negative control. The heads, 1.9 mm in length, are grouped in two rows of four. It is also suggested for use in infants with different preparations [131]. In 72 Estonian 4- to 6-year-olds [71] and in older children [15], it appears to be exact and reproducible, except for drawbacks due to an excessive test proximity (each head is separated by 2 cm, and the two rows are separated by 3 cm). It seems to be suitable as a screening test with several major allergens [15], similarly to the Quintest, a five-headed device [105].

Testing Methods

Before Execution

- Check whether the child has previously shown severe and/or anaphylactic reactions to the allergen to be tested; in particularly sensitive children and when AD lesions are extended, it is wise to revert directly to an in vitro test.
- Investigate whether the children referred have withheld medications that could influence their response to SPTs [30]. The following withholding periods apply: for hydroxyzine and clemastine, 2–4 days; cyproheptadine, diphenhydramine, chlorpheniramine, promethazine and all short-acting antihistamines (acrivastine, azelastine, cetirizine, fexofenadine, levocabastine, levocetizizine, loratadine, oxatomide) and ketotifen, 7 days; theophylline 24–48 h. There is no need to discontinue inhaled short-acting bronchodilators and cromolyn or nedocromil sodium and inhaled corticosteroids (CSs). Oral CSs may interfere with late-phase hypersensitivity reactions only if administered for more than 1 week, whereas application of high-potency topical CSs should be discouraged [95].

Execution Technique

- Adequate skin cleaning can be accomplished by an ether-soaked cotton-wool wad to remove the grease from the skin, so facilitating the permanence of allergenic extracts at the site of application.
- Mark the skin with a ball-point pen for the allergens to be tested.
- Apply a small drop of each test extract to the skin of the volar forearm.
- Drops are placed about 5 cm from the wrist and about 3 cm distal to the elbow crease (reduced measures in younger children).
- Direct the sterile lancet through the allergen droplet, at an angle of 60° to the skin surface to reduce the variable pressure exerted by the investigator's hand.
- The puncture should be moderate to avoid unnecessary bleeding as well as false-positive tests, and lancets preloaded with allergen should remain in the skin for 1 s.
- When testing a battery of allergens, perform the tests in parallel lines placing the drops about 2–3 cm apart, occasionally using the left forearm, always discarding the lancet on completion of each test to avoid mixing allergens [95].
- Perform a positive control with histamine hydrochloride, 1 mg/ml [49] always approximately 4 cm away from other tests, otherwise histamine can infiltrate the area of other tests, giving questionable results [80] and then a negative control (normal saline, 0.9%). For children aged 9 years, 10 mg/ml histamine has been suggested [143]. Both controls must be applied in the same fashion and at the same distance as all the other tests [165]. Alternatively one can place one at the beginning and one at the end of the test battery.
- Gently wipe away the excess solution with a paper tissue (different for each test) approximately 1 min later, avoiding smearing of test solutions to adjacent test sites: this operation does not interfere with the intensity of skin response.
- Extracts should be kept refrigerated at 40 °C.

Especially in infancy, a laser technique is advisable instead of puncture testing, insuring a greater reliability and reproducibility, but with a disadvantage that cannot be overlooked: its high cost [75].

SPTs for allergy diagnosis should be performed in duplicate and quadruplicate for research purposes [59].

Scoring System

SPTs are read within 15–20 min in a standard manner. The size of skin reactions is related to the size of the histamine wheal resulting from the positive control (diameter, at least 3 mm) considered.

We no longer use the scoring system of Aas and Belin [1] and consider positive only children with a ≥3-mm wheal (equal or twice the size of the histamine wheal) with an area of ≈7 mm^2 (cut-off), to record the highest percentage of positivities [128]; if smaller (2 mm) it renders any evaluation difficult and does not warrant the trauma caused by testing [49]. The difference between 2 and 3 mm in mean diameter is equivalent to a tenfold difference in skin sensitivity, an important factor in epidemiological studies [59].

Cut-off values have been recently evaluated as follows (mean diameter/surface of wheal): CM 5 mm/29 mm^2, egg 4 mm/16 mm^2, wheat 3 mm/7 mm^2, peanut 6 mm/40 mm^2, soy 3 mm/9 mm^2, with significant differences in wheal size between children allergic or tolerant to the above foods, except for soy (NS) [52].

The method of comparing SPT responses with controls ensures the greatest reliability and reproducibility, also balancing the operator bias [98]. Studies that do not conform to this universal grading system (Table 5.1) make any evaluation and reproducibility of data difficult [98]. SPT dimensions were analyzed, for example, by Sears et al, who noted that the highest prevalence of asthma corresponded to a diameter >8 mm (Chap. 11), and Hill et al suggest that a response of 4+ is equivalent to a positive FCT [66]. More precisely, this equivalence is seen when skin wheal diameter is greater than a given size, that is CM, 8 mm; egg, 7 mm; and peanut, 8 mm; smaller in children aged <2 years: 6, 5, and 4 mm, respectively [160]. Especially with food and inhalant allergens and in very sensitive children, we see wheal diameters *>1–2 cm,* more with the erythema with food allergens and with inhalants, also 2–5-fold greater than the histamine wheal.

Evaluations are carried out and made more precise in three ways:

1. Calculating (in parallel with controls) the mean wheal diameter, by adding or multiplying the largest diameters and calculating their mean; however, since the reactions can be oval or irregular in shape, the largest and smallest wheal diameters are measured, added and divided by 2, to obtain the mean wheal diameter.
2. With a transparent millimeter ruler or one equipped with holes coinciding with increasing diameters (1, 2, 3, 4, 5 mm, etc.) to determine the wheal diameter and erythema diameter.
3. Using a computerized program with a tablet and a digitizer pen to very precisely outline the wheal on transparent paper; subsequently the SPT scanner calculates SPT areas [133].

Positive and negative controls should always be included:

- A positive control is extremely helpful to compare various responses, check the technique's reliability and exclude the inhibition of skin reactions possibly caused by a concurrent treatment.
- A negative control can reveal a likely aspecific skin hyperreactivity, as a marked red dermographism occurs in some children following the puncture microtrauma.
- A doubtful reaction due to wheal dimensions can be considered as negative in the presence of a great histamine reaction.
- Generally a smaller histamine dilution would be preferable, thus ensuring better reproducibility, inducing wheals which facilitate both comparison and differentiation between negative and positive responses [185].

Table 6.8. Mean value (cm) of the wheal induced by histamine according to age

Age (months)	Histamine	
	1 mg/ml	10 mg/ml
0–3	0.77±0.75	1.90±0.92
3–6	1.07±0.58	3.07±0.88
6–12	1.67±0.69	3.40±1.18
12–24	2.23±1.14	3.29±0.86
Adult	2.48±1.0	4.75±1.11

Data from [99].

Failure to respond to a positive control suggests that there is some interference with SPTs, such as parents failing to discontinue antihistamine drugs before testing [120]; one should consider such an occurrence and repeat the tests at the subsequent control visit.

Several investigators have considered the *end-point titers* as the extract progressive dilution giving a wheal size of 3 mm or a wheal size similar to that of the histamine-positive control [37].

IgE-mediated reactions appear within 1–2 h occasionally followed after 4–6 h by a delayed-type hypersensitivity (DTH) resolving in the subsequent 24–48 h. Possible systemic reactions, however exceptional, should not be underrated: thus it is recommended that SPTs are done directly by pediatricians or under their personal supervision [37].

- After SPTs are done, children should be supervised by pediatricians in the office/hospital for at least 20 min, the reading interval, as for SIT (specific immunotherapy), or longer for high-risk children [49].
- In children aged a few months to 2 years, positive control response (1 mg/ml) until 12 months is always <3 mm, as Table 6.8 [99] shows. If doubt arises with an 1-mg/ml dilution, it is advisable to repeat the test with a 10-mg/ml dilution [99]. Even in children aged 5–25 months, the control diameter is not significantly related to age: the 1.8±1 mm mean diameter (histamine 1 mg/ml) is <2 mm in children aged <12 months [45]. The popular notion that infants cannot be tested stems from the idea that they rarely produce detectable sIgE levels; however, we have seen infants with positive test results, including a 6-month-old girl with a 1 × 1-cm response to egg white.

Evaluations

One point should be clear: SPTs measure reactions to antigen-specific IgE; however, *SPTs are not diagnostic,* since a positive SPT alone does not indicate a definite clinical sensitivity to a given allergen, so it is necessary to analyze any response thoughtfully, case by case, con-

Table 6.9. Sensitivity, specificity and positive predictive value of SPTs, total IgE and PP in infants aged 6–18 months

sidering history data. A puzzling test should be repeated and/or confirmed before making a decision, recurring to FCT or BPT (bronchial provocation test) if foods or inhalant allergens, respectively, are concerned.

During recent years, *SPT-negative results* have been the subject of intense discussion: it has been recently confirmed that if children with suspected FA present properly performed negative SPTs for one or more incriminated foods it would make an IgE-mediated FA very unlikely. These children might be better diagnosed by searching the allergens to which they may be sensitive. We have demonstrated that FCTs were positive in 7 out of 35 children with AD and negative SPTs to CM; therefore a method with a 20% ineffectiveness cannot be considered as fully reliable. In a recent study, 74% of diagnoses made with SPTs were not confirmed by FCTs [25]. In cases of rhinitis or conjunctivitis with a history highly indicative of allergic disease, SPTs can be negative since sensitizations are localized to the target organ; thus we suggest a nasal provocation test (NPT) and/or a conjunctival provocation test (CPT) (see "Provocation Tests").

Recently the SPT characteristics were evaluated at the cutoff level of 3 mm: CM hat 0.72 sensitivity and 0.62 specificity, and α-lactoglobulin (ALA) 0.66 and 0.64, β-LG 0.84 and 0.53, casein 0.55 and 0.87, respectively; PPV (positive predictive value) was highest for casein (0.78) and NPV (negative predictive value) highest for β-LG (0.81) [56]; see also Table 6.9 [91]. In general, SPTs (and RAST/CAP) for more standardized allergens (peanut, fish and egg white) are the most reliable, especially with immediate reactions to foods [149].

Prick + Prick Testing

P+P is a technique first employed in 1978 (Table 6.10) [33, 48], because fresh fruits and vegetables have extremely labile allergens that cannot be preserved. Therefore, for diagnostic purposes, it is preferable to employ fresh foods instead of commercial allergenic extracts, as using fresh material without preservatives such as glycerol is particularly suitable [48]. Some fruits contain vasoactive substances able to produce false-positive results. Foods should be fresh and not frozen since storing them at –16 °C causes some food proteins to lose their allergenic qualities; furthermore, several substances lose their allergenicity within 48 h [63]. The P+P technique is also very worthwhile when commercial extracts are not at hand, for example, exotic fruits, or when allergens are denatured to produce extracts and for a direct diagnosis of latex allergy.

Table 6.10. Studies done with the P+P method

Authors	Year	Fresh foods tested

P+P prick + prick.

Indications

We have successfully employed P+P with several foods, including CM, egg, wheat, the most common foods of children's diet and frequently suggested as inducing FA even by the 1st year of life, and several fresh fruits and vegetables, demonstrating P+P's greater reliability compared to commercial extracts disk. In addition to being easily arranged, P+P could be a safe and useful diagnostic method (Table 6.10). Applying the analytical reliability criteria for CM, egg and wheat, we have found a lower sensitivity for CM and wheat, and a higher effectiveness compared to SPTs. The P+P technique applied to hydrolysate formulas (HFs) has shown good diagnostic reliability (Table 6.11) [136]. The high P+P PPV and NPV supports the use of this simple and noninvasive method before prescribing HFs to babies with CM allergy (CMA) [136]. P+Ps gave unexpected results in a 9-month-old girl with severe CMA seen by us who had negative SPTs for CM. By performing P+P tests with CM diluted 1:1 with saline there was a wheal 1-cm-large-plus a 2-cm-large erythema (see also in Chap. 9). Similarly, this technique is specifically applicable to pollen-allergic babies with OAS [48].

Techniques

The technique is very simple. One pricks a normal, sterile lancet into a fresh food, assuming that it is solid, and immediately thereafter into the skin, as when doing an SPT [48]. When testing liquid foods such as CM and egg, one dips the lancet directly into the food. With other foods, including wheat, a mixture of flour and boiled water can be prepared [33] (Figs. 6.20, 6.21); similarly, HF formulas were diluted fresh according to the instructions on the can, as for a normal preparation [136]. As regards latex, one can perform puncture skin testing with latex gloves, obtaining positive results in 70 % of cases [114].

Patch Test or Epicutaneous Test

The PT (patch test) is the diagnostic tool of choice for ACD and selected AD cases. The significant correlation with total and specific IgE suggests a prominent IgE role in the reaction mechanisms, mirroring the sensitization process [84].

Indications

PTs confirm an ACD suspected case, recognize a sensitizing substance among many suspected ones, bring out the relevant but unsuspected substances, mainly in doubtful cases, and establish which materials can be tolerated by patients without risk, above all when very sensitive [16]. Because PT can aggravate an acute and disseminated dermatitis, or elicit an unspecific response in correspondence with the application site, it is wise to postpone testing to a later date until the lesions improve [153]. However, the risk of applying a standard panel is insignificant compared to the wealth of the information obtained [53].

Techniques

PT consists in placing the test material, usually commercial substances or extemporaneously prepared by specialists, in a proper vehicle and an adequate concentration is applied under occlusion on the child's upper back for 48 h. The ICDRG (International Contact Dermatitis Research Group) [16] and the NACDG (North American Contact Dermatitis Group) [95] have published lists of allergens for PTs, establishing pertinent concentrations and indicating application methods:

- Prefer the upper back skin, examining the area and excluding zones with minimal evidence of lesions [84], putting off testing if lesions are acute or disseminated. Applications on healthy skin yield positive results in 87 % of cases [153].
- Mark the outline of test sites with a spotlight fluorescent pen. Children should remain still during testing to avoid skin folds or streaking.
- Commonly available standardized test material varies according to the occlusive patches employed, requiring dilution to be nonirritating under patch conditions. The test substance is classically applied to 1 cm^2 of soft fabric under occlusion by an impermeable substance and subsequently applied to the skin with nonallergenic Blenderm tape.
- Test material is mounted on cellulose acetate and coated on a water-impermeable sheet of polyester covered with a protective sheet of polyethylene, and packed into a pouch of laminated foil made of Al, polyethylene, and polyester.
- Draw map of PT location on PT form.
- Inform patients that test sites should remain dry until removed. However, they should be immediately removed if severe itching, a burning sensation, or irritation occurs.
- Remove test 48–72 h [53] or 24 and 48 h [84], or 24 h for foods, after application [119]. Reading is done after at least 30 min (mostly after 1 h), so that a possible irritation produced by adhesive tape is reduced, making a delayed reading at 24 h [16, 53].

In children, the employment of *Finn chambers* is more practical and less invasive. These chambers are formed by small Al cups with an 8- to 12-mm diameter, a 50-mm^2 surface and a 20-ml volume, applied to the skin on nonallergenic tape (Scampor). The test substances, when incorporated in semisolid supports, can be directly applied to the small cups, when liquid a small disk of filter paper placed in the chamber is saturated by the test substance [37]. Another method, the TRUE test, consists of a mixture of 20 allergens incorporated in hydrophilic gels, coated on a water-impermeable sheet of polyester and dried to a thin film; the film once applied to the skin is hydrated by skin perspiration and releases the allergen; the high accuracy of the whole system and allergen distribution on a 9×9-cm polyethylene support provide a homogeneous allergen bioavailability [37, 53, 95]. The allergen material at hand is widely available, but you do not find it everywhere, thus test utility is limited to routine investigations [16].

The *Rapid Patch Test* is similar and includes three panels with a total of 30 allergens. *Epiquick* consists of 20 allergens on Finn chambers mounted on Scanpor tape. In children aged <4 years with AD and ACD, it is suggested to do a SAFT (skin application food test) to study food and contact allergens applied on uninvolved skin in a 0.5-cm^2 small cup [119]. Since children with AD are probably more likely to have irritant or false-positive reactions to metals, a shortened standard PT series for pediatric patients has been proposed [145].

To patch test latex, test latex hapten by means of specific extracts or apply a latex glove fragment on the upper back, to be read after 48–72 h [114].

The latex exposure test is required for a convincing diagnosis. In the test used, the child's wet hands are exposed to a wet rubber latex glove finger for 15 min, and if there is no reaction the whole hand is exposed to the whole glove for 30 min; vinyl or Tactylon gloves are used on the other hand as control [114].

Recently, the PT with foods (PTF), such as *the atopy patch test* (APT), has been introduced as a procedure enabling the identification of AD children reacting with AD worsening to the administration of the offending food [110], as well as reducing the need for OFC in these children [142]. In the case of *peanuts,* for the preparation of the PT material, peanuts were whipped and a

mixture was made with one part of petrolatum and two parts of peanuts: 20 mg of this material was applied to the uninvolved skin of the back using Finn chambers and Scanpor tape as above. The suggested occlusion time is 72 h and the results are read 30–60 min after removal. SPTs were positive in 16 patients (12%), whereas PTs for foods proved positive in 25 (19%) and a positive challenge was observed in 12 subjects (9%) [152]. For CM, egg, wheat, and rye, APT sensitivity was 60%–93% and specificity was 71%–97%. The SPT corresponding figures were 13%–41% and 97%–99% [162]. In infants with CMA the APT had a sensitivity of 79% and a specifity of 91% [44]. The *recent ready-to-use APT* had 79% sensitivity vs 44% of the APT, a similar specificity (93.8%) and a test accuracy of 82.9% vs 63.4% [74].

Evaluation of Patch Test Reactions

Evaluation of PT reactions can be based on ICDRG guidelines:

0 No skin change compared to controls
1 Weak positive, nonconfluent erythema and discrete papules
2 Strong positive, confluent erythema, papules, vesicles
3 Severe positive, redness plus blistering [53]
or based on the following scale [152]:
1 Erythema and edema
2 Erythema, edema, and few papules
3 Erythema, edema, and papules covering most of the patch test area
4 Erythema, edema, and papules spreading outside the patch test area or vesicles

Frequency of positivities greatly decreases from infancy to adulthood, as seen in a Der p study: 1–5 years, 60%; 6–10 years, 76%; 11–15 years, 50%; 16–20 years, 21%; 21–25 years, 29% [153]. Especially in AD children it is suggested that the cells infiltrating the PT site be studied with suitable techniques [153].

Photopatch Testing

A PT variant used for the diagnosis of photodermatitis is done by applying the suspected allergen on the skin in duplicate; after 24 h one of the tested skin sites is exposed to sunlight (10 min in summer, 30 min in winter). After 48 h the diagnosis is made with the same PT modalities [16]. Alternatively, artificial light sources can be adequate and provide enough of the long-wave ultraviolet light A (UVA) [95].

In vitro Immunoallergic Tests

Total Serum IgE

In allergy diagnosis, assay of total serum IgE levels (PRIST, paper radioimmunosorbent test) can play a significant role, taking into account the potential lack of correlation with the child's clinical state.

Indications

PRIST measurement has some definite indications:

- At birth, in cord blood as a predictive method of allergy (see Chap. 3)
- At every age as a mass screening
- To correctly classify allergic and nonallergic children
- In wheezing children
- To confirm an AD or FA diagnosis [27]

Total IgE Level Determination

The most commonly employed assays to measure total serum IgE levels (or other biological specimens) are:

- *Radioimmunologic assay* (RIA): the most classic is the Pharmacia PRIST, which measures anti-IgE antibodies covalently attached to a solid phase such as a paper disk, or a plastic microtiter well is incubated with an appropriate dilution of the serum or other biological liquid. A complex of anti-IgE-IgE antibodies is formed and by adding anti-IgE marked with I^{125} a new complex of anti-IgE antibodies–anti-IgE-marked antibodies is formed and directly measured.
- *Immunoenzymatic* assay (EIA, enzyme immunoassay, ELISA, enzyme-linked immunosorbent assay, and Instant ELISA), employing enzymes such as alkaline phosphatase and peroxidase as a detector system, instead of a radioisotope. The unit of measure used is the kilo-unit × l (ku/l) or the International Unit × ml (IU/ml).

An IgE assay in stools was also proposed as a noninvasive and economic indicator of food sensitization [5].

Total serum IgE values in healthy children according to their age are shown in Tables 6.12 and 6.13 [76, 82]. A study on 1,160 newborns determined IgE levels at 1, 2, 3, 5, and 6 years of age and the data were compared with the original population-based sample of 4,082 children [82]. Data given in ku/l (1 U/ml=1 ku/l) [82] are more widespread than the GM data [76]. Statistically significant higher total IgE values were found in boys than in girls at each age; this sex difference was not statistically significant within the group of atopic children [82]. IgE levels absent or very low at birth subsequently increase compared with the rise and sum of single sensitizations,

Table 6.12. Normal values of total IgE (UI/ml)

Age levels	GM	Limits	GM ± 2 SD

in turn dependent on genetic and acquired factors, but above all correlated with the extent and persistence of contact and the antigenic stimulus (Fig. 6.22).

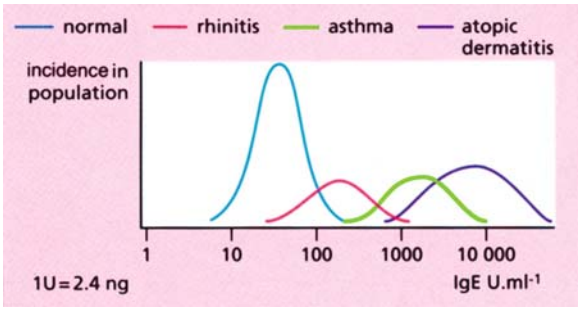

Fig. 6.22. IgE levels in allergic disease. Determination of total IgE serum and cord blood is of some value in allergy diagnosis, even if there is a great overlap between normal and allergic children. In general, however, the more severe the IgE inflammation, the higher the serum IgE

Total IgE Level Determination in Neonates and Infants

Total serum IgE levels in these early ages are nearly always less than 0.02 UI/ml (Fig. 2.10). Since the greater part of assays allows measurements from 0.5–10 UI/ml, it is indispensable to use ultrasensitive assays, that is, RIA (Pharmacia IgE RIA Ultra 50) or ELISA (Pharmacia IgE EIA Ultra 50). Values of >1 UI/ml at birth, >5 UI/ml at 1–3 months and >10 UI/ml at 4–6 months are suggested as probably pathological [127].

Advantages and Disadvantages

As regards predictive values, PRIST has an uncertain clinical significance at birth (Chap. 3), but is a useful tool to identify atopic disease early, before clinical symptoms are evident in children previously manifesting severe reactions, anaphylactic shock or severe AD, and for research purposes in prospective studies aimed at atopy prevention [27]. Total IgE associated with sIgE for Der p and egg white in 6-month-old infants are predictive of a conversion to sIgE values positive for Der p at 5 years, resulting in a reliable screening method [150]. In addition, we have reported valuable results in children with bronchiolitis, CNO, OME and hyper-IgE syndrome [27]. In children, especially preschool children, such an assay could have a diagnostic value significantly higher than in adults [32]. However, the diagnostic value of *PRIST in pediatrics* also has disadvantages, as Table 6.9 summarizes, such as low levels in subjects definitely allergic [120], high IgE levels in nonallergic diseases and in nonatopic children and conversely normal IgE levels in some atopic children [69].

Specific IgE Antibody Determination

sIgE are antibodies specifically directed against specific allergens present in serum of allergic individuals: the allergic interaction of sIgE, linked to mast cell and basophil surface by the Fc fragment, induces mediator release with vasoactive and inflammatory properties. There are discordant opinions on the RAST value in allergy diagnosis: we stress the prerequisite of evaluating case by case, mainly because there is widespread use by nonspecialists, leading to unbalanced interpretations when RAST results are not critically evaluated by experts [4, 37].

Indications

- History of previous episodes of anaphylaxis triggered by a particular food
- Children <2 years because of the discomfort of performing SPTs
- Highly sensitive children
- Disagreement between history and SPT responses
- Severe and/or chronic cases
- Children with dermographism
- Food allergens that are not very well purified and/or standardized
- Allergens not employable for SPTs (toxic, not hydrosoluble or highly sensitizing substances)

Assays for sIgE Determinations

The most commonly employed assays are of radioimmunological or immunoenzymatic types. sIgE are expressed in arbitrary units, according to the commercial kit employed for sIgE determination.

The most common is Pharmacia *Phadebas RAST,* with allergens covalently linked to a solid phase such as a paper disk incubated with a patient's serum specimen. When the serum contains sIgE vs some allergens, these bind to allergens and nonspecific IgE antibodies are washed away. Anti-IgE marked with I^{125} are then added and the amount of measured radioactivity increases in proportion to bound IgE concentrations in the serum sample. We believe an important clarification must be made, also from the point of view of false-positive and false-negative results: RAST is not a quantitative record of sIgE in a rigid sense, but only the binding between IgE antibodies and the allergen bound to the solid phase. In practice, allergen-specific IgE results are reported by different assays in nonequivalent arbitrary units or classes that are not always comparable [183]. Moreover, the results are expressed in RAST units, devoid of any correspondence with PRIST IU/ml. A conventional RAST scoring relates all allergen-specific IgE values to a standard curve divided into classes:

1st class IgE levels <0.35 IU/ml
2nd class IgE levels >0.35 IU/ml and <0.7 IU/ml
3rd class IgE levels between 0.7 IU/ml and 17 IU/ml
4th class IgE levels higher than 17 IU/ml [120]

RAST, long used, has been studied thoroughly in children only by a few authors [141] in addition to our data [97, 136]. Additional sandwich methods exist:

- *Second-generation RAST-type* assays have evolved to provide more quantitative, sensitive, precise IgE antibody results [62]. Modified RAST (mRAST), able to detect lower IgE values, is used in mold allergy [113] and in pollen and mite allergy [184], as are Phadezym RAST (Pharmacia) (PhRAST), Riallergy, RAB and Sferikit.
- Immunoenzymatic assays (EIA) are different regarding the solid phase employed to bind allergens, detector systems, and final scoring methods.
- ELISA, similar to RAST.
- FAST using a fluorogenic substrate for the antiserum conjugated to alkaline phosphatase.
- *MAST-CLA* with a chemiluminescence-based reading allows manifold tests with a single assay, 36 aeroallergens and 36 trophoallergens or 24 aeroallergens and 12 trophoallergens, useful in FA, whereas sensitivity is modest in respiratory allergy [102]. Instead, in asthmatic children, one study has found a 54.5%–93% concordance with SPTs and RAST for Der p, grasses, Fel d, Can d and molds including Alt a [134], and another has found a good agreement with BPT (87%), SPTs (80%) and RAST (74%) [106]. MAST-CLA has 69.2% sensitivity to foods, slightly lower than RAST. However, a greater annoyance, in this and other methods, is the frequent crossed allergy within foods [102]. MAST-CLA sensitivity compared to SPTs may decrease to 54% for CM and egg, with 82% and 93% specificity, respectively, and 77% concordance [177]. Other studies have noted no difference with SPTs and RAST [2]. MAST-CLA is not correlated with total IgE [177] and, considering its high cost, it should be referred to specific cases, for example, when the doctor is faced with a silent history [177] or in doubtful cases [127].
- *Phadiatop* (Pharmacia), qualitative test eliciting results of the positive/negative type. This assay is composed of a mixture of inhalant allergens and is used as a general assessment of allergic responsiveness [81]. It measures the presence of sIgE to the following antigens: Der p, Der f; Phl p, Bet v, Ole e, Art v, Par o; Cla h and cat, dog, and horse dander, so that it is useful as a screening test for atopy. We and others have demonstrated 90%–92% sensitivity, 88%–98% specificity [51, 191] up to 100% [31], 90%–92% effectiveness [31, 90, 191], 100% PPV and 86% NPV [31], with significant differences related to asthma diagnosis [31] (p=0.0001). It is not indicated for children <4 years [156]. The percentage of positivities decreases with age [174]. PP (Pharmacia) now includes food allergens, and is thus positive in 49% of infants aged ≤18 months [155]. In 36 atopic children aged 5–6 years with SPT+, its specificity was 89%, effectiveness 85% and sensitivity 72%, which decreased to 56% to identify clinical atopy [90] and to 22%–40%

Table 6.14. Comparison between CAP and RAST (%)

	CAP	RAST
Sensitivity	94	87
Specificity	96	96
Positive predictive value	97	97
Negative predictive value	92	84
Effectiveness	95	91

Data from [124].

in 6- to 18-month-old infants [91] (Table 6.9). Thus in young babies, it appears less sensitive [45]. The analytical reliability criteria varied in children between 85% and 87% compared to RAST: assuming a 20% prevalence of atopy, the NPV would be 97% and effectiveness 86% [42]. Also because of the absence of false-negative results [31], Phadiatop fared better than PP for the screening of children aged 5–6 years, whereas PP appeared to be more useful in preschool children [90] and for correctly classifying children early with suspected symptoms of allergic disease [31]. Once confirmed by means of PP clinical suspicions, the child should be referred to a specialized division to further refine the diagnosis.

- *CAP System FEIA* (Pharmacia & Upjohn), can be employed for both radioimmunologic and immunoenzymatic assays. The allergen under examination is covalently bound to a hydrophilic carrier polymer, encased in a capsule, which catches all allergen-specific IgE in the sample. Allergen-specific IgE is detected directly with a combination of polyclonal and monoclonal anti-IgE antibodies labeled with β-galactosidase, generating fluorescence: CAP sensitivity is 95% and specificity 98% [22, 123] and is positive in 95.1% of symptomatic, in 88.7% of asymptomatic and in 4.8% of control patients, with sIgE levels significantly higher between groups [122]. Table 6.14 brings together additional CAP results compared to RAST [124]. In patients with pollinosis and OAS, the mean concordance between CAP and RAST was 82%, suggesting a CAP preference [17]. Examining the standard RAST, mRAST and CAP results compared to conventional SPTs, mRAST is the most sensitive, standard RAST the most specific, and mRAST and CAP the most effective [75]. CAP, with the advantage of automation, demonstrates a good correlation with both RAST, history and SPTs [22] and appears useful as a guide for the prescription of environmental controls and SIT [22], and it is not influenced by high levels of total IgE (up to 3,000 kU/l), thereby excluding possible false-positive results, or of sIgE (up to 20,000 kU/l). A cross-reactivity vs other immunoglobulins (Ig) is $<1/20\times10^6$ with no IgGs interference [22]. With the CAP System, levels of sIgE to Der p, Der f, cat and dog danders, *Cryptomeria japonica* and orchard grass were determined. [112]. CAP is more sensitive than RAST in the diagnosis of allergy to Hymenoptera venom [88], and it is also more sensitive to pollens, molds and mites than mRAST [184]. CAP System FEIA results, when compared with DBPCFC outcomes, are generally comparable to those of SPTs in predicting symptomatic FA; by measuring sIgE concentrations with this test, it is possible to identify a subset of children and adolescents who are very likely (>95%) to experience clinical reactions to egg, CM, peanut, or fish with high efficiency and specificity, but not for wheat and soy, which should be improved. However, the values found for SPT were slightly higher [149]. Moreover, there may be an advantage for in vitro test results done with CAP System FEIA, which provides results in terms of IgE for food allergens comparable to DBPCFC studies [149]. Thus the need for OFC could be reduced by about 50% by quantitatively measuring food-specific IgE antibody levels in serum and applying these 95% predictive decision criteria [148], or when the cutoff value of sIgE to CM is of ≥2.5 KUA/l [56]. The performance characteristics of CAP System FEIA at the cutoff level of 0.35 KUA/l were as follows: CM had 0.84 sensitivity and 0.56 specificity, and ALA 0.55 and 0.84, β-LG 0.59 and 0.80, casein 0.71 and 0.75, respectively, PPV was highest for ALA (0.74) and NPV highest for CM (0.81) [56].
- In 98.6% of children, *UniCAP Phadiatop* (Pharmacia), semiautomated, was shown to differentiate positive or negative sIgE antibodies to a variety of inhalants in 2 h and 30 min [186]; in the comparison with ADVIA Centaur, using a panel of food and inhalant allergens, UniCAP had a sensitivity of 81%–100% and a specificity of 62%–70%, ADVIA Centaur of 82%–100% and 52%–79%, respectively. Both register the lowest specificity score with egg and mite allergens and the highest sensitivity scores with cat allergen, the UniCAP also with pollen allergen [137].
- *ADVIA Centaur* is a specific IgE assay, a reverse sandwich immunoassay using direct chemiluminescent technology. The monoclonal mouse antihuman IgE antibody is covalently bound to paramagnetic particles (PMPs) in a solid phase. The anti-IgE coupled with the PMPs capture the sample IgE. Non-IgE is removed by washing. Biotinylated allergen is added in excess and binds to the allergen-sIgE antibody captured on the solid phase [137].
- *Enzallergy,* polyclonal anti-IgE marked with alkaline phosphatase.

There are several automated and semiautomated in vitro methods to identify sIgE, all with varying menus, technologies, and performance. These include *rapid tests,* sandwich or EIA assays utilizing mixtures including the most common allergens, some of which allow sIgE determination in very short times (about 2 h), resulting in useful screening systems:

Last, automated and semiautomated systems have been fixed delivering responses within 3–19 h, namely:

- AlaTOP Allergy Screen EIA and Immulite.

- Arianna, a screening test employing allergenic pollen mixtures selected according to relative local prevalences and controlled with positive sera of local individuals.
- AutoDELFIA (Pharmacia), automatization of DELFIA semiautomated system, the same kits of which are employed because they are also utilizable for IgE antibodies, by performing double-triple marked assays.
- CARLA System with BRIO.
- DALIA is a very sensitive technique selective for specific (s)IgG determination, not influenced by competitive antibodies such as sIgA, sIgM and nonspecific IgG [192], and provides a wide application field for SIT.
- The ENEA II system, a totally automated instrument, permits in vitro assays, even synchronous, of total IgE and sIgE, with great rapidity (a test every 40 s). Evaluating concordance with both history and SPTs as reference values has 83.4% sensitivity, 82.8% specificity and 83.4% effectiveness [132].
- With IgE-Screen, a test on a multiallergen strip for food and inhalant allergen, antiserum is conjugated with alkaline phosphatase and readings are done with a direct optical system.
- Matrix (Abbott) is an automated system measuring sIgE against a pool of allergens, inserting serum in a cartridge. Anti-IgE are conjugated with alkaline phosphatase.
- Profilo provides a simultaneous identification of total IgE and sIgE to groups of various allergen (grasses, molds and mites, trees, animals, herbs).
- Additional automated systems include ACCESS Allergy System, Eurospital Tech, MILENIA AlaStat, Saver Allergy System, Step, etc.

In conclusion, systematic improvements in some assay systems and ongoing monitoring with blind clinical samples are needed to assure that all commercial measurements of sIgE are accurate and reliable [183].

Additional Tests

Allergodiagnostics. For asthmatic anti-inflammatory treatment, a method has been developed to monitor high ECP (eosinophil cationic protein) serum levels in the presence of inflammation and normalized levels following the reduction of the inflammatory process. In children, however, this technique does not appear to correlate with peripheral blood eosinophilia, nor is there as yet a clear relationship between ECP concentrations and variations in lung function (see Chap. 11).

Additional markers of allergic inflammation include [62, 173]:

- Endothelial cells: CD62E
- Eosinophils: EPO, END, MBP
- Mast cells: tryptase
- Monocytes/macrophages: lysozyme, neopterin
- Neutrophils: MPO, elastase, lactoferrin and a not yet identified protein of 40 kD
- Platelets: β_2-thromboglobulin
- T lymphocytes: IL_2-R, IL_5

Eosinophils. Blood eosinophilia *per se* is not diagnostic in an absolute sense, being a characteristic of several conditions, nor does its absence exclude an allergic pathogenesis of the affection under scrutiny (Table 6.15). Nasal eosinophilia (>10% of cells) is instead an indicator of IgE-mediated AR and, especially in children, is associated with SPT positivity (p=0.0159] [19], but it is also found in nonallergic eosinophilic rhinitis

Table 6.15. Causes of eosinophilia

Allergic and pseudoallergic diseases
Allergic contact dermatitis
Allergic rhinitis
Allergic vasculitis
Atopic dermatitis
Black widow spider
Bronchial asthma
Bronchopulmonary aspergillosis
Drug allergy
Antibiotics
ASA
Sulfonamides
Erythema multiforme
Food allergy
Heiner syndrome
Hypersensitivity pneumonitis
Persistent eosinophilia
(+ splenomegaly and lymph node tumefaction)
Serum sickness
Stevens-Johnson syndrome
Tropical eosinophilia
Urticaria-angioedema

Immunodeficiency diseases
Chronic granulomatous disease
Graft-versus-host disease
Hyper-IgE syndrome
Selective IgA deficiency
Wiskott-Aldrich syndrome
Parasitic infestations
Amebiasis
Ankylostomiasis
Ascaridosis
Bilharziosis (+ splenomegaly)
Cysticercosis
Echinococcosis
Fasciola hepatica
Filariasis
Hydatidosis
Löffler's pulmonary infiltrate with eosinophilia (ascaridiasis)
Nematode infestation
Onchocercosis
Oxyuriosis

Table 6.15. (Continued)

Parasitic infestations (Continued)

Paragonimiasis

Papular urticaria
Pemphigus vulgaris
Pyoderma gangrenous
Pityriasis rubra
Pityriasis versicolor
Prurigo
Psoriasis
Sézary's syndrome
Strophulus

Gastroenteric diseases

Crohn's syndrome
Eosinophil gastroenteritis
Protein-losing enteropathy
Ulcerative colitis
Whipple's syndrome

Infectious diseases

Brucellosis
Cat-scratch disease
Chlamydia infections
(trachomatis: bronchiolitis, conjunctivitis, secretory otitis media; pneumoniae: asthma)
Erythema infectiosum
Lymphocytosis infectiosa acuta
Measles (during the incubation period)
Mononucleosis
Scarlet fever

Autoimmune (connective) diseases

Allergic granulomatosis or Churg-Strauss necrotizing angiitis
Dermatomyositis
Felty's syndrome
Libman-Sacks' endocarditis
Löffler's fibroplastic parietal endocarditis with eosinophilia
Lupus erythematosus
Rheumatoid arthritis
Scleroderma, systemic

Hemopoietic and vascular system diseases

Erythema nodosum
Periarteritis nodosa
Pernicious anemia
Polycythemia
Postsplenectomy syndrome
Schönlein-Henoch syndrome
Waterhouse-Friderichsen's syndrome

Hormone disturbances

Addison's disease
Hypopituitarism
Inanition
Myxedema
Thyrotoxicosis

Neoplastic and myeloproliferative diseases

Acute lymphocytic leukemia
Angioimmunoblastic lymphadenopathy
Carcinomatosis
Cerebral neoplasms
Chronic myelogenic leukemia
Chronic myelosis
Eosinophilic granuloma
Eosinophilic leukemia
Epithelial neoplasms
Grawitz hypernephroma
Heavy chain disease (Franklin's disease)
Histiocytosis
Hodgkin and non-Hodgkin lymphoma
Idiopathic hypereosinophilic syndrome
Kimura's disease
Melanomata
Ovarian neoplasms
Panmyelopathy
Systemic mastocytosis
Wells-Whimster disease

Toxic reaction

l-tryptophan syndrome (myalgia-eosinophilia)
Scleroderma-like syndrome

Miscellaneous

Chronic renal disease
Goodpasture syndrome
Hansen's disease
Hereditary eosinophilia
Hypoadrenocorticism
Hypoxia
Peritoneal dialysis
Pleural effusion
Pneumonitis
Radiotherapy
Sarcoidosis
Thymic disease
Tuberculosis
Wegener granulomatosis

The attributions to different systems is in several cases only probable or tentative.

[14]. This assay may be helpful when in vivo and in vitro tests are negative although history confirms an atopic disease, or if the test cannot be performed for any reason [14]. Concerning the technique, see Appendix 6.5 [14, 59]. Counting the cells is suggested in provoked expectorations; however, it is commonplace that the majority of children swallow the sputum instead of expectorating it [14].

Serum IgGs in FA. As discussed in Chap. 1, serum IgGs in FA are found in pediatrics in nonallergic subjects [37] and therefore are devoid of any diagnostic significance.

IgG Subclasses. Assays are not indicated in general [158], but are useful in children undergoing SIT and in children with recurrent respiratory infections, and in all cases of relapsing broncho-obstructive affections, above all those with high susceptibility to infections. However, we underline that a recent AAAAI Position Statement, as discussed in Chap. 1, excludes any practical advantage from the determination of such antibodies.

Tests of Cell Immunity. Tests of cell immunity deal with the quantitative and functional evaluation of lymphocyte subsets (Tables 1.34–1.41).

Additional Immune Tests. Total IgE levels are not correlated with sCD23 and IL_4 levels [116].

Prerequisites, Advantages and Disadvantages of Diagnostic Tests

All diagnostic tests should possess definite characteristics and correspond to specific prerequisites, which are evaluated by means of *analytical reliability criteria* such as sensitivity, specificity, efficiency and positive and negative predictive values.

The *sensitivity* of a method is defined in terms of concentration (weight/volume), and is represented from a minimal quantity of antigen, distinct from the sample not containing it and is called standard zero, linked chiefly to the method's precision, which is variable from one method to another within the limits of a variability coefficient.

Precision represents the valuation of a method's reproducibility, defined precisely when a series of repeated measures of a single sample yields an identical result within an accepted variability. The comparison between measurements is expressed as a variation coefficient, or standard deviation (SD), an index of the method's precision.

Specificity is the ability of a compound to bind exclusively to a given substance, neglecting possible interferences with other molecules. During total IgE and/or sIgE determination, specificity depends on antigen purity and concentration, but chiefly on the antiserum used. Specificity evaluation is based mainly on cross-reactivity trials.

The *efficiency* of a method is defined from the interval between the value found and the true value stemming from the level of the substance sought.

Following this analysis, an allergy test should have:

- *Sensitivity:* the test should yield a high percentage of positive tests in patients correctly classified as truly having allergen-specific IgE, with the target of eliminating false-negative results (such as a high PPV).
- *Specificity:* the test should supply a high proportion of negative results in patients correctly classified as truly free of allergen-specific IgE; the target is that of eliminating false-positive results (such as a high NPV).

In conclusion, a test should supply a high *efficiency*, providing a high percentage of patients correctly classified among all subjects examined (atopic and nonatopic) based on the above results. Table 6.16 [158] outlines how to calculate these parameters.

Table 6.16. Formulas to calculate sensitivity, specificity, efficiency and positive and negative predictive values

Example

	Effective diagnosis	
Result	Positive	Negative
Positive	a (true +)	b (false –)
Negative	c (false –)	d (true –)

Sensitivity: the percentage of positive test results in all patients having the disease

$$v = \frac{a = \text{true-positives}}{a = \text{true-positives} + c = \text{false-negatives}} \times 100$$

Specificity: the percentage of negative test results in all patients free of the disease

$$v = \frac{d = \text{true-negatives}}{d = \text{true-negatives} + b = \text{false-positives}} \times 100$$

Efficiency: the percentage of patients correctly classified as having or as free of disease

$$v = \frac{a = \text{true-positives} + d = \text{true-negatives}}{\text{No. of cases}} \times 100$$

Positive predictive value: the percentage of positive tests that correctly predict disease

$$v = \frac{a = \text{true-positives}}{a = \text{true-positives} + b = \text{false-positives}} \times 100$$

Negative predictive value: the percentage of negative tests that correctly predict the absence of disease

$$v = \frac{d = \text{true-negatives}}{d = \text{true-negatives} + c = \text{false-negatives}} \times 100$$

Data from [158].

Advantages and Disadvantages of In vivo Tests

Skin Prick Tests

One of the main limits of SPTs is the interpretative problem of false-negative and false-positive results. The *causes of false-negative SPTs* [158] are:

- Potential decreased reactivity in very young infants [99]
- Variations among individuals
- Inadvertent employment of allergenic extracts of poor potency
- Variations from lot to lot of allergenic material
- Improper extract preservation
- Inadvertent employment of inactivated allergenic extracts
- Taking medications modulating the allergic reaction (during or before SPT execution)
- Test negativity in children with a true allergy (17% of children with pollinosis) [41]
- Particular foods: soy in 25% of cases [119]
- Improper test execution

Causes of False-Positive SPT Results

- Use of allergens with preparation defects (altered pH or osmolarity, irritants with low MW)
- Substances causing aspecific histamine release
- Measurable mediators within the extracts [185]
- Excessive proximity of positive tests

– Possible inadvertent contamination by irritants and/or allergens during skin testing

- Skin hyperreactivity (dermographism)
- Particular foods: wheat, fish, soy in 20%–27% of cases (Chap. 9)
- Improper test execution

An apparent false-positive can result from a latent sensitization (not yet clinically expressed) or from persistence of positivity after symptom remission [158].

Besides these specific problems, there are others of a more general type:

- Improper technique: execution done by operators with insufficient experience [163], use of poorly standardized lancets [179], too little distance between positive SPTs possibly resulting in aspecific reaction (axonal reflex) [80]
- Lack of standardization and/or different power of commercial extracts [49]

In summary, *SPTs have advantages and disadvantages* [19, 120]:

Advantages

- Indicate IgE-mediated allergy.
- Their sensitivity is usually high.
- Testing is an easy procedure.
- Results available in 15–20 min.
- Minimal equipment required.
- Inexpensive on a per test basis.
- Children's compliance is good because SPTs are for the most part noninvasive.
- They are safe and reproducible.
- Wide variety of allergens tested in the same sitting [120, 176].

Disadvantages

- Not very useful to detect reactions of the delayed type.
- Painful or uncomfortable, with possible irritations, depending on the child's age and reactivity.
- Time-consuming (15–20 min).
- Dependent on skin conditions (lesions more or less extended).
- Affected by drugs.
- Mild risk of reactions.
- Possible false-negative and false-positive results.
- Subjective evaluation of results.

In FA, SPTs are less reliable. Since they are unreliable with labile allergens, a cross-reactivity between different vegetal species is likely, when foods are cooked and digested, allergen modification ensues, as demonstrated by the classic test of Prausnitz and Küstner (Chap. 9), further resulting in poorly specific results in delayed forms, as in CMA with prevailing gastrointestinal symptoms. While SPT scoring and quantification are not challenging, interpretation related to diagnostic and therapeutic results requires a particular experience in pediatric allergy [120].

SPTs trigger usually local or relevant reactions but with wholly reversible functional inability [7]. Adverse effects of the systemic type are relatively sporadic: only two adults (0.02%) have shown such effects following an intradermal test [92].

Prick + Prick Test

This technique can elicit false-positive results with histamine-rich foods (Chap. 10) and foods with high lectin content; moreover, it is difficult to quantify the allergen to be introduced. A retrospective study has reported six infants <6 months of age subjected to multiple P+Ps, whose generalized reactions responded promptly to epinephrine: the babies were breast-fed and were tested with fresh foods [46].

Patch Test

- Causes of *false-positivity* depend on a high concentration or abundant quantity of test material, hypersensitive skin, use of irritant material, skin lesions in an active phase and/or microbial infection at the site of application, active, intense reactions to straps or patches, etc.
- Causes of *false negativity* include insufficient penetration of the allergen, inadequate concentration, poor

level of patient sensitization, technique defects such as inconvenient site, ineffective occlusion, ineffective tightness, scarce adherence of PT, use of high-dose CSs, etc. [16].

Advantages and Disadvantages of In vitro Tests

Concerning *total IgE* and *sIgE* sensitivity, specificity and precision of radioimmunologic and immunoenzymatic methods closely overlap.

Serum IgE (PRIST)

Advantages

- Useful in symptomatic patients with positive history but with negative tests or inconclusive investigations [179].
- When their values are in the normal range it is a practical, predictive method to establish a nonallergy [9].

Disadvantages

- Serum IgE levels exemplify only about 5% of total IgE, also because their passage into the circulation is transient and they have a short half-life. The remaining 95% of IgE is instead at the tissue level, bound to specific receptors of metachromatic cells.
- IgE concentration is also dependent on allergen stimulation and receptor saturation; therefore if atopic children are only slightly stimulated by allergens, normal PRIST results can be elicited, whereas in wholly healthy children serum IgE may be high, up to 330 UI/ml in nonatopic children [9].
- Likewise, children may deliver a positive PRIST result and respond to FCT negatively [26, 109].
- It is unreliable if employed as the only test for atopy screening [27] and is not correlated with RAST [163].

Radioallergosorbent Test

Like PRIST, RAST does not measure the absolute sIgE quantity, but their binding to allergens attached to a solid phase. sIgE are able to bind to tissue mast cells before being present in serum [45]. This binding is highly influenced by various factors, including type and quantity of allergens, quantity and avidity of sIgE present in serum, total IgE levels, serum autoantibodies belonging to other Ig classes such as IgG antibodies.

Advantages

In addition to the advantages noted for PRIST, the technique has the following:

- No risks for children
- Allergen stability in the solid phase
- Wide range of test allergens [79]

Disadvantages

- RAST measures only circulating IgE whereas SPTs point out allergen-induced histamine release at the skin level.
- It fails to give information on mast cell mediator release.
- It is less sensitive than SPTs.
- Cost-effectiveness is higher than SPTs, especially when several allergens are to be tested.

From the first point arises a lack of correlation that is not dependent on method imprecision and not settled by using purified allergens [190].

RAST also has the disadvantage of possible *cross-reactions,* for example, between several grass allergens (usually testing with a few allergens is sufficient), between Der p and Der f, frequent but inconstant Der p results are more reliable and with greater levels of specific binding), constant instead between *P. judaica* and *P. officinalis* [37]. Consequently, the number of allergens to be tested in current practice should be limited, apart from diverse history indications. In addition, RAST alone may not effectively discriminate between SPT-positive and SPT-negative patients [60]:

Causes of False-Positive Results

- Elevated values of total serum IgE.
- Employment of plant allergens with lectin groups binding IgE antibodies in a nonspecific manner.
- Serum IgG antibodies with the same allergenic specificity of IgE, able to bind to the paper disk and interfere with RAST results because IgE-IgG circulating immune complexes (CIC) are formed, generating a false IgE binding [140, 172], thus a positive RAST for soybean or wheat should be verified with a FCT [26].
- No concordance between in vitro tests and exposure to inhalant allergens [96, 109].

Causes of False-Negative Results

- Anti-IgE and anti-sIgE IgG antibodies that appear as IgGs [69] of sIgE in target organs but not in serum, of anti-food serum CICs, an often physiological occurrence [37]. Such data may explain the negative results of some studies related to SIT (Chap. 13).
- In the IgE early response to Der p, other Der p allergens distinct from both Der p 1 and Der p 2 can be dominant and constitute about 50% of the total [28] (Table 1.74).

• sIgE probably bind to mast cells before they are detectable in serum.

The problem of anti-IgE antibodies is generally by-passed by applying procedures able to restrict IgGs interferences, for instance, because of a preliminary removal of such antibodies.

Rapid Tests

Rapid tests provide a single advantage: their rapidity, but depending on the available models, certain *disadvantages* arise such as the need to check their positive results by means of different tests as well as the same limits other tests present, but at a higher cost [120]. A new test, *ImmuneCap Rapid,* allows the diagnosis of the 20 more diffused allergens, including Can f, Fel d, pollens (grasses), Der p, CM, ovalbumin. The test requires a drop of blood and can be done by a pediatrician (P. Restani, pers. comm., 13. 2. 2006).

The advantages and disadvantages of in vitro tests compared to in vivo tests are listed in Table 6.17 [42, 120, 179], those of SPTs are compared to in vitro tests in Table 6.18 [163, 179], and to history and FCTs in Table 6.19 [179]. Representative data on pathological and not pathological causes of Ig abnormalities are shown in Table 6.20 [179] and a panorama of available diagnostic tests in Fig. 6.23 [179].

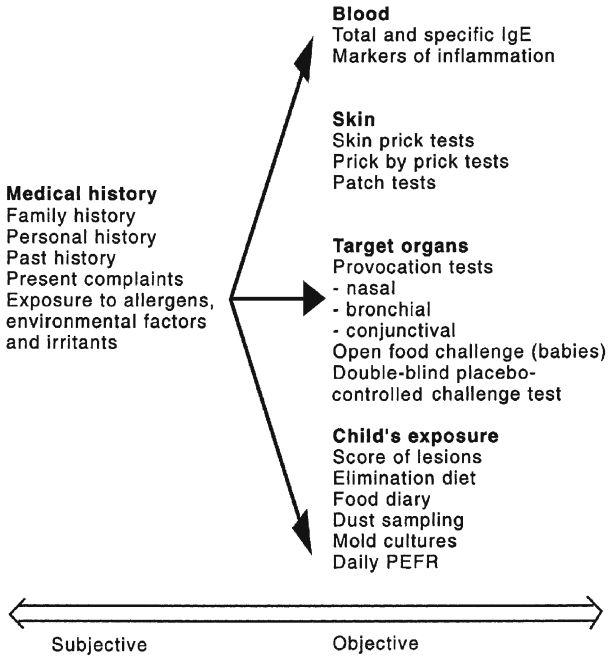

Fig. 6.23. Overview of diagnostic tests. (Modified from [179])

Table 6.17. Advantages and disadvantages of in vitro tests in the pediatric diagnosis of atopic disease

Advantages
Safe
Not affected by skin state or drug assumption
Independent of child cooperation
Less time-consuming
Good reproducibility
Elimination of SPT false positivity and negativity
Single invasiveness
Disadvantages
More expensive
Less sensitive
Done in selected centers
Delayed results
Less sensitive in food allergy
Missed recognition of not proteic antigens
Aspecific antibody entrapment by lectins
Only circulating IgE are measured
Cross-reactivity between inhalant and food allergens

Modified from [42, 120, 179].
SPTs skin prick tests.

Table 6.18. Advantages and disadvantages of SPTs in the pediatric diagnosis of atopic disease

Advantages
Cost–benefit ratio favorable
Excellent for respiratory allergy
Higher reliability
Sensitivity
Long established
Rapid results (<20 min)
Safe and reproducible even in babies <1 year
Technically easy
Disadvantages
Affected by drugs
Dependent on child compliance
Dependent on skin conditions
Difficult quality control
Slight risk of reactions
Time-consuming
Invasive

Modified from [163, 179].

Table 6.19. Comparison between sensitivity and specificity of medical history, in vivo and in vitro tests and provocation tests

Test	Airway	Skin	Anaphylaxis	Gastroenteric	Time necessary for results
History					20–30 min
Sensitivity	++++	++	++++	+	
Specificity	+++	+	++	+++	
Total serum IgE					>24 h
Sensitivity	+	++	+	+	
Specificity	–	–	–	–

Ataxia-telangiectasia
Chronic lymphocytic leukemia
Chronic myelogenic leukemia
Dysgammaglobulinemia type III
Heavy chain disease (Franklin's disease)
Hepatic cirrhosis
Hereditary telangiectasia
IgG myeloma
Lupus erythematosus systemic
Lymphoid aplasia
Macroglobulinemia
Malabsorption
Nephrotic syndrome
Otitis media with effusion
Selective IgA deficit
Still disease
High IgD levels
Chronic infections
IgD myeloma
High IgE levels
Addison's disease
Atopic dermatitis

Table 6.20. (Continued)

High IgE levels (Continued)

- Autoimmune diseases
- Bone marrow transplantation
- Bullous pemphigus
- Burns
- Chronic acrodermatitis
- Cigarette smoking
- Cystic fibrosis
- Drug-induced interstitial nephritis
- Erythema nodosum
- Gluten enteropathy
- Guillain-Barré syndrome
- Hepatic cirrhosis
- Infantile polyarteritis nodosa
- Infections
  - AIDS (human HIV infection)
  - Allergic bronchopulmonary aspergillosis
  - Coccidioidomycosis
  - Cytomegalovirus mononucleosis
  - EBV infections
  - Leprosy
  - Pertussis
  - Systemic candidiasis
  - Viral respiratory infections
- Kawasaki's syndrome
- Mononucleosis
- Nephrotic syndrome
- Neoplastic diseases
  - Bronchial carcinoma
  - Hodgkin's disease
  - IgE myeloma
- Parasitosis
  - Ascariasis
  - Capillariasis
  - Echinococcosis
  - Fascioliasis
  - Filariasis
  - Malaria
  - Onchocerciasis
  - Strongyloidiasis
  - Trichinosis
  - Visceral larva migrans
- Primary immunodeficiencies
  - Cellular immunodeficiency with immunoglobulins
  - DiGeorge syndrome
  - Hyper-IgE syndrome
  - Nezelof syndrome
  - Selective IgA deficit
  - Wiskott-Aldrich syndrome
- Pulmonary hemosiderosis
- Rheumatoid arthritis
- Wegener granulomatosis

Low IgE levels

- Familial IgE deficit with recurring sinopulmonary infections
- HIV-1 infections
- Primary biliary cirrhosis

High IgG levels

- Hepatic cirrhosis
- Hepatitis
- IgG myeloma
- Lupus erythematosus systemic
- Rheumatoid arthritis

Low IgG levels

- Agammaglobulinemia
- Chronic lymphocytic leukemia
- Dysgammaglobulinemia type I
- Heavy chain disease
- IgA myeloma
- Macroglobulinemia
- Nephrotic syndrome

High IgM levels

- Congenital infections
- Dysgammaglobulinemia type I
- Hepatic cirrhosis
- Hepatitis
- Hyper-IgM immunodeficiency
- Infectious mononucleosis
- Lupus erythematosus systemic
- Macroglobulinemia
- Rheumatoid arthritis
- Trypanosomiasis

Low IgM levels

- Agammaglobulinemia
- Chronic lymphocytic leukemia
- Dysgammaglobulinemia type II
- Heavy chain disease
- Hepatoma
- IgA myeloma
- IgG myeloma
- Lymphoid aplasia

High levels of all immunoglobulins

- AIDS
- Chronic active hepatitis
- Chronic bacterial infections
- Chronic granulomatous disease
- Cystic fibrosis
- Down syndrome
- Hyperglobulinemic purpura
- Infectious hepatitis
- Intestinal parasitism (mainly IgE)
- Intravenous drug use
- Lupus erythematosus
- Pulmonary hypersensitivity disease
- Regional enteritis
- Rheumatic fever
- Rheumatoid arthritis
- Ulcerative colitis
- Visceral larva migrans

An increase in IgM is found in about 4% of neonates, a third of whom can suffer from an infection, even at a subclinical level. An increase in IgM and IgA during the perinatal period can occur as a result of blood leakage from mother to fetal circulation, with IgM and IgM returning to normal levels within 1 week; if the increase depends on an infection the levels remain elevated in the absence of treatment.
Data from [179].

Table 6.21. Sensitivity, specificity and predictive value of skin prick tests (SPTs) and RAST for cow's milk (CM) and egg in children with atopic dermatitis (immediate and total = immediate + late reactions)

	Sensitivity		Specificity		Predictive value			
					Positive		Negative	
	SPT	RAST	SPT	RAST	SPT	RAST	SPT	RAST
Immediate reactions								
CM	0.88	0.71	0.28	0.56	0.19	0.24	0.92	0.91
Egg	1.00	0.90	0.28	0.59	0.23	0.33	1.00	0.96
Late reactions								
CM	0.83	0.59	0.32	0.60	0.47	0.52	0.72	0.67
Egg	0.91	0.73	0.32	0.65	0.46	0.57	0.85	0.79

Data from [97].

In conclusion, the correspondence between SPTs and in vitro tests is usually 80% [16], with a highly significant correlation ($p<0.0001$) [19, 32]. The analytical reliability criteria show identical values of 0.95–1; however, when excluding false-positive and false-negative results they are equal to 0 and 0.02, respectively, with a 95.6% concordance [159]. Therefore, SPTs can always be done, apart from the above inadequacies, and are preferred in epidemiological studies [59, 163], whereas in vitro tests are recommended when SPTs cannot technically be performed or they elicit undefined results [41]. Employing SPTs with 3,000 BU/ml concentrations, the total predictive value was 91% compared to RAST [108]. However, the Achilles heel of SPT and RAST is in their poor reliability in IgE-mediated reactions: *both fail to account for the late reactions characteristic of FA*. Comparisons between SPTs and in vitro tests are not always concordant: in the young asthmatics reported by Roth et al [144], SPT positivity is 80%, but RAST positivity is 27% and Phadiatop 20%; the latter two show, compared to SPTs, 24% and 31% sensitivity and 60% and 80% specificity, respectively [31]. Table 6.21 applies the analytical reliability criteria to SPTs and RAST for CM and egg in AD children (immediate + late reactions) [97]. However, a direct SPT and RAST comparison shows in general greater SPT sensitivity compared to RAST, independently of the tested allergens [32, 97], including a higher effectiveness for pollens and lower effectiveness for dog epithelia [163]. Therefore, in vivo and in vitro immunological tests make up a combined diagnostic aid [7]. Often we find children, especially infants, with positive clinical history and symptoms, but totally negative to SPTs: we have found a remarkable pair of these patients positive to P + Ps. *SPT safety* has been challenged by a retrospective study showing that the 6 infants out of 1,152 tested over 3 years (0.17% for each year) suffered from generalized allergic reactions after P + Ps with fresh foods [46]. Each infant was tested with several foods (2–4 foods), and the same food was tested in duplicate in the same baby, which doubles the risk of provoking the reaction which can also be generalized. We have done 2,200 SPTs without seeing any generalized allergic reaction [32].

Future Diagnostic Avenues

Recombinant Allergens

Purified RAs are currently available from different foods of plant origin such as apple, celery, cherry, and hazelnut. They might be produced in suitable purity and batch consistency and hence might offer a perfectly standardized diagnostic material. These proteins are much more stable than antigens in food extracts because constituents of the plant matrix responsible for degradation are absent [11]. This study evaluated Swiss patients allergic to cherry and exposed to birch pollen, patients with birch allergy who tolerated cherry, Spanish patients with cherry allergy without birch pollen exposure, and nonatopic controls with SPTs and serum immunoblot analysis. Nonatopic controls had no binding/positive SPT. Patients with cherry allergy from Switzerland and those with birch pollen allergy alone bound primarily to recombinant Pru av 1 and Pru av 4 (related to birch pollen Bet v 1 and Bet v 2), whereas the Spanish patients with cherry allergy bound more extensively to Pru av 3, an LTP (lipid transfer protein). Sensitization to Pru av 3 was positively associated with symptom severity, thus showing that RAs may improve the diagnostic value of allergy tests [11].

CD203c

CD203c (Table 1.2) can be used as a novel specific marker of IgE-dependent activation of basophils. Using RAs and basophils of sensitized individuals, up-regulation of CD203c might provide a reliable basis for a sensitive and specific allergy test. CD203c and a panel of RAs were

applied to establish a novel basophil test that allows for a reliable quantification of IgE-dependent responses at the effector cell level. Incubation of basophils with RAs resulted in up-regulation of CD203c in sensitized individuals (those with a positive RAST result and a positive case history), whereas no effects were seen in healthy control subjects. Therefore, flow cytometric quantitation of CD203c on blood basophils exposed to RAs is a useful approach to determine the allergic state in sensitized individuals and represents a basis for a sensitive innovative allergy test [64].

Provocation Tests

CPT, NPT and BPT are helpful in dubious cases, when there is a clear discrepancy between history and allergometric tests, especially in vivo, for example, in patients with a significant history, when a skin positivity vs a suspected allergen cannot be demonstrated. Obviously, such investigations are not routine, since a specific skill is required, and are feasible only in a specialized university or hospital setting equipped for possible emergencies, thus ensuring the safety of patients subjected to such tests. Both CPT and NPT are relatively easy to achieve, while BPT cannot be carried out when patients do not cooperate; therefore it is necessary that children are 5–7 years old.

Conjunctival Testing

Experimented by Blackley [18], CPT is free of risks, simple to execute and score, reproducible, not influenced by T of test solutions, usually more accurate than SPTs and better standardized than NPTs. There is no absolute correspondence between skin and/or serum and eye reactivity (at the most 70%) because IgE antibodies are chiefly produced in the tears [89]; nonetheless, CPT is utilizable in asthmatic children instead of BPTs [35].

Indications

CPT is employed to meet the following goals: to confirm the sensitization to a given allergen, establish the degree of sensitivity of a shock-organ, evaluate the effects of a drug management, and verify SIT results.

Technical Procedure

Older children are usually seated, younger children commonly lie down. Then they are requested to look upward, not to rub their eyes if there is itching, to avoid the by-product of aspecific irritations. The procedure is as follows: a drop of diluent or normal saline at 0.9% is instilled in the inferior conjunctival sac to exclude an aspecific reactivity. If no reaction ensues within 10 min a drop of a solution of the allergenic extract under study is instilled every 10–15 min. The untreated conjunctiva is used as control. The progressively increasing concentrations start with dilutions in an aqueous solution giving an allergenic extract concentration of 1×10^4/1×10^3 (or from 20 to 2,000 AUR/ml), normally different from that used for SPTs, to a maximum of 1/10, until a positive reaction occurs [3, 35, 139], graduated by an appropriate scoring [139]. Allergic reactions start generally after a few minutes, including itching, tearing, conjunctival injection, and lid-swelling [139], showing the test positivity, confirmed by finding higher levels of mediators in the tears compared to the test start [135]. Tears can be collected and assessed for inflammatory mediator and marker cells [135]. At the CPT end the eye is cleaned with normal saline. The CPT diagnostic efficacy, with the NPT as the reference method, was 89% in adults with SPTs and RAST positive to Der p [138].

Nasal Testing

NPT is more complex, and is usually performed by means of rhinomanometry.

Indications

NPTs are frequently employed when a clear discordance between symptoms, history data and SPT results is noted, or when the doctor and/or the parents have sound motives to mistrust the reliability of potential negative results of previous investigations, and to monitor SPT effectiveness. It is indispensable to previously ascertain that children are in good clinical conditions, free of nasal symptoms, and have stopped all medications, as for SPTs [14].

Technical Procedure

The nasal mucosa is examined by means of an inert substance (for example the diluent) to exclude possible aspecific symptoms. After approximately 10 min, the test is scored: when the resistance measured with a rhinomanometer increases >200% (mean value of at least five measurements), the specific test continues based on SPT positivity evaluated with an end point. Then, 0.2–0.5 ml of allergen extract dilution in a 1:1,000 aqueous solution that is not glycerinated (avoiding Freon propellents) [14] is instilled in the nasal mucosa by means of a pressurized dose inhaler capable of provoking an aspecific stimulation. Alternatively, commercial allergenic extracts can also be prepared in a phosphate buffer. Paying attention that no systemic reactions de-

velop, the allergen concentration is progressively increased at 15-min intervals, until the maximal value (not >1/10) able to provoke a clinical response – itching, rhinorrhea, sneezing, nasal obstruction, serous drainage – or that measurable by rhinomanometry (anterior and posterior), characterized by a 400% resistance increase or a >50% flux reduction. After 6–8 h or more, it is checked a second time to assess whether delayed reactions are present [50].

Occasionally, a metered dose inhaler with 0.4–0.05 ml of a solution containing 10,000 AU of an allergenic extract is insufflated, until a total dose of 800–1,000 AU in both nostrils is reached [10]. The child's responses are measured by a subjective symptom scoring system, referred to the highest or lowest clinical severity, by rhinomanometry, or by dosing selected mediators in subsequent nasal lavages. NPT with a single dose and successive clinical survey have been useful in clinical practice, whereas other techniques can be employed for research purposes [14, 50]. It may be desirable to test both nostrils (concordance = 95%) [159], also because the two may respond diversely [10]. In children with AR, NPT is preferable to CPT, although limited by poor patient acceptance. Moreover, clinical scoring can virtually supplant rhinomanometry [159].

Bronchial Provocation Testing

BPT is based on the assumption that different immunological stimuli (allergens) and nonimmunological stimuli such as acetylcholine, methacholine, histamine, carbachol, cold air, fog, ozone, hyperventilation, and exercise can trigger attacks of wheezing in asthmatic children, but not in healthy children [125]. It consists in PFT performance before and after allergen inhalation (specific provocation) or of substances such as methacholine or histamine (aspecific provocation); BPTs can be completed by an inhalational challenge with bronchodilator drugs.

Indications

Inhalational challenge with aerosolized allergen extracts are a valid instrument in testing for asthma, but for routine diagnosis the indications are limited, since this procedure requires active cooperation. Consequently, it is not normally applicable in children aged <6 years [67]. In addition, it is not always simple to estimate the dose-response relationship. BPTs with chemical mediators could acquire data to monitor BHR (bronchial hyperreactivity). The weight of such appraisal depends on BHR variation ranges: while present in the general population with a Gaussian distribution, asthmatics are at the end of most reactive subjects. Although BHR, as we shall see in Chap. 11, is also seen in other affections, and conversely an asthmatic can transiently be in a state of no reactivity, test interpretation is essentially clinical.

Patient Prerequisites

Patients with basal ventilatory conditions marked by forced expiratory volume in one second (FEV_1) >70% of PV are admitted for BPT. Possible medications are discontinued before the test, for a variable time according to the drug or drugs taken. The factors that can modify BPT results, increasing or reducing individual reactivity, are shown in Table 6.22 [178].

Table 6.22. Factors able to modify the results of bronchial provocation tests, increasing or reducing individual reactivity

Before the test	
Factors increasing the bronchial hyperreactivity	
Exposure to allergens with delayed response	1–3 weeks
Cigarette smoke	2–4 h
Infections of lower and higher airway	6 weeks
Environmental pollutants (O_3, NO_2, SO_2)	days or weeks
Influenza and rubella vaccination	3–6 weeks
Factors reducing bronchial hyperreactivity	
Anticholinergics	18 h
Antihistaminics	48–72 h
β_2-Agonists	4–12 h
Corticosteroids	?
DSCG	8–48 h
Theophylline	12–24 h
Sustained release theophylline	48–72 h
The day of the test	
Airway caliber (reduction increases hyperreactivity)	
Time of day (increased hyperreactivity in the evening and at night)	
The test	
Type of substance with bronchoconstrictor action (allergens, irritants, drugs, etc.)	
Method of administration or nebulization	
Breathing way	
Dosage type	

Modified from [178].

Technical Procedure

As in the case of the aerosol technique, it is difficult to quantify the dose–response relationship, since all subjects above a given age inhale the same quantity of nebulized solution, independently of their complexion, with the exception of young children (1–2 years old). Therefore each clinic or laboratory should fix useful and reproducible parameters to evaluate pediatric results [180]. This explains why specialized techniques for infants and young children are almost beyond reach, reliable for preschool children only in research laboratories [129], whereas textbooks describe PFTs for this age range with minimal variations compared to methods for adults [146]. Thereby, with current techniques, babies aged >1 year always receive the same dose as older children, despite a wide variability in several parameters during their growth, with the net result that 10-year-old children inspire double the adult dose, even if doses are corrected for weight, thoracic gas volume, and the surface area of the air–tissue interface [85]. Consequently, the younger the child is, the higher the level of responsiveness that occurs at a lower allergenic concentration, as with the mediator challenge test [86]. Hence, young children should receive by inhalation a part of the adult dose: what is a right dose? [146]. Further, young babies tend to breathe through their noses, and the resulting lung deposition may be only about 33%–50% of that after oral inhalation, also taking into account their different RRs [85]. The inability to assess PFTs in young children is a serious drawback since many respiratory affections may occur with children of this age group [180]. A recent technique using a computerized lung sound analysis has enabled application of the histamine challenge test to young children unable to perform spirometry [13]. We divide child BPTs according to their age; here we overview children aged at least 6–7 years [43, 86, 101].

Technical Procedure for Allergen Challenge Tests

Substances to be tested are best selected when based on the child's history. After a prior analysis of ventilatory mechanics, inhalations involve either continuous aerosol generation or an intermittent aerosol generation using the dosimeter method, in case of soluble substances or extracts available at a known concentration, starting with very low doses that are progressively increased, following curves of the cumulative type [179]. With insoluble substances or with an irritant activity, exposure in inhalator rooms can be employed. In both cases, a preliminary blank inhalation must be done with buffer or an inert control substance. Only one substance per day can be tested and if the patient has a delayed positive response, a second BPT can be done no sooner than 1 week later, to avoid possible false-positive results due to an aspecific reactivity increase secondary to the first inhalation. Allergen extracts are administered in moderate doses at first, and then increased by twofold increments until the desired resistance increase and compliance decrease is achieved. The usually assessed parameter used to estimate BPTs is the FEV_1, measured twice before and after the blank aerosol, after a series of inhalations every 4 h in the subsequent 8 h [178]. The highest of two reproducible (within 5%) measures of FEV_1 is recorded as the baseline FEV_1: all baseline FEV_1% (FEV_1/FVC) values <80% should be regarded as indicative of baseline airway obstruction [178]. These repeated observations are explained by bronchospastic responses that can be immediate (within 20–30 min), delayed (from 6–8 to 24–96 h and more) or biphasic (immediate, followed by a time interval when PFT values return to normal). BPTs are stopped (and thus positive) after a provocative dose causing a 20% or higher drop in FEV_1 (PD_{20} = provocation dose 20) compared to the blank value. Patients should remain under observation and controlled from the clinical point of view in the interval between the two procedures and over the following 24–48 h, the onset of an acute or late asthmatic attack being foreseeable.

Technical Procedure of Mediator Challenge Tests

BPTs are performed using methacholine or carbachol (aspecific test) with the previously outlined procedure: asthmatic patients react to small doses of methacholine, while allergic nonasthmatic patients react only to high doses. Mediators are delivered in incremental concentrations provoking a 20% FEV_1 reduction. BPT is considered positive when the employed doses are <1,600 µg for methacholine and <400 µg for carbachol [129]. In practice, BPT is positive or negative according to mediator concentration reached; in children positive responses are 94%–95% [43, 129]. Some authors believe that an aspecific test with methacholine is well standardized to elicit BHR even in children aged 7 [43], taking into account both asthma severity and male sex [101]; others have noted differences in responsiveness in asthmatic children, probably related to a larger dose of methacholine for their size, or additional factors, including the airway mucosa permeability and delivery system reliability (dosimeter, nebulizer) [86].

In parallel, histamine is often used; however, with this mediator tussigenic attacks are precipitated even at low doses, while headache and heat flashes gradually become more frequent when the dosage is increased. Cockcroft et al [36] suggested a modification based on a histamine BPT inducing a 20% fall in FEV_1 = PC_{20}. When PC_{20} is >8 (or 16) mg/ml, a diagnosis of asthma is almost always overlooked (92.6% of cases), values <1 mg/ml are instead diagnostic (100% of cases) and those between 1 and 8 mg/ml are intermediate. Data

show 100% sensitivity, 92% specificity, a 34% PPV, and a 100% NPV [36].

BPTs with ultrasonic fog, distilled water, cold air, etc. are rarely employed in pediatrics: a positive response for the first test was 32% [43] and for the second 36% [54].

When BPT is over, children should remain hospitalized until late-phase or biphasic reactions can be ruled out. In case of attacks of violent bronchospasm or spasmodic cough, children are best treated with β_2-agonist aerosols.

The ISAAC has recommended the hypertonic saline challenge test as the method to assess BHR. Two FEV_1 recordings are done as above. Hypertonic saline (4.5%) is nebulized and connected to a 60-cm tube and a two-way valve. The child is encouraged to maintain tidal breathing. The exposure time is progressively increased from 30 s to 1, 2, 4 and 8 min each. After each exposure, two or three reproducible (within 5%) FEV_1 measurements are taken. The exposure time is doubled if the fall in FEV_1 is >10%. The same dose is repeated if the fall is between 10% and 15%. The challenge test should be stopped and considered to be positive when the decline in FEV_1 is >15%. The maximum inhalation period should be 15.5 min and the canister with tubing weighed before and after the challenge test to measure the total dose (g) of inhaled saline. The dose–response ratio represents the degree of BHR, defined as the percentage fall in FEV_1 divided by total dose of inhaled saline (%/ml, 1 g/ml used as density for saline) [94, 115].

Overall Evaluation of Provocation Tests

These in vivo methods are applied as a second diagnostic level, useful for patients when an accurate and detailed history, in vivo and in vitro tests, or other methods have failed to sufficiently clarify or confirm the diagnosis, or there have been multiple positive tests. Such data are relevant when pediatricians register discrepancies between incomplete asthma symptoms and a poorly assessed bronchoreactivity.

In addition, we find several disadvantages to provocation tests such as limited utilization in younger children, latent onset of adverse reactions, the perspective of testing only one allergen at a time, relatively complex and roundabout methods, difficult standardization of the administered allergen amount, quantification and interpretation of allergen response, and the requirement that challenges be undertaken only in specialized centers.

Conjunctival Provocation Test

Positive Aspects

CPT is a fairly easy procedure:

- For diagnostic purposes it is a valuable tool in asthmatic children without eye signs and symptoms and gives clear results, similar to BPT results [35].
- It is useful when both SPTs and RAST are negative despite an intriguing history, or when SPTs cannot be done [89].
- The analytical reliability criteria show values equal to 1, excluding false-positive and false-negative results with 0 values [159].
- Contrary to a demonstrated lack of correlation with systemic allergometric tests [89], there is agreement with SPTs and sIgE: 97.8% [159].

Limitations

- Not always easy to carry out in very young children
- Not appropriate to identify a possible SPT negativity
- Not utilizable for studying the pattern of clinically relevant allergens in multiple sensitizations [89]

Nasal Provocation Test

Positive Aspects

- Free of bronchopulmonary complications [10].
- The analytical reliability criteria show values between 0.94 and 1, excluding false-positive and false-negative results with values of 0.04 and 0, respectively [159].
- Concordance with SPTs and sIgE is 97.8 and 98.8%, respectively, and with CPT is 100% [159].
- Helpful when SPTs are unrealizable or together with RAST are inexplicably negative.
- Adequate control of SIT effectiveness, especially in children.
- Shared use in intranasal SIT [14].

Limitations

- In children, above all in young children, rhinomanometry is difficult to use because of extreme intra- and interindividual variability [14].
- It is time-consuming, since only one allergen can be tested each time.
- Cannot be done when patients suffer from nose signs and symptoms.
- Systemic reactions are not uncommon.
- Can be performed provided that at least 6 weeks have elapsed from the end of pollen season, due to the priming effect (Chap. 12).

- Selected children should be free of other underlying diseases that may confound the interpretation of symptoms.
- It is not yet a sufficiently standardized test [50].

Bronchial Provocation Test

Positive Aspects

- BPT [180] is a tool of great utility for studying the pathophysiology and pathogenesis of asthma and comparing the utility of antiasthmatic drugs.
- It is useful in evaluating children with atypical symptoms such as chronic cough, cough variant asthma, dyspnea, and EIA to confirm or exclude an asthma diagnosis, and all cases in which it is impossible to formulate a reasonable diagnosis, to elucidate BHR impact, either spontaneously or following drug therapy, as well as the effectiveness or ineffectiveness of drug protective effects, as in the case of EIA and SIT results, when for various reasons in vivo and in vitro tests are not available.
- It can be used to investigate selected cases, mainly to persuade patients and their families about the utility of environmental controls, also because *BPT is safe* and no significant morbidity occurs if correctly done in a hospital setting.
- It can be used to correlate pre-BPT FEV_1 with final values, a more precise pattern of risk factors associated with BHR, whether or not symptomatic (the BHR) is [179].

Limitations

- It is not routinely applicable because it is either long and annoying or more valuable information can be obtained from less invasive and less time-consuming tests [154].
- Several studies have assessed that BPT varies greatly in sensitivity (19%–70%) and PPV (11%–76%) in identifying children with wheezing [125].
- BPT is not reliable without an opportune standardization of testing procedures in young children and/or with other airway disorders such as infectious bronchitis, cystic fibrosis, or other affections altering PFTs.
- BPT is best done in specialized clinical settings, with accurate indications and calls for a qualified personnel with experience and well versed in doing BPTs, who are present during the entire duration of testing. Equipment and medications must always be on hand to reverse the possible onset of an asthmatic attack; an emphasis on prompt initiation of emergency measures and with activation of complete first-aid and resuscitation procedure is advisable [93]. A severe reaction was reported in a 22-year-old *asymptomatic patient with a FEV_1/CV of 88%* after 1 min and death after 15 min, despite rapid, aggressive treatment [147].
- A positive test may be helpful to confirm an asthma diagnosis, however, without an absolute value, because different conditions may be associated with BHR such as URTIs [129].
- The degree of reactivity both in normal and asthmatic children forms a *continuum;* therefore, borderline results should be interpreted with a great moderation.
- Considering varying types of challenges, no correlation was found, undoubtedly because of the lack of standardization and the diversity of the acting mechanisms [65], also requiring follow-ups and several visits to the clinic [93].

Additional Aspects to Be Considered

- The dose for a 10-year-old child should be reduced, based on his weight, by 50% compared to an adult dose. As a consequence, the reductions for children aged 0.5 to 1 year should be 75%–80% and 90%, respectively [86].
- Doses that are too high can yield a false-positive result.
- When pollens are to be inhaled, the larger granules (20–30 µm) remain trapped in the nose, while the pollen extract (droplets of 1–2 µm) provokes bronchoconstriction in children with rhinitis [41].
- As much as 42% of AAAAI committee members claim that BPT prescription is unnecessary and several members have suggested simplifying BPT and above all making it less expensive [154].
- The grading of asthma severity is seldom based on PFT values and may be used to fill out the history [93]; others [125] maintain that one BPT is not sufficient to confirm the clinically diagnosed asthma.

Additional Tests

Exercise challenge is suggested for children suffering from EIA and as an asthma screening method [182]: the child is asked to run freely at the speed of 6 km/h for 6–8 min on an equipped track with a maximum slope of 5%, preferably in a dry environment, and a relative humidity <40% and T approximately 22°C. The test is positive when the fall in PEF is >12% and/or in FEV_1 is >15% compared to baseline values. However, if such equipment is not available, the test can be done using a bicycle ergometer or a treadmill test (Fig. 6.24): the child exercises for 5 min, controlling that HR is not >80% for the age; the fall in FEV_1 (≥15%) occurs 5–15 min after the end of treadmill test. Therefore we suggest sequentially measuring RRs 1, 5, 10, 15 and 20 min after the end of the test. When it is necessary to monitor a possible late reaction, RR records are done hourly over the subsequent 12 h. The free running test is objectively the simplest and more asthmogenic [182], while the treadmill test is the most standardized, unlike

Fig. 6.24. Treadmill test

other exercises, including the bicycle ergometer, and jumps or running up stairs. Environmental and atmosphere trends, as well as dry or cold air, are able to adversely influence the results [129].

Pulmonary Function Testing

PFT is a very valid adjunct to assess the lungs in children with ascertained or suspected pulmonary disorders.

Indications

- To confirm an asthma diagnosis by documenting the reversible airflow limitation
- To quantitate limitation extent by assessing its reversibility after bronchodilator administration
- To monitor responses to therapy with bronchodilators and to follow the course of a child with asthma over time

Strictly speaking, PFTs are not diagnostic tests but they make it possible to define the characteristics of obstructive or restrictive airflow disorders and the type of pulmonary pathophysiological impairment likely present, also ensuring the necessary measurements before BPT is undertaken. The more practically used tests are PEF and spirometry.

Peak Expiratory Flow Rate

Peak expiratory flow rate (PEFR) is the simplest test of lung function, a valuable test to correlate diagnosis with appropriate therapeutic recommendations [68].

Definition

PEFR is the maximum flow rate generated during a forced expiratory maneuver. It is therefore a test measuring the maximum mid-expiratory flow (MMEF), commonly obtained during the first tenths of a second following a forced expiration from total lung capacity (TLC).

Available Devices

PEFR can be assessed by a number of specifically made hand-held devices such as peak flow meters (PFM) (Fig. 5.18), with the following requisites:

- Low cost. Models include the Mini Wright PFM, with two models for normal and low ranges (Airmed), the PFM DHS, the Vitalograph Pulmonary Monitor, the AssessPeak Florometer, and others
- Portable
- Well suited to monitoring children aged 4–5 years and older.

Among these devices, we suggest the mechanical models, which do not require daily calibration, since the first calibration done by the manufacturer is valid, which makes them certainly suited for home PEF monitoring. However, as the accuracy and linearity of different portable PFMs may yield different values when used for the same child [100], for a useful home PEF monitoring, we suggest using the same model in the home and the clinician's office. Alternatively, parents can bring their PFM to the office to compare the results of the two PFMs [168].

Indications

PEFR can be useful as a quantitative and reproducible assessment of lung function in a pediatrician's office; however, its main employment is at home [168]. Given the great interindividual variability of this parameter [57], a single monitoring is scarcely useful to make a diagnosis: it is recommended that home monitoring be done morning and evening (about 7:00 AM and 7:00 PM) to recognize and evaluate each circadian variation in lung function [68], thus allowing the clinician to provide a treatment adequate to the individual child's requirements [168]. When PEFR is measured only daily, it should always be done at the same time of day. If daily measurements cannot be taken twice a day, two or three times a week, then recording readings first thing in the morning and last thing at night of the same day is suggested [68]. In each case, PEFR also evaluates the reversibility of a possible airflow limitation in response to a single dose of β_2-bronchodilator [68]. Obtaining three PEF records is commonly recommended, entering the best one on a diary card, and when children are adequately treated, to establish which are the best personal values with the least circadian variability. The best personal value is the highest PEF value achieved in children under an effective anti-asthma treatment [68]. It must be kept in mind that PEF measures only large airway function, not the small airways, so children with

mild asthma may be underdiagnosed. In addition, 2 weeks may be required to obtain a panel of reliable values. A single daily monitoring does not allow extrapolating data utilizable to detect early stages of airway obstruction [57]. A useful marker of asthma disease is mean diurnal variations (MDV) of PEF, whose values range between 9.6% and 22.6% in children with asthma, with mean/median normal pediatric values ranging from 5.6% to 9.9%. MDV values are normally distributed after logarithm transformation to avoid data dispersion and to obtain a reliable analysis of PEF variability [57]. Pediatricians should therefore be experts in the analysis of both PEF and MDV results before suggesting an instrument to parents. Until this parameter is standardized, a *peak flow diary* can offer the pediatrician a longitudinal record by which disease activity and management efficacy are evaluated [128]; therefore it is advisable to continue to monitor in terms of PEF/PEFR.

Measurement of Flow Rates

All PFMs are portable. Since the maneuver required to perform PEFR is effort-dependent, children, especially younger ones, may need to be coached to correctly perform the test, requiring a notable cooperation not attained in children aged <4–5 years. Time should be allowed for small children to become comfortable with the machinery and to practice blowing with an unattached disposable mouthpiece or other similar tools (Fig. 6.25 a and 6.25 b, c) [180].

Measurement Technique

- Place the indicator at the base of the numbered scale.
- Stand up.
- Take a deep breath.
- Place the meter in the mouth and close lips around the mouthpiece.
- Blow out as hard and fast as possible (a prolonged expiration is desirable when performing spirometry, not in PEFR).
- Write down the value reached.
- Repeat the procedure two or more times as judged by the pediatrician.
- Record the highest value reached (do not calculate the mean of the recorded values).

Normal Values for Male and Female Patients Aged 4–16 Years

Appendix 6.6 [181] shows the equations for the predictive determination of mean PEF values in children aged 4–16 years; Figs. 6.26–6.31 provide the values in males and females related to age (4–16 years) [181], and Table 6.23 [180] the average (50%) related to height (between 1 m and 1.76 m), including forced vital capacity (FVC) and FEF_{25-75} [180].

Interpretation of PEFR Results

A 20% variation from baseline after adequate bronchodilation in subjects in stable asthma indicates an overall worsening asthma, thereby suggesting careful monitoring.

The following is a classification of asthma severity, with the pertinent FEV_1 values in parentheses:

- Mild: PEF >80% predicted at baseline, variability <20% (<100%–≥75%)
- Moderate: PEF 60%–80% predicted at baseline, variability 20%–30% (<75%–≥60%)
- Severe: PEF <60% predicted at baseline, variability >30% (<50%–≥34%)

The term "variability" refers to the difference between morning and evening values, or to the different values recorded in the morning within the span of 1 week. It is important, as discussed earlier, to establish the circadian variability that correlates with the degree of disease instability [68].

Management Implications

The zone system has been adapted to a traffic light system based on the percent of the best personal value.

- PEF 80%–100%, *green,* no asthma symptoms, routine treatment
- PEF 50%–80%, *yellow,* possible acute exacerbation and/or inadequate control of overall asthma
- PEF <50%, *red,* medical alert: immediate therapy and/or admission to emergency department

We stress that only children aged ≥5 years can usually undergo a PEF measurement with reliable results [68]. In our experience, organizing the test as a game or a party favor, one can teach PEF maneuvers to children as young as 3 years of age. An example of such coaching might be to ask the child to blow all the candles on a party cake in one breath, or to try a competition on who blows a trumpet louder and longer, etc. (Fig. 6.25 a–c). In case these games do not seem practicable, the doctor could recur to an airway computerized phonopneumography based on the analysis of lung sounds, easily recorded even in young children [166]. As previously mentioned, an early and correct recognition of atopic disease could avoid a series of problems such as those outlined in Table 6.24 [179], thus resulting in a more satisfying approach to asthma management [168].

Spirometry

Spirometry is the measurement of air movements into and out of the lungs during various breathing maneuvers [39]. In cooperative chest patients, spirometry is a routine clinical examination measuring the volume of air exhaled from the lungs during a maximal respiratory maneuver. The vital capacity (VC) and the functional residual capacity (FRC) are recorded by spirometry measuring the expiratory flow. Even if more testing procedures are combined to assay the potential presence and entity of bronchial obstruction, in monitoring the evolution and therapy effectiveness, spirometry is not inferior to any other test in clinical practice, provided that it is not used as the only test [93].

Definitions

There are five basic subdivisions of lung volumes (Fig. 6.32):

- Tidal volume (TV) is the amount of air inhaled and exhaled during a normal respiratory cycle.
- IRV, inspiratory reserve volume, is the maximal volume of air that can be inhaled over and above the TV: the sum of both volumes is the inspiratory capacity (IC).
- VC is the amount of air that after a maximal inspiration can be expelled with a maximal expiration. It corresponds to the sum of IRV, TV and expiratory reserve volume (ERV).
- RV, the residual volume, is the amount of gas that remains after a maximal exhalation.
- FRC is the air remaining in the lung at the end of a spontaneous expiration, *the only measurement assessed in infants* [6], thus FRC = ERV + RV; while RV = FRC –ERV.

The expiration begins from TLC, the total amount of gas in the lung after a maximal or forced inhalation, that is the sum of TV + IRV + RV + ERV ending with RV [180]. FVC represents the maximal amount of air exhaled irrespective of time (Table 6.23). If FVC is the difference between TLC and RV, the sum of ERV, TV and IRV is the total amount of air that remains after a maximal inhalation at the end of the normal expiration.

The increase in some proportions, RV/TLC = 22% and FRC/TLC = 45%, is an index of respiratory insufficiency of an obstructive type [23].

Figure 6.33 outlines the normal volumes and those bound with moderate airway obstruction.

Additional parameters include:

- FEF, forced expiratory flow
- $FEF_{25–75}$, forced expiratory flow at 25%–75% of VC, more often used than $MMEF_{25–75}$, maximal mid-expiratory flow at 25%–75% of VC (Table 6.23)

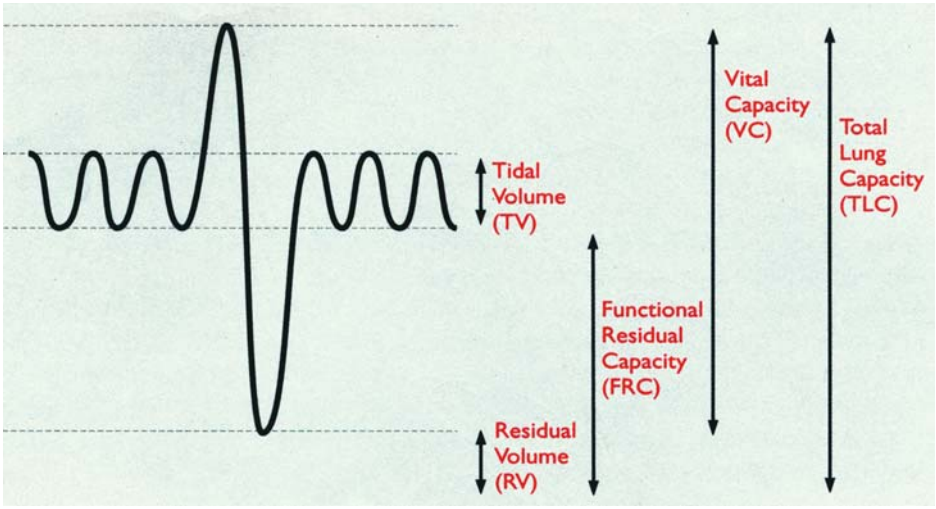

Fig. 6.32. Subdivision of lung volumes

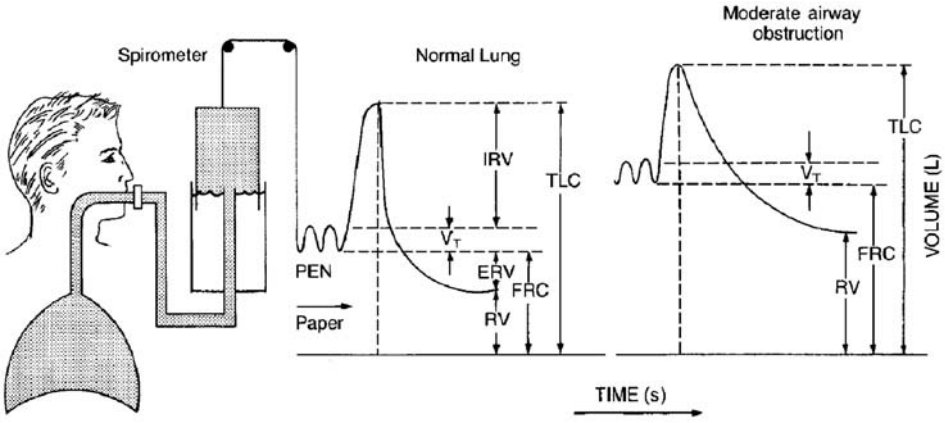

Fig. 6.33. Normal lung volumes and capacities compared with an example of those found with moderate airway obstruction

- FEV_1, forced expiratory volume in one second (in liters)
- Tiffenau index: FEV_1/FVC
- $\dot{V}_{max}$ 75, $\dot{V}_{max}$ 50 and $\dot{V}_{max}$ 25, at 75%, 50% and 25% of VC, respectively

FEV_1, the most frequently employed index, is a maximal forced expiratory maneuver going from full inspiration to full expiration but relies on the child's (aged >6 years) cooperation, since it depends initially on the resistance of large airways and then of the small airways in the second part of a respiratory act. FEV_1 is a sensitive and reproducible expression (with a coefficient of variation between 0% and 8%) of the central and lower airway function, whose reduction is an index of generalized airway obstruction, reversible after bronchodilator administration. FEV_1 expresses the degree of median airway obstruction certainly more accurately than FEF; however, small airway obstruction is scarcely represented.

FEF_{25-75} is defined as the slope of a line connecting the first and last quarter of an FVC, the effort-independent part of FEV_1; it essentially explores the degree of resistance to airflow of lower airways: it is a very sensitive indicator that in case of limited airway obstruction, can be a better measure for following disease in children with a normal FEV_1 [87]; helpful information to quantify variable obstruction can be given in children by $\dot{V}_{max}$ 50 and $\dot{V}_{max}$ 25.

In children, the FEV_1/FVC ratio is a value >85%–90% (percent of PV) and is consistent with normal airflow, since it is the fraction of the VC that is exhaled in the 1st s; the reduction to <80% is one of the best indices of respiratory insufficiency of an obstructive type. However, it is less sensitive to small airway obstruction and can result in an insufficient and/or delayed indication of distal obstruction [23].

In conclusion, FEV_1 compared to previously discussed measures requires a lower compliance, has a greater reproducibility and employs less costly devices [23].

Indications

Spirometry can be performed in children aged ≥6, generally able to cooperate. In selected cases, younger children can undergo the examination [73, 180]. Spirometry should be performed in all true or suspected asthmatics, especially when PEF values do not fit the clinical severity of asthma, to provide adequate information on the child's conditions. It is mandatory that spirometers respond to absolute standards [100].

Interpretation of Spirometry Results

Spirometers offer an immediate digital reading of the main indices, making it possible to visualize airflow obstruction, assess prognosis and quantify the response to therapeutic agents over time. With computerized equipment, the PVs and their relative percentage are automatically measured: the models to be preferred are those displaying flow-volume curves (FVCs), over those showing only readouts of numerical results, by which it is possible to determine whether the child is cooperating. Spirometry does not offer a precise diagnosis, but rather ensures a result setting, based on the belief that the more severe the obstruction is, the more reduced the airflow is during a forced expiratory maneuver, compared to PVs recorded on average in healthy subjects [39].

The lack of FEV_1 responses to a bronchodilator does not preclude a diagnosis of asthma: caveats are a possible persistence of effects related to previous therapy or an inappropriate aerosol administration, in addition to the reflex bronchospasm in response to airway irritation caused by aerosol ingredients and the bronchoconstrictor procedure effect (spirometry-induced bronchospasm) [180].

It is important that results are compared with normal standards for age, sex, race, and height: indeed the normal PVs are different depending on whether sub-

jects are children or adults [85] (Table 6.23). We believe that a comparison should be valid when children are used as their own controls or children of the same or a similar size are compared [85] (longitudinal evaluation).

Pulmonary Function Tests in Children Under 12 Months to 6–7 Years

Approximately one-third of infants, during the first 12 months of life, present a recurrent bronchospasm: independently of the basic disease, PFTs, in particular of flow rates and volumes, are invaluable tools in the management of the basic disease. Flow–volume analysis in severe airway obstruction has led to the understanding that when the curve of forced flows overlaps with FVCs, there is no air reserve left, a problem that during the first months of life can also be observed in asymptomatic infants [83]. As pointed out above, PFTs in children aged <7 years show notable differences: children are thereby divided into three age groups [23, 129], also taking into account the infant's somatic growth and the related functional developmental changes, an issue not facilitating PFT standardization in the pediatric domain [6, 129].

Between 4 and 7 years of life, it is not easy to measure VC, FEV_1 and other related parameters in a reliable and reproducible way, while some cooperation can be attained for the following measures:

- PV (pulmonary volume) at the FRC level.
- BPT of bronchoconstriction or bronchodilation based on Raw (airway resistance), obtainable at this age without excessive discomfort.
- Specific Raw (sRaw) is measured in most specialized centers using whole-body plethysmography in young awake children accompanied by an adult, which yields comparable and equally repeatable estimates of sRaw in young children [77]. Raw measurement can be unreliable since as much as half of the total Raw (expressed in cm H_2O/l/s) in children may be from the upper airways. It can also facilitate the evaluation of the response to bronchodilators causing paradoxical decreases in FEV_1 since it does not require full inflations or sustained expirations, frequent causes of bronchospasm [180]. We note that premature infants have an increased Raw in the 1st year of life (>50 cm H_2O/l/s), predictive of symptoms within the 3rd year of life [58].
- The reciprocal Raw, airway conductance (Gaw).
- RSR (respiratory system resistance), measured by the impulse oscillation technique, facilitates the child's cooperation, since the plethysmographic cabin is absent. However, the entire RSR is not measured, but only the respiratory airway resistance, and this technique is also potentially insensitive to small changes. It is less sensitive than sRaw in detecting Raw changes after methacholine challenge. Thus several methodological issues, including the optimum site for application of the oscillations and the effect on upper airways have yet to be resolved [78].
- The interrupter resistance (Rint) appears more promising for detecting bronchodilator responses than induced bronchoconstriction in wheezy preschool children [130]; however, Rint is not recommended for BHR assessment, since Raw changes may be underestimated during the challenge, because there is no equilibration of pressure changes throughout the respiratory system [55].

Between 2 and 4 years of life, except sporadic exceptions, is the period of non-cooperation to opposition; however, BPTs can be performed, comparing induced bronchoconstriction and dilation to modifications of transcutaneous O_2 tension ($PtcO_2$): several studies have demonstrated the correlation between PFT parameters and $PtcO_2$ in children [170, 187, 188] and infants [164, 167]. These studies are certainly of great relevance, anticipating the diagnosis of asthma to an age level usually escaping such consistent findings, often due to poorly indicative symptoms [23].

Whole-body plethysmography, the helium dilution method (closed circuit), and partial expiratory flow–volume curves (PEFV) have been adapted to *children aged <24 months,* in whom FRC is the only measurable lung volume [6]. The first technique measures thoracic gas volume (TGV), the second one the gas volume accessible in the lungs, and the last technique the maximal flow of FRC [23].

Plethysmography is used to better study lung volumes and Raw, conductance and specific conductance, and to measure gas trapped in the thorax, producing rapid and accurate results. However, the technique could underestimate changes in the small bronchi, unlike compliance assessment. Plethysmography has been appropriately modified, so that the same equipment can also be used for the helium dilution method without modifying the position of the young child [96]. The infant is placed in a supine position inside the body plethysmograph (a closed telephone-booth-like box) and then sedated: only when the infant appears to be in a quiet sleep is a face mask connected to a pneumotachograph and the shutter is sealed around the nose and mouth [96]. Through a mouthpiece the infant performs various respiratory maneuvers. This application takes advantage of Boyle's law, stating that the volume of a gas in a container varies inversely with the pressures to which it is subjected [180]. At a predetermined point in the respiratory cycle, the expiration is blocked for a while, closing the shutter placed between the infant's mouth and the pneumotachometer (Fig. 6.34) [96]. In this way FRC is measured as TGV in synchrony with airway conductance corrected by TGV to calculate the specific conductance [129]. FVC curves can be measured by using plethysmography and a face mask, a method that has gained much interest, since it does not require active cooperation other than a natural TV. Consequently, it can be obtained in awake infants and young children.

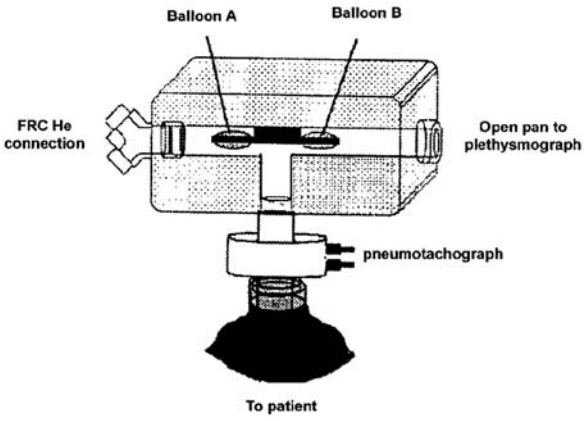

Fig. 6.34. Balloon inflated valve system. Diagram of two-way balloon occluder device permitting redirection of air flow from children to either the dilution or plethysmograph with no movement. The pneumotachograph is positioned distal to the mask as shown in the figure

To obviate the necessity of the face mask, the curves may be measured by respiratory inductive plethysmography [34]. Plethysmography is expensive, and may therefore be restricted to specific centers [96]; the expensive and invasive equipment required can be bypassed with the *pressure sensor method* [12].

The *helium dilution method* requires no infant cooperation; the equipment needed is simple, reliable and relatively economic [129]. The infant is placed in an enclosed system and is attached by a face mask to a spirometer breathing circuit that contains a known volume of air with a pre-set helium concentration (about 10%); the mixture is rebreathed until the helium concentration has remained stable for 30 s. A manometer measures the maximal inspiratory and expiratory flow rates, normally at least 30 cm H_2O, to appraise the neuromuscular component of the ventilation. FRC is calculated considering the initial volume, the mask dead space and the initial and final helium concentration and is proportional to the variations in gas levels [157]. However, in children with gas trapping due to airway obstruction, TGV may be underestimated [129]; similarly, air leaks in the system can induce an inaccurate measurement [157]. To compensate for O_2 consumption during the first minutes of equilibration, O_2 must be added to the circuit during the test. Thereby a third method of measuring FRC can estimate the volume of nitrogen (N_2) washed out of the lungs when the infant rebreathes from a gas-free reservoir, thus estimating the FRC volume (N_2 washout). The amount of N_2 expired during a normal respiration depends on the initial and final concentration in the lungs and on PV [21]. The intensifying use of sophisticated gas analyzers and computers has led to adaptations and refinements of the *N_2 technique,* so that breath-to-breath measurements of expired volume and N_2 concentrations are made; therefore, the procedure may require <1 min in healthy children. This time is significantly shorter than the time required for plethysmographic measurements, which along with the less frightening appearance of the equipment may make it more applicable to infants and young children [21].

However, it is not clear why FRC measurement in infants will differ depending on the technique used, resulting in a greater difference when using plethysmography compared to helium dilution [96]. Even considering that infants are studied in the supine position, asleep and after having received sedation (three notable differences between infants, children and teenagers), and taking into account that FRC values are related to posture, we can speculate that the results may reflect a unique quality of normal infant respiratory physiology, causing a small but significant amount of airway closure [96].

We see that flow can be measured on the forced expiratory curves. In young children, the PEFV curve assessment is done as above with a nose clip and mouthpiece attached to a pneumotachygraph. This technique has been modified to include an inflatable and flexible thoracoabdominal plastic jacket encircling the infant's trunk from the axillae to the anterior superior iliac spines, as originally described for this test referred to as the *squeeze technique*. The bag is connected to a pressure reservoir by a large tubing. The test, called rapid thoracoabdominal compression (RTC), is performed in the supine position 15–20 min after the infant has fallen asleep either spontaneously or sedated [6], applying at the end inspiration in 1–2 s an initial positive pressure of 30–40 cm H_2O to inflate the jacket, causing a partial forced expiration [103]. Using a reservoir that is at least ten times the bag volume ensures that a relatively constant pressure is applied throughout the procedure [129]. Testing is repeated at progressively increasing reservoir pressures (usually from 20 to 80 cm H_2O), until the maximal expiratory flow is reached, finally calculating the mean coefficient of variation (COV) [103]. The amount of intrasubject COV in $\dot{V}_{max}$ FRC has been found to be 37% in the 1st year of life [103]: a value globally similar to that obtained in older children and adults [129]. The technique, helpful to prevent spirometry-induced bronchospasm, measures intrathoracic airway function when a flow limitation is reported, a frequent finding in infants with airway obstruction. PEFV curves have been applied to epidemiological studies of the youngest of infants to determine normal lung growth and development, effects of early lung function, such as the effects of maternal smoke (Chaps. 4 and 24) and BHR. Work done so far has confirmed that males tend to have severe wheezing illness [129].

Another method employs FVC curves compared with the forced expiratory flow–volume loops, roughly ovoid, without or with little peak flow and convex relative to their origin. When an obstruction is present, the loops become triangular with a peak flow, resulting in a straight or concave aspect compared to their origin

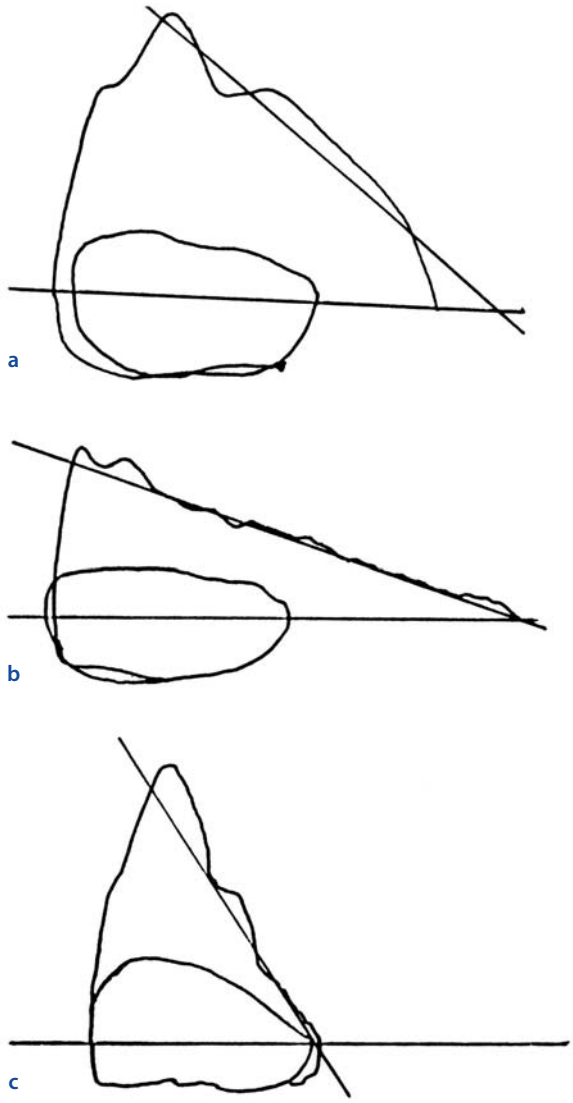

Fig. 6.35 a–c. Flow-volume loops

(Fig. 6.35). The most frequently characterizing indices are the tidal expiratory flow pattern quantified as Tme/Te (percentage of expiratory time to reach peak tidal flow; normal values are between 0.20 and 0.30), and the total duration of an expiration. An early increase to PEF is to be expected in cases of bronchial obstruction, since PEF is also a reflection of muscle strength and effort [129]. Tme/Te may reflect the degree of neuromuscular inspiratory activity at the moment of expiration [6], so the pressure of elastic retraction provokes a greater expiratory flow [23]. Thus the relationship of Tme/Te to total expiratory time may represent a sensitive parameter of great potential, very useful in the setting of severely obstructed children, either in the presence or absence of clinical manifestations, which can be considered predictive of the subsequent development of respiratory dysfunctions [83].

Table 6.25. Mean PaO_2 levels (mmHg) during childhood

Age	Levels
10 days–2 years	72±5
2–8 years	88±4
>8 years	93±6

Data from [23].

The FVC curves show typical patterns in infants with obstructive airway disease (bronchiolitis, asthma), as well as the effect of bronchodilator medications and also a predictive effect of the subsequent development of wheezing [34].

Children <5 years are not capable of exhaling air at a low flow rate in a reproducible way, as they do not understand the instructions and biofeedback signal and cannot exhale over a prolonged time (10–15 s). Short-lasting exhalation at a high flow rate implies that *measurement of eNO at high exhalation flow* does not compromise the power of eNO to detect allergic disease with good reproducibility in children aged ≥37 months [169]. Reproducible measurements of eNO can be obtained without control of expiration flow using a face-mask fitted with a one-way valve on the nasal compartment which reduces the admixture of nasal NO, thus improving the reliability of eNO measurements in young children during tidal breathing [40].

Blood gas analysis measuring the gas dissolved in blood is reliable since a hypoxic state documented by subsequent tests and the delayed appearance of hypercapnia indicate worsening of the prognosis. A useful tool is PaO_2 (partial pressure of O_2) (Table 6.25) [23]. Arterial O_2 saturation (SaO_2, easily measured with pulse oximetry; Chap. 11) as well as transcutaneous arterial O_2 and CO_2 are indirect measures of lung function. SaO_2 is particularly helpful in monitoring acutely ill asthmatic children and acute attacks in young children [34].

In conclusion, we stress that reliable corrections for the size of the child and for air entrainment during inhalation are necessary [85]. In children aged >4.5 and even younger (>37 months) an exhalation flow rate of 350 ml/s is feasible to determine exhaled nitric oxide (NO) *to detect pediatric asthma* [169]. The repetition at regular intervals of PaO_2, SaO_2, and blood gas analysis is a very precise guideline for disease progression and the possible effect of management.

Medicolegal Aspects of Immunoallergic Testing

Several official statements of various societies, including SIAIC [38] and EAACI [49], state that both prescription and/or execution of such tests may induce risks and/or provoke damage to children, concerning the following issues:

- Prescription: absence of specific indications, or presence of specific counterindications
- In vivo execution: superficial, insufficient or absent evaluation of children (by means of history and clinical examinations), including previous allergic dysfunctions and degree of sensitivity to the allergens to be tested, inaccurate identification of children at risk for severe reactions, inadequate equipment in the doctor's office as regards both instrumentation and availability of first-aid drugs
- Risks related to allergenic extracts: defective storage, excessive potency
- Risks related to the child: potential counterindications, even temporary, apart from untoward, unpredictable reactions
- Risks related to incorrect interpretation of results

These precautions are necessary only if the doctor fears that a possible lack of experience, negligence, or imprudence may harm the child.

We emphasize that the examinations should be performed in a facility equipped with the essential supplies and medications available on site and staffed to undertake emergency measures,

Finally, the in vivo tests and SIT can follow a programming schedule, and avoid emergency interventions. In the pediatric domain, we emphasize that FCT should usually be done in a hospital, and that in all cases informed consent should be required from the father, mother, or legal guardian of children to be examined, as shown in the Appendix 6.7 [38]. Since this proposal is adaptable to SIT, in this case doctors shall disregard the section.

Pediatricians and Diagnostic Whereabouts

Atopic diagnosis is usually a challenge to the pediatrician's skill and patience. The diagnostic criteria for allergic disease comprise a wide array of symptoms that make objective appraisal difficult and are often differently assessed depending on the opinion of the examining clinician. Most important, the results of diagnostic tests should not be viewed in isolation. Preferably, the clinical history and physical diagnosis should expedite the diagnosis [62]. The most valuable tools are the pediatrician's eyes, ears and fingertips; however, they are subjective and difficult to standardize. Pediatrics is the only branch of medicine where the history-taking process may depend on secondhand information: infants and little children have either an insufficient language development or the skills to verbalize their disorder, or a poor understanding of their body to help the inquiring pediatrician. To bring about stable compliance, the psychological implications should be taken into account: the unaware child brought to a consulting room will certainly be frightened by an unfamiliar setting, as well as by the presence of other babies moved to tears, while the parents trying to pacify them more or less awkwardly will appear unconvincing, especially during testing, the seemingly unending needles, the coercive measures often called for by hurried doctors, etc. Not only will the pediatrician's experience be disclosed, especially his/her patience and understanding to make the event less startling for the accompanying parents, but also to help and distract, as much possible, the young patient. For example, special software displayed a birthday cake with burning candles on the computer screen: the stronger the expiration, the easier it was for schoolchildren to blow the candles. The cooperation was good, but measurements should nevertheless be performed by trained pediatricians [180].

Atopic Dermatitis

The First Clinical Manifestation of Atopy

Among the skin allergy diseases, we distinguish atopic dermatitis (AD) and urticaria-angioedema, characterized by IgE-mediated reactions, as well as allergic contact dermatitis (ACD), with prevalent delayed-type hypersensitivity (DTH) cell-mediated reactions, where the allergens reach the skin directly (unlike AD). Urticaria, the most immediate, also occurs in the first phase of AD. Depending on its onset, AD is the first atopic disease in an absolute sense: the dendritic cells (DCs) appear first in the skin and then in the lungs (Fig. 2.24), and CLA (cutaneous lymphocyte-associated antigen) [195] is expressed by 45% of skin T cells [24], but not by lung T cells [196].

The first description of AD could go back two millennia as, according to the historian Svetonius, Emperor Augustus suffered from an extremely itchy skin disease, in addition to chest tightness and seasonal rhinitis. In 1891, Brocq and Jacquet classified AD as neurodermatitis [27], a term that often occurs in the German literature, but this is confusing because one might deduce that AD could be caused by a nervous system instability. The following year, Besnier separated AD from the diseases with itching and described it with the term "prurigo diathèsique," underlining its hereditary nature, the frequent association with asthma and pollinosis in the same patient, as well as its typical skin lesions [16]. In 1933, Wise and Sulzberger coined the term "atopic dermatitis," indicating that it could be considered as the "skin analogous of asthma and allergic rhinitis" (AR) [314]. The term "eczema," although widely employed, is merely descriptive, being a simple transliteration of the Greek word εκζεμα, meaning "boiling out," and is misleading, since it fails to imply both the serum exudation in infants and the dry and scaling lesions in older children. This is why we cannot comply with the term "atopic eczema/dermatitis syndrome" proposed by the European Academy of Allergy and Clinical Immunology (EAACI).

Several factors are implied by AD appearance and subsequent evolution. Recent evidence suggests intriguing aspects of the Th1-Th2 contraposition [269]: aeroallergens such as Der p (also as a contact allergen) and pollens can contribute to AD outbreaks and the study of some staphylococcal enterotoxins (SEs) has attracted growing interest, since they are able to act as microbial superantigens (Table 1.29), in addition to the possible keratinocyte pathogenic role capable of producing a veritable arsenal of inflammatory interleukins (ILs). Since AD is an IgE-mediated disease, blood and tissue eosinophils express CD137 [100]. In high-risk (HR) neonates, it is hypothesized that a drop in IFN-γ secretion is predictive of AD development, and a specific response to bovine proteins predicts the association with food allergy (FA) [302]. Table 7.1 outlines the main characteristics of AD [147].

Definition

AD is a disease with a poorly understood etiology, exceedingly complex and multifactorial, with a chronic recurring course. Due to its complexity, AD is a disease that defies attempts at definition, with no clear-cut marker such as one type of basic lesion, specific histological patterns and typical laboratory data, but with a chronic and inflammatory state accompanied by intensely pruritic lesions, erythematous, exuding or papulovesicular eruption, where phases of upsurge alternate with periods of remissions, and skin hyperreactivity. Particularly in its severe, chronic form, AD is a distressing and even disabling disease, due to the irritation, dryness, sweating, and itching. The itching with nocturnal exacerbations disrupts nocturnal sleep of both infants and parents, while skin lesions can socially marginalize the affected child/adolescent. Persistence into adulthood is possible, even if some features may be absent [36, 96].

Epidemiology

AD is a disease common in atopic infants (Table 5.6), never observed at birth and rarely in the first 6 weeks of life, the mean age of onset generally being around the 3rd month, thus earlier than that of asthma [48]. In genetically at-risk babies, the onset in 48%–65% of cases was in the first 6 months of life, but even before 4 months of life in 66 babies (57%) [48], in 75%–80% of cases within the 1st year, with a male prevalence higher than females: 1.3–1.5:1 (Table 5.5). Table 5.8 stresses the increasing frequency of AD in the last 25 years.

Table 7.1. Immunological and clinical features of AD

Genetic-immunological features
Influence of genetic factors
Increased serum and skin IgE levels
Increased production of Th2 lymphocytes
Decreased CD8 suppressor/cytotoxic number and function
Increased CD23 expression on B cells and PBMCs
Activation of $IL_4/IL_5/IL_{10}$ and other Th2-like ILs
Decreased production of IFN-γ/IL_{12} and other Th1-like ILs
Deficient PBMCs not producing IFN-γ/IL_{12}
Increased basophil releasability
Activated chemokines (TARC, RANTES, eotaxin) by skin keratinocytes and endothelial cells
Persistent activation of macrophages with hypersecretion of GM-CSF, PGE_2 and IL_{10}
FFA altered metabolism
Role of infections
Role of foods and food additives
Role of aeroallergens
Role of CD137 expression on blood and tissue eosinophils
Clinical features
Typical flexural lesions
Irregular and unpredictable course
Severe itching
Skin hyperirritability
Impact of stress and irritant factors

Data from [147].
FFA free fatty acids, *sIgE* specific IgE.

Skin Immunopathophysiology

AD pathogenesis is complex. Therefore it is necessary to focus, beyond the immunological abnormalities, on the particular stigmata characterizing the skin such as xerosis or constitutional dryness associated with alterations of surface lipids and transepidermal water loss and with anomalies of both microvasculature and skin surface barrier function.

The Role of Skin Surface Barrier

The anatomo-functional unit called skin protects the organism from injurious external influences, either passively by means of its basal properties, integrity and impermeability, or actively by developing inflammatory reactions [104]. The main skin constituents are, from the external to the internal layer, epidermis, dermis, and hypodermis. The transitional zone between epidermis and dermis is the dermoepidermal junction. The *epidermis*, a stratified squamous epithelium, as seen in sections perpendicular to the surface, is formed by four main layers, disposed from the skin to the dermoepidermal junction: the corneum, granular, lucidum and basal layers. The last three layers form the *stratum Malpighi*, where 95% of the cells are keratinocytes [10], Langerhans cells (LCs), melanocytes, and less immunocompetent CDs (but IL-producing), disposed in the stratum above the basement membrane, which has no immunological functions being devoid of cells. It is distinctly lamina lucida rich in laminine, lamina densa and sublamina densa, consisting of fibronectin, elastin, collagen and myofibrils anchoring to the underlying dermis. Keratinocytes progress through a program of differentiation as they move up through the skin to become corneocytes, dead bundles of precipitated keratin proteins wrapped in remnants of plasma membrane. These proteins form the cutaneous barrier called the *stratum corneum.* The *dermis*, placed immediately beneath the epidermis, consists of fibrous bundles (collagenous and elastic fibers) and connective cells, in addition to a cementing substance formed by ialuronic acid, fibronectin and proteoglicans. The dermis plays an active role in thermoregulatory phenomena, metabolic and nutritive exchanges and immunopathological events. The *hypodermis* consists of adipose and loose connective tissue and performs functions of mechanical support, thermal protection and energy store [70, 104].

The epithelial integrity is maintained by several mechanisms, including the molecular forces which ensure the cohesion between the cells and their peculiar disposition: the adjacent cells are kept together by cytoplasmic processes, forming intercellular bridges, called desmosomes (*macula adherens*), effectively ensuring the connections between epithelial cells, also through keratin filaments formerly known as tonofilaments, which from one side penetrate inside the cells and from the other converge toward the dense plaque of desmosomes [104]. Epithelial integrity is thus ensured by desmosomes disposed among the keratinocytes; the connection systems between columnar and basal cells are completed and strengthened by hemidesmosomes, which promote the adhesion between cell basal facies and basal membrane by tight junctions (*zonula occludens*), and by *zonula adherens,* with no keratin filaments, located just below the junctions [59]. To understand some typical aspects of AD, especially the significance of dry skin and easy aggressiveness of irritants [70], it is necessary to contend with problems related to defective water retention, increased skin permeability and the resulting transepidermal water loss, a characteristic feature [277]. The *stratum corneum* plays a fundamental role in ensuring the skin barrier function, since

it is composed of epidermal lipids (10%–30%) and has a low permeability, retarding water and electrolyte loss from inner more hydrated layers [104]. Therefore it consists of ≈15 layers of flat anucleate cells tightly linked to one another, thus functioning as a sort of intercellular cement [245] surrounded by complex lipids acylceramides), cholesterol, essential fatty acids (EFA), nonessential fatty acids and gangliosides [159].

Acylceramides, the major components of *stratum corneum* lipids, are disposed within the cells in multiple and parallel layers; they are considered essential to prevent water loss [104]. Any perturbation disrupting the barrier integrity initiates the intervention of protective factors, namely a rapid secretion of lamellar bodies by the *stratum granulosum* cells, an increase in cholesterol and EFA within 1–2 h and in sphingolipid synthesis after 6 h or later [159]. In patients with AD, a reduced total content of stratum corneum ceramides was instead discovered, thereby leading to the hypothesis that such deficiency represents a predisposing factor leading to skin xerosis, a basilar characteristic of AD [116]. The deficiency has been demonstrated in both injured and unaffected skin: with the passing of time it has progressively increased in healthy individuals and more markedly in atopics [57]. Disturbances of epidermal lipid metabolism not only underlie low ceramide content, but are also responsible for the reduced LC-SFA (long-chain saturated fatty acid) and EFA production and for an increased SC-SFA (short-chain saturated fatty acid) production. Given that LC-SFAs are essential components of acylceramides, this reduction is negatively reflected on their synthesis: in particular, an altered LC-SFA/SC-SFA rate is commonly observed in all forms of hyperkeratosis [202]. It is conceivable that another disturbance of acylceramide properties may depend on an EFA dysregulation (EFAD); consequently linoleic acid is replaced by oleic acid in their structure. It has been shown that the barrier existing in the lower part of *stratum corneum,* in the intercellular lipid sheets, is rich in linoleic acid to ensure a proper state of hydration and impermeabilization, thus depending on the incorporation into acylceramides of normal amounts of linoleic acid secreted by keratinosome components of the same layer, which are abnormal in the dry, noneczematous skin of atopics [25]. Linoleic and linolenic acid are EFAs with roles in the normal epidermal barrier structure and function [25]. As a consequence, there is an altered acylceramide biosynthesis and the relative disposition in single intercellular lines, a condition leading to an increased transepidermal water loss [70], as seen in patients with AD compared to healthy controls during the exposure to irritant agents [116], hence leading to dry, scaling skin and to a reduced barrier function [281]. This explains the particular skin susceptibility to irritant agents.

Both in injured skin and in apparently healthy skin there is a high content of *phospholipids* (60%) and EFAs, dependent on the defective acylceramide synthesis, which increases the chance of a shunt toward phospholipid production [245]. Phospholipids predominate in the lower and spinosum epidermal layers and in normal conditions are absent from the *stratum corneum* [163]. Constituting the substrate for phospholipase A_2 (PLA_2), notably increased in AD lesions, phospholipids lead to the production of arachidonic acid (AA) and subsequent pro-inflammatory mediators (Fig. 1.57). It is concluded that allergens including inhalants, microbial agents such as *Staphylococcus aureus* and toxins can easily penetrate through a disrupted skin barrier, provoking an inflammation that results in increased PLA_2 activity and the release of polyunsaturated fatty acids (PUFAs), representing the substrate for both lipoxygenase and cyclooxygenase and inflammatory mediators such as PGF_2, LTB_4. These mediators, in turn PLA_2 activators, are the key players in the aggravation of a vicious circle [163].

Skin Immune System

Recently, the defense mechanisms of skin barrier was credited with a more markedly active role. Interestingly, the skin is able to promote immunological activities autonomously, which can be divided into:

- *Stimulating activities,* induced especially by LCs, which after exposure to different allergens promote allergen-specific T-cell proliferation and their maturation into cytotoxic lymphocytes reactive against allergen-modified syngeneic epidermal cells
- *Modulating activities,* responsible for late and contact reactions and for skin immune tolerance

For these characteristics of the skin, the seat of immuno-specific reactions, the term "skin immune system" (SIS) was proposed [24], to emphasize the integrated system of immunosurveillance formed by lymphocytes, CDs, keratinocytes, etc.

Relationships Between Skin and Immune System

Antibodies and complement diffuse into dermal perivascular layers and thus can reach the epidermis, since the basal membrane does not constitute an obstacle to this diffusion. An immunohistological study has provided evidence that monocytes, macrophages and polynucleated neutrophils (PMNs) are equally able to infiltrate the epidermis under the influx of chemotactic factors, some of which are specifically of epidermal origin [226]. The SIS cell types that are the focus of a great deal of research are mast cells, T lymphocytes, LCs, and keratinocytes [272]. Normal skin contains ≈8,000 mast cells/mm^3; in AD there is a density of ≈20,000–40,000 cells/mm^3, 94% of which are TC (tryptase and chymase-containing) [117]. Mast cells derive from the bone marrow from $CD34^+$ myeloid precursors, distributed along

the dermal vasculature, and differentiated into mature cells migrating toward skin areas, through *HEV* (high endothelial venules) residing in lymph nodes, and toward capillary endothelium and lymphatics of superficial dermis, under the influence of chemoattractants and adhesion molecules, namely CD62L receptor of CD34 [185]. Thus equipped, mast cells participate in IgE-mediated hypersensitivity reactions, so often expressed at the cutaneous level [51, 117], as identified in the epidermis of patients with AD [114], as well as in the epithelium of intestinal mucosa [185]. In the skin, mast cells release histamine in responding either to polymers of L-arginine and L-lysine, or to neuropeptides such as SP (substance P), VIP (vasoactive intestinal peptide), somatostatin and a wide variety of nonimmunological stimuli [51]. Histamine release is extended to eosinophil cationic proteins, two of which, MBP (major basic protein) and EPO (eosinophil peroxidase), are able to inhibit SP-mediated histamine release [186]. Dermal mast cells also dismiss ILs, including tumor necrosis factor (TNF)-α cross-linked to FcεRI [300], in 10 min following IgE stimuli [49]. The direct mast cell activation by IgE molecules and by interactions also by independent ways of CD40-CD154/CD40L, the latter expressed by metachromatic cells and eosinophils, is highlighted by the synthesis of IL_4 (90% by skin mast cells), logically involved in the amplification and propagation of Th2 responses.

In the epidermis in acute and chronic lesions, a low number of infiltrating lymphocytes (CD3, CD4, CD45RO) that are highly positive for HLA class II antigens have been seen, thereby indicating that they are activated [226], because of prior antigen contact, since naive T cells are rarely located in the skin [194]. T cells interact with DCs and allergens that have previously crossed the barrier of the stratum corneum [226]. Even if SIS lymphocytes belong to two phenotypes, the great majority of cells locally are usually T cells, and almost only in AD do T lymphocytes represent an important constituent of the cellular infiltrate [70]. The pattern is completed by *vascular endothelial cells* expressing high CD62E, CD54 = ICAM-1 and CD106 = VCAM titers [297] as well as HEVs, specialized in CD62L expression interacting with CLA [251], likely provided with CD15s (Table 1.50), regulating naive T cell adhesion to HEVs [148]. In the Springer three-step model (Fig. 1.61), the subsequent stage gives rise to MCP-1 (monocyte chemotactic protein-1), another important chemoattractant for lymphocytes, which in this step is a $G\alpha_1$-protein-coupled receptor, while the final step is regulated by CD49d/CD29 (VLA-4) and CD11a/CD18 ($\alpha_L\beta_2$) binding to CD106 and CD54/102, respectively [251] (Tables 1.45, 1.46). Thus, skin-specific adhesion molecules (Tables 1.44) bind preferentially to T CLA^+ (or $MCP\text{-}1^+$) cells, promoting their accumulation in sites of chronic inflammation, while regional draining lymph nodes link the skin with the systemic circulation via afferent and efferent lymphatics [213, 272]. CD62E, most likely

Table 7.2. Cytokines released by epidermal cells in the pathogenesis of AD

Cells	Cytokines
Keratinocytes	IL_1, IL_3, IL_6-IL_8, IL_{10}, IL_{12}, G-CSF, GM-CSF, M-CSF, PDGF, TGF-α and -β, TNF-α
LC	IL_1, IL_6, IL_8, IL_{10}, G-CSF, GM-CSF, M-CSF, TNF-α
Melanocytes	IL_1, IL_6, IL_8, G-CSF, GM-CSF, M-CSF, PDGF, TGF-α and -β, TNF-α

Data from [155, 260].
LC Langherans cells.

driven by IL_1 and TNF-α [213, 251], has the ability to modulate selected subsets of circulating T cells, especially activated $CD45RO^+$ [303] expressing CLA or MCP-1, up-regulating their homing to skin sites and the adhesion to endothelial cells [25]. In detail, CD106 ligand of CD49d/CD29 modulates eosinophil and monocyte migration toward inflammatory sites [20].

Keratinocytes make up about 95% of the cell mass of human epithelium and are responsible for its integrity, protecting the epidermis against external injury [10]. In addition to altering the balance between proliferation and differentiation, keratinocytes participate in immune responses by releasing signaling molecules. They can release complex arrays of proinflammatory factors when provoked by stimuli such as physical trauma, ultraviolet (UV) irradiation, bacterial products, and underlying fibroblasts, triggering the innate immune system. ILs and especially contact allergens allow keratinocytes to recruit inflammatory cells, regulate their behavior, and up-regulate gene transcription of epidermal pro-inflammatory ILs (Table 7.2) [155, 260]. It is not clear whether these are products of a single type of keratinocyte activation or whether they derive from several qualitatively different responses. In either case, these factors convey signals in a paracrine fashion to other cells, including leukocytes, endothelial cells and fibroblasts, as well as in an autocrine fashion to the keratinocytes themselves. Moreover, the hypersensitivity of atopic skin to irritants may result in the increased synthesis of ILs by keratinocytes [253]. Able to induce their own release, regulating the expression of receptors, mediators, integrins and chemotactic factors similarly to LCs, keratinocytes may play a vital role by triggering the start and amplification of lesions [10, 155], facilitating the interaction with adhesion molecules and subsequent influx of immunocompetent cells [253]. Initially, these cells were presumed to be passive targets for toxic substances and for immunological attack from infiltrating T cells [10], but according to recent studies they could play an active role in concert with peripheral blood mononuclear cells (PBMCs) in initiating and maybe directing the mucosal immune response [306]. Keratinocytes interact with PBMCs, probably by an

increased CD54 expression correlated with the lymphoid infiltration [10], and express the CD36 antigen, fibroblast growth factor, Stat3 and PDGF (platelet-derived growth factor) able to repair tissue [4] and release adhesion molecules. Specific *Stat3 gene deletion* in keratinocytes blocks their responses to epidermal growth factor (EGF), hepatocyte growth factor (HGF) and IL_6. Although Stat3-deficient keratinocytes can form approximately normal skin, they are defective in wound healing. While EGF is an important cytokine for keratinocytes, some deficits in Stat3-deficient keratinocytes may also be due to their inability to respond to IL_{20} [19]. Similarly to differentiated cells of diverse tissues, keratinocytes produce several surface antigens, or cytoplasm, such as HLA-A, -B, -DR, β_2-microglobulin, etc., as well as systemic antigens or those with organ specificity (of cellular line), which are found only in the Malpighian epithelium [10]. These antigens can be of three types:

1. Antigens found in all keratinocytes, in whatever differentiation phase, thus elucidating why certain autoimmune diseases are exclusively localized in the skin and Malpighian mucosa.
2. Allergens expressed only by one subset defined as maturational allergens allowing interactions with monoclonal antibodies directed against keratinocyte subsets.
3. Specific antigens characterized by a polymorphism internal to a single species. The repertoire of specific alloantigens, presently studied only in experimental animals, could open new perspectives on the challenge of skin grafts [70].

Keratinocytes lack expression HLA-DR normally, but only in connection with a primary sensitization, when, it is hypothesized, HLA-DR$^+$ concur to enhance lymphocyte activation, driving allergen-specific T cells to develop [306]. However, keratinocytes, despite expressing class II molecules amplified by IFN-γ generated by Th1 T cells, are not able to process peptides [253]. However, no expression of HLA-DR by keratinocytes would pave the way to the Th2 differentiation and explosion of the atopic march [306]. Further studies shall explain whether this is the primary event or the lymphocyte development is the factor upstream of the HLA-DR expression defect. Keratinocytes can be transformed into valid APCs (antigen-presenting cells) via their association with CD80 [179]. IFN-γ expressed by T cells, which up-regulates Fas (CD95) on keratinocytes, thus making them susceptible to apoptosis in the skin. Keratinocyte apoptosis is induced by Fas ligand (CD178) expressed on the surface of activated T cells [3]. Remarkably, the anti-apoptotic genes, *bcl-2* and *bcl-xL*, were expressed at increased levels in AD patients [204]. Recent data show that IL_{30} may induce melanocortins in the skin to protect both keratinocytes and melanocytes from apoptosis [21].

Langerhans cells are CD1a$^+$ (3%–4%), belong to DCs, and since the middle of the 1970s have been identified as

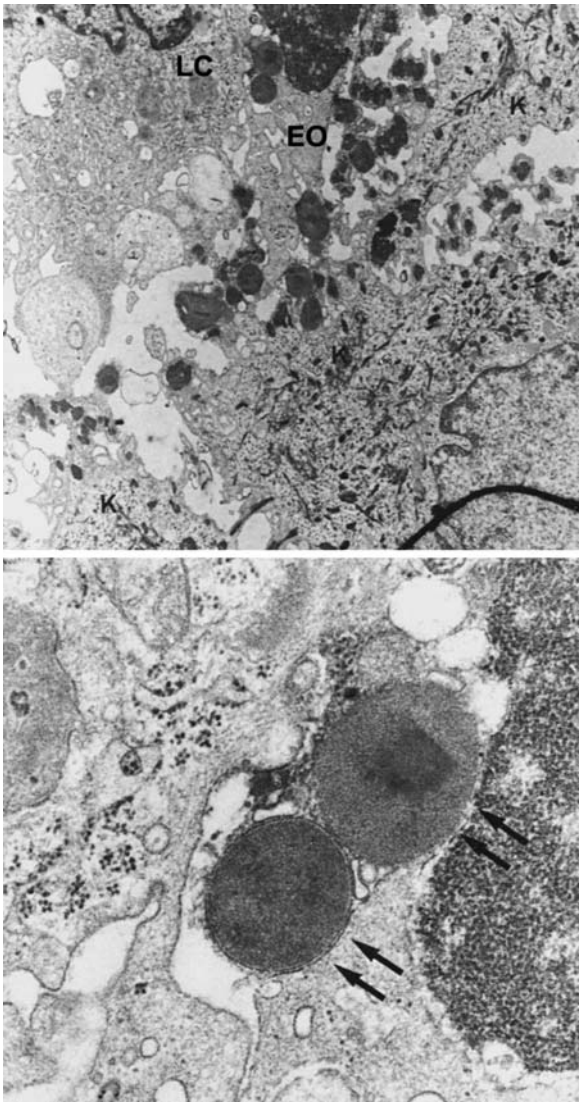

Fig. 7.1 a,b. Electron microscopic section of epidermis in **a** Langerhans cell (*LC*) lying between keratinocytes (*K*) in contact with an eosinophil (*EO*) (magnification 6097×). **b** Magnification showing eosinophil-derived granules (*double arrow*) (magnification ×20,904)

APCs expressing HLA class II antigens, and bear CD1a and CD4 antigens and receptors for IgG and C3b FcR [24, 30]. Viewed as AD-specific, LCs reside in the epidermal suprabasal layer and are in close contact with nearby keratinocytes via an E-cadherin-dependent mechanism [265] (Table 1.51). Ultrastructurally, LCs are characterized by a cytoplasmic organelle with an unusual rod-shaped structure, called the Birbeck granule, originating from the Golgi or from the cell membrane (Figs. 7.1, 7.2) [73]. LC function is still unclear, but they are apparently involved in the intracellular traffic of surface antigens after their endocytosis [30]. Compared to macrophages, LCs have a negligible phagocytic activity; in the skin *the predominant role of LCs is the initiation*

Electron microscopic section showing Langerhans cell (*LC*) in the lamina propria close to the basal membrane containing at least two Birbeck granules (*inserts*), one of them with the typical racket shape; note part of the cytoplasm of an eosinophil (*EO*) (magnification ×13,000, *insets* ×88,000)

of immune responses as APCs for T cells and as stimulant cells in the allogenic reactions between lymphocytes and epidermal cells [90]. LCs also have a surface structured to favor adherence [272], so it is likely that they are the preferential intradermal seat for any substance that has penetrated the epidermis, either exogenous or endogenous; equally important are the IgE antibodies on the LC membrane [28]. Binding of IgE occurs via FcεRII on CD1/IgE$^+$ (studies with CD1$^+$ have clarified that binding occurs via both FcεRI and FcεRII) [18] in different proportions: 6.63±1.92 vs 0.67±1.12 cells, respectively [90]. LCs also express CD11a, CD11b, CD36 and HLA-DR in chronic skin lesions, but not in healthy patients [146, 268], thus increasing the reactivity of autologous T cells in inflammatory lesions [268]. Moreover, CD40 and BcR link to CD80 and CD86 (Table 1.28). Foreign antigens are captured by LCs and other APCs, which migrate and interact with T cells: LC aeroallergen presentation may be very important in sustaining Th2 and IgE responses because LCs overwhelmingly express CD86 rather than CD80 [150]. After capturing allergens, IgE-bearing LCs likely activate memory Th2 cells in atopic skin and also migrate to the lymph nodes to stimulate naive T cells to further expand the pool of systemic Th2 cells [150]. Activated T cells, supported by secondary cytokines from the epidermis, dermis and leukocytes, proliferate and release ILs that promote cellular (Th1, involving IFN-γ) or humoral (Th2, involving IL_4) immune responses. Signals that control IL_{20} expression are unknown; however, IL_{20} receptor ($IL_{20}R$) is upregulated in the epidermis, as well as some leukocytes and endothelial cells [19].

In the epidermis there are *melanocytes* (2%–3%), provided with melanosomes, which are melanin granules subsequently transferred to keratinocytes [59], also expressing ILs (Table 7.2). *Merkel cells* (<1%) function as signal transducers for neurites, and as an unquantified contact site for keratinocytes [105]. LCs and melanocytes are devoid of desmosomes, but have cytoplasmic filaments that protrude into intercellular spaces [328].

The rich vascular set aids the passage of various substances from the circulation: the perivascular area of postcapillary venules in the papillary and deep dermis is the major target for a vascular dilatation that triggers the migration into dermis of intraluminal inflammatory cells, so the dermis contains the highest percentage of cells related to immune responses [328]. In some inflammatory reactions, such venules are similar to HEVs transporting lymphocytes to lymph nodes [328]. Mast cells, PBMCs, T cells and DCs, most of which are LCs, are frequently found next to the endothelial cells and vascular pericytes of these sites. Since they are in close vicinity of epidermis, these structures are literally bombarded by ILs as soon as epithelial damage occurs; as a consequence, the endothelial cells increase their expression of adhesion molecules necessary to T-lymphocyte transmigration [244].

Inflammatory Infiltrates of AD Lesions

Immunohistochemical analysis of the inflammatory infiltrate in AD reveals lesions characterized by epidermal edema, which initially infiltrates the intercellular spaces

leading to spongiosis, and are then grouped in intraepidermal vesicles that dissociate the cells, while the dermis shows a perivenular multicellular infiltrate [321]. In chronic or lichenified lesions, there is more hyperplasia than spongiosis of the epidermis and hyperkeratosis is prominent [226], frequent sequelae of inflammation associated with abnormal hyperproliferation of keratinocytes [10]. Histopathological studies show that in the dermis, in addition to vasodilation, inflammatory edema and demyelination and fibrosis of cutaneous nerves [70], there is a cell infiltrate consisting of PBMCs and lymphocytes bearing a Th2 phenotype, some of which migrate into the epidermis [25]. In addition, most cells in the infiltrate are highly positive for HLA class II antigens, indicating that they are activated [25] in various degrees of degranulation, $CD3^+/CD4^+$ cells, with a few $CD3^+/CD8^+$ cells, usually bearing the αβ TcR [74], and more LCs as detected by the CD1 surface antigen, HLA-DR antigens, and DCs [29]. An influx of elevated basophil and eosinophil numbers suggests, also because of an immunoglobulin absence, the meaningful interference of a cell-mediated immunity (CMI) [226]. During late-phase reactions (LPR) on the coexpression of CD45 (leukocytes) and CD19 (B cells), the B cells in the skin were as high as 50% of circulating B cells after 5–8 h and 25% after 9–12 h, whereas T cells were 16.5% (CD3) [307].

In areas of $CD3^+$ lymphoid infiltrates, as soon as an aspecific stimulus initiates an inflammatory state, physical disruption and infection such as with *S. aureus* can lead to activation of *keratinocytes* [253]. In the first phase of the cutaneous immunoregulatory effects, the permeability increase stimulates both recruitment and transmigration of lymphocytes across the vessel walls and into the tissues. The concurrent secretion of IL_1 and IL_8 from keratinocytes is concretized into a chemotactic gradient, in particular for T cells, inducing their migration into the epidermis, which is CD11a/CD18/CD54-dependent [10]. The subsequent stages of proliferation are characterized by interactions between LCs, keratinocytes and epidermotropic T cells with a resulting dermal infiltrate or granuloma, and recirculation, which autoactivates after both cessation and elimination of the skin insult and weakening of APC activity [272].

To underline the complexity of physiopathological events, several cellular patterns reflecting AD changes have been schematized [226]. In *acute AD* the majority of T cells are $CD4^+$ with a few $CD8^+$, the CD4 in the epidermis and around small blood vessels of deeper dermis, the cytotoxic CD8 T lymphocytes (CTLs) in the superficial dermis, with some cells in the basal epidermal layer [70]. In the dermis, $CD1^+/IgE^+$ LCs are grouped in sparse foci and within the mononuclear cell infiltrate, while in the epidermis they are arranged in a tight network extending from the superficial *stratum corneum* to the basal epidermal layer [147]. Basophils, eosinophils and mast cells that are frequently less degranulated and numerically normal are also found; rare monocytes and macrophages are seen around venous plexus in the dermis [226]. In *subacute AD*, CD4 and CD8 localizations and distributions are similar to those in acute lesions, although in smaller numbers, especially in areas with intercellular edema of the Malpighian layer. B cells [147] are seen only occasionally, and the same is true for NK cells [303] compared to serum levels [307]. The LC number and distribution varies: interdigitating cells are seen in the epidermis and in the dermal superficial infiltrate [70]. In *chronic lesions*, there are more CD8 than CD4 T lymphocytes; the number of CLs is notably increased. They appear as focal aggregates in the epidermis near subepidermal *foci* of inflammatory cells [70], while macrophages dominate the dermal mononuclear cell infiltrate, and the number of mast cells [226] and basic proteins [142] is increased as well.

Pathogenesis

AD pathogenesis remains largely unknown, even if recent progress in asthma pathogenesis offers interesting insights. Indeed AD patients exhibit numerous disturbances of the autonomic system, which are more or less assimilable to abnormalities seen in asthmatics such as an increased α-adrenergic vasoconstriction and piloerection, white or delayed dermographism, a reduction in β-adrenergic inhibition of epidermal mitosis and in lymphocyte and neutrophil responses to β-adrenergic stimulation [192]. Both conditions are characterized by a deficit in G-proteins; however, such diseases are primarily linked by common aberrations of lymphocytes and ILs that may fuel the rise in the IgE level. Further advances in histochemistry and molecular biology have been of invaluable support in unraveling the role of SIS immune abnormalities and shedding light on the study of enigmatic AD [25]. It was not a surprise to find that thymus and activation-regulated chemokine *(TARC) is also active in AD lesional sites:* serum TARC and CTACK (cutaneous T cell-attracting chemokine) serum levels are high in patients with AD and significantly correlated with AD activity [101]. Moreover, in the lesional skin of patients with AD, immunoreactive TARC was positive in keratinocytes in the epidermis, in vascular endothelial cells, T cells, DCs in the dermis, and infiltrating cells. Serum TARC levels significantly correlated with eosinophil number, SCORAD score, serum CD62E levels, but weakly with serum IL_2R receptor (sIL_2R) levels [123]. TARC and CCR4 mRNAs were more positive in acute AD lesional skin [327]; thus *TARC may be an important chemokine in the pathogenesis of AD* [123, 327].

Genetics

The available evidence suggests that AD is inherited with an autosomal dominant or recessive pattern, always associated with abnormal IgE production. How-
