Lactate dehydrogenase (LDH) activities are high in various tissues of the body. Therefore, measurements of LDH are not organ specific. Molecules of LDH are tetrameric, made up of four subunits of the two parent molecules, M (muscle) and H (heart). Various combinations of those subunits result in five isoenzymes of LDH, which can be separated by electrophoresis. The M monomer is found in purest form in skeletal muscle as the isoenzyme M4 (or LDH5), whereas the H monomer is found predominantly in the heart muscle as the isoenzyme H4 (or LDH1). The other three forms are molecular hybrids forming the isoenzymes M3H (or LDH4), M2H2 (or LDH3), and MH3 (or LDH2), and they are found in various amounts in different organs. The H4 isoenzyme is maximally active at low concentrations of pyruvate and strongly inhibited by excess pyruvate (Dawson *et al.*, 1964), which favors the oxidation of lactate (Dawson *et al.*, 1964; Sund, 1969). The M form, on the other hand, maintains activity at relatively high pyruvate concentrations (Dawson *et al.*, 1964), which favors anaerobic reduction of pyruvate (Dawson *et al.*, 1964; Sund, 1969). Thus, tissues with essentially aerobic metabolism, such as heart muscle, contain mostly heart-specific isoenzymes, whereas tissues with more viable or flexible metabolic properties, such as skeletal muscle, contain predominantly the muscle-specific isoenzyme (Dawson *et al.*, 1964).

The LDH isoenzyme pattern within skeletal muscle seems to be under genetic control (Dawson *et al.*, 1964), but is influenced by environmental factors (Sjodin, 1976). Total LDH activity and muscle-specific LDH activity are higher in fast-twitch myofibers than in slow-twitch myofibers. Positive correlations have been

TABLE 16.3 Normal Values of Serum Aspartate Aminotransaminase Activity in Some Animals

Species	AST activity (U/liter) Comment	Mean	Std. dev.	Range	Reference[a]
Bovine	Bull, 1–97 weeks	11.4	±8.3	—	1
	Cows, 2–10 years	21.0	±2.7	—	2
	Calves, 7–27 days	11.3	±1.8	—	2
Canine	>9 months	10.9	±2.6	—	2
	<2 years	12.8	±0.8	—	3
	4–12 months	10.6	±2.6	6–23	4
	1–5 years	12.4	±3.7	6–25	4
	>5 years	10.4	±2.5	7–14	4
Equine	Unexercised, not in training	165	±33.8	—	2
	>1 year	79.2	±16.2	58–161	5
		89.3	±8.6	53–91	6
		72.5	±25.0	48–170	7
	Exercised, in training >1 year	166	±75.4	48–456	5
		120	±14.9	88–154	6
Feline	1 month	9.1	±2.3	6–13	8

[a] 1, Roussel and Stallcup (1966); 2, Cornelius *et al.* (1959a); 3, Hibbs and Coles (1965); 4, Crawley and Swenson (1965); 5, Cornelius and Burnham (1963); 6, Cardinet *et al.* (1963); 7, Cardinet *et al.* (1963); 8, Cornelius and Kaneko (1960); 9; Blincoe and Marble (1960); 10, Lagace *et al.* (1961); 11, Franzmann and Thorne (1970); 12, Lewis (1976); 13, Cornelius (1960).

found between both the individual percentage of fast-twitch myofibers and muscle lactate concentration, and between lactate concentration and total LDH activity and muscle-specific LDH activity, respectively (Tesch *et al.*, 1978). Because the fast-twitch myofibers derive more of their energy for contraction via anaerobic metabolism than do slow-twitch myofibers, it seems reasonable that fast-twitch myofibers should contain more of the muscle-specific LDH isoenzymes. Skeletal muscle LDH activity was found to increase with training in men (Suominen and Heikkinen, 1975; Sjodin *et al.*, 1976) and swine (Jorgensen and Hyldgaard-Jensen, 1975), whereas it has been reported to decrease with training in horses (Guy and Snow, 1977). The reasons for this difference are not obvious.

Elevated LDH activities have been reported in selenium-vitamin E deficiency of cattle (Allen *et al.*, 1975), sheep (Whanger *et al.*, 1970), and swine (Ruth and Van Vleet, 1974) and in myoglobinuria in a double-muscled heifer (Holmes *et al.*, 1972) and in horses (Rose *et al.*, 1977). Elevations in LDH activity have also been reported in a variety of hepatic disorders. Therefore, unless isoenzyme analysis is utilized, the measurements of LDH elevations are not organ specific.

4. Serum Pyruvate Kinase

Measurements of serum pyruvate kinase (PK) activities have been found to be more discriminatory than creatine kinase in distinguishing between stress-susceptible pigs (Duthie and Arthur, 1987; Duthie *et al.*, 1988). Employing PK measurements, homozygous, halothane-reacting (malignant hyperthermic) pigs could be discriminated from homozygous nonreacting pigs. Isoenzymes of PK exist and their distinction may be important in the application of this enzymic assay.

B. Muscle-Specific Serum Proteins and Antibodies

With the advent of immunochemical procedures such as enzyme-linked immunosorbent assay (ELISA), radial immunodiffusion assays, radioimmunoassays, and immunocytochemical assay, sensitive tests for the detection of tissue-specific proteins and antibodies in serum are being applied to the diagnosis of neuromuscular disorders. The potential sensitivity and specificity of these procedures will no doubt in the future replace a large number of the clinical enzymology assays currently employed.

1. Myoglobin

Myoglobin is a 17,500-Da heme protein that stores and transports oxygen in myofibers. Elevated levels of myoglobin have been found in myopathies of humans (Penn, 1986). The specificity of myoglobin for skeletal and cardiac muscle and its plasma clearance make myoglobin determinations a potentially effective method for monitoring myonecrosis (Holmgren and Valberg, 1992). Plasma myoglobin concentrations were compared to aspartate aminotransferase (AST) and creatine kinase (CK) activities following exercise in horses susceptible to rhabdomyolysis (Valberg *et al.*, 1993). The authors report that the detection of myoglobin was the most sensitive indicator of myonecrosis.

2. Myosin Light Chains and Troponin

Application of myosin light-chain assays are evolving for use in the diagnosis of inflammatory muscle disease (Mader *et al.*, 1994) and myocardial infarctions (Nicol *et al.*, 1993), whereas troponin I assays are being promoted for use in the diagnosis of acute myocardial infarctions in humans (Edleman, 1995). These assays offer the potential for improved specificity and sensitivity and are likely to find applications in veterinary diagnostic clinical chemistry.

3. Acetylcholine Receptor Antibodies

Detection of circulating autoantibodies to acetylcholine receptors (AChR) by an immunopreciptation assay (Lindstrom *et al.*, 1981) is a valuable adjunct to the diagnosis of immune-mediated myasthenia gravis (MG) in humans (Engel, 1994c) and dogs (Lennon *et al.*, 1978; Shelton *et al.*, 1988). It has been estimated that approximately 80% of human patients with MG have detectable AChR antibodies (Engel, 1994c).

A valuable immunocytochemical screening test for circulating AChR antibodies in canine MG employs staphylococcal protein A conjugated to horseradish peroxidase (SPA-HRP), a reagent that localizes IgG. Control sections of muscle containing neuromuscular junctions when incubated with canine MG patient sera and subsequently with SPA-HRP localizes IgG at neuromuscular junctions (Cardinet and Bandman, 1985). This immunoreagent has also served to detect antinuclear antibodies, antistrial antibodies, and sarcolemmal associated antibodies in immune-mediated myasthenia gravis and inflammatory muscle disorders in the dog (Shelton and Cardinet, 1987).

VII. MUSCLE BIOPSY AND HISTOCHEMISTRY IN THE DIAGNOSIS OF NEUROMUSCULAR DISORDERS

The use of muscle biopsies in the evaluation of neuromuscular disorders (motor unit diseases) allows examination of myofibers, neuromuscular junctions, intramuscular nerve branches, connective tissues, and blood vessels. As discussed previously, histochemical examination of skeletal muscle provides information relative to the morphological, biochemical, and presumed physiological properties of myofibers. Therefore, the application of histochemical techniques in conjunction with routine light and electron microscopic examination of muscle biopsies offers the potential to evaluate and integrate the pathoanatomical, biochemical, and physiological manifestations of neuromuscular disorders. Further, the advent of immunocytochemistry has extended our ability to recognize immunopathologic mechanisms and disorders as well.

The application of histochemical techniques has become an essential diagnostic procedure for the evaluation of neuromuscular disorders in humans (Engel, 1962, 1965, 1967, 1970; Dubowitz, 1968; Dubowitz *et al.*, 1973). Their application has been most helpful in determining which portion of the motor unit (neuron, myofiber, or both) is involved in the disease process. Their use has been particularly successful in distinguishing between neuropathies and myopathies and/or providing profiles specific for selected neuromuscular disorders (Engel, 1970; Dubowitz *et al.*, 1973). Routine histochemical procedures have been less informative in the evaluation of junctionopathies (disorders of neuromuscular transmission). However, immunocytochemical methods add to the evaluation of immune-mediated diseases of the neuromuscular junction in which deposits of immune complexes are localized along the end plate in myasthenia gravis (Engel *et al.*, 1977; Pflugfelder *et al.*, 1981).

Histochemical techniques have been employed in the evaluation of neuromuscular disorders in animals of comparative biomedical research interest such as in the hereditary muscular dystrophies of animals. How-

ever, only in recent years have such techniques begun to be routinely applied to the evaluation of muscle biopsies in clinical cases of neuromuscular diseases in animals. A detailed consideration of muscle biopsy techniques in the evaluation of neuromuscular diseases is beyond the scope of this chapter. For details, the reader is referred to Dubowitz *et al.*, (1973), Engel (1994b), and Banker and Engel (1994).

During the past two decades, there has been an evolving recognition of the broad spectrum of neuromuscular disorders that occur in animals. Neuromuscular disorders in animals are associated with spontaneous and inherited endocrine, immune-mediated, infectious, metabolic, and neoplastic diseases. With continued application of those procedures and newer technologies, undoubtedly many heretofore unrecognized neuromuscular disorders in animals will be recognized (Cardinet and Holliday, 1979). To date, disorders of carbohydrate, lipid, electron transport and electrolyte metabolism have been recognized in skeletal muscles of domestic animals common to clinical veterinary medicine.

VIII. SELECTED NEUROMUSCULAR DISORDERS OF DOMESTIC ANIMALS

A. Ion Channelopathies

1. Acetylcholine Receptor Ion Channels and Myasthenia Gravis

Myasthenia gravis is a disorder of neuromuscular transmission in which there is a reduction in the number of ligand-gated AChR, ion channels on the postsynaptic sarcolemmal membrane (PSM). This condition results in weakness due to the reduced sensitivity of the PSM to the transmitter, ACh. Two basic forms of MG exist: (1) acquired autoimmune MG and (2) congenital MG. Different mechanisms are responsible for the reduction of AChRs in these two disorders.

a. Acquired Autoimmune Myasthenia Gravis

Acquired MG is an immune-mediated disorder of humans (Engel, 1994c), dogs (Lennon *et al.*, 1978, 1981), and cats (Indrieri *et al.*, 1983) in which autoantibodies are produced against AChRs. The density of AChRs is reduced by the complement-mediated destruction, accelerated internalization, and degradation of AChRs by cross-linking of the receptors by antibody. In humans (Tzartos *et al.*, 1982) and dogs (Shelton *et al.*, 1988), the autoantibody response is heterogeneous. Most antibodies are IgG and directed against the main immunogenic region (MIR), a specific external portion of the α-subunit that is distinct from the ACh-binding site; however, autoantibodies are also produced against all of the other subunits. Only a small percentage of antibodies is directed against the ACh-binding sites on the α-subunits.

Dogs with MG usually exhibit some form of muscular weakness; however, this can be quite variable and may include the following presentations: acute quadriplegia, degrees of exercise-related weakness, gait abnormalities, or no apparent limb muscle weakness with dysphasia or regurgitation associated with a megaesophagus. There appears to be a bimodal distribution in the onset of this disease in dogs (early and late onset). Dogs are rarely affected before one year of age and peak frequencies were found at 3 and 10 years of age, respectively; the prevalence did not appear to be gender related (Shelton *et al.*, 1988). Frequently, overt signs may be limited to esophageal dysfunction. In a study of 152 dogs afflicted with idiopathic megaesophagus, 40–57 dogs (26% to 38%) had MG (Shelton *et al.*, 1990).

A definitive diagnosis of MG is provided by detection of circulating antibodies to the AChR. Additional diagnostic tests that provide for a presumptive diagnosis include clinical, pharmacologic, electrodiagnostic, and immunocytochemical methods of evaluation. When clinical signs permit the objective assessment of strength, pharmacologic testing can be employed through the intravenous administration of 1–10 mg of edrophonium chloride, an ultra-short-acting anticholinesterase agent. Improved strength with edrophonium provides a presumptive diagnosis of MG. A presumptive diagnosis of MG is also suggested when the application of low-frequency (2–10 Hz), repetitive nerve stimulation results in the reduced amplitude of the first few evoked compound MAPs (decrementing response).

Two immunocytochemical procedures provide sensitive presumptive tests for MG. In muscle biopsies of human and canine MG patients that contain neuromuscular junctions, it is possible to localize the IgG bound to the PSM using the immunoreagent SPA-HRP (Engel *et al.*, 1977; Pflugfelder *et al.*, 1981). Similarly, patient sera applied to control sections and subsequently treated with SPA-HRP will detect circulating antibodies that bind to the PSM of neuromuscular junctions (Cardinet and Bandman, 1985; Cain *et al.*, 1986; Shelton and Cardinet, 1987).

b. Congenital Myasthenia Gravis

Congenital MG is a developmental disorder of humans (Engel, 1994d) and dogs (Lennon *et al.*, 1981 Miller *et al.*, 1983; Oda *et al.*, 1984a). In the dog, the synthesis of AChRs appears to be normal and degradation does not appear to be accelerated. The reduced

AChR density is believed due to a low insertion rate of AChRs into the PSM (Oda *et al.*, 1984b). In humans, several congenital myasthenic syndromes are recognized and include putative failure of packaging or resynthesis of ACh, the absence of AChE from the basal lamina, and a deficiency of AChRs and abnormal channel function. Because congenital MG is not immune mediated, the immunodiagnostic tests used in acquired MG are of no value in establishing the diagnosis of congenital MG.

2. *Sodium Ion Channels and Periodic Paralysis*

Equine hyperkalemic periodic paralysis (HYPP) is a dominantly inherited disorder of muscle that causes episodes of stiffness (myotonia), weakness, tremors, and/or paralysis in association with elevated serum potassium (Spier *et al.*, 1990, 1993). Weakness or paralysis can be induced by the ingestion of potassium.

Linkage studies have revealed that HYPP cosegregates with the equine adult skeletal muscle sodium channel α-subunit gene (Rudolph *et al.*, 1992a) involving a Phe to Leu mutation in the transmembrane domain IVS3 (Rudolph *et al.*, 1992b). Patients are heterozygous and express both normal and mutant α-subunits. The primary physiological defect in mutant sodium channels is impaired inactivation (Cannon *et al.*, 1995). With incomplete inactivation, sodium ion conductance into myofibers is sustained, which in turn sustains depolarization of the sarcolemma. It appears likely that the clinical variability and severity of signs is associated with the ratio of mutant to normal sodium ion channels expressed in the skeletal muscles of affected horses (Zhou *et al.*, 1994).

This disorder in horses is similar to primary HYPP in humans in which there is also a mutation involving the gene encoding the sodium ion channel α-subunit. A number of mutations involving the gene encoding the α-subunit of the skeletal muscle sodium ion channel have been identified in humans that are responsible for the HYPP disorder and paramyotonia congenita, an exercise and cold-induced stiffness and weakness (Lehmann-Horn *et al.*, 1994).

Diagnosis of equine HYPP is aided by knowledge of the breed and pedigree, clinical signs, and the assessment of serum potassium ion concentrations during an episode of weakness or stiffness. Oral administration of potassium chloride can be used as a test to induce weakness in susceptible horses. A definitive diagnosis is possible by base-pair analysis of the DNA sequence responsible for encoding of the α-subunit (Rudolph *et al.*, 1992b).

3. *Chloride Ion Channels and Myotonia*

Myotonia is a clinical sign in which the uncontrolled, prolonged, and painless contraction of skeletal muscles occurs. The condition is due to hyperexcitability of the sarcolemma and the abnormal production of repetitive depolarizations of the sarcolemma followed by delayed repolarization and relaxation. Affected patients exhibit varying degrees of muscle stiffness with the onset of exercise. The stiffness will often subside with continued exercise or repeated movements and is not aggravated by cold. Muscles may be grossly hypertrophied with well-defined muscle groups. Percussion of muscles results in local contractions that create dimpling of the surface overlying the contracting muscles.

Myotonia congenita (MC) occurs in goats in which there is impaired conductance of chloride ions across the sarcolemma of T-tubules (Bryant and Morales-Aguilera, 1971; Adrian and Bryant, 1974). Unlike, HYPP, MC is a nonprogressive disorder that improves with exercise ("warm-up") and is not induced by cold. Histopathologic changes in skeletal muscle are usually minimal and nonspecific.

Two principal myotonic disorders occur in humans: (1) myotonia congenita (Rudel *et al.*, 1994) and (2) myotonic dystrophy (MD; Harper and Rudel, 1994). Myotonia congenita is a nonprogressive childhood disorder in which there is a diminished chloride conductance across the sarcolemma caused by mutations of the skeletal muscle chloride ion channel. Two forms of MC are recognized in which the mutations of the chloride ion channel involve autosomal dominant (Thomsen's disease) and recessive (Becker's myotonia) modes of inheritance (Koch *et al.*, 1992).

Myotonic dystrophy is an autosomal dominant myotonic disorder in humans that differs from MC in that it is progressive and variably involves a variety of other systems (e.g., smooth muscle of hollow organs, heart, brain and peripheral nerves, endocrine glands, eyes, skeletal system, and integument). The underlying cause of this disorder has not been established even though the gene has been localized. Onset of signs may be recognized in childhood or later in adults, hence MD can also have a congenital presentation. The systemic features are most helpful in differentiating between MC and MD in addition to histopathologic features, which include increased central nuclei, ringed fibers, sarcoplasmic masses, and type 1 fiber atrophy.

In addition to goats, myotonic disorders have been described in horses (Steinberg and Botelho, 1962; Jamison *et al.*, 1987; Reed *et al.*, 1988) and dogs (Kortz, 1989). In attempting to draw comparisons between these disorders and the human disorders, some confusion exists

since most reports describe a congenital onset compatible with MC but physical and histopathologic features that are similar to MD. In the horse, two reports provide clinical and histopathologic features in foals that appear comparable to MD (Jamison *et al.*, 1987; Reed *et al.*, 1988). In dogs, congenital presentations are described in chow chows (Griffiths and Duncan, 1973; Wentink *et al.*, 1974; Amann *et al.*, 1985) among a number of other breeds. The histopathologic features observed in these dogs have been variable. More detailed studies of membrane function and molecular genetics will be required to elucidate fully the pathogenesis and comparative features of these disorders.

4. Voltage-Sensitive Calcium Ion Channels of the Sarcoplasmic Reticulum and Malignant Hyperthermia

Malignant hyperthermia (MH) is an inherited, autosomal dominant, pharmacogenetic disorder of humans and swine, and possibly dogs and horses, in which there is a rapid increase in body temperature and muscle rigidity associated with the uncontrolled contraction and metabolism of muscles leading to rhabdomyolysis, and death (Gronert, 1994). The condition is triggered by the administration of volatile anesthetic agents and exacerbated by succinylcholine. In swine, stresses such as fighting, transport, and exercise also trigger its onset.

In swine, MH is due to an alteration in the calcium ion release channel (ryanodine receptor) of the SR due to a mutation in the gene for encoding the ryanodine receptor (Fujii *et al.*, 1991). The alteration increases the sensitivity of the calcium release channels and results in their prolonged open state and release of calcium into the sarcoplasm. In humans, the same mutation has been observed in some families; however, other mutations are likely and some cases do not appear to be linked to the ryanodine receptor gene (MacLennan and Phillips, 1992).

Diagnostic testing for susceptibility to MH involves a standardized *in vitro* contracture test employing muscle biopsy samples in which contractures induced by caffeine or halothane are measured (Larach, 1989). During an attack, serum enzyme activities are markedly elevated due to extensive myonecrosis. No specific histopathologic features are present in susceptible individuals. With the identification of the mutation in the gene for encoding the ryanodine receptor, molecular genetic testing will provide a definitive test in swine (Houde *et al.*, 1993; O'Brien *et al.*, 1993).

There are reports of MH-like presentations in horses associated with halothane anesthesia (Hildebrand and Howitt, 1983; Manley, *et al.*, 1983) and in dogs associated with exercise (Rand and O'Brien, 1987). Contracture testing (Nelson, 1991) and calcium homeostasis defects (O'Brien *et al.*, 1990) suggest the stress / exercise-induced syndrome in dogs may be MH.

B. Cytoskeletal Dystrophin Deficiency and Muscular Dystrophy

Duchenne muscular dystrophy is an X-linked recessive disorder of skeletal muscle in humans (Engel *et al.*, 1994), dogs (Kornegay *et al.*, 1988; Cooper *et al.*, 1988), cats (Carpenter *et al.*, 1989; Gaschen *et al.*, 1992) and mice (Bulfield *et al.*, 1984).

The disorder is due to a deficiency of dystrophin (Hoffman *et al.*, 1987), a subsarcolemmal cytoskeletal protein that participates in the attachment of myofibrils to the sarcolemma. Dystrophin in concert with a transmembrane protein complex (dystrophin-associated protein) is believed to provide stability to the sarcolemma. Presumably, the deficiency of dystrophin creates instability of the sarcolemma; however, the precise mechanisms for initiating myofiber necrosis are not known.

A number of mutations of the dystrophin gene have been identified. In the dog, dystrophin deficiency is due to a splice-site mutation in which there is an RNA processing error (Sharp *et al.*, 1992). The mutation in the cat has not been identified.

The expression of the disease varies among species but may be characterized as a progressive degenerative disorder of muscle in which there is a marked increase in serum enzyme activities, gross hypertrophy of some muscle groups, and a stiff, "bunny hopping" gait in dogs and cats. Affected individuals may also have a cardiomyopathy since the dystrophin deficiency also involves cardiac myofibers (Moise *et al.*, 1991). In dogs, the onset of clinical signs is usually evident by 2–4 months of age and somewhat later in cats. In dogs, this disorder was first observed in golden retrievers and has subsequently been identified in other breeds, including Irish terriers, rottweilers, and samoyeds.

Histologic sections reveal focal lesions consisting of myofiber clusters undergoing the spectrum of change from myonecrosis through macrophage infiltration and phagocytosis to regeneration. Individual fibers may be atrophic or hypertrophic, calcified, and hypercontracted and possess central nuclei. The focal clustering of necrotic fibers may be due to the local effects of mast cell accumulations and degranulation (Gorospe *et al.*, 1994).

Beyond clinical signs and biopsy features, immunoblotting and immunocytochemical staining for dystrophin are valuable diagnostic methods for detecting

deficiencies of dystrophin within muscle biopsies (Cooper *et al.*, 1990; Gaschen *et al.*, 1992).

C. Immune-Mediated Canine Masticatory Muscle Myositis

The muscles of mastication are selectively affected in two inflammatory muscle disorders in dogs known as *eosinophilic* and *atrophic myositis*. Limb muscles are essentially spared. These disorders may be distinct and separate entities or merely variations of the same disorder that distinguish between acute and chronic onsets, respectively.

The muscles of mastication in the dog are principally composed of type 2M myofibers, fast-twitch fibers that possess a unique myosin isoform, heavy chain, and light chains (Shelton *et al.* 1985a). Recent evidence suggests this disorder is an autoimmune disease (Shelton *et al.*, 1985b, 1987). Dogs afflicted with this disorder produce autoantibodies directed against type 2M fibers and there is little cross-reaction of the antibodies against type 2A fibers of limb muscles. The specificity of these antibodies for 2M fibers provides presumptive evidence for its immune pathogenesis and the limited distribution of lesions to the muscles of mastication.

Diagnosis of the disorder includes muscle biopsy demonstration of an inflammatory disorder, localization of immunoglobulins fixed to type 2M fibers within the biopsy, and demonstration of circulating antibodies against type 2M fibers employing SPA-HRP.

D. Disorders of Glyco(geno)lysis Affecting Skeletal Muscle

Disorders of glyco(geno)lysis affecting skeletal muscles variably involve some excess storage of glycogen within affected myofibers, resulting in the presence of glycogen-containing vacuoles. In humans, glycogen storage diseases (GSD) affecting muscle include deficiencies of α-1,4-glucosidase (GSD-II), debranching enzyme (GSD-III), branching enzyme (GSD-IV), myophosphorylase (GSD-V), phosphofructokinase (GSD-VII), phosphoglycerate kinase (GSD-IX), phosphoglycerate mutase (GSD-X), and lactate dehydrogenase (GSD-XI; Engel and Hirschhorn, 1994; DiMauro and Tsujino, 1994). Though variably documented, some of these disorders also occur in domestic animals (Walvoort, 1983).

1. α-1,4-Glucosidase Deficiency (GSD II)

Lysosomal α-1,4-glucosidase deficiency, also known as Pompe's disease, generalized type II glycogenosis, and acid maltase deficiency, occurs in humans with childhood (infantile and juvenile) and adult forms, which are variations of the same disorder based on the age of onset and tissue and organ involvement. This disorder is inherited as an autosomal recessive trait (Engel and Hirschhorn, 1994).

This disorder has also been reported in shorthorn and Brahman cattle (Jolly *et al.*, 1977; Richards *et al.*, 1977; O'Sullivan *et al.*, 1981). Both infantile and late onset equivalent variations have been described (Howell *et al.*, 1981). Clinical signs in Brahman calves become evident at 2–3 months of age with a loss of condition, poor growth, and lethargy followed by incoordination and muscle tremors with death by 9 months of age. Although the onset of clinical signs may also occur within the first 2–3 months of age, some affected shorthorn calves appear clinically normal until 5–9 months of age when weight gains are not maintained and progressive muscular weakness develops with death by 12–16 months of age. Excessive accumulation of glycogen occurs in skeletal and cardiac muscle, brain, and spinal cord. The disorder in cattle is also inherited as an autosomal recessive trait (Howell *et al.*, 1981).

In other species, single cases of generalized glycogenoses in which α-glucosidase deficiency were demonstrated in the Lapland dog (Walvoort *et al.*, 1982) and Japanese quail (Murakami *et al.*, 1980). In addition, generalized glycogenoses have also been described in sheep (Manktelow and Hartley, 1975), cats (Sandstrom *et al.*, 1969) and dogs (Mastofa, 1970; Walvoort *et al.*, 1981); however, those conditions were not characterized biochemically.

2. Debranching Enzyme Deficiency (GSD III)

Debranching enzyme possesses two activities, α-1,4-glucan transferase and α-1,6-glucosidase. In the hydrolysis of glycogen, myophosphorylase acts on the α-1,4 linkages of the terminal glucose residues up to the last four glucose residues preceding the α-1,4 linkages. The α-1,4-glucan transferase transfers the last three residues to another branch and the α-1,6-glucosidase hydrolyses the α-1,6 branch point.

Several presumed cases of debranching enzyme deficiency have been described in the dog (Rafiquzzaman *et al.*, 1976; Ceh *et al.*, 1976; Otani and Mochizuki, 1977). Biochemical demonstration of debranching enzyme deficiency is limited to a single case (Ceh *et al.*, 1976). There is diffuse organ involvement with glycogen storage. Onset of signs appear at 2 months of age and the disorder is progressive with death by 10–15 months.

3. Branching Enzyme Deficiency (GSD IV)

Glycogen storage associated with branching enzyme deficiency has been reported in a family of Norwegian forest cats (Fyfe *et al.*, 1992). Clinical signs and

involved organs include skeletal muscle, heart, and the central nervous system. Abnormal glycogen was evident in tissues at birth. Hepatic involvement and function was reportedly normal.

4. Myophosphorylase Deficiency (GSD V)

Myophosphorylase deficiency (McArdle's disease) is an inherited, autosomal recessive, glycogenosis in humans (DiMauro and Tsujino, 1994) and Charolais cattle (Angelos *et al.*, 1995).

In cattle, clinical signs include recumbency and fatigue with forced exercise and elevated serum enzymes. Muscle glycogen concentrations were elevated 1.6 times higher than controls. Histopathologic changes are modest with some vacuolated myofibers; however, the vacuoles did not contain glycogen. A rapid diagnosis is possible by employing the histochemical staining method for demonstrating myophosphorylase activity in frozen sections of biopsy specimens, which may be confirmed by quantitative analyses.

5. Phosphofructokinase Deficiency (GSD VII)

Phosphofructokinase (PFK) is a key enzyme of the Embden–Meyerhof pathway in all tissues and inherited deficiencies of this enzyme in humans are expressed primarily as a myopathy in which it is designated as type VII glycogen storage disease (GSD-VII). There is a partial expression of hemolysis and the deficiency is otherwise quite heterogeneous (Rowland *et al.*, 1986; Kaneko, 1987).

Deficiency of PFK was reported in springer spaniel dogs that presented a clinical picture remarkably similar to that seen in humans. The dogs presented with a history of intermittent severe hemolytic episodes, and total erythrocyte PFK activity was 10% of normal controls (Giger *et al.*, 1985). The disorder is inherited as an autosomal recessive trait (Giger *et al.*, 1986).

Mammalian PFK is present in different tissues as tetramers of three subunits, PFK-M (muscle), PFK-L (liver), and PFK-P (platelets). Human muscle and liver contain homogenous tetrameric PFK-M4 and PFK-L4, respectively. The erythrocytes contain an admixture of PFK-M and PFK-L tetramers. In normal dogs, a similar isoenzymic distribution pattern exists except in the erythrocytes where the PFK tetramers consist of an admixture of PFK-M and PFK-P subunits (Vora *et al.*, 1985). As in humans, PFK deficiency was found to be a deficiency of the PFK-M subunits and the erythrocytic hybrids consisted of the PFK-L and PFK-P subunits. Giger *et al.* (1985) speculate that exertional stresses inducing hyperventilation and respiratory alkalosis in turn directly or indirectly enhance the alkaline fragility of their erythrocytes and subsequent hemolysis.

Early reports suggested that affected dogs did not manifest severe muscle-related signs, which were possibly masked by signs referable to hemolysis. However, biochemical studies have revealed reduced glycolysis in muscle (Giger *et al.*, 1988a, 1988b), and pathologic studies have established the presence of a myopathy that included the presence of PAS positively stained polysaccharide storage vacuoles in up to 10% of the myofibers (Harvey *et al.*, 1990).

6. Polysaccharide Storage Myopathy

A polysaccharide storage disorder has been described in quarterhorses, quarterhorse crossbreds, american paints, and appaloosa horses (Valberg *et al.*, 1992). The horses had recurrent episodes of exertional rhabdomyolysis and myoglobinuria. Up to 5% of the type 2 muscle fibers had vacuoles that contained acid mucopolysaccharide inclusions that were brilliantly stained with the periodic-acid Schiff's (PAS) stain. These inclusions consisted of β-glycogen particles and fibrillar material. When treated with amylase, the PAS staining intensity was reduced only slightly. Glycogen concentrations were approximately 45% greater in the muscles of horses with these polysaccharide inclusions.

An *in vitro* biochemical method was employed for screening deficiencies of enzymes involved in anaerobic glyco(geno)lysis. Affected muscles were capable of utilizing glycogen, glucose-1-phosphate, glucose-6-phosphate, fructose-6-phosphate, and fructose-1,6-phosphate as substrates to produce lactate; however, the amount of lactate produced was significantly lower than the controls. This study strongly points to an underlying metabolic abnormality that remains to be precisely defined.

E. Mitochondrial Myopathies

A large number of complex mitochondrial myopathies have been described in humans (Morgan-Hughes, 1994) and, recently, there have been reports of mitochondrial muscle disorders in animals. When the utilization of oxygen is reduced, lactate formation is favored and results in elevated blood lactate even at low-intensity levels of exercise. Disorders of the respiratory chain often result in increased numbers of mitochondria and aggregates of mitochondria under the sarcolemma. In sections, these mitochondrial aggregates impart a "ragged-red" appearance to the periphery of myofibers when stained with the modified trichrome stain. The presence of ragged red myofibers

and elevated lactate concentrations with exercise warrant investigation of metabolic abnormalities involving mitochondria.

1. Respiratory Chain Complex I (NADH Ubiquinone Oxioreductase) Deficiency

A deficiency of Complex I was observed in an Arabian mare with severe limitations to even mild exercise in which there was an elevated venous pO_2, low oxygen consumption, and lactic acidosis (Valberg *et al.*, 1994). Complex I of the respiratory chain is one of four complexes involved in oxidative phosphorylation and transfers electrons from NADH to CoQ in the conversion of oxygen to water.

2. Cytochrome c Oxidase Deficiency

An episodic weakness reported in Old English sheepdog littermates is accompanied by elevated serum enzymes, lactic acidosis, and increased pO_2 (Breitschwerdt *et al.*, 1992). This disorder may involve a reduction in cytochrome *c* oxidase (Vijayasarathy *et al.*, 1994).

F. Endocrine Myopathies

Signs referable to muscle weakness are frequently observed as part of the clinical presentations of endocrine disorders.

1. Corticosteroid Myopathy

Hyperadrencorticism causes muscle wasting (atrophy) and weakness in dogs with Cushing's disease and following corticosteroid administration (Braund *et al.*, 1980a, 1980b; Duncan and Griffiths, 1977). The muscle wasting is due to a rather selective anguloid-to-angular atrophy of type 2 myofibers; however, quantitative studies reveal atrophy of type 1 fibers as well. Myotonia is a variable accompanying sign of this disorder (Duncan and Griffiths, 1977). Muscle wasting appears to be due to catabolism with decreased protein synthesis and increased protein degradation mediated by altered transcription in protein metabolism (Kaminski and Ruff, 1994).

2. Hypothyroid Myopathy

Thyroid status has a profound affect on skeletal muscle and hypothyroid states are often accompanied by manifestations of neuromuscular disease. However, descriptions of muscle disorders in clinical veterinary medicine are limited (Braund *et al.*, 1981). Selective type 2 myofiber atrophy and type 1 myofiber predominance (or type 2 myofiber paucity) are common findings in canine hypothyroidism. Experimental studies reveal that the proportion of myofiber types is influenced by thyroid status in which thyroidectomy results in type 1 myofiber predominance, and thyroid excess results in type 2 myofiber predominance (Ianuzzo *et al.*, 1980). These changes may be mediated via neural influences since denervation abolishes these effects of thyroidectomy (Johnson *et al.*, 1980).

CHAPTER

17

Kidney Function

DELMAR R. FINCO

I. INTRODUCTION

In mammals, the kidneys function as a major excretory organ for elimination of metabolic wastes from the body. In most species, death occurs within a week after total cessation of renal function. Partial loss of renal function results in variable deviations from normal, depending on the quantity of functional tissue remaining. The term *azotemia* refers to accumulation of nitrogenous wastes in the blood. Blood concentrations of creatinine and urea are measured as indices of azotemia, although neither imparts significant toxicity because of its accumulation. Animals with moderate to severe azotemia may have a constellation of clinical signs, including lethargy, anorexia, mucosal ulcers, vomiting, diarrhea, weight loss, anemia, and altered urine output. These signs are referred to as *renal failure*, *uremia*, or uremic syndrome, and reflect the development of abnormalities in a multitude of tissues secondary to subnormal renal functions.

The role of the kidneys in maintaining life is a composite of several functions. Water and many electro-

lytes are conserved by the kidneys in times of negative body balance and are excreted in times of positive balance. During the processing of body fluids, the kidneys avidly conserve nutrients such as glucose and amino acids; consequently, urine is almost devoid of such materials. Hydrogen ions are excreted or conserved so that blood pH is kept within narrow limits. End products of nitrogen metabolism, such as urea, creatinine, and allantoin, are removed from the body via the urine so that blood levels remain low and relatively constant. The kidneys produce several hormones, including renin, erythropoietin, and prostaglandins, and perform a vital hydroxylation of vitamin D that is required for its activation. The kidneys also respond to several hormones, including antidiuretic hormone (ADH), parathyroid hormone (PTH), aldosterone, thyroid hormone, and others.

The story of the evolution of the kidneys to fullfill the changing needs of the organism has been told eloquently by Homer Smith (1959), a pioneer in the study of the kidney. Single-celled and primitive organisms had little need for excretory specialization because simple diffusion of materials to and from their iso-osmotic aqueous environment was adequate both for intake and for excretory processes. As the complexity of organisms grew, an extracellular space developed that mimicked the osmolality and electrolyte makeup of the original aqueous environment. Simple excretory organs sufficed because extracellular water and wastes could be extruded, and needs could be replaced easily by ingestion. However, the threat of osmotic imbalance occurred as the seas increased in salinity. Some animals such as the shark solved this problem by retaining urea as a compound to balance the osmolality of the seas. Others depended on renal excretion of excess salt via renal tubular systems.

The animals that eventually moved to freshwater from the ocean faced a different problem. The osmolality of their environment being nil, there was an influx of water from the environment into their tissues. A high glomerular filtration rate evolved to facilitate the removal of this water. But then there was a movement of some animals from freshwater to land and a need to conserve water rather than to excrete it. The high-filtration kidney was then modified so that most of the filtered water was reabsorbed while solute wastes were still excreted.

An understanding of the evolutionary processes previously outlined provides insight into an apparent paradox involving the mammalian kidney. In mammals, there is a continuous potential loss of sodium-rich fluid equal to 4–6% of cardiac output via glomerular filtration. Energy is then expended by the tubules to reabsorb more than 99% of the filtered sodium, together with accompanying water. Certainly an engineer asked to design an excretory organ would be unlikely to choose this devious approach to the end result.

The evolutionary development of the kidney has clinical relevance. In renal failure, one must deal not only with problems of inadequate excretion because of decreased glomerular filtration, but also with problems of excess losses arising from alterations in function of the tubular system reclaiming filtrate. Polyuria of renal failure is an example of such a problem.

II. NORMAL RENAL FUNCTIONS

A. The Nephron as a Structural and Functional Unit

Most renal functions are sums of the activities of thousands of nephrons. Each nephron consists of several anatomical divisions (Fig. 17.1). Glomeruli are composed of a tuft of capillaries supplied by an afferent arteriole and drained by an efferent arteriole. Bowman's capsule surrounds the glomerular capillaries

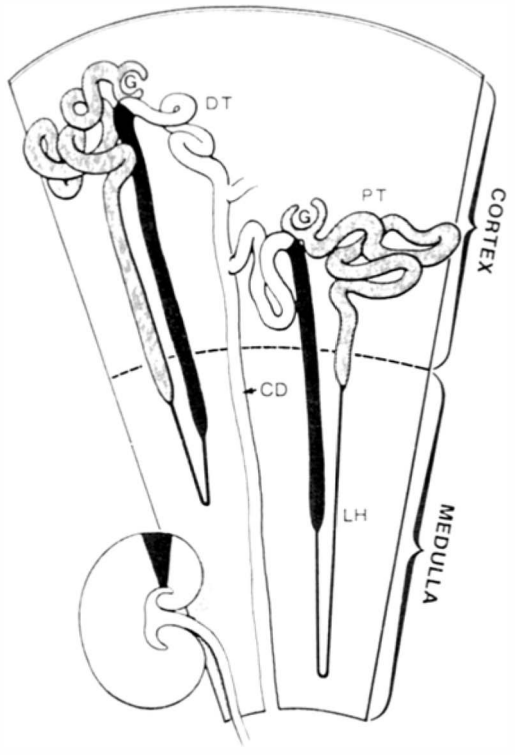

FIGURE 17.1 Nephrons as functional units in the kidney. Outer cortical and juxtamedullary nephrons have some differences in structure and in function. Subdivisions of nephrons include the glomerulus (G), proximal tubule (PT), loop of Henle (LH), distal tubule (DT), and the collecting duct (CD).

and channels filtrate into the proximal tubule. The convoluted portion of the proximal tubule assumes a meandering path within the cortex before the straight portion (pars recta) descends toward the medulla. A marked thinning of the straight portion occurs abruptly as it descends; this constitutes the beginning of the loop of Henle. This structure courses into the medulla, makes a hairpin turn, and ascends into the cortex. At some point in its ascent, the epithelium becomes thicker, which persists to the point of apposition of the loop of Henle with the glomerulus from which the tubule originates. The afferent and efferent arterioles of the glomerulus are adjacent to the ascending tubule. These structures, at the site of their confluence, are referred to as the *juxtaglomerular apparatus.* Modified tubular cells at this site are called the *macula densa.* The distal tubule is considered to be that segment of the nephron between the macula densa and the first union of two distal tubules into a collecting duct. Collecting ducts empty into the renal pelvis.

The number of nephrons varies among species, with larger species having more of them. For example, the cat has about 190,000, the dog about 430,000, and the cow about 4 million per kidney (Smith, 1951). Within the canine species, where there are large body size differences between breeds, nephron size rather than nephron number varies with body size (Finco and Duncan, 1972; Zhu *et al.*, 1992).

A simple view of nephron function can be summarized as follows. Perfusion of glomerular capillaries with blood under pressure results in the passage of material (filtrate) through the capillary walls into Bowman's space. Filtrate then passes through the tubular system of each nephron and is modified in composition during its passage. Modification occurs primarily by reabsorption of lumen contents by tubular cells for return to the body. In addition, important secretory functions are performed by tubule cells, whereby materials delivered to the renal interstitium by the blood are transported from the interstitium to the tubule lumen for excretion. The end result of these tubular activities is a marked reduction in the volume of filtrate and a modification of its character.

B. Nephron Heterogeneity

Common clinical methods for measuring renal function determine the sum of operation of all functional nephrons. However, both anatomical and physiological data indicate that all nephrons are not the same. Internephron heterogeneity has been described in a variety of species (Lameire *et al.*, 1977; Valtin, 1977; Sands *et al.*, 1992). Anatomic differences between outer cortical (OC) and juxtamedullary (JM) nephrons are most apparent. Physiologic differences appear to exist also (Walker and Valtin, 1982). Shunting of blood from the OC nephrons to the JM nephrons could alter renal function by decreasing function of the OC nephrons and increasing function of the JM nephrons. However, studies that have investigated the role of blood shunting in pathologic processes have not led to unanimity of opinion on its relevance (Lameire *et al.*, 1977; Brenner *et al.*, 1986; Steinhausen *et al.*, 1990).

C. Renal Perfusion

1. *Renal Vasculature*

Although some variations occur, vascular patterns of renal perfusion are similar in the mammalian species that have been studied. The renal artery divides into several interlobar arteries that are of about equal size. Further vascular subdivisions occur (arcuate, interlobular arteries) until afferent arterioles supply the glomeruli. Efferent arterioles drain the glomeruli and divide into another capillary network. The site perfused by this network is dependent on the anatomical location of the glomeruli from which the efferent arteriole originates (Beeuwkes, 1971). In the superficial cortex, efferent arterioles supply only the tubule of the parent glomerulus. In the midcortex, efferent arterioles supply either superficial or deep tubules of different glomerular origin. In the juxtamedullary area, efferent arterioles provide capillary networks for the juxtamedullary zone and straight vessels (vasa recta) that course into the medulla.

Venous drainage of renal blood is similar in most mammals, but the cat has a system of subcapsular veins that drains the outer cortex exclusively (Nissen and Galskov, 1972).

Owing to lack of collateral circulation, abrupt blockage of renal arterial vasculature results in infarction of the renal tissue normally supplied (Siegel and Levinsky, 1977). However, slow occlusion of the renal artery divisions may result in survival of some renal parenchyma because of communications between extrarenal arteries and interlobar or arcuate arteries. Such communications apparently do not carry significant quantities of blood under usual conditions, but do dilate when normal renal vasculature is slowly compromised (Christie, 1980).

2. *Renal Blood Flow*

The kidneys receive roughly 15–25% of cardiac output (Kaikara *et al.*, 1969). This rate of perfusion is very high compared to that of most other tissues. Clearance procedures (discussed in Section VI) and electromagnetic flowmeters provide reliable methods for measur-

ing total renal blood flow (RBF) but give no information on intrarenal distribution of blood. Other methods (inert gas washout, microsphere injection) have been used for intrarenal blood flow measurements but all have been criticized (Dworkin and Brenner, 1991). However, renal medullary blood flow rate is known to be comparable to that of other tissues of the body and much lower than the high cortical flow rate.

3. *Autoregulation*

Both RBF and glomerular filtration rate (GFR) remain fairly constant during variations in systemic arterial pressure from 10.7 to 24 kPa (80 to 180 mm Hg) (Pitts, 1974). This phenomenon is known as *autoregulation,* and it occurs secondary to modulation of afferent arteriolar resistance. It occurs in the isolated perfused kidney and thus is not dependent on renal innervation or on extrarenal humoral agents. Two major theories are provided to explain autoregulation (Dworkin and Brenner, 1991). The myogenic theory postulates a direct vascular response to changes in systemic arterial pressure. The tubuloglomerular feedback theory postulates that some intratubular signal is transmitted via the macula densa to the adjacent arterioles, causing their response to changing arterial pressure.

Autoregulation of RBF and GFR operates under physiologic conditions, but it may be abolished with disease, which has significance in clinical medicine.

4. *Role of Neural Stimuli in Renal Perfusion*

The kidney receives sympathetic fibers, with evidence for direct innervation of renal tubular cells (Barajas and Mueller, 1973), which may play some role in renal function (Gottschalk *et al.,* 1985). Current thought suggests that the kidneys are under minimal basal neural tone so that denervation produces minimal changes in renal function. However, neural stimulation beyond the basal tone may alter renal function, particularly by vasoconstriction and decreased renal blood flow. An example is given in Section III.B.2.

D. Glomerular Filtration

1. *Nature of Filtrate*

Material that passes from the capillary lumen into Bowman's space has been collected by micropuncture techniques and compared to the composition of blood. The composition of glomerular filtrate is nearly identical to that of blood from which the cells and protein have been removed. A small difference in ion concentration exists as a consequence of Gibbs–Donnan factors generated secondary to protein restriction to the capillary lumen (Pitts, 1974). Another difference is that glomerular filtrate is not totally devoid of protein. Filtrate harvested from proximal tubules of dogs by micropuncture techniques had albumin concentrations of 20 to 30 mg/liter (2.0 to 3.0 mg/dl), and contained lower molecular weight proteins as well (Dirks *et al.,* 1965; Maack *et al.,* 1992). The relevance of this protein is discussed in Section V.C.

2. *Anatomic Considerations for Filtration*

In order for material to pass from the glomerular capillary lumen into Bowman's space, it must traverse three anatomic barriers: the capillary endothelium, the basement membrane, and the capillary epithelium. Glomerular capillaries are different from other capillaries of the body in several ways. The endothelial fenestrae are larger and account for proportionately more surface area, the basement membranes are thicker, adventitial connective tissue is absent, and the epithelial cells have an elaborate arrangement of interdigitating foot processes (Farquhar, 1975). An intercapillary cell, the mesangial cell, acts as a scavenger cell for particles lodged in the capillary wall. The mesangial cell also has contractile properties and may influence the filtration area of the glomerulus (Raij and Keane, 1985).

It is generally acknowledged that the endothelium can function only to restrain cellular elements since the fenestrae are 50 to 100 nm in diameter. Athough the gaps between the epithelial foot processes are very wide (25 nm), slit membranes which cover the gaps could act as filters. The uninterrupted nature of the basement membrane suggests that it is likely to be the major filtration barrier (Farquhar, 1975).

3. *Glomerular Filtration Dynamics*

Forces relevant to glomerular filtration are shown in Fig. 17.2. Hydraulic (hydrostatic) pressure of cardiac origin provides the energy for glomerular filtration. The major force opposing filtration is the oncotic pressure of plasma proteins. An additional force opposing filtration is hydrostatic force in Bowman's space. One potential force, oncotic pressure in Bowman's space, is usually ignored because protein concentration in filtrate is so low compared to that of plasma.

The permeability and the surface area of the capillary filtering area are other factors that influence the rate of filtration (Maddox and Brenner, 1991). As fluid traverses the glomerular capillary bed, plasma proteins are concentrated because filtrate leaves the capillary. This concentration results in a progressive rise in oncotic pressure as the efferent arteriole is approached. In rats, oncotic pressure in the capillary matches net effective hydraulic pressure before the end of the capil-

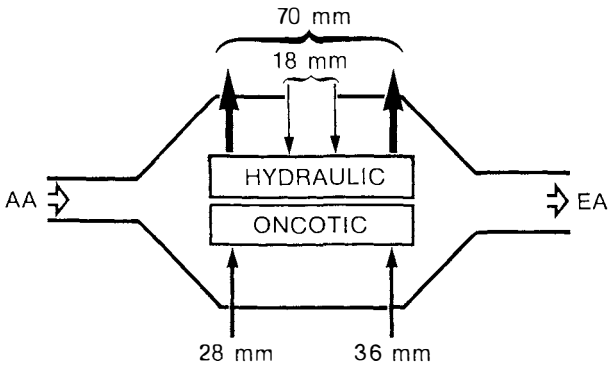

FIGURE 17.2 Schematic representation of forces significant in glomerular filtration. Hydraulic (blood) pressure is the major factor forcing fluid from the capillary lumen into Bowman's space. This pressure is opposed by plasma oncotic pressure and hydraulic pressure in Bowman's space.

lary, causing filtration to cease prematurely. This is called *filtration pressure equilibrium.* With these conditions, an increase in plasma flow rate increases GFR as follows. An increase in flow rate would decrease the proportion of plasma that became filtrate. Intraluminal oncotic pressure would not rise as rapidly as it would at a slower flow rate, so a positive filtration pressure would exist over a greater span of the capillary loop. Thus, with filtration pressure equilibrium, plasma flow rate markedly influences GFR (Tucker and Blantz, 1977). However, filtration pressure equilibrium does not exist in dogs and probably does not exist in most other species (Fried and Stein, 1983).

4. *Filtration of Macromolecules*

Common methods of detecting proteinuria that are used as a part of urinalysis are negative in normal animals because the glomerular filter does not allow passage of large quantities of protein into filtrate. The idea that pores in the filtration barrier prevent macromolecules and cells from entering filtrate led to the concept that the size and shape of molecules influenced their filtration (Pitts, 1974). In addition, filtration is influenced by electrical charge (Rennke and Venkatachalam, 1977; Brenner *et al.*, 1978). Negatively charged sialoproteins are components of all three layers of the capillary wall. These negative charges facilitate passage of cationic macromolecules, and impede passage of anionic macromolecules through the filter. Albumin has a size and shape that marginally prevents its passage through the glomerular capillary wall. However, its negative charge at blood pH further impedes its loss into filtrate. If the negatively charged sialoproteins lining the filtration barrier are removed experimentally or with disease, then albuminuria occurs (Brenner *et al.*, 1978).

For quantitative comparisons, the passage of macromolecules through the glomerular barrier can be compared to water movement through the barrier (Table 17.1).

E. Tubular Modification of Filtrate

Death from hypovolemia and electrolyte depletion would occur in less than 1 hour if all the glomerular filtrate formed were lost from the body. The renal tubules modify glomerular filtrate to achieve body homeostasis for water and most electrolytes. Large quantities of filtrate (65–80%) are reabsorbed in the proximal tubules. As the reduced volume of filtrate traverses the more distal portions of the nephron, further reabsorption takes place. Secretion of certain endogenous materials (i.e., protons, potassium, organic anions) as well as exogenous materials (certain drugs, toxins) from tubular cells into the tubular lumen also is important in renal excretory functions.

The concept of tubular maxima (T_m) for reabsorption and secretion applies to many materials handled by the tubules. This concept originated before cell receptors and transport kinetics were studied in other systems. Whole kidney T_m values, however, represent the composite of all segments of the nephron and the action of both the luminal and the basolateral cell membranes. The T_m value for maximal tubular reabsorption or secretion by the kidney is expressed as milligrams transported per 100 ml of filtrate, or milligrams transported per unit time.

Another measurement that evaluates the role of the tubules in body homeostasis is the determination of fractional excretion (FE). The FE is defined as that fraction of filtered substance (S) that is excreted in the urine (i.e., not reabsorbed by tubules). The FE of a substance S can be calculated from values for its filtered load and its urinary excretion. For an S that passes freely through the glomerular barrier, the filtered load is calculated as the product of GFR × plasma concen-

TABLE 17.1 Permeability of the Glomerular Capillary Barrier

Substance	MW	Permeability coefficient[a]
Urea	60	1
Creatinine	113	1
Glucose	180	1
Inulin	5,500	0.98
Myoglobin	17,000	0.75
Hemoglobin	65,000	0.03
Albumin	69,000	<0.001

[a] Coefficient = permeability compared to water.

tration. The FE value is calculated as urinary excretion divided by filtered load,

$$FE = \frac{S\ (U\text{: mmol/liter}) \times \text{volume}\ (U\text{: ml})}{\text{GFR (ml/m)} \times S\ (P\text{: mmol/liter})},$$

where S is substance, for example, sodium; U, urine; and P, plasma concentration. All units will cancel when the timed urine collection period is expressed in minutes.

In health, values for FE are not fixed, but vary depending on requirements placed on the kidney for maintaining homeostasis. For example, if intestinal absorption of inorganic phosphate increases and body needs for phosphate are constant, then FE_P would increase. Clinical use of FE measurements is discussed in Section VI.

F. Conservation of Nutrients

1. Glucose

Glucose (MW = 180 Da) passes freely through the glomerular filtration barrier and attains the same concentration in filtrate as in plasma. The normal mammalian renal tubule has evolved into a highly efficient structure for reclaiming filtered glucose. At normal blood levels of glucose, reabsorption of filtered glucose is nearly complete within the first 20% of the proximal tubule. At the luminal membrane, glucose is reabsorbed by secondary active transport coupled to sodium reabsorption. Glucose attains a high concentration in the tubule cell and is transported into the renal interstitium through the basolateral membrane by a sodium-independent mechanism. Although nearly all glucose is normally reabsorbed in the proximal tubule, more distal sites for reabsorption also have been identified (Wen, 1976). Despite this system, urine from a normal animal still contains a small quantity of glucose that is undetectable by the urinalysis methods of glucose assay.

The kidney has definite limits for glucose reabsorption. Blood and thus filtrate concentration of glucose may exceed the T_m for glucose. Rate of fluid flow through the tubule also influences whether glucosuria occurs (Pitts, 1974). The interpretation of glucosuria is discussed in Section VE.

2. Amino Acids

Several hundred millomoles of amino acids is potentially lost daily by glomerular filtration. In nearly all species, more than 99% is reabsorbed by specific mechanisms by the tubules (Silbernagl, 1985). An exception is the domestic cat, which normally has 1 to 1.8 g/liter of a sulfur-containing amino acid (felinine) in its urine. The role of this amino acid in feline metabolism and its relevance in urine are unclear (Westall, 1953; Tallan *et al.*, 1954; Trippet, 1957; Avizonis and Wriston, 1959; Greaves and Scott, 1960).

The bulk of amino acid reabsorption occurs in the early portions of the proximal tubule. If blood levels of amino acids are increased so that greater amounts are filtered, the late portions of the proximal tubule are recruited for reabsorption. However, the more distal portions of outer cortical nephrons, evaluated by micropuncture, are incapable of amino acid reabsorption.

Several distinct transport mechanisms exist for amino acid reabsorption. These mechanisms are carrier mediated and saturable, and they obey standard kinetic principles. At least one mechanism exists for the acidic amino acids, at least one for the basic amino acids, and several for the neutral amino acids. The transport mechanisms are ion dependent (sodium, potassium, chloride) for many of the amino acids (Silbernagl, 1985).

3. Other Metabolites

Metabolic intermediates may be present in the blood in low concentrations and could be lost in the urine because of their low molecular weight. Tubular reabsorption of these compounds occurs, but with high blood levels some may appear in the urine when tubular maxima are exceeded (Pitts, 1974). Acid–base status also may influence urinary loss of citrate, α-ketoglutarate, and succinate (Packer *et al.*, 1995). Blood forms of lipids apparently do not pass the glomerular filter, and thus the urine of most species is devoid of fat. However, fat is a normal constituent of the urine of dogs and cats, presumably because of exocytosis from the tubular cells into the lumen.

G. Electrolyte Homeostasis

The kidneys play a significant role in maintaining the concentration of many plasma electrolytes within narrow limits. These electrolytes include sodium, potassium, inorganic phosphate, chloride, and magnesium. The kidneys play a prominent role in electrolyte homeostasis because of the lack of discrimination by the intestinal tract in absorption of electrolytes. In carnivores, nearly all of the sodium, potassium, and chloride and much of the inorganic phosphate ingested is absorbed from the gut without regard for body need. The kidneys serve as a monitor of the blood to excrete these electrolytes when body excess occurs.

1. Sodium Homeostasis

A large quantity of sodium is filtered daily and most is reabsorbed in the proximal tubules. At this site, sodium moves from the tubular lumen into the cell

passively because of both concentration and electrical gradients. Sodium is actively extruded from the cell across the basolateral membrane by operation of the sodium–potassium ATPase system. Water passively follows the sodium according to osmotic gradients, so that fluid leaving the proximal tubule is isotonic. Additional sodium is removed from luminal fluid in the ascending limb of the loop of Henle. Transport is passive in the thin portion of the loop, but active in the thick portion. As in the proximal tubule, sodium reabsorption occurs in the loop without regard for body need. The diuretics furosemide and ethacrynic acid act on the luminal border of the cells of the thick portion of the loop of Henle to prevent electrolyte reabsorption.

Further reabsorption of sodium occurs in the more distal portions (distal tubule, collecting duct) of the nephron. Control of body sodium balance rests primarily with homeostatic mechanisms in these areas. However, perturbations in proximal tubule or loop of Henle function by disease or drugs may result in flooding of the control areas so that their capacity is exceeded.

Body sodium balance is closely related to water balance; sodium retention usually results in water retention. Baroreceptors, osmoreceptors, and intrarenal receptors detect abnormalities in plasma volume and osmolality and cause appropriate renal responses. Several mechanisms act in concert to direct the kidneys to achieve homeostasis, including intrarenal angiotensin II effects on sodium reabsorption, the renin–angiotensin–aldosterone system, pressure natriuresis, renal sympathetic nerve activity, and atrial natriuretic peptide (Gonzales-Campoy and Knox, 1992).

2. *Potassium Homeostasis*

Both extrarenal and renal mechanisms exist for potassium homeostasis. After potassium is ingested and absorbed from the gut, it is quickly transported into cells to prevent hyperkalemia. Cell uptake is facilitated by insulin and epinephrine. Only later are appropriate adjustments made to body potassium content by renal excretion of excess (Rosa *et al.*, 1992).

In the kidneys, potassium freely passes through glomerular capillary walls and appears in filtrate in the same concentration as in blood. Nearly 70% of filtered potassium is reabsorbed in the first two-thirds of the proximal tubule. Both passive influx into the descending limb and efflux out of the thick ascending limb of the loop of Henle occur.

The major nephron sites for potassium homeostasis are the terminal distal tubule and the cortical collecting duct. Potassium is secreted from cells into the tubular lumen at these sites. This secretion occurs passively via a favorable electrochemical gradient, but the amount excreted is controlled to maintain body potassium balance. Several factors influence tubular potassium secretion including aldosterone, tubular fluid flow rate, tubular sodium delivery rate, acid–base state, ADH, and the presence of unreabsorbable anion in the distal nephron (Wright and Giebisch, 1992).

The normal kidney is able to undergo adaptive changes when dietary intake of potassium increases. Aldosterone secretion is increased by several stimuli, including hyperkalemia. Aldosterone enhances renal potassium excretion in association with an increase in activity of the sodium–potassium ATPase system in the basolateral membranes of the renal tubular cells (Sebastian *et al.*, 1986). However, aldosterone-dependent changes may not be the exclusive mechanism for renal adaptation to potassium excess. Enhanced potassium excretion can be demonstrated in isolated perfused kidneys (Silva *et al.*, 1977), and the sodium–potassium ATPase system is stimulated in animals in renal failure by aldosterone-independent mechanisms (Schon *et al.*, 1974).

Cattle normally excrete a much larger percentage of the filtered load of potassium than do carnivores because of higher dietary potassium intake (Pickering, 1965). It appears that this excretory pattern is an acquired one, since dogs develop the same increase in excretory capacity if placed on a high potassium diet (Pickering, 1965).

3. *Inorganic Phosphorus (Phosphate)*

The inorganic portion of blood phosphorus exists in both the mono and dibasic salts; a ratio of four HPO_4^{2-} to one $H_2PO_4^-$ exists at normal blood pH levels (Knochel and Jacobson, 1986). The kidney is the major organ for control of plasma phosphate concentration. The concentration of phosphate in glomerular filtrate is nearly the same as plasma, and nearly all phosphate reabsorption occurs in the proximal tubule by a sodium-dependent mechanism.

It is well established that parathyroid hormone (PTH) inhibits tubular reabsorption of phosphate. Cellular mechanisms of PTH action include the generation of cyclic AMP (Knox, 1977). In states of hyperphosphatemia, increased plasma levels of PTH result in an increase in the FE of phosphate. Earlier studies considered PTH to be the exclusive mechanism for control of renal phosphate excretion, but subsequent investigations indicate that thyroparathyroidectomized animals can adequately respond to an excess or deficit of phosphate with appropriate modification of urinary excretion of phosphate (Trohler *et al.*, 1976; Haramati *et al.*, 1983). Many factors are now known to alter renal

tubular phosphate reabsorption, including vitamin D metabolites, insulin, thyroid hormone, growth hormone, glucocorticoids, acid–base balance, extracellular volume state, and the diuretic furosemide (Berndt and Knox, 1992).

4. *Chloride*

Chloride is freely filtered into Bowman's space and is reabsorbed by the renal tubular system according to body needs. As the most prevalent anion in filtrate, chloride often is reabsorbed in concert with sodium by sodium-dependent mechanisms. However, distinct sodium-independent mechanisms also exist, which explains the clinical observation that plasma sodium and chloride concentrations may vary independently. Specific cellular mechanisms of chloride transport are less defined than for sodium (Berry and Rector, 1991).

5. *Calcium*

In most carnivores and omnivores, intestinal absorption of calcium is the major controlling factor in calcium homeostasis, and the role of the kidney is minor.

Regarding renal handling of calcium, plasma-ionized and chelated calcium readily pass the glomerular filtration barrier, but protein-bound calcium is retained in the blood. In the tubule, calcium is reabsorbed roughly in parallel to sodium in the proximal tubule, but differences exist between handling of calcium and sodium more distally (Costanzo and Windhager, 1992).

Hypercalcemia due to a variety of causes may exist in animals with normal renal function. This fact emphasizes the limited role that the kidney plays in calcium homeostasis in many species. However, dietary intake of calcium can modestly influence urinary calcium excretion, and may be a factor in formation of calcium-containing uroliths. Horses normally excrete large amounts of calcium in the urine; the kidneys may play a more significant role in calcium homeostasis in this species.

Factors known to modify renal excretion of calcium include PTH, vitamin D metabolites, extracellular fluid volume, acid–base balance, phosphate depletion, hypercalcemia, and diuretics (Costanzo and Windhager, 1992).

6. *Magnesium*

The kidney is responsible for control of plasma magnesium concentration. From 70 to 80% of plasma magnesium is filterable through the glomerular capillary, implying less protein binding of magnesium than of calcium (Quamme, 1992). Tubular handling of magnesium seems unique compared to other electrolytes. Proximal tubule reabsorption is only 20–30% of the amount filtered. The major site of reabsorption under normal conditions is the thick ascending limb of the loop of Henle (Quamme, 1992). About 10% of filtered magnesium is normally reabsorbed more distally. Major renal control of magnesium homeostasis rests in tubular detection of peritubular magnesium concentration (Quamme, 1992).

H. Acid–Base Balance

The lungs and the kidneys are the primary organs concerned with acid–base regulation. Although the lungs may cause sudden and dramatic changes in blood pH by altering pCO_2, the maneuver is not associated with loss of hydrogen ions (H^+) from the body. When pCO_2 is reestablished at normal levels, the H^+ reappears due to dissociation of H_2CO_3 to H^+ and HCO_3^- according to the law of mass action. Thus, the kidney is ultimately responsible for H^+ excretion.

1. *Conservation and Generation of Bicarbonate*

Bicarbonate is an important buffer and is available to neutralize H^+ ingested or produced during metabolism. Since bicarbonate passes freely through the glomerular filter, it is necessary that it be reabsorbed. Most bicarbonate is reabsorbed in the proximal tubules by a process that requires H^+ secretion and action of carbonic anhydrase. Filtered bicarbonate is converted to CO_2 by the reaction

$$HCO_3^- + H^+ \rightarrow H_2CO_3 \rightarrow H_2O + CO_2.$$

After CO_2 is formed, it diffuses into tubular cells and is reconverted to bicarbonate. Since H^+ are recycled in the process, no net secretion occurs in association with bicarbonate reabsorption.

If a tendency for decreased plasma bicarbonate exists, all filtered bicarbonate is reclaimed, and new bicarbonate is synthesized utilizing CO_2 derived from renal cell metabolism. The synthesis of new bicarbonate in renal tubular cells requires net secretion of H^+ into the tubular lumen.

If a tendency for an increased plasma bicarbonate exists, then bicarbonate reabsorption is incomplete and the excess bicarbonate is excreted in the urine.

A T_m for bicarbonate has been found in intact animals. However, this T_m is apparently a regulatory maximum rather than an absolute one since isolated perfused tubules do not demonstrate a T_m phenomenon for bicarbonate. In the intact animal, the amount of bicarbonate reabsorbed can be modified by several factors including extracellular volume, plasma concentra-

tions of certain blood constituents (systemic pH and pCO_2, aldosterone, PTH, glucocorticoids, thyroid hormone, ANP), and body stores of potassium and chloride (Gennari and Maddox, 1992).

2. *Secretion of H^+ (Protons)*

In addition to preservation of bicarbonate as a buffer, the kidney secretes H^+ as a direct defense against acidosis. Parts of the nephron differ in their ability to secrete H^+. Large quantities of H^+ are cycled by the proximal tubules in association with bicarbonate reabsorption, but no net proton secretion occurs with this process. Although proximal tubules have a high capacity to secrete H^+, the gradient against which they can secrete H^+ is modest. Thus, fluid leaving the proximal tubule has a pH no lower than 6.0 even in conditions of acidosis. In the distal tubule and collecting duct, the capacity for H^+ secretion is less than the proximal tubule, but the cell-to-lumen concentration gradient against which H^+ can occur is much greater (1:1000). When such gradients are attained, for instance, during periods of metabolic acidosis, urine pH values of about 4.5 occur.

3. *Facilitation of H^+ Excretion by Urinary Buffers*

Buffers that accept H^+ effectively remove protons from solution and negate their pH effect. Appropriate urinary buffers allow secretion of more H^+ since the secretory process for H^+ is gradient limited. The urinary excretion of phosphate provides a buffering action to facilitate further H^+ secretion. The HPO_4^{2-} that is filtered can accept a H^+ to be excreted as $H_2PO_4^-$. Since urinary excretion of phosphate is an ongoing part of phosphate homeostasis, this mechanism operates without induction. By contrast, the ammonia buffer system is induced in response to needs of the animal to combat an increased acid load. Ammonia is synthesized in the nephron, predominantly from the amino acid glutamine (Halperin *et al.*, 1985). This synthesis can be increased 5 to 10-fold during acidosis (Pitts, 1974). Ammonia that is generated diffuses from renal cells into the tubular lumen. In the distal tubule where luminal pH is low, H^+ secretion is enhanced because H^+ are removed by the reaction

$$NH_3 + H^+ \rightarrow NH_4^+.$$

The pK of this reaction is about 9.15, so in the cell the ratio of NH_4^+ to NH_3 is less than 1000 to 1, while in the tubule lumen (pH less than 5) it is greater than 10,000 to 1.

An alternate explanation for the beneficial effects of the ammonia system has been proposed (Halperin and Jungas, 1983). This explanation states that an anion that is metabolized to neutral products consumes H^+ in the process. Deamination of glutamine yields α-ketoglutarate$^-$, which can be metabolized either to water and CO_2 or to glucose. Both metabolic pathways for α-ketoglutarate degradation consume H^+. Ammonium from deamination, if converted to urea in the liver, consumes bicarbonate during the urea cycle, leaving the overall effects of glutamine metabolism neutral. Excretion of ammonium in urine results in body alkalinization, because only the H^+-consuming portion of glutamine metabolism occurs.

The functions of the kidney in acid–base balance may be simplistically defined as both conservation of bicarbonate and excretion of H^+ in times of acidosis, and excretion of bicarbonate and retention of H^+ in times of alkalosis. However, the interrelationships between acid–base functions and homeostatic functions for other electrolytes sometimes result in compromises of function. For example, metabolic alkalosis can occur under certain circumstances because of complex relationships between extracellular volume, chloride balance, and acid–base control mechanisms (Jacobson and Seldin, 1983). Interaction between potassium and acid–base balances also have been described (Gennari and Cohen, 1975).

I. Water Homeostasis

1. *Overview*

All mammals and birds have some ability to concentrate urine above the osmolality of plasma. This capability provides a mechanism for conserving water when intake is sporadic. Animals also have the ability to excrete hypotonic urine so that excess body water can be excreted without solute depletion.

The massive amount of water potentially lost because of the high GFR of mammals dictates that most filtrate be reabsorbed even in instances of overhydration. Thus, water reabsorption in the proximal tubule, descending limb of the loop of Henle, and early distal tubule occurs without regard for the state of water balance.

In the proximal tubule, 60–80% of filtrate is reabsorbed secondary to solute reabsorption. In the descending limb, loop of Henle, and in the proximal portion of the distal tubule, further rebsorption occurs so that only about 9% of filtrate remains as fluid enters the terminal portion of the distal tubule and the collecting duct. Urine volume is determined by the amount of this 9% that is reabsorbed. In times of body water deficit, nearly all of the 9% is reabsorbed and the urine voided is very low in volume and high in solute concentration. In times of body water excess, little if any

of the 9% is reabsorbed, so that urine volume is high and solute concentration is low.

The proximal tubules and loop of Henle normally are not major sites of water homeostasis, but impairment of their function by disease or drugs may have profound effects on urine volume. If the more proximal portions of the nephron do not function to reabsorb water at the normal rate, then the distal portions are flooded with large volumes of fluid that they are unable to handle, and polyuria ensues. Osmotic diuretics such as mannitol cause polyuria in this way (Gennari and Kassirer, 1974).

2. *Mechanism of Water Conservation*

Reabsorption of water throughout the nephron occurs secondary to osmotic gradients. In the proximal tubule, the reabsorption of solute (sodium, chloride, etc.) is associated with water reabsorption because proximal tubule cells are water permeable. The ascending limb of the loop of Henle is impermeable to water but solute moves into the interstitium because of both active and passive transport. This solute movement, coupled with an anatomic arrangement of blood vessels (vasa recta) that minimizes removal of solute, contributes to the development of medullary interstitial hypertonicity. This hypertonicity provides an osmotic gradient for water reabsorption from the lumen of the distal tubule and collecting duct into the interstitium when cells at these sites are made water permeable by the action of ADH.

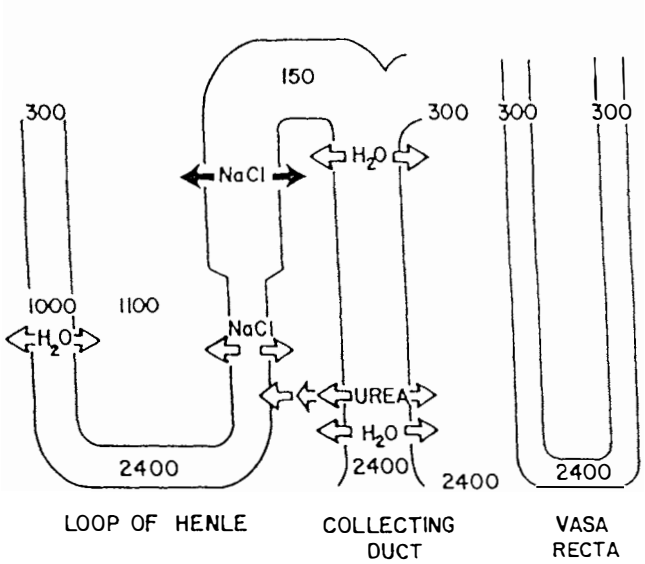

FIGURE 17.3 Schematic representation of a popular theory of the urine-concentrating mechanism in the renal medulla. Numbers represent milliosmoles per liter. Solute in the descending loop of Henle is concentrated by passive movement of water into the hyperosmolar interstitium. The ascending limb is impermeable to water, but NaCl moves into the interstitium passively (open arrows) in the inner medulla and by active transport (solid arrow) in the outer medulla, creating dilute urine in the distal tubule (150 mOsm/liter). Water may be reabsorbed in both the outer and inner medulla if collecting duct cells are rendered water permeable by ADH. Urea passively reabsorbed in the inner medulla in the presence of ADH contributes to interstitial hyperosmolarity. The vasa recta provide nutrition to the medulla and remove quantities of solute and solvent beyond that necessary to maintain normal interstitial volume and osmolality.

3. *Events in the Tubule*

Proportionate reabsorption of solute and water in the proximal tubule results in an isotonic fluid entering the descending limb of the loop of Henle (Fig. 17.3). As this fluid descends into the medulla, water is absorbed into the hypertonic interstitium, causing a reduction in fluid volume and an increase in sodium concentration. The high concentration of sodium achieved at the loop exceeds that in the interstitium, allowing passive movement of sodium from the lumen into the interstitium in the thin ascending limb.

The entire ascending limb is impermeable to water. Consequently, as the fluid column ascends into the cortex, volume does not change. Active transport of sodium chloride from the thick ascending limb into the interstitium increases interstitial osmolality and makes intraluminal fluid hypo-osmolar to plasma.

Both solute and water are removed from early distal tubule fluid, in proportions that vary with species. Urine remains hypo-osmolar in the dog, chinchilla, some strains of rats, and monkeys. It becomes isosmolar in the cat and in some strains of rats (Jamison, 1976; Suzuki, 1971).

Fluid has now reached the segment of the tubule in which urine volume is controlled. In the terminal distal tubule and cortical collecting duct, ADH affects the permeability of luminal cell membranes to water. With ADH present, water moves from the lumen through the cell into the hypertonic interstitium according to osmotic gradients. In the absence of ADH, very little water is absorbed. The inner medullary portion of the collecting duct is affected by ADH in the same manner. In addition, urea permeability of cells of this segment is facilitated by ADH, allowing urea to enter the interstitium.

4. *Cellular Role of Antidiuretic Hormone in Urine Concentration*

ADH is released in response to several stimuli, including increased plasma osmolality. Circulating ADH is bound to receptors on the basolateral membrane of collecting duct cells. Binding initiates generation of cAMP, which mediates intracellular events that culmi

nate in a change in the luminal membrane from water impermeable to water permeable. Water channels studied in more detail in other tissues probably explain the change in membrane permeability (Agre *et al.*, 1993).

A large number of agents have been identified that modify the intracellular events initiated by ADH. These include prostaglandin E_2, calcium, protein kinase C, aldosterone, and certain amino acids (Hays *et al.*, 1987). Compounds that modify events initiated by ADH are probably important in the pathogenesis of polyuria in many diseases of animals which are unresponsive to ADH.

5. Role of Urea in Urine Concentration

In 1931 Jollife and Smith observed that urine-concentrating ability improved when dogs were changed from a low protein diet to a high protein diet. The role of urea in the concentration of urine has been elucidated more recently, and it explains the effect of protein previously observed. As filtered urea flows through the nephron, it is concentrated as water is reabsorbed. Accordingly, fluid reaching the inner medullary collecting duct has a high urea concentration. Cells of the medullary collecting duct are permeable to urea when ADH is present, and the high intraluminal urea concentration favors diffusion from tubule lumen into the interstitium (Fig. 17.3). The high interstitial concentration of urea achieved in this manner results in some urea passing into the lumen of the thin ascending limb of the loop of Henle, further increasing the concentration of urea in the medullary collecting duct and creating a cycle to concentrate urea. The addition of urea to the sodium chloride in the medullary interstitium increases the osmotic gradient for water reabsorption beyond that achieved with sodium chloride alone and thus increases maximum concentrating ability by the animal.

6. Renal Medullary Factors

The efferent arterioles of juxtamedullary glomeruli give rise to vessels (vasa recta) which course straight down into the medulla, make a hairpin turn deep in the medullary area, and then return to the cortex (Fig. 17.3). These vessels function to provide nutrients to medullary structures and to facilitate removal of materials from the medulla. The path of these vessels and the slow rate of blood flow through them are factors instrumental in the preservation of medullary hypertonicity. Equilibrium is achieved between interstitium and blood at all levels of the medulla, so that influx of salt and urea occurring as the vasa recta descends into the medulla is reversed by efflux as fluid ascends toward the cortex. Rapid blood flow through the medulla would not allow for equilibration and "washout" of solute from the medulla would occur (Jamison, 1976).

Renal medullary cells are subjected to an environment with a very high osmolality. To balance high interstitial osmolality, cells of medullary structures generate and maintain high intracellular levels of organic osmolytes. Polyols, methylamines, and amino acids are used; mechanisms exist for rapid changes in intracellular osmolality to accommodate interstitial fluctuations (Handler and Kwon, 1993).

7. Factors Impairing Urine Concentration

Several factors may impair reabsorption of water from tubule lumens. Such factors can result in the production of volumes of urine larger than are appropriate for maintaining water balance. Polyuria is a common sign detected in a variety of diseases of domestic animals. Based on existing knowledge concerning the mechanisms of urine concentration, all concentrating defects resulting in polyuria fall into three categories (Table 17.2).

J. Renal Maturation and Senescence

Renal function in the neonatal animal has relevance in clinical practice in all species. Unfortunately, our knowledge about renal maturation is limited. Structur-

TABLE 17.2 Mechanisms for Development of Polyuria in Animals

Defect	Examples of diseases or conditions causing this defect
1. Retention of particles in tubule lumens	
a. High blood concentration of filtered particles	Hyperglycemia (diabetes, mellitus, iatrogenic) Mannitol administration
b. Lack of particle reabsorption	Fanconi syndrome (impaired absorption of solute in the proximal tubules)
2. Decrease in interstitial osmolality	"Washout" secondary to increased urine flow rate of any cause "Washout" due to increased medullary blood flow Treatment with loop diuretics (furosemide, ethacrynic acid)
3. Impermeability of collecting duct to water	Diabetes insipidus (deficiency of ADH) Nephrogenic diabetes insipidus (kidneys normal except for response to ADH)

ally, species vary at birth in the degree of renal maturation.

In newborn dogs, nephrogenesis is incomplete and immature glomeruli are visible in the subcapsular area until about 3 weeks of age. Most growth of kidney that occurs with maturation is due to lengthening of tubules. Functionally, the GFR of individual superficial nephrons of pups increased sevenfold between 2 and 77 days of age (Horster and Valtin, 1971). This increase was due not only to increased glomerular volume but also to increased glomerular permeability. Tubular functions appear to lag behind glomerular functions. Canine fetuses 10 days or less from whelping had urine specific gravity readings of 1.008–1.025 (Rahill and Subramanian, 1973), indicating some concentrating ability. Random urine samples in pups at 2 days of age had an osmolality about twice that of plasma, and the ratio increased to seven times that of plasma at 77 days of age (Horster and Valtin, 1971). Thus, pups have a rapid increase in concentrating ability with maturation. Studies on 2-day-old pups demonstrated that they could excrete an oral water load, but their ability to do so was inferior to that of adults (McCance and Widdowson, 1955). Newborn pups have less capacity for excretion of a potassium load than adult dogs, but the same distal tubule site of potassium excretion exists for both (Lorenz *et al.*, 1986).

The ability of young calves to concentrate urine seems limited, because, with diarrhea, mean urine osmolality values were only 406 mOsm/liter (Thornton and English, 1976). With indiscriminant water drinking, young calves may develop water intoxication because of limited abililty for renal excretion of a water load (Kirkbride and Frey, 1967).

Few data are available for domestic animals concerning the effects of aging on renal function. In human beings, slight decreases in GFR and concentrating ability were observed with age (Dontas *et al.*, 1972; Slack and Wilson, 1976; Lindeman, 1986), but the effects were minor when compared to the total quantity of renal reserve. Morphological changes observed in association with aging in human beings include shrinkage in nephron size after the fourth decade, as determined by nephron dissection, and a gradual increase in thickness of basement membranes of both glomeruli and the tubules (Darmady *et al.*, 1973). Differences in renal clearance were found in dogs of different ages by Asheim *et al.* (1961), but the range of ages studied was not reported. In a more comprehensive study, dogs were uninephrectomized at 7 to 8 years of age, and the effects of high-protein and low-protein diets were compared. The GFR values increased to more than 75% of normal following uninephrectomy, and no subsequent decrement in GFR occurred over 4 years. These results indicated that reduction of renal mass to 50% of normal did not place the remaining kidney at risk for functional deterioration, nor did the high-protein diet have adverse effects (Finco *et al.*, 1994). Thus, deterioration of renal functions is not inevitable in aging dogs, and routine dietary protein restriction seems unneeded.

K. Renal Metabolism

A high metabolic rate exists in the kidneys. Although both kidneys make up about 0.5% of body weight, they account for about 10% of total oxygen consumption by the body under basal conditions (Klahr and Hammerman, 1985). Anaerobic metabolism also occurs in some regions of the kidney.

Uptake of substrate from the blood by the kidney is somewhat selective, and not necessarily related to the concentration of substrate in the blood. The kidney uses primarily free fatty acids (mostly palmitic), lactate, glutamine, glucose, and citrate. Other substrates used by the kidney, but probably accounting for an insignificant amount of the total renal metabolism, are inositol, α-ketoglutarate, pyruvate, fructose, glycerol, acetoacetate, β-hydroxybutyrate, low-molecular-weight proteins, polypeptides, and certain amino acids (Klahr and Hammerman, 1985).

Products of certain metabolic pathways are released by the kidney into the blood. During starvation the kidney produces glucose via gluconeogenic pathways to provide up to 50% of the body glucose synthesized (Owen *et al.*, 1969). Alanine is released by the kidney after its synthesis from pyruvate, and serine is produced from glycine. Both amino acids are used by the liver for gluconeogenesis (Klahr and Hammerman, 1985).

Earlier studies on renal metabolism suggested that renal requirements for O_2 were attributable to the energy requirements for reabsorption of the filtered load of sodium. However, this belief has been questioned and at present it appears that endergonic metabolic syntheses in the kidney (glucose, serine, creatine) explain energy usage as well (Cohen, 1986).

Areas of the kidney differ in their metabolic characteristics. Oxidative metabolism appears to be highest in the ascending loop of Henle and in the proximal tubule, based on the plethora of mitochondria and enzymes of the citric acid cycle at these sites. Gluconeogenesis is a function of the renal cortex and probably occurs mostly in the proximal tubules. Anaerobic glycolysis appears to be the major metabolic pathway in the medulla and papilla, anatomic sites at which thin loops of Henle and medullary collecting ducts dominate.

III. ALTERATIONS IN RENAL FUNCTION DUE TO EXTRARENAL FACTORS

The kidneys perform many of their functions in synchrony with activities of other organs. Under certain circumstances the kidneys may be anatomically normal but may function abnormally because of extrarenal factors. When azotemia occurs as a consequence of this situation, it is called *extrarenal azotemia.* Extrarenal azotemia may be the result of several factors. When it is due to increased generation of nitrogenous wastes or to faulty delivery of such wastes to the kidney, it is called *prerenal azotemia.* Extrarenal azotemia also may be due to impairment of flow of urine from the body; this is called *postrenal azotemia.* Some of the extrarenal factors affecting renal function are subsequently discussed. It is important in clinical medicine to be aware of such factors so that extrarenal causes of renal dysfunction are not confused with renal disease.

A. Diet and Protein Catabolism

Blood urea nitrogen (BUN) values of some species are modestly increased when protein intake of a normal animal is increased, apparently because of the generation of more urea (Watson *et al.,* 1981; Epstein *et al.,* 1984). The increase in BUN occurs despite the fact that a high-protein meal may increase GFR in dogs by up to 100% for several hours (Smith, 1951). Dietary protein intake also affects GFR in sheep, although the increase is not as large as in dogs (Rabinowitz *et al.,* 1973). The effects of diet on BUN and its relevance to clinical interpretation are discussed in Section VI. The effects of diet on the progression of preexisting renal failure are discussed in Section IV.

Tissue protein catabolism also has been incriminated as a cause of extrarenal azotemia. Some of these factors are discussed in Section VI.

B. Renal Perfusion

Because the kidney depends on hydraulic force generated by the cardiovascular system for filtration, it is not surprising that factors influencing glomerular perfusion pressure may alter renal functions. Because blood flow to the kidneys far exceeds the quantity required for sustaining renal tissues in a viable state, perfusion defects (ischemia) can influence renal excretory functions without causing renal damage. The degree and duration of renal ischemia determines whether renal dysfunction is accompanied by renal damage. Several diseases and conditions occur in which renal parenchymal damage does not occur, but prerenal azotemia develops because of a decrease in GFR. At the other extreme, complete occlusion of the renal artery for 4 hours under normothermic conditions results in ischemic necrosis of the kidneys that is irreversible (Hamilton *et al.,* 1948).

1. Systemic Circulatory Abnormalities

a. Dehydration

Dehydration can cause hypovolemia, which leads to impaired excretion of urea and creatinine secondary to reduced renal blood flow (RBF) and GFR. Dehydration azotemia was experimentally induced in dogs by controlled occlusion of the gastric pylorus. The dehydration that occurred secondary to vomiting caused reduced cardiac output, decreased RBF, and markedly reduced GFR. The pronounced effect on filtration occurred as a consequence of increased oncotic pressure of plasma proteins. The autoregulatory capacity of the kidney also was lost (Balint *et al.,* 1975; Balint and Sturcz, 1959; Balint and Fekete, 1960; Balint and Forgacs, 1965; Balint and Visy, 1965). Dehydration in dogs also may cause changes in intrarenal patterns of perfusion. Outer cortical flow may be preserved longer during the period of dehydration than inner cortical flow. In addition, sudden and intermittent periods of ischemia of 1 to 60 minutes in duration may occur in localized areas of the cortex during dehydration (Kirkebo and Tyssebotn, 1977).

b. Decreased Cardiac Output

Any cardiac disease causing decreased cardiac output has the potential to produce prerenal azotemia by affecting renal perfusion. Cardiac tamponade in dogs caused a fall in GFR, apparently because of decreased cardiac output (Mandin and Davidman, 1978).

In some instances, several factors may interact to cause a renal perfusion defect. For example, dogs with induced right atrioventricular valve insufficiency, pulmonic stenosis, and renal denervation had normal RBF during exercise. However, dogs with the same vascular defects but with renal nerves intact had RBF reduced to 30% of normal during exercise (Millard *et al.,* 1972).

2. Selective Renal Hypoperfusion

Dehydration and cardiac dysfunction sufficient to cause prerenal azotemia usually are easily detected clinically. By contrast, selective renal hypoperfusion cause by increased resistance in renal afferent arterioles may be clinically undetectible.

Hepatorenal syndrome is a term used to describe a condition in human beings in which hepatic failure leads to azotemia. In many instances, the azotemia is prerenal in cause, renal lesions are absent, and kidneys function normally when transplanted to people with-

out hepatic failure (Conn, 1973; Kew, 1972; Papper, 1975). The pathogenesis of the renal failure remains speculative, but roles for renal nerves (DiBona, 1984), cardiovascular dysfunction (Better, 1986), and a humoral agent (Levy, 1992) have been supported.

Because selective renal hypoperfusion is undetectible by routine clinical procedures, it is difficult to differentiate from acute renal failure.

C. Renal Outflow Impairment

Obstruction of urine outflow leads to azotemia because kidney function is affected by the obstruction. As is the case with prerenal factors, urinary obstruction may or may not cause injury to renal parenchyma, depending on the duration and severity of the obstruction.

1. Acute Effects—Unilateral Obstruction

Complete ureteral occlusion results in rapid changes in determinants of glomerular filtration. Due to occlusion, pressure within the proximal tubule increases rapidly to twice normal values. Within 5 hours pressure begins to decline, however, and by 24 hours it is normal or subnormal. The GFR decreases as intratubular pressure increases but it does not return to normal as intratubular pressure falls because afferent arteriolar constriction occurs, resulting in a decreased capillary hydraulic pressure. The afferent arteriolar constriction may be due to production of thromboxane by infiltrating cells and mesangial cells (Klahr, 1991). Despite complete ureteral occlusion, glomerular filtration does not completely stop because tubular reabsorption of filtrate accommodates formation of new filtrate (Klahr *et al.*, 1986).

2. Acute Effects—Bilateral Obstruction

With bilateral ureteral obstruction, the increase in intratubular pressure is greater and more sustained than with unilateral obstruction. The decrease in GFR that occurs with bilateral obstruction is due solely to the increase in intratubular pressure because normal values for intracapillary pressure are found (Klahr *et al.*, 1986). Another difference between unilateral and bilateral obstruction is that a diuresis occurs following release of bilateral obstruction, but not after release of unilateral obstruction.

3. Events after Release of Acute Ureteral Obstruction

Following release of unilateral obstruction, GFR remains decreased because of persistent vasoconstriction. Effects vary from nephron to nephron; some are filtering at a subnormal rate whereas others are nonfiltering. The GFR increases with time. One hour (3600 seconds) after release of unilateral ureteral obstruction of 18,000 seconds (5 hours) in duration in the dog, GFR of the affected kidney was 70% of normal (Vaughan *et al.*, 1971).

Tubular pressure declines after release of bilateral obstruction, but not to normal levels. Glomerular capillary pressures are higher than with unilateral obstruction and more nephrons are filtering, the net result being a higher GFR. Recovery of function depends on the duration of obstruction. Rats with 30 hours of bilateral ureteral obstruction had a return to nearly normal function after 5 days (McDougal and Wright, 1972).

Some events after release of acute bilateral obstruction may represent homeostatic responses of the kidney to alterations in body composition that occurred as a consequence of obstruction. Postobstructive diuresis is attributed to positive water and electrolyte balance and retention of nitrogenous wastes that accumulated during obstruction. However, renal dysfunction also may influence postobstructive events. Dehydrated cats that should be conserving water have impaired concentrating ability after relief of acute obstruction (Finco and Cornelius, 1977). Hypotheses to explain postobstructive diuresis include washout of the medullary hypertonic gradient, impaired response of the collecting ducts to ADH, and accumulation of atrial natriuretic factor (Klahr, 1991). An acidifying defect occurs in dogs following removal of acute, complete ureteral obstruction (Thirakomen *et al.*, 1976), which was not present in dogs studied after recovery (Kerr, 1956). After release of obstruction, cats with hyperkalemia may develop hypokalemia. The pathogenesis of the hypokalemia has not been studied, but it is presumed to be a consequence of transient renal dysfunction.

4. Function after Release of Chronic Obstruction

Postrenal azotemia may lead to primary renal azotemia because damage to the kidney during obstruction may be irreversible. The duration and degree of obstruction are two important factors governing the amount of renal damage. In dogs, 2 weeks of total unilateral ureteral obstruction resulted in 25% of original function immediately after release, and stabilization at 50% of function of the contralateral kidney at 2 months (Kerr, 1956). In another study in dogs, the duration of total obstruction was varied and maximum recovery of function was subsequently measured. Full recovery followed 7 days of obstruction, 70% recovery followed 2 weeks of obstruction, and 30% function followed 4 weeks of obstruction. Almost no function was recovered after 42 days of obstruction (Kerr, 1954).

In dogs, partial ureteral occlusion for 14 to 60 days resulted in 100% recovery of GFR with 14 days of occlusion, 31% with 28 days, and 8% with 60 days; recovery was measured 28 days after relief of obstruction (Leahy *et al.*, 1989).

IV. PRIMARY RENAL DYSFUNCTION

A. Acute Renal Failure

Acute renal failure can be defined as primary renal dysfunction of sudden onset. Clinically, it is important to differentiate acute renal failure from chronic renal failure because the acute disease is potentially reversible but the chronic form is not.

1. Causes

a. Ischemia

As previously indicated, perfusion defects that initially result in prerenal azotemia may progress to acute primary renal failure. Species differences may exist regarding vulnerability to ischemic renal damage. Experimental results suggest that the dog may not tolerate hypovolemia as well as the human being; dogs may succumb to shock rather than surviving to develop acute ischemic renal failure (Phillips *et al.*, 1946).

b. Drugs and Other Nephrotoxins

The kidney is particularly vulnerable to effects of noxious agents because of its high perfusion rate, its ability to concentrate many substances in the tubule lumen, and its high rate of metabolism. Many materials are nephrotoxic to domestic animals but nephrotoxic antibiotics may be the most common cause of acute renal failure. In addition, heavy metals, organic chemicals (ethylene glycol, carbon tetrachloride, chloroform, herbicides, pesticides), acorn poisoning, hemoglobin and myoglobin, and snake venom nephrotoxicity are described in animals (Kosek *et al.*, 1972; Churchill *et al.*, 1974).

c. Infectious Agents

Some infectious agents, such as *Leptospira* spp. may cause acute nephritis and acute renal failure (Low *et al.*, 1956). In domestic animals this cause is uncommon compared to nephrotoxic agents, but may occur occasionally. Infection of dogs with *L. grippotyphosa* has been reported, presumably because existing vaccines may not protect against this serotype (Rentko *et al.*, 1992).

2. Pathogenesis

Acute renal failure has been studied extensively in laboratory animals. Models of nephrotoxic acute failure have been produced with a variety of agents including glycol, uranium salts, mercury, or hemoglobin. Ischemic renal failure has been produced by clamping the renal artery or injecting epinephrine. Several theories have been proposed to explain the pathogenesis of acute renal failure. One theory is that impaired GFR is due to renal vasoconstriction. Another theory is that tubular blockage occurs as a consequence of intraluminal debris and interstitial edema. Another theory surmises that glomerular filtrate forms but is totally reabsorbed (passive backflow) because of tubular necrosis. Changes in the glomerular ultrafiltration barrier also have been postulated (Harrington and Cohen, 1975; Oken, 1975; Levinsky, 1977; Brezis *et al.*, 1986). Many paradoxes and contradictions can be found about the role of these factors when individual studies are compared, and it is apparent that no theory of pathogenesis has been proved to the exclusion of others. It is likely that different causes of acute renal failure have different pathogenetic mechanisms and that a unified theory of pathogenesis of acute renal failure for all causes is unrealistic.

B. Chronic Renal Failure

Chronic renal failure is often the consequence of slow, insidious destruction of renal parenchyma. The reserve capacity of the kidneys and ongoing compensatory processes that occur coincident with renal damage result in the absence of clinical signs until very little viable renal tissue remains. Thus, chronic damage to renal tissue is irreversible, and clinical improvement can be achieved only by removal of extrarenal factors which are superimposed on the renal disease, or by replacement of renal function by dialysis or renal transplantation.

1. Etiology

Causes of chronic renal failure in domestic animals remain poorly defined. Some causes (i.e., chronic pyelonephritis, chronic glomerulonephritis) have been identified in individual animals, but it is likely that other presently unidentified factors are responsible for most cases. An old theory derived from studies in rats blamed high dietary protein intake as a cause of renal failure, but this idea has been disproved (see next section).

2. Progression of Renal Failure

Progressive destruction of renal tissue has been presumed to occur because of persistence of the initiating cause. Because the cause is usually unknown, the hypothesis can rarely be tested. More recently it has been proposed that renal damage becomes a self-perpetuating phenomenon once functional renal mass

has been reduced to some critical level (Hostetter *et al.*, 1981). The self-perpetuation hypothesis implies that renal damage will be progressive despite disappearance or removal of the initial cause. In young dogs, reduction of renal mass by three-fourths was not associated with functional impairment or development of significant renal lesions in residual tissue after periods of up to 4 years (Bovee *et al.*, 1979; Robertson *et al.*, 1986). However, 11/12 or greater reduction of renal mass in dogs is associated with development of renal lesions in as little time as 3 months (Finco *et al.*, 1985; Polzin *et al.*, 1988). Lesions are similar to those observed in dogs with naturally occurring chronic renal failure. Some dogs with 15/16 reduction of renal mass have progressive decreases in GFR and develop uremia (Finco *et al.*, 1992). All of these observations support the hypothesis that renal disease is a self-perpetuating phenomenon in dogs, but only when renal mass has already been markedly reduced.

Several dietary factors have been hypothesized to influence the rate of progression of renal failure. Dietary protein has received the most attention as a potentially harmful nutrient. As previously indicated, increased protein intake causes an increase in GFR and RBF by causing afferent arteriolar dilation and an increase in hydraulic pressure within glomerular capillaries. With time, renal hypertrophy accompanies the increase in RBF and GFR and either the pressure or the hypertrophy have been incriminated as causes of renal damage. Although dogs with induced renal failure have increased glomerular capillary pressures (Brown *et al.*, 1990), several studies have failed to verify that high-protein diets cause decrements in renal function or structural damage to the kidneys (Finco *et al.*, 1992; Polzin *et al.*, 1993; Finco *et al.*, 1994). Caloric restriction has been documented as a protective factor in progression of renal failure in rats (Tapp *et al.*, 1989). A combination of protein and calorie deprivation was considered beneficial in cats with induced chronic renal disease but the role of protein versus calorie deprivation was not established (Adams *et al.*, 1992).

Intake of dietary phosphate also has been blamed for progression of chronic renal failure. Studies in dogs have demonstrated a benefit of phosphate restriction on survival and decline in GFR, but benefits on renal morphology and renal mineralization were not observed (Finco *et al.*, 1992). Theories explaining toxic effects of phosphate include tissue calcification, increased metabolic rate by renal tubule cells (Lau, 1989), and cell damage by uptake of calcium (Harris *et al.*, 1986).

3. Pathophysiology of Chronic Renal Failure

In contrast to the abrupt sequence of events in acute renal failure, most changes take place gradually during chronic failure. Insidious reduction of renal function goes undetected during the months or years prior to development of clinical and biochemical abnormalities. Many abnormalities are only apparent when GFR is reduced to less than one-third of normal.

a. Functional Adaptations

A compensatory response occurs in concert with tissue destruction so that remaining viable tissue maximizes its function. The damaged kidneys retain remarkable ability to attend to the functions which are required for water, electrolyte, and acid–base homeostasis. Individual nephrons respond to stimuli for homeostasis in an appropriate fashion, even though some morphologic abnormalities may be present. Thus, patients with chronic renal failure have no clinical and few detectable biochemical changes until most tissue is destroyed. These orderly and appropriate (i.e., "normal") responses by residual nephrons have been referred to as the *intact nephron hypothesis* (Bricker *et al.*, 1960; Bricker, 1969).

Several examples of adaptation and successful homeostasis by the diseased kidney are available. Single-nephron GFR (SNGFR) increases as renal mass is reduced. For example, SNGFR increased from 71 nl/minute in normal dogs to to 132.5 nl/minute in dogs with three-fourths nephrectomy and to 161.8 in dogs with seven-eights nephrectomy (Brown *et al.*, 1990). Despite the increased filtration by individual nephrons, whole body GFR is decreased because there are fewer functional nephrons. The decrease in GFR results in a decrease in filtration of blood components. If tubular adaptation to this decrease did not occur, blood components would be retained to accumulate in the body. A progressive increase in FE occurs for sodium, chloride, phosphate, and magnesium as GFR declines, resulting in clinically normal plasma concentrations until GFR is very low.

Another example of adaptation is an increased tubular secretion of potassium. Reduced GFR results in less potassium elimination via filtration; increased tubular secretion by residual functional nephrons prevents hyperkalemia until GFR is reduced drastically.

b. Morphologic Adaptations

Mature animals are incapable of generating new nephrons and thus adaptive mechanisms are restricted to altering existing ones. Hypertrophy is the major mechanism for structural adaptation, but hyperplasia also occurs in immature animals and in adults with a

greater loss of renal mass (Kaufman *et al.*, 1976; Larsson *et al.*, 1980; Van Urk *et al.*, 1978).

The events involved in compensatory change in existing nephrons begin very soon after reduction of renal mass. Increased incorporation of phospholipid into renal cell membranes is detectable 5 minutes after contralateral nephrectomy (Toback *et al.*, 1974). An increase in the ratio of RNA to DNA in tubular cells (hypertrophy) was noted 6 hours after contralateral nephrectomy of rats, and an increase in kidney weight occurred at 12 hours (Van Urk *et al.*, 1978). A marked increase in kidney weight exists 10 days after unilateral nephrectomy of dogs (Carriere and Gagnan-Brunette, 1977), but maximal increase in size does not occur until 8 weeks (Rous and Wakim, 1967). Dissection of nephrons of dogs with chronic renal disease indicates that hypertrophy involves a marked increase in glomerular size and in proximal tubule diameter and length (Oliver *et al.*, 1941).

Tubular cells are capable of producing and responding to several growth factors; these factors may be important in the process of hypertrophy (Fine *et al.*, 1992).

C. Consequences of Renal Failure

1. Uremia

The clinical signs associated with renal failure (uremia) may have multiple causes. An early concept was that the signs and effects of renal failure could be explained by the retention of a compound normally excreted by the kidneys. The success of hemodialysis in alleviating most signs of renal failure supported this idea. The culprits accused of being responsible for uremia include ammonia, uric acid, hippuric acid, leucine, tyrosine, sulfates, phosphates, chloride, potassium, acidosis, organic anions, indicans, guanidine and its derivatives (i.e., methyl guanidine, guanidinosuccinic acid), magnesium, phenols, aromatic oxy acids, urinary alkaloids, and hyperosmolality (Schreiner and Maher, 1961) as well as parathyroid hormone (Massry, 1977). However, no concensus has been reached that any of these factors alone is the uremic toxin. Urea and creatinine, although commonly used as indices of renal function, have little or no toxicity until blood concentration exceed levels commonly detected with renal failure (Giovannetti and Barsotti, 1975).

An alternate theory to explain signs of uremia is that a multitude of biochemical abnormalities that exist in extracellular fluid during renal failure result in abnormal cell metabolism, which is manifested as uremic signs (England and Mitch, 1993).

2. Clinical Signs of Uremia

Almost all body systems are affected by uremia. The nervous system is affected both centrally and peripherally. Cerebral dysfunction (depression) occurs in many species, and cattle grind their teeth. Uremic dogs had EEG alterations that correlated with increases in brain calcium levels after induction of uremia (Arieff *et al.*, 1975). In brain synaptosomes from rats with chronic renal failure, derangements in acetylcholine metabolism (Smogorzewki and Massry, 1993) and in calcium ATPase were found, but both were preventable by parathyroidectomy. Peripheral neuropathy also occurs with chronic uremia. Motor nerve conduction velocity is decreased in human beings in association with primary axonal degeneration and segmental demyelination (Raskin and Fishman, 1976).

The gastrointestinal tract is severely affected by uremia. Anorexia is common, and both acute and chronic renal failure may cause vomiting in carnivores. The vomiting may be partially inhibited by ablation of the chemoreceptor trigger zone in the medulla, suggesting a circulating factor as one cause (Borison and Herbertson, 1959). Chronic renal failure also may cause oral and gastrointestinal ulcers. The ulcers have been attributed to ammonia released by bacterial action on urea (Black, 1970). The gastrointestinal lesions may contribute to vomiting by initiating afferent impulses to the vomiting center. It is suggested that uremia causes abomasal atony in cattle (Divers *et al.*, 1982). Diarrhea or constipation also has been associated with renal failure. A typical "uremic breath" may be noted in patients with advanced renal failure. Studies in human beings indicate that dimethylamine and trimethylamine are responsible for this odor (Simenhoff *et al.*, 1977).

Endocrine, muscular, skeletal, cardiovascular, respiratory, ocular, and dermatologic signs also are described in uremia (Mujais *et al.*, 1986). Many signs attributable to these systems have been described in domestic animals, but they appear less common than the neurologic and gastrointestinal problems previously discussed.

3. Derangements in Water Homeostasis

Changes in urine volume have long been associated with renal failure. A very marked decrease in GFR is associated with oliguria or anuria. This may occur secondary to massive, sudden injury (acute failure) or as a terminal event with chronic failure. The effects of oliguria or anuria on water balance are dependent on water intake and extrarenal losses; fluid retention and edema are potential complications of oliguric or anuric renal failure.

Polyuria is a common sign observed with renal failure. The pathogenesis of the polyuria has been investigated to determine whether it was a consequence of renal damage or secondary to homeostatic changes in renal function dictated by reduced functional mass. Studies of dogs with unilateral renal disease produced by infection or aminonucleoside nephrosis indicated that the diseased kidney could concentrate urine as well as the normal kidney (Bricker *et al.*, 1959). Likewise, dogs with remnant kidneys could concentrate urine as well as normal dogs when the solute load was adjusted with urea to reflect GFR (Coburn *et al.*, 1965). Remnant kidneys also had the same ability to concentrate urine in the uremic as in the nonuremic environment (Morrin *et al.*, 1970). Thus, several lines of evidence indicate that the major cause of polyuria during renal failure is an adaptation occurring for purposes of homeostasis. However, a decrease in medullary interstitial hypertonicity occurs with renal failure (Eknoyan, 1977), which could be secondary to the diuresis and thus pathologic. Another factor favoring a role of renal damage is a diminished response of collecting ducts to ADH (Fine *et al.*, 1978).

Polyuria, although studied in models of chronic renal failure, may occur in acute renal failure as well (Anderson *et al.*, 1977). Some data from human beings indicate that more severe acute renal failure results in oliguria, but that less severe acute failure may result in polyuria (Brezis *et al.*, 1986).

Failure to dilute urine adequately also occurs in dogs with reduced renal mass (Coburn *et al.*, 1965). Nevertheless, some dogs with chronic renal disease may have hyposthenuria, presumably due to some retention of function by the ascending limb of the loop of Henle (Finco, 1979).

Inability to regulate water excretion predisposes the patient with polyuric renal failure to water imbalance. Dehydration is a common finding when water losses from polyuria are not replaced. Severe dehydration can cause prerenal uremia, which is then superimposed on existing polyuric renal failure.

4. Hematologic Abnormalities

A nonregenerative, normocytic, normochromic anemia often is observed in association with chronic renal failure. Anemia is frequently but not invariably present in dogs and cats when chronic azotemia is discovered.

Erythropoietin (EPO) is a glycoprotein probably produced by renal interstitial cells, which circulates to the bone marrow and stimulates erythrocyte progeners at several stages of maturation. EPO production is decreased during renal failure, and this deficit is primarily responsible for the anemia of chronic renal failure. The human gene controlling EPO synthesis has been cloned (Jacobs *et al.*, 1985) and EPO is commercially available. Use of human EPO in uremic dogs and cats has resulted in a significant increase in hematocrit, but in dogs some adverse reactions have occurred (Cowgill, 1992).

Although EPO deficiency is the major factor responsible for anemia during renal failure, serum from uremic animals contains factors that are directly toxic to bone marrow cell cultures (Lamperi *et al.*, 1974) or inhibitory to EPO (Wallner *et al.*, 1977). In addition, red cell survival time is shortened in uremic human beings (Naets, 1975). Some studies in dogs suggest that parathyroid hormone may shorten red cell survival (Akmal *et al.*, 1985), but other studies do not support this theory (Anagnostou and Kurtzman, 1986).

Abnormalities in leukocyte numbers and in platelet function also have been described in the uremic state (Anagnostou and Kurtzman, 1986). Platelet defects may cause clotting problems in uremic people; hemostatic abnormalities related to abnormal platelet adhesion also have been reported in dogs (Brassard *et al.*, 1994). Clinically, bleeding abnormalities are uncommon in uremic dogs, but are fairly frequent in cattle (Divers *et al.*, 1982).

5. Blood Chemical Effects

a. Plasma Electrolyte Concentrations

The homeostatic mechanisms previously described maintain plasma electrolyte concentrations in the normal range until GFR reaches very low levels. Control of some electrolytes may be better than others, and species variation may exist.

In dogs, plasma sodium concentration remains normal until terminal stages of chronic renal failure. Hyponatremia has been described in acute renal failure in cattle (Brobst *et al.*, 1978; Divers *et al.*, 1982), and in chronic renal failure in horses (Koterba and Coffman, 1981; Tennant *et al.*, 1982). The pathogenesis of the hyponatremia has not been well studied; possibilities include lack of sodium intake, sequestering of sodium, or dilution of sodium because of water retention.

In most species, plasma potassium concentration remains normal during the polyuric phase of renal failure, but hyperkalemia develops with oliguria or anuria. The life of the animal with anuria is threatened because of the cardiotoxic effects of hyperkalemia. In cattle with acute renal failure and cattle with bilateral nephrectomy, hypokalemia was common (Divers *et al.*, 1982). This finding was attributed to anorexia, increased salivary excretion of potassium, and impaired intestinal absorption (Watts and Campbell, 1970; Divers *et al.*, 1982).

In cats fed a commercial food with 0.35% potassium, renal failure, increased FE of potassium, acidosis, and hypokalemia occurred (Dow *et al.*, 1987). Polymyopathy also was observed in cats fed this diet. Subsequent studies incriminated ingestion of a low-potassium, acidifying diet in the renal dysfunction (Dow *et al.*, 1990).

Hypermagnesemia occurs in advanced renal failure in monogastric species, but it has received little attention clinically.

Calcium and phosphate metabolism are markedly altered during uremia, and are involved in the development of renal secondary hyperparathyroidism in monogastrics. Although all details are not known, it seems that early in the course of renal failure there is an analytically imperceptible hyperphosphatemia and hypocalcemia. The hyperphosphatemia is due to decreased GFR. The hypocalcemia may be a direct physicochemical effect of hyperphosphatemia (calcium $\times$ phosphate = constant), a deficiency of the active form(s) of vitamin D, or both. The hypocalcemia stimulates PTH release, which in turn induces phosphaturia by inhibiting renal tubular reabsorption of filtered phosphate. The enhanced phosphaturia results in normalization of plasma phosphate and calcium values, but PTH secretion must be maintained at the increased rate to sustain the effect. As renal function deteriorates, increased PTH secretion is required to maintain normophosphatemia (Slatopolsky *et al.*, 1971).

Although PTH affects renal excretion of phosphate in the manner just described, renal adaptation to hyperphosphatemia also occurs with PTH absent (Cramer and McMillan, 1980; Caverzasio *et al.*, 1982). The renal mechanisms for phosphate homeostasis, whether PTH dependent or independent, are effective in maintaining normophosphatemia unless renal dysfunction is severe. Hyperphosphatemia occurs at about the same level of renal dysfunction as does azotemia. When renal failure advances further, hypocalcemia may be present. The hypocalcemia has several causes, including impaired intestinal calcium absorption because of lack of renal hydroxylation of 25-hydroxycholecalciferol, precipitation of calcium from blood because of hyperphosphatemia, and skeletal resistance to the effects of PTH in mobilizing bone calcium.

Occasionally, hypercalcemia occurs during renal failure in both dogs (Finco and Rowland, 1978) and in horses (Tennant *et al.*, 1974, 1982). Caution must be used in interpreting total calcium values, since only the ionized portion of calcium is biologically active. During renal failure, accumulation of agents that chelate calcium may lead to increased plasma concentration of total calcium while ionized calcium is normal. However, there is evidence for increased ionized calcium as well. Studies indicate that the setpoint for PTH release is raised in dispersed cells from hyperplastic parathyroid glands (Brown *et al.*, 1982). Studies in dogs indicate that hypocalcemia may not be required for stimulation of PTH secretion (Lopez-Hilker *et al.*, 1986). These findings suggest that moderate hypercalcemia may be perceived to be appropriate by the hyperplastic parathyroid glands of some dogs in chronic renal failure.

Hypercalcemia in uremic horses may have a different cause. Normally the horse avidly absorbs ingested calcium from the gut and excretes the excess in the urine. With renal failure, renal excretion is impaired and hypercalcemia may ensue if dietary intake of calcium persists (Tennant *et al.*, 1982; Divers, 1983).

Plasma phosphate concentrations seem variable during renal failure in both cattle and horses, apparently because of the interplay between ingestion, renal excretion, and extrarenal excretion (Watts and Campbell, 1970; Koterba and Coffman, 1981; Tennant *et al.*, 1982; Divers *et al.*, 1982). The status of PTH secretion during renal failure in these species does not seem well established.

In species in which renal secondary hyperparathyroidism occurs, its effect on the skeleton may be dramatic. During uremia in the growing animal, bone growth is impaired and calcification is faulty. Pups may be "dwarfed" in size compared to littermates with normal renal function. Decalcification also occurs in the adult; "rubber jaw" syndrome may occur in some dogs and on rare occasions exostosis occurs (Norrdin, 1975).

b. Acid–Base Alterations

The prominent role of the kidneys in acid–base balance suggests that perturbations would be likely with renal dysfunction. Metabolism of the usual foodstuffs of carnivores and omnivores results in net production of protons that must be neutralized or excreted. A reserve capacity exists for these functions in health; compensatory hypertrophy that follows renal injury increases the capacity of individual nephrons to respond during renal disease. Effects of compensatory hypertrophy include enhanced proximal tubule bicarbonate reabsorption and ammonia generation, and enhanced proton secretion by the distal nephron. A consequence of these factors is that with generalized renal failure, acidosis usually does not develop until GFR is less than one-fourth of normal (Harris *et al.*, 1986).

The acid–base status of uremic ruminants may be different from that of carnivores. Although data are limited, it appears that a metabolic alkalosis occurs

fairly frequently in cattle, possibly in association with abomasal stasis (Brobst *et al.*, 1978; Divers *et al.*, 1982).

6. Metabolic Alterations Associated with Uremia

Several alterations in body metabolism have been noted as a result of renal failure. Glucose intolerance has been reported in dogs with induced renal failure (Swenson *et al.*, 1973; Akmal *et al.*, 1985) but this may be a terminal event (Finco *et al.*, 1994).

Alterations in serum lipids and lipid metabolism have been found in several species during renal failure. Hypercholesterolemia occurs in association with the nephrotic syndrome in several species. Increases in blood levels of very low density lipoproteins (VLDL), which are mainly triglycerides, have been found in non-nephrotic human beings and rats with chronic renal failure. The elevations are apparently due to increased liver production and decreased peripheral uptake of VLDL. A decrease in high-density lipoproteins in chronic uremia of man also occurs (Mujais *et al.*, 1986). Other than for hypercholesterolemia, the presence of lipid alterations during uremia in domestic animals has not been well examined.

Protein metabolism in renal failure is altered but the mechanisms are not all known. Animals with chronic renal failure often suffer from a caloric deficit and weight loss due to anorexia. Alterations that occur in protein metabolism may be due either to malnutrition itself or to the deleterious effects of uremia on metabolism. Plasma and intracellular profiles for free amino acids change with uremia (Mujais *et al.*, 1986). Both dialysis and dietary manipulation in man seem to normalize the amino acid profiles (Bergstrom *et al.*, 1975; Furst *et al.*, 1980).

Dietary manipulation of protein, amino acids, and amino acid analogs has been conducted in patients with renal failure for several reasons. These reasons include normalization of plasma and tissue amino acid profiles on the assumption that such normalization would be beneficial to the patient, protein restriction to avoid catabolism of amino acids and accumulation of nitrogenous wastes, reversal of the negative nitrogen balance observed with both acute and chronic uremia, and a halt to the progression of renal damage. Clinical observation supports restriction of dietary protein intake for alleviation of some signs of uremia, but other beneficial effects of dietary manipulations are not as well documented. Many conflicting studies are reported (Mitch and Walser, 1986).

7. Effects of Renal Failure on Drug Metabolism

Compromised renal function affects the excretion and, therefore, the blood levels of drugs that are normally excreted by this route. Plasma binding of drugs also may be affected by renal failure. In uremia, anionic drugs have decreased plasma protein binding, whereas cationic drugs have normal or increased binding (Reidenberg, 1976, 1977a). Plasma binding affects both distribution and renal excretion of drugs. In addition, biotransformation of drugs is altered during the uremic state (Reidenberg, 1977b). During uremia, drug oxidations by microsomal oxidative systems are normal or accelerated while reductions are slowed. These observations probably apply to domestic species, although made in experimental animals.

8. Effects of Uremia on the Immune System

Uremia causes suppression of the immune system in a variety of species. Both humoral and cellular factors are impaired (LoGrippo *et al.*, 1970; Souhami, 1973; Touraine *et al.*, 1975; Dobbelstein, 1976; Raskova and Morrison, 1978). Abnormalities are found in acute as well as chronic uremia but seem more severe in the latter. Several explanations have been given for the suppressed immune response, but none has been satisfactory. The degree of suppression of immunity seems to vary from patient to patient, but is generally mild.

V. URINALYSIS

Urinalysis usually is performed as a screening method for acquiring a large amount of information about several body systems, with minimal expenditure of resources. It also is performed specifically for evaluation of the kidneys. Its value in studying the kidneys is related to the detection of abnormal components in the urine that may be of renal origin (casts, protein) and to the relation of urine-concentrating ability to kidney function. In the subsequent discussion, emphasis is placed on the underlying principles and interpretations rather than on methodology.

Analysis of urine is conducted routinely on samples collected at random. Such collections offer convenience in obtaining the sample but have the disadvantage of sampling an unknown and possibly unrepresentative portion of total daily urine production. For example, a sample of urine obtained from a dog or cat in the postprandial period may be alkaline because of the alkaline tide that follows food ingestion, but a composite of daily production may be acidic. Likewise, analysis of 10 ml of urine of a daily output of 100 ml represents a 10% sample of daily urine components; a 10-ml sample of 1 liter represents a 1% sample.

Quantitative urinalysis has been used in people and advocated for use in dogs and cats (DiBartola *et al.*,

1980; Russo *et al.*, 1986). Although cumbersome, such measurements provide much more reliable information about daily urine composition. Because of their infrequent use, the subsequent discussion deals with urinalysis of random samples.

The specific gravity of random samples of urine should be considered when all other urinalysis tests are interpreted. Urine volume usually is inversely related to its specific gravity, and therefore urinary components are concentrated in urine of high specific gravity and diluted in urine of low specific gravity.

The method of collection of urine is of utmost importance in interpreting a urinalysis, and should be part of the urinalysis report. In that way, the urinalysis results can be properly interpreted beyond the time period of mental recall of the method of urine procurement. Spontaneously voided urine may contain bacteria and white blood cells (WBCs) that are normal constituents of the genitalia. In the normal animal, samples obtained by cystocentesis are devoid of bacteria, contain but few WBCs, but may contain abnormal numbers of red blood cells (RBCs) due to trauma of cystocentesis. Samples of urine obtained by catheterization are devoid of lower tract contamination if collected properly but may have increased numbers of RBCs due to iatrogenic trauma.

Urine samples should be obtained in clean containers, or sterile ones if microbial studies are desired. The sample should be analyzed within 30 minutes; if urinalysis cannot be performed within that time, the sample should be refrigerated to minimize changes in urine composition. Refrigerated specimens should probably be examined within 43,200 seconds (12 hours) (Osborne and Stevens, 1981). Refrigerated samples should be warmed to room temperature prior to analysis, particularly to avoid errors in specific gravity measurement if a urinometer is used.

A. Urine Color, Odor, and Turbidity

Urine color is normally yellow in all domestic species. The cause of coloration is reported to be urochrome, which is a combination of urobilin and urobilinogen with a peptide (Anonymous, 1965). The intensity of the color usually varies with the urine concentration; thus, concentrated urine is dark yellow, and dilute urine is pale yellow.

Abnormal constituents may alter the color of urine. Bilirubin or its degradation products may give urine a darker yellow color than normal. Hemoglobin or hematuria may impart a red or brown color, and myoglobin a reddish brown appearance. Some drugs or diagnostic reagents also may alter the color of urine.

Urine odor varies somewhat from species to species, and the specific reasons for the differences have not been well studied. Sex differences in urine odor within a species may also exist. Infection with urea-splitting organisms may result in a highly ammoniacal urine odor, and certain drugs may impart an odor to urine.

Turbidity of urine varies among species and among samples in the same individual. Horse urine is normally markedly turbid because of calcium carbonate content and from mucus originating from glands in the renal pelvis. Cow urine becomes turbid on standing because of calcium carbonate crystals. Dog and cat urine is often clear but may be turbid in the absence of abnormalities. Some abnormal components (cells, mucus, bacteria) or normal components present in excess amounts (crystals) also may cause turbidity.

B. Specific Gravity

As previously discussed, the amount of water in urine is determined by passive movement of water from tubules to the renal interstitium secondary to osmotic gradients. Osmotic forces are determined by numbers of particles per unit of solvent. Specific gravity is used to estimate the number of particles per unit of solvent. Making this estimate has clinical value since urine specific gravity may be "abnormal" under a variety of circumstances. However, caution must be exercised in interpreting urine specific gravity readings because of the homeostatic role played by the kidney in water balance. In times of ingestion of large amounts of water, urine specific gravity as low as 1.001 is normal because of the need to excrete water for homeostasis. In times of dehydration, a marked conservation of water is expected, and urine specific gravity is increased to the maximum possible for that animal. Thus, the "normal" range of specific gravity readings encompasses the extremes between maximal diluting and maximal concentrating capabilities and includes specific gravity readings that are considered abnormal.

Apart from the normal range, it is appropriate to consider the range of specific gravity readings appropriate for a species under existing environmental conditions and husbandry practices. Because carnivores and most herbivores do not normally overdrink, some concentration of urine is usually anticipated. Interpretation of urine specific gravity as normal or abnormal is facilitated by considering the state of water balance during the time the urine was excreted. A urine of low specific gravity produced by a dehydrated animal indicates abnormal water conservation by the kidneys. Several causes of low urine specific gravity have been identified in domestic animals. States in which dilute

urine may be produced in the dog are given in Table 17.3.

Some error exists in using specific gravity measurements made with a urinometer for estimating osmolality of urine. Specific gravity readings are a reflection not only of the number of particles but of their size and attraction for one another. Thus, protein may falsely elevate specific gravity by 0.001 per 400 mg/dl; glucose falsely elevates readings by 0.001 per 270 mg/dl (Wolf, 1969).

Refractometry has the advantages over urinometry of accuracy, simplicity, and the requirement of but a few drops of urine. With some refractometers, urine with specific gravity readings above 1.035 must be diluted (1:1) with distilled water to obtain readings. The actual specific gravity is obtained by doubling results to the right of the decimal point. Refractometry is the preferred method of measuring urine concentration because it is more accurate than urinometer readings and it is simpler to perform than osmometry. Osmometry is considered the definitive method of measuring solute–solvent ratios in urine since osmometers measure one of the colligative properties of urine (freezing point depression, vapor pressure). Whereas specific gravity readings are expressions of the relative density of urine compared to water, osmotic pressure readings are expressed as milliosmoles per kilogram of water. Normal serum osmolality in domestic animals is about 280–300 mOsm/kg. Urine values are discussed in Section VI.B.

TABLE 17.3 Causes of Dilute Urine in the Dog

Condition	Postulated or known pathogenesis
Overdrinking	Compensatory polyuria
Generalized renal failure	Osmotic diuresis, medullary washout, ADH refractoriness
Hepatic failure	Decreased urea production; toxic effects of hyperammonemia on tubules; primary polydipsia
Hyperadrenocorticism	Interference with ADH activity
Diabetes mellitus	Glucose diuresis
Diabetes insipidus	ADH deficiency
Nephrogenic diabetes insipidus	ADH-refractory tubules
Pyometra	Endotoxin effects on tubules
Hypercalcemia	Interference with ADH activity; later, renal failure
Pyelonephritis	Medullary washout
Postobstruction (urinary)	Osmotic diuresis; natriuretic hormone; renal damage
Hypoadrenocorticism	Natriuresis, medullary washout, ADH resistance
Potassium deficiency	Unknown
Hyperreninemia	Primary polydipsia, secondary polyuria
Fanconi syndrome	Osmotic diuresis

C. Urine Protein Determination

As previously discussed, a small amount of protein is present in the urine of all species. The amount found in normal urine is determined by the net result of normal leakage through glomerular capillaries, protein reabsorption by the proximal tubules, and addition of proteins to the filtrate as it passes through the tubules, pelvis, ureters, bladder, urethra, and genital tract. It is important to establish whether the degree of proteinuria is normal or abnormal. In the clinical laboratory, an effort is made to distinguish normal levels of protein in urine from pathologic proteinuria. A "negative" protein reaction is anticipated when amounts in urine are not large enough to be indicative of disease. A study of common methods used to detect proteinuria revealed that false-positive and false-negative results were obtained with all procedures (Thysell, 1969). This suggests that a degree of skepticism should exist in interpreting protein results.

Dipstick methods are in common use for the assessment of proteinuria in domestic animals. The procedure is dependent on color changes in tetrabromphenol blue at various protein levels. However, pH may also cause color changes. To keep pH constant, the reagent square is impregnated with buffer. In domestic animals, it appears that false-positive values occur frequently. This may be related to the pH dependence of the sticks and leaching of buffer from the strip by prolonged contact with alkaline urine. The sticks are also more sensitive to albumin than to globulins (Bowie *et al.*, 1977), and severe proteinuria due to globulins may give a false-negative reading. Difficulty in interpretation of the color change also appears to be a problem since, in one study, different readings were obtained by different technicians on the same urine (James *et al.*, 1978). In women with hypertension and pregnancy, dipsticks were considered to give an unacceptable number of both false-positive and false-negative results for proteinuria (Meyer *et al.*, 1994).

All urine samples should be evaluated by an alternate procedure if they are positive for protein by the dipstick procedure. The sulfosalicylic acid test and the nitric acid ring test are two semiquantitative methods that may be used. The sulfosalicylic acid test may give false-positive values with X-ray contrast media and large doses of penicillin, cephaloridin, and sulfisoxazole.

Semiquantitative methods of urine protein determination that are a part of routine urinalysis on random

samples may be inadequate in cases of equivocal proteinuria, or in cases where the measurement of daily urinary loss of protein is required. Quantitative methods of protein measurement must be combined with provisions for consideration of 24-hour urine output in order to increase the reliability of the assessment. For quantitative measurement of protein concentration, the Coomassie blue method (Bradford, 1976) is a simple spectrophotometric procedure that can be used. Quantitative measurement of urine protein excretion can be determined on 86,400-second (24-hour) urine collection periods but such collections usually require a metabolism cage and urinary catheterization to be assured of accurate collections. The 24-hour urinary excretion of protein by normal dogs has been measured (Table 17.4). The 24-hour urinary excretion of protein by normal cats was 17.4 ± 9.1 mg/kg/day (Russo *et al.*, 1986), 12.7 ± 1.6 (Monroe *et al.*, 1989), and 4.93 ± 1.34 mg/kg/day (Adams *et al.*, 1992); in 4- to 12-week-old kittens protein excretion was 2.54 to 11.39 mg/kg (Hoskins *et al.*, 1991).

An alternative to 24-hour collections is the determination of the urine protein-to-creatinine ratio (UP/C) on a random sample of urine, based on the following logic. Creatinine excretion can be expected to be fairly constant between 86,400-second (24-hour) periods except in animals with acute renal dysfunction or severe renal failure. The concentration of creatinine in urine depends on urine volume just as protein concentration does. With daily creatinine excretion being constant, proteinuria can be related to creatinine concentration, and the urine volume factor cancels,

$$\text{Urine P/C} = \frac{\text{U protein (mg/dl)} \times \text{U volume (ml)}}{\text{U creatinine (mg/dl)} \times \text{U volume (ml)}} = \frac{\text{Protein}}{\text{Creatinine}} = \text{P/C ratio},$$

where U is urine; P, protein; and C, creatinine. The use of urine P/C ratio allows more precise evaluation of proteinuria than determination of protein concentration on a random sample, and a good correlation between values obtained between 10 A.M. and 2 P.M. versus 24-hour collections has been found in dogs (White *et al.*, 1984). Subsequent studies revealed excellent correlation between samples taken randomly throughout the day (Grauer *et al.*, 1985) as well as day versus night (McCaw *et al.*, 1985). Significant differences were not found between urine samples collected by voiding (midstream), cystocentesis, or catheterization (Barsanti and Finco, 1979). However, in both dogs and cats, voided urine from males had a higher protein concentration than that from females (Barsanti and Finco, 1979; Monroe *et al.*, 1989). Increased dietary protein intake significantly increased UP/C in both normal and remnant kidney cats (Adams *et al.*, 1992), but effects of dietary protein in dogs is equivocal (Jergens *et al.*, 1987). Because dietary protein may affect GFR, and thus creatinine clearance, confounding factors (creatinine excretion, protein leak) may affect overall results. As expected, hemorrhage and inflammatory disease of the urinary tract increased the UP/C values (Bagley *et al.*, 1991). Values for UP/C in normal dogs and cats are <0.5 when both protein and creatinine are expressed as mg/dl; values above 1.0 are clearly abnormal (Lulich and Osborne, 1990).

TABLE 17.4 Twenty-Four-Hour Protein Excretion by Normal Dogs

Author	Analytical method	No dogs	Protein excretion (mg/kg/24 hours)	
			Mean	Range
Barsanti and Finco, 1979	Coomassie blue	10	7.0	2.4–19.7
Barsanti and Finco, 1979	Ponceau S	10[a]	3.8	0.8–15.1
Biewenga *et al.*, 1982	Ponceau S	29	6.6	2.7–23.2
White *et al.*, 1984	Ponceau S	8	4.8	1.9–11.1
McCaw *et al.*, 1985	Coomassie blue	14	7.7	1.8–22.4
Grauer *et al.*, 1985	Coomassie blue	16	2.3	0.6–5.1
Center *et al.*, 1985	Turbidometric	19	2.5	0.2–7.7

[a] Same dogs as Barsanti; Coomassie blue method.

Once it has been established that the magnitude of proteinuria is abnormal, its source and cause should be considered. Proteinuria in the absence of RBCs or inflammatory cells is usually of renal origin and may be due to a glomerular leak or to a lack of proximal tubular reabsorption, or both. Proteinuria in the presence of RBCs and WBCs in the urine is difficult to interpret. Hemorrhage is associated with direct leakage of RBCs and plasma proteins; the presence of WBCs implies inflammatory responses with potential leakage of plasma proteins. When RBCs or WBCs are present and the protein reaction is positive, the possibility of concomitant disease at separate sites or of differing causes exists. It may be necessary in such instances to eliminate the cause of the WBC or RBC and establish whether proteinuria disappears or persists.

In human beings, proteinuria is reported in such conditions as fever, passive renal congestion, and the biped postural stance in the absence of renal or urinary tract disease (Rubin and Balish, 1971). In beagle dogs, neither running nor swimming caused an increase in proteinuria comparable to that observed in pathologic processes (Huisman *et al.*, 1982; Joles *et al.*, 1984).

Proteinuria has been classified into types in human beings (Hardwicke, 1975), and the same types exist in domestic animals. Overflow proteinuria occurs as a consequence of increased levels of low-molecular-

weight proteins in the blood. Such proteins pass through the normal glomerular filter and appear in the urine when tubular resorptive mechanisms are saturated. Newborn calves may have proteinuria as a consequence of absorption of proteins of colostrum from the gut into the blood. Low-molecular-weight components are subsequently lost in the urine. The proteinuria disappears when gut absorption of protein ceases after the first few days of life (Pierce, 1959, 1961). The appearance of Bence Jones light-chain proteins in the urine of animals with multiple myeloma is another example of overflow proteinuria. These proteins may not be detectable by conventional urine protein methods but are detectable by urine electrophoresis.

Glomerular proteinuria occurs as a consequence of injury to glomeruli. Amyloidosis and glomerulonephritis are two broad catagories of disease in domestic animals which cause glomerular proteinuria. The defect in the filter may vary in magnitude among diseases or in the same animal at different stages of disease. Glomerular proteinurias are often relatively selective so that albumin is the main component of the urinary protein. Severe proteinuria in the absence of RBCs and WBCs is usually of glomerular origin. Tubular proteinuria occurs as a consequence of normal passage of low-molecular-weight proteins through the glomerular filter combined with defective tubular reabsorption. Proteins in the urine of these patients are predominantly low-molecular-weight globulins, and amino acids may also be present (Fanconi syndrome). Basenji dogs with glucosuria, aminoaciduria, and proteinuria probably have this type of abnormality. In general, tubular proteinurias result in mild to moderate protein loss (Rubin and Balish, 1971).

A high-molecular-weight mucoprotein (Tamm–Horsfall mucoprotein) has been isolated from the normal urine of several species, including dogs and cats (Lewis *et al.*, 1970; Schenk *et al.*, 1971). This mucoprotein is apparently secreted by cells of the ascending loop of Henle and the macula densa portion of the distal tubule. It is believed to be a component of some urinary casts. Its concentration in the urine is normally too low to be detected by semiquantitative screening methods.

D. Occult Blood Reactions

The dipstick method used for the detection of blood is highly sensitive and fairly specific. It detects both myoglobin and hemoglobin. The positive reaction is due to the peroxidase activity of the heme molecule. Hydrogen peroxide in the strip is converted to oxygen, which then oxidizes *o*-tolidine to cause the formation of a blue color. Microbial peroxidase or oxidizing contaminants such as H_2O_2 or sodium hypochlorite may cause false-positive reactions.

A positive occult blood reaction on urine indicates either leakage of free hemoglobin through glomeruli (hemoglobinuria), of myoglobin through glomeruli (myoglobinuria), extravasation of RBCs directly into the urogenital tract (hematuria), or of contaminants previously listed. The size and shape of the hemoglobin molecule are such that a small percentage of hemoglobin in the plasma that is unbound to haptoglobin passes the glomerular filter and appears in urine. This occurs in diseases in which intravascular hemolysis is occurring. Hemorrhage anywhere from glomerular capillaries to the tip of the genitalia may cause hematuria; thus, its presence should not be considered a localizing sign. Attempts have been made in humans to localize the source of hematuria by examining red cell morphology (Offringa and Benbasset, 1992) and by the coincident excretion of red cells and specific urinary proteins (Guder and Hofmann, 1993) but such methods have not been applied to domestic animals.

Differentiating hemoglobin from myoglobin in urine requires a special analysis since sequestered blood may have the same color as myoglobin (Glauser *et al.*, 1972). Differentiating hemoglobinuria from hematuria may be difficult, but the following observations are helpful. With hemoglobinuria, plasma may also be observed to have hemolysis. The urine may be clear red with hemoglobinuria but cloudy red with hematuria. The urine sediment may have no RBCs or a disproportionately low number of RBCs with hemoglobinuria. Care must be exercised to distinguish intravascular hemolysis from hemolysis of RBCs once they are in urine. Red cells may hemolyze in urine of low osmolality (Vaughan and Wyker, 1971).

E. Glucosuria

Dipstick procedures use the glucose oxidase method of glucose measurement. This enzyme converts glucose to gluconic acid. In the presence of hydrogen peroxide and peroxidase incorporated into the strip, an indicator in the strip (o-tolidine) is oxidized to cause a color change. Although the method is specific for glucose compared to other sugars, contamination of urine with H_2O_2 or sodium hypochlorite can cause false-positive reactions. Conversely, ascorbic acid and formaldehyde in urine may prevent positive samples from giving a positive reaction (Mayson *et al.*, 1972). Because of the enzymatic basis for the test, temperature affects the speed of the color change, and it is important that the test be done with components at room temperature.

The strip is not sufficiently sensitive to detect the small quantity of glucose found in the urine of normal animals but gives positive results when glucose concentration is 0.56 mmol/liter (10 mg/dl) or more (Mayson *et al.*, 1972).

Glucosuria occurs when the renal tubular maximum for reabsorption from filtrate is exceeded. This may occur with any cause of hyperglycemia or with decreased tubular glucose reabsorptive capacity. Generally, hyperglycemia greater than 10 mmol/liter (180 mg/dl) results in glucosuria, but the flow rate of fluid through the tubules and the nephron heterogeneity with regard to resorptive capacity are also factors. Common causes of hyperglycemia sufficient to cause glucosuria are parenteral therapy with dextrose and diabetes mellitus. Any cause of the Fanconi syndrome may result in glycosuria during normoglycemia because faulty renal tubular reabsorption occurs with this syndrome.

F. Urine pH

The pH of urine usually is determined by renal regulation of blood bicarbonate and H^+ levels. Since pH is a measure of free ions, the actual amount of acid being excreted by the kidney depends not only on pH, but on the amount of undissociated hydrogen present in urine buffers. The titratable acidity of urine is defined as the amount of base required to titrate urine back to the pH of blood. Measurement of titratable acidity and H^+ excreted as NH_4^+ gives an estimate of hydrogen ion excretion, while urine pH does not. Nevertheless, measurement of urine pH is useful since unusual results provide one with insight concerning many abnormalities. The urine pH of domestic animals usually is determined by dietary generation of acid. Animals on diets of high animal protein content usually have acidic urine, whereas those on cereal diets or mostly forages have neutral or slightly alkaline urine. Anorexia usually results in acid urine in all species. The extremes of urine pH values in domestic mammals are 4.5 to 8.5.

Some generalizations can be made about the acid–base status of an animal by measuring urine pH, but the generalizations must be qualified by many exceptions. A very low (acidic) urine pH implies a large excretion of H^+ by the kidneys. Whether this excretion has adequately maintained blood pH and bicarbonate values cannot be ascertained by urine pH measurement alone. Likewise, a high (alkaline) urine pH may indicate a need to conserve H^+ and excrete bicarbonate in order to maintain an acid–base balance. Whether the kidneys were successful in this endeavor can only be determined by blood pH and plasma bicarbonate determinations.

Generalizations about acid–base status from urine pH must take the state of renal function into consideration. Impaired ability of the kidneys to manipulate bicarbonate or excrete H^+ can lead to abnormal acid–base states which are not reflected in urine pH values. With chronic generalized renal failure of carnivores and omnivores, urine pH is usually moderately to markedly acidic when acidosis is present. Proximal renal tubular acidosis and distal renal tubular acidosis are two groups of abnormalities of human beings that probably exist in several species of domestic animals. In proximal tubular acidosis, renal reabsorption of bicarbonate is faulty. This may initially cause alkaline urine, but it soon becomes acidic as the plasma bicarbonate level and the filtered load of bicarbonate fall while normal distal H^+ secretion persists. With distal tubular acidosis, proximal bicarbonate reabsorption is normal, but distal acidification is faulty, so that urine pH is acidic but greater than 5.3 (Thier *et al.*, 1977).

Urine pH may be altered by bacterial contamination after urine is procured. Acidification or alkalinization may occur depending on the end products of metabolism of the contaminating organism. Urine pH does not change in sterile urine stored at room temperature for several hours (Finco, 1979).

Aciduria during alkalemia occurs in the vomiting dog; this paradox may be associated with anion reabsorption, as previously mentioned.

G. Acetonuria

Ketone bodies refer to acetoacetate, β-OH-butyrate, and acetone. These compounds are products of fat degradation; the quantity produced is markedly increased under conditions in which oxidation of fats provides the bulk of the energy. Ketone bodies appear in filtrate and are reabsorbed by the tubules until the T_m is exceeded. Under normal conditions, very low plasma levels of ketone bodies exist, and they are absent from the urine. Species differences exist regarding circumstances under which ketone bodies appear in the urine. They are commonly found in the ruminant during starvation, but rarely in the dog and cat. Diabetes mellitus is the disease classically associated with ketonuria.

The urine ketone reaction is based on the reaction of acetoacetic acid or acetone with nitroprusside. No reaction occurs with β-OH-butyrate. False-positive reactions may occur with BSP, phenyl ketones, or L-dopa metabolites.

H. Bile Pigments in Urine

The interpretation of bilirubinuria or urobilinogenuria is discussed in another chapter.

I. Urine Sediment

1. General Considerations

The examination of urine sediment is the single most important part of urinalysis. Because this process is slightly more time consuming than the dipstick analysis, there may be a tendency among veterinarians to perform only dipstick tests and specific gravity determinations. This approach is inexcusable considering the value of sediment examination and the false sense of security that is left when urinalysis is reported to be done but sediment is not examined.

Quantitative overinterpretation of the sediment is another problem. Although the analyzer provides numerical values for many microscopic findings (i.e., number of cells, casts, etc., per low-power or high-power field) the many variables that influence these counts must be kept in mind. Early studies of urine sediment in human beings were made to determine the 86,400-second (24-hour) urinary content of various elements. Few studies have been reported in domestic animals, and so our concept of normal versus abnormal is based on the examination of random samples of urine and the interpretation of normal on semiquantitative bases. Some of the variables that influence the concentration of elements in urinary sediment include the volume of the urine used, how that volume relates to daily urine production, the period of time between formation of urine and its examination (some components disintegrate crystals may form), the speed and time of centrifugation, the volume used to resuspend the sediment for viewing, the volume of suspension used to prepare the slide, and the thickness of the slide preparation. Each laboratory must standardize its procedure and define the limits for normal with those procedures in order to obtain meaningful results.

An acceptable procedure is to centrifuge 5 ml of urine in a conical tube for 5 minutes at 700 *g*. Although the speed of centrifugation for urine sediment examination is often stated as revolutions per minute, this value is meaningless for determining force unless the length of the centrifuge arm is known. The supernatant fluid is removed except for 0.5 ml, which is used to gently resuspend the sediment. One drop is placed on a clean slide, and a 22-mm^2 coverslip is placed on the drop. After 1 minute to allow for sedimentation, the slide is scanned under low power (×100) with reduced light. Final identifications are usually made at ×440 under reduced light. At least 10 fields should be counted and numbers of elements averaged (Duncan and Prasse, 1976).

Several stains for urinary sediment are available commercially. The experienced technologist generally finds these stains unnecessary, but they may be helpful to the novice. New methylene blue stain may be used by mixing a drop directly with the sediment. However, cellular elements do not always take up the stain. Heat-drying of the slide with subsequent application of stain gives a better stain. Neither type of stained slide should be used for semiquantitative measurements since the concentration of components in the sediment has been altered by the manipulations.

Components of urinary sediment decompose with time, depending on conditions. For example, casts are likely to solubilize in alkaline urine. Urine sediment should be examined as soon as possible after urine is obtained to minimize errors in interpretation of urinalysis.

2. Epithelial Cells

These cells are normal components of urine sediment. Their number may vary depending on the presence of inflammation or degeneration, neoplasia, and the method of urine collection. The concept that the site of origin of epithelial cells can be deduced from their morphological character appears to have been borrowed from human medicine. A study in dogs and cats revealed that neither the presence of, nor specific morphologic characteristics of transitional cells, caudate cells, or squamous epithelial cells could be used to localize their source in the urogenital tracts (Batamuzi and Kristensen, 1995).

Epithelial cells in sediment have little diagnostic significance in themselves. It is necessary to correlate their presence with other findings in the urinalysis or with other studies in the animal.

3. Casts

Casts are cylindrical structures that are formed from cells, cell fragments, and macromolecules that are present in the lumens of renal tubules. They conform to the shape of the lumen from which they originate. When relatively intact RBCs, WBCs, or epithelial cells make up the bulk of the cast, they are identified by reference to these cells. Hyaline casts are clear, structureless, colorless objects barely discernible from the background. Immunofluorescence studies have revealed that hyaline casts from human patients are made up of Tamm–Horsfall mucoprotein but do not contain serum proteins (Orita *et al.*, 1977). One study suggested that adherence of mucoprotein was essential for cast formation (Lindner and Haber, 1983). Granular

casts are homogenous in appearance except for the presence of small (fine) to large (coarse) granules. Some immunofluorescence studies revealed that the granules are composed of fractions of various serum proteins (Rutecki *et al.*, 1971; Orita *et al.*, 1977). These findings contradict those of others, who concluded that granules in casts were remnants of tubular epithelial cells (Relman and Levinsky, 1971). In another study it was concluded that subtypes of granular casts exist; type I were from leukocytes; type II were from renal tubular epithelial cells; type III were from unidentified mucopolysaccharides; and type IV were from bacteria (Lindner *et al.*, 1983). Waxy casts are similar to hyaline casts except that they are distinctive because of a hard, refractile outline. They are believed to be degenerative stages of cellular casts.

The size of casts appears to be related to their site of formation. Small-diameter casts are probably of more proximal origin, whereas broad casts are likely to be of collecting duct origin.

Some of the conditions conducive to cast formation have been identified. Tamm–Horsfall mucoprotein is readily precipitated by highly acidic urine pH and by high electrolyte concentrations (McQueen and Engel, 1966). Thus, casts are often formed in acidic urine and may be dissolved *in vitro* by alkaline urine. Rate of urine flow also seems to be a factor, with slow flow in the distal segments of the nephron favoring cast formation.

The presence of casts in the urine is interpreted as an indication of abnormal concentrations of their precursors in the tubular lumens. Thus, proteinuria, pyuria, hematuria, and cell desquamation of renal origin may provide the material for cast formation. Urine flow rate and pH are factors that interact with these components.

A few casts per low-power field are considered normal. Data for domestic animals are not available, but in normal human beings 5000–10,000 casts are excreted per day (Relman and Levinsky, 1971). Most of the casts normally found are of the hyaline type.

4. Crystals

Several types of crystals may appear in the urine of domestic animals. These may be categorized as one group which is formed from normal components of urine and another group which originates from exogenous compounds, abnormal metabolism, or abnormal excretion.

The formation of crystals from compounds normally in the urine occurs as a consequence of physiochemical factors, such as changes in urine concentration or pH. Many components of urine are present in a supersaturated state; disruption of this state results in precipitation of its components. Phosphate crystals in dogs and cats and carbonate crystals of cattle and horses fall in this category. They reflect conditions of urine formation and their presence should not be interpreted as abnormal. Since dalmatian dogs normally excrete urates as well as allantoin as end products of purine metabolism, urate crystals also are normal for this species. Bilirubin crystals may also be normal in concentrated urine specimens.

Abnormal crystalluria usually is indicated by the presence of the remaining crystals listed in Table 17.5. Ammonium biurate and tyrosine crystals are observed in canine urine in association with hepatic dysfunction, oxalate and hippuric acid crystals may be observed in some cases of ethylene glycol toxicity (Thrall *et al.*,

TABLE 17.5 Components of Urinary Sediments

1984; Kramer *et al.*, 1984), and sulfonamide crystals may be observed after therapy with these drugs.

5. Miscellaneous Components

Other constituents of urine sediment that are considered normal include lipid droplets, which are particularly common in dog and cat urine. Spermatozoa are normal in urine from the male and may be present in urine obtained from dogs by cystocentesis (Hubbert, 1972). Mucous threads and amorphous debris vary considerably from one urine sample to another within a species. No specific pathologic significance seems to be attached to their presence.

6. Infectious Agents

Infectious agents may appear in the urine as a consequence of contamination of normal urine during collection, infection localized to the genitourinary tract, or occasionally polysystemic infection, which includes the urinary tract.

The presence of bacteria in urinary sediment must be interpreted with caution because of possible contamination of urine during or after procurement. Conversely, cocci are difficult to visualize by examination of urinary sediment and their presence may become apparent only with culture of the urine. Mycotic agents in the urine are usually contaminants or evidence of polysystemic infection.

Parasite ova in the urine usually present no diagnostic problem. Occasionally, ova of enteric origin may contaminate voided urine and must be distinguishable from the parasites listed in Table 17.5.

VI. TESTS OF RENAL FUNCTION

A. Tests for Azotemia

Blood, serum, or plasma urea (expressed as urea, or urea nitrogen) and serum or plasma creatinine concentrations (SC) are used as indices of retention of nitrogenous wastes by the kidneys. The quantity of urea in blood may be expressed in terms of the entire urea molecule (blood urea) or in terms of only the nitrogen portion (BUN). Blood urea and BUN levels are related on the basis of molecular weight (60 versus 28, respectively). Thus, BUN values are only 0.47 of blood urea levels.

An understanding of the genesis, metabolism, and excretion of urea and creatinine should aid in their assessment as renal function tests. The subsequent discussion summarizes information obtained in domestic animals and humans.

1. Urea Metabolism

Small quantities of urea are ingested in animal foodstuffs because urea is present in all tissues of mammals. Urea also enters the gut in pancreatic secretions (Altman and Dittmer, 1971) and secondary to water movement into the intestines. Little or no urea is found in the stool of azotemic human beings (Brown *et al.*, 1971), so urea is either well absorbed or it is metabolized as it passes through the gastrointestinal tract.

Urea synthesis provides a mechanism for excretion of ammonium. The urea cycle incorporates two molecules of ammonium into each urea molecule. Formation of urea is an energy-requiring reaction, which occurs almost exclusively in the liver (White *et al.*, 1973). Although apparently rare in domestic animals, biochemical defects in the urea cycle were found in a dog with signs of hyperammonemia (Strombeck *et al.*, 1975).

Protein is the major source of ammonium for urea synthesis, and thus the rate of urea formation depends on the rate of protein (i.e., amino acid) catabolism. An increase in BUN may reflect an accelerated rate of protein catabolism rather than decreased urinary excretion of urea. In a study involving 14 clinically normal dogs fed diets of known protein content for 3 days, blood urea decreased from 5.71 mmol/liter (BUN = 16.0 mg/dl) with an 8.5% protein diet to 4.89 mmol/liter (BUN = 13.7 mg/dl) with a 5% protein diet. Preprandial and 4-hour postprandial studies indicated that blood urea increased from 4.89 to 5.71 mmol/liter (BUN = 13.7 to 16.0 mg/dl) with the 5% protein diet and from 5.71 to 9.57 mmol/liter (BUN = 16.0 to 26.8 mg/dl) with the 8.5% protein diet (Anderson and Edney, 1969). In another study, blood urea was elevated for 10–18 hours after food ingestion (Street *et al.*, 1968). The degree of elevation of blood urea in these studies was probably not clinically important since the normal canine range of 3.57–10.71 mmol/liter (BUN = 10–30 mg/dl) was not exceeded. However, higher protein diets could feasibly cause clinically important increases, and thus an 18-hour fast has been recommended to eliminate the influence of diet on BUN (Street *et al.*, 1968). Patients with marginal renal function and impaired urea clearance may have a greater increase in BUN as a result of diet than normal animals. For this reason, patients with an elevation of BUN that decreases into the normal range with fasting should have their renal function evaluated with more sensitive tests.

The rate of urea formation may be more rapid in cattle than in dogs or people. Nephrectomized cattle had a more rapid increase in BUN than was reported for other species (Watts and Campbell, 1970). The role

that rumen metabolism of urea played in the BUN values has not been established.

Any process inducing protein catabolism can result in an increased BUN. In man, specific causes include (1) hemorrhage into the small bowel with digestion, absorption, and catabolism of amino acids; (2) fever; (3) burns; (4) corticosteroid administration; (5) starvation; (6) infection; and (7) tetracycline administration (Dossetor, 1966; Kopple and Coburn, 1974; Shils, 1963). The magnitude of increase in BUN associated with enteric hemorrhage is apparently related to the amount of hemorrhage. Hypovolemia associated with hemorrhage or dehydration may lead to concomitant prerenal retention of nitrogenous wastes, as previously discussed (Section III). Administration of large amounts of whole blood by gavage to dogs with reduced renal function caused a detectible but not massive increase in BUN (Finco, 1995), suggesting a minor role for intestinal hemmorhage as a cause of prerenal azotemia in dogs. Fever apparently results in increased BUN because of increased tissue catabolism. The magnitude of increase in BUN with burns is infrequently stated, but one human being with 50% third-degree burns had blood urea values of 21.4–28.6 mmol/liter (BUN of 60–80 mg/dl) coincident with a normal SC (Dossetor, 1966).

The effect of corticosteroids on BUN was determined in a study comparing azotemic human renal transplant recipients given prednisolone with chronic renal failure patients of comparable dysfunction who had not been given corticosteroids. The SC was from 177 to more than 442 mmol/liter (2–5 mg/dl) in both groups. Patients treated with an average of 70 mg prednisolone per day had BUN values from 1.5 to 2 times that of azotemic patients not given corticosteroids (Kopple and Coburn, 1974). Dogs with a transplanted kidney treated with prednisone and azathioprine had larger BUN-to-creatinine ratios than dogs with induced renal failure, suggesting that catabolic drugs or catabolic events affect BUN in dogs as well (Finco *et al.*, 1984).

Starvation was reported in a man in which SC was 62 mmol/liter (0.7 mg/dl) and blood urea was 89.3 mmol/liter (BUN 250 mg/dl). The BUN decreased to normal with an adequate diet (Kumar *et al.*, 1972).

Administration of tetracycline to azotemic human beings was followed by acidosis, anorexia, vomiting, and weight loss. The BUN and serum phosphorous concentration increased, but the SC remained unchanged. Patients without renal compromise given tetracycline at the same dosage did not develop these symptoms. Because SC was not altered by tetracycline in the azotemic group, it was concluded that the increase in BUN was due to protein catabolism rather then nephrotoxicosis (Shils, 1963). Six dogs with impaired renal function given tetracycline at a dose of 50 mg/kg body weight TID had no significant change in BUN, although two dogs had moderate increases in both BUN and creatinine while remaining clinically normal. These results were interpreted as reason for caution when using tetracycline in dogs with azotemia, because of potential renal effects (Finco, 1995).

Nonrenal factors reported to cause decreased BUN values are (1) anabolic steroids, (2) diminished protein intake, and (3) severe hepatic insufficiency. Anabolic steroids apparently prevent the increase in BUN associated with the use of tetracycline in man (Shils, 1963).

The ingestion of decreased quantities of high-quality protein results in decreased BUN because nearly all ingested protein is used for protein synthesis. However, inadequate caloric intake coincident with low protein intake may not result in decreased BUN because the protein ingested may be catabolized for energy. Conversely, intravenous administration of large quantities of amino acids and adequate amounts of nonprotein sources of energy to azotemic human beings and dogs results in anabolism and decreased BUN (Abel *et al.*, 1973; Van Buren *et al.*, 1972). Thus, the fate of amino acids (i.e., protein anabolism versus catabolism) as well as their quantity must be considered in relating diet to BUN.

Acid–base status may influence the rate of BUN increase in acute renal failure. Rats made azotemic by ureteral ligation that had acidosis prevented (blood pH 7.32) by treatment with sodium bicarbonate had blood urea values of 79.6 mmol/liter (BUN 223 mg/dl). Untreated rats and physiological saline-treated rats had blood pH values of 7.04 and blood urea values of 106.7 and 108.2 mmol/liter, respectively (BUN 299 and 300 mg/dl, respectively) (Simon and Luke, 1971). Other studies in rats documented that acidosis stimulated protein catabolism *in vivo* as well as in isolated muscle preparations (Mitch *et al.*, 1994).

Vigorous prolonged exercise (cross-country ski racing) in human beings caused about a 60% increase in BUN. During racing, production rates of urea increased 60–80% over resting values, and urinary excretion of urea was reduced (Refsum and Stromme, 1974).

Once formed, urea is carried from the liver via the vascular system and passively diffuses throughout total body water. Urea administered to nephrectomized dogs reached equilibrium with body fluids within 5400 seconds (1.5 hours) (Schloerb, 1960). Brains of dogs with induced acute uremia had equal blood and brain concentrations of urea (Arieff *et al.*, 1975), indicating that urea passes the blood-brain barrier in the azotemic patient.

2. *Urea Excretion*

a. Extrarenal

Most urea is excreted by the kidneys, but lesser routes of excretion have been identified. In clinically normal human beings, studies with isotope-labeled urea indicated that at least 25% of the urea synthesized is subsequently degraded by enteric organisms (Walser and Bodenlos, 1959). Bacterial ureases catalyze the breakdown of urea to ammonia and carbon dioxide. When enteric bacteria were killed by oral administration of neomycin, nearly all ^{14}C-labeled urea given orally was recovered in the urine. In azotemic human beings, the number of strains of anaerobic bacteria that produce urease increases as BUN increases (Brown *et al.*, 1971). The hydrolysis of urea, and presumably hydrogen ion trapping by ammonia, results in a pH of the colon that is higher in acidotic, uremic human beings than in clinically normal human beings (Brown *et al.*, 1971).

Although these findings would imply that the gastrointestinal tract serves as a significant route of exit of urea from the body, such is not the case. Nearly all ammonia from bacterial degradation is used to resynthesize urea in the liver. Thus, a futile cycle occurs, and enteric loss of urea because of bacterial degradation is minimal (Mitch *et al.*, 1975).

Such a futile cycle does not occur during ruminant digestion. In ruminants, ammonia derived from urea may be utilized to form amino acids from keto and hydroxy acid precursors that are normal products of digestion (Houpt, 1959).

In man, small quantities of urea may be lost via perspiration (Altman and Dittmer, 1971). Prior to the use of hemodialysis, induction of profuse sweating was considered an adjuvant treatment of uremia (Sobel, 1964). Because of poorly developed sweat glands in the dog and cat, urea loss by perspiration is probably negligible.

Severe vomiting and diarrhea have been suggested as mechanisms by which urea may be lost from the body (Dossetor, 1966). Quantitative data on loss by these routes are not available.

b. Renal

Urea appears in glomerular filtrate in the same concentration as in plasma as a result of simple filtration through the glomerular basement membrane (Smith, 1951). However, not all filtered urea is excreted in the urine, owing to passive reabsorption in the collecting ducts. It is important clinically to note that the amount of filtered urea that is reabsorbed is dependent on the rate of water movement through the collecting ducts. More rapid passage of fluid allows less reabsorption of urea. At the highest urine flow rate attainable in the dog, the fractional excretion of urea is about 60%, but it decreases as urine flow rate decreases (Shannon, 1936). Thus, changing urine flow rate can influence the FE for urea and BUN concentration independent of changes in GFR. Dehydrated patients with renal failure that are treated with large quantities of fluids may experience a large decrease in BUN unrelated to changes in GFR, merely because the FE for urea has increased.

Urea reabsorbed from filtrate enters the interstitium and the general circulation via the renal vasculature. Its role in the interstitium as a urine concentrating agent is discussed in Section II.I.

3. *Creatinine Metabolism*

Small quantities of creatinine are ingested by animals consuming diets containing animal tissues, since creatinine is distributed throughout body water. Muscle tissue contains phosphocreatine, which undergoes spontaneous cyclization with loss of inorganic phosphate to form creatinine. Creatinine is apparently well absorbed from the intestinal tract (Goldman, 1954).

Most of the creatinine eventually excreted originates from endogenous creatine. The amino acids arginine and glycine combine to form guanidinoacetate in the pancreas, kidneys, and small intestine. In the liver, methionine provides a methyl group for conversion of guanidinoacetate to creatine (Tyler, 1972). Creatine circulates in the plasma and is taken up by muscle, where it stores energy in the form of phosphocreatine. The serum concentration of creatine in man is about 34 mol/liter (0.45 mg/ dl), but values for domestic animals are not available (Altman and Dittmer, 1971).

Creatine undergoes no catabolic reactions other than decomposition to creatinine (Bloch *et al.*, 1941). Creatine is excreted in small quantities in the urine of man (Bleiler and Schell, 1962; Bloch *et al.*, 1941; Hoberman *et al.*, 1948), but older literature indicates that large quantities of creatine are present in the urine of the dog (Hawk, 1910). Another study indicates that creatine clearance in the dog approaches zero at low plasma concentrations (Pitts, 1934). These conflicting data indicate that conclusions concerning urinary excretion of creatine by the dog cannot be made. This is important since creatine is the sole precursor of creatinine; an understanding of creatine excretion is needed to evaluate its effect on creatinine metabolism.

Creatine conversion to creatinine is a nonenzymatic, irreversible process that occurs at a rate of 1.6–2% daily (Bloch *et al.*, 1941; Hoberman *et al.*, 1948). Creatinine is distributed throughout body water, but it diffuses

more slowly than urea and requires about 14,400 seconds (4 hours) for equilibration in the dog (Schloerb, 1960).

The quantity of creatinine formed each day depends on the total body content of creatine, which in turn depends on dietary intake, rate of synthesis of creatine, and muscle mass. Withdrawal of meat from the diet of clinically normal human beings for a period of 6 weeks resulted in a decrease in SC of about 25% (Bleiler and Schell, 1962). However, dietary intake of creatine may inhibit its endogenous synthesis (Walker, 1960, 1961). Severe, prolonged exercise of man caused an increase in SC and BUN of about 60% (Refsum and Stromme, 1974). Because urine creatinine excretion during the exercise period was normal, it was concluded that the increased SC was due to increased creatinine production.

Factors influencing muscle mass such as disease of muscle, tissue wasting, and character of muscle as influenced by physical training, may also affect the size of the creatine pool and thus the daily production of creatinine. Horses with myoglobinuria were reported to have higher SC values than anticipated from the degree of renal dysfunction, because of rhabdomyolysis (Koterba and Coffman, 1981).

Even in patients with normal renal function, a direct relationship seems to exist between muscle mass and SC. The SC level is 30% higher in clinically normal human males than in females (Doolan *et al.*, 1962). A SC concentration of 133 mol/liter (1.5 mg/dl) may be normal in a muscular working animal but may indicate impairment of renal function in a sedentary one. The decrease in SC associated with loss of muscle mass was termed "significant" (Doolan *et al.*, 1962; Newman, 1971), but specific values were not given.

Some diurnal variation in SC occurs in human beings. In one study, afternoon samples were about 10% higher than morning values (Doolan *et al.*, 1962).

4. *Creatinine Excretion*

a. Extrarenal

The concentration of creatinine in sweat ranges from 9 to 115 mol/liter (0.1 to 1.3 mg/dl) (Altman and Dittmer, 1971). Lowered ratios of BUN to SC in uremic human beings who are vomiting profusely (Dossetor, 1966) suggest proportionately less creatinine than urea in vomit, but quantitative studies have not been reported. Creatinine is absent from the feces of uremic human beings, probably because of intestinal reabsorption or bacterial metabolism or both. Bacterial metabolism of creatinine appears to be a major method of removal from the body. Colonic flora of the rat can be induced to catabolize creatinine (Jones and Burnett, 1972). Isotope studies in azotemic human beings revealed that 15.9–65.7% of the creatinine formed was metabolized or excreted via nonrenal routes (Jones and Burnett, 1974). Metabolic products identified were CO_2 and methylamine. More recently, recycling of some creatinine breakdown products back to creatinine was found in uremic human beings (Mitch *et al.*, 1980), but the amount of recycling appears to be much less than what occurs with urea.

b. Renal

In all mammalian species, creatinine is freely filtered through the glomerulus and appears in glomerular filtrate in the same concentration as plasma (Smith, 1951). Species differences exist with regard to tubular action on creatinine. In man, creatinine is secreted by renal tubules. In the male dog, an extremely weak proximal tubular secretory mechanism exists for creatinine (O'Connell *et al.*, 1962; Swanson and Hakim, 1962). The mechanism is absent in the female dog. Studies in cats (Finco and Barsanti, 1982) and ponies (Finco and Groves, 1985) indicated that no tubular secretion of creatinine occurred in these species, whereas considerable tubular secretion of creatinine occurred in the goat (Brown and Finco, 1987). In species secreting creatinine, the process is by active transport in the proximal tubule; thus tubular secretion of creatinine is not influenced by urine flow rate.

5. *Precision of BUN and SC Measurement*

Two general techniques are used for urea analysis (Davidsohn and Henry, 1969). With enzymatic methods, urea is converted to ammonia by urease. The ammonia concentration is measured by a color reaction. These methods are specific because urease acts only on urea. Free blood ammonium concentration does not interfere since it is present in such low concentration compared to urea. The other general method of urea analysis is based on the formation of colored products from direct combination of urea with compounds such as diacetylmonoxamine. This method is less specific, and dibasic amino acids may also cause a color reaction. With spectrophotometric methods of urea analysis, the two methods give comparable results when blood urea is <36 mmol/liter (BUN <100 mg/dl). Above this value, results with the diacetylmonoxamine method are 5–15% higher. A dipstick method of estimating blood urea by the urease method is available, but the accuracy is poor. It has been recommended that dipsticks be used only for emergency analyses and that samples reading greater than 7.1 mmol/liter for blood urea (20 mg/dl for BUN) be analyzed by more reliable methods (Bold *et al.*, 1970).

Clinical measurement of SC involves a reaction between alkaline picrate solution and creatinine. Several products of the creatinine–picric acid reaction have been proposed (Blass *et al.*, 1974). Unfortunately, the reaction is not specific; more than 50 compounds interfere, including glucose, fructose, ascorbic acid, hippuric acid, protein, urea, ketones, histidine, arginine, glycocyamidine, and pyruvic acid. Interfering compounds are collectively called *noncreatinine chromogens* (Henry, 1964; Newman, 1971; Narayanan and Appleton, 1972; Blass *et al.*, 1974).

More specific methods of measuring SC have been devised. A clay (Lloyd's reagent) can be used to absorb creatinine selectively prior to reaction with alkaline picrate, but the method is cumbersome (Henry, 1964). Enzyme-specific methods for creatinine analysis also are available and have been applied to the serum of domestic species (Jacobs *et al.*, 1991). The enzymatic methods are not in widespread usage presumably because of cost.

Noncreatinine chromogens were reported to be absent from the urine of the dog (Balint and Visy, 1965). However, values for urine creatinine in dogs were about 6% lower with an enzymatic creatinine assay than with the Jaffe method (Finco *et al.*, 1993).

The relative absence of urinary excretion of noncreatinine chromogens is important for two reasons. First, creatinine clearance in animals is erroneous if both urine and serum are analyzed by the alkaline picrate method. Urine creatinine concentration U_c is accurately measured, but plasma creatinine concentration P_c is erroneously high. Since the U_c/P_c ratio is calculated in making clearance determinations, apparent creatinine clearance will be low compared to actual clearance. Second, it indicates that extrarenal mechanisms exist for the elimination of noncreatinine chromogens. This implies that noncreatinine chromogen concentration in blood does not increase in parallel with creatinine during the progression of renal dysfunction. Consequently, SC determined by the alkaline picrate method becomes a progressively more accurate estimate of actual SC concentration as the degree of renal function decreases.

6. Interpretation of BUN and SC Values

Both BUN and SC are relatively insensitive in detecting renal dysfunction. The GFR must be reduced to 25% of normal or less before BUN values outside the normal range are obtained (Bernstein, 1965). There are no data to indicate that either compound is more sensitive than the other in detecting renal dysfunction.

In most domestic species, serum concentrations of both urea and creatinine are crude estimates of GFR.

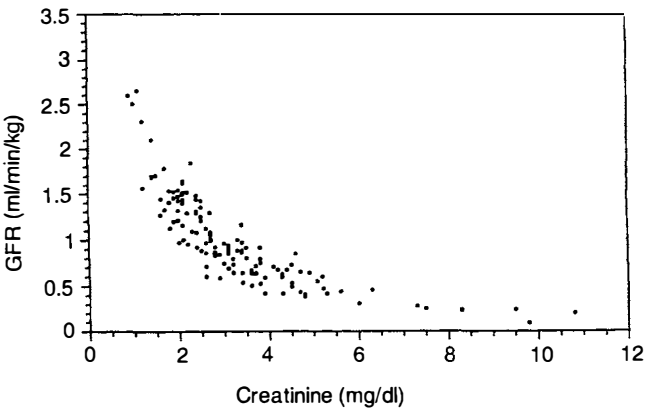

FIGURE 17.4 Relationship between serum creatinine concentration and GFR in 129 clinically normal dogs with reduced renal function. Comparison with Fig. 17.5 (BUN versus GFR in the same dogs) indicates that SC is a better predictor of GFR than BUN.

On the basis of the mechanism of renal excretion of the two compounds, creatinine is a better indicator of GFR (Figs. 17.4 and 17.5). However, studies in humans indicate that SC does not increase in proportion to the decrease in creatinine clearance (Doolan *et al.*, 1962; Enger and Blegen, 1964; Goldman, 1954). This discrepancy is attributable to the extrarenal losses of creatinine previously discussed and suggests that extrarenal losses increase progressively as the degree of azotemia increases. Studies in dogs also indicate that SC values do not increase in proportion to the decrease in GFR, but the deviation in SC from values predicted by GFR is not large (Finco *et al.*, 1995). The practical application of recognition of extrarenal creatinine loss is that a patient whose creatinine has doubled may have considerably less than half the previous GFR. It may also mean that two patients of the same size with the same SC may have different GFR values, if the two differ in extrarenal creatinine disposition. The same statements

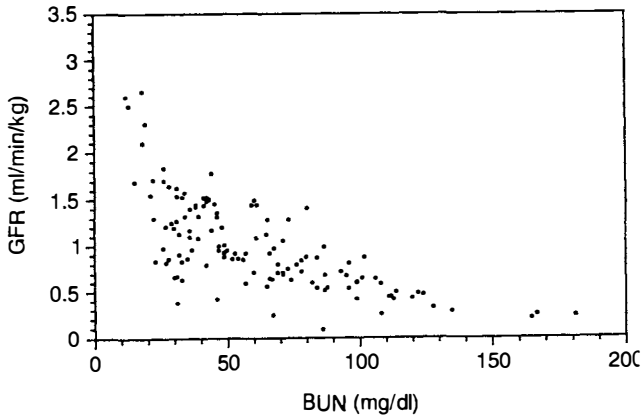

FIGURE 17.5 Relationship between GFR and BUN in the 129 clinically normal dogs with renal dysfunction.

may apply to BUN values and emphasize that measurement of serum levels alone is not a precise method of assessing renal function.

In man it is reported that BUN correlates more directly with symptoms of uremia than SC. Patients with a high BUN are more likely to have uremic symptoms than patients with a low BUN, even when the two groups have similar SC values (Kassirer, 1971).

Levels of BUN and SC should be interpreted while considering two types of errors. Concluding that renal disease does not exist when it actually does constitutes one error. Because of factors previously discussed, it should be apparent that animals with GFR values as low as 25% of normal may not have elevated BUN and SC values. Concluding that renal disease exists when it actually does not constitutes the second type of error. All causes of prerenal azotemia fall in this category. Human patients referred to a nephrology service were studied to compare GFR with BUN and SC values. Normal BUN and SC values were found in patients proved abnormal by GFR measurements in 26% and 22% of the evaluations, respectively. Abnormally high BUN and SC values were found in patients with normal renal function in 9% and 4% of the patients, respectively (Rickers *et al.*, 1978). Although similar statistics have not been generated for domestic animals, it is likely that both types of errors are made. The error of false-positive values occurs with readings that are slightly above the normal range. When such values are obtained, prerenal factors should be considered, and more sensitive tests of renal function should be considered.

Some effort has been made to use BUN-to-SC ratios to evaluate the pathogenesis of azotemia in human beings. However, studies in the dog revealed that BUN-to-SC ratios were of no value in differentiating prerenal, renal, or postrenal failure or in differentiating acute renal failure from chronic renal failure (Finco and Duncan, 1976). Because ruminant microflora may metabolize a greater percentage of urea than do enteric flora in nonruminants, BUN values may not increase proportionately to SC levels in renal failure in ruminants until anorexia occurs. This phenomenon should be considered when evaluating BUN values.

Progressive deterioration of renal function can be monitored with measurement of either BUN or SC, subject to the variables previously enumerated for each test. Observations of SC values from people in renal failure revealed that the reciprocal of SC declined linearly with time in many but not all patients as disease progressed (Mitch, 1985). The plot was used to predict when hemodialysis or transplantation was required or to monitor effects of diet on the progression of renal failure. Plotting of the reciprocal of SC against time in dogs with renal failure has resulted in linear relationships in some cases (Allen *et al.*, 1987) but not in others (Barsanti, 1987), suggesting that either extrarenal creatinine disposition or progression of renal failure is not invariably related to time in a linear fashion.

B. Urine Concentration Tests

Polydipsia and polyuria are related signs in which one factor is primary and the other is secondary (i.e., a response to the primary factor). Primary polydipsia with compensatory polyuria occurs in domestic animals. When water is restricted in such animals, urine volume decreases and urine concentration increases.

Primary polyuria is normally accompanied by secondary polydipsia. When water is restricted in such animals, neither urine volume nor urine concentration changes markedly.

Unfortunately, both renal and nonrenal causes of primary polyuria exist (Table 17.3). Nevertheless, urine concentration tests are valuable for distinguishing primary polydipsia from primary polyuria, and for aiding in differentiating causes of primary polyuria from one another.

1. Indication for Urine Concentration Tests

When polydipsia and polyuria exist, a urine concentration test may distinguish the primary factor from the compensatory one. For the diagnosis of generalized renal disease, the test is indicated when polyuria but not azotemia is present. As indicated in Section IV, polyuria precedes azotemia during the progression of chronic renal failure in most species, the cat being a notable exception (Ross and Finco, 1981). Urine concentration tests serve no purpose in animals with unequivocal azotemia since renal dysfunction has already been established.

2. Types of Urine Concentration Tests

Stimulus for the production of a concentrated urine may be elicited by inducing endogenous secretion of ADH by withholding water. ADH secretion occurs in dogs with a body water deficit of 2–3% (Pitts, 1974). Both abrupt and gradual water deprivation tests have been described. The gradual test has been advocated because of concern that any cause of polyuria may secondarily affect the concentrating mechanism by causing medullary washout of solute. Under such circumstances, production of concentrated urine would be impossible until the medullary hypertonicity was reestablished.

The amount of time required for the normal kidney to reestablish medullary hypertonicity is not well de-

fined in domestic animals. One study in dogs found that repletion following water diuresis had not occured after 10 hours (Boylan and Asshauer, 1962). In dogs, washout reported as a consequence of furosemide occurred within 5 minutes of intravenous administration of the drug. On the other hand, not all causes of polyuria are associated with medullary washout. Dogs with induced diabetes insipidus maintain a degree of medullary hyperosmolality (Appelbloom *et al.*, 1965), and dogs with spontaneous diabetes insipidus respond to Pitressin tannate within 24 hours (Finco, 1979). Various other diseases in domestic animals have not been examined for the status of the renal medullary gradients, nor have comparative trials of abrupt and gradual water deprivation tests been made. Because the cost of hospitalization makes the gradual deprivation test expensive to perform and because its superiority has not been documented, the abrupt deprivation test is a logical choice over the gradual test for initial study. If the animal fails to concentrate urine with the abrupt test, a gradual deprivation test may be considered.

An alternative form of urine concentration test is performed by supplying an exogenous source of ADH. Regardless of the animal's state of hydration, concentrated urine should be produced in the presence of ADH if the kidney is normal. Aqueous pitressin or DDAVP (1-deamino-8-D-arginine-vasopressin) may be used for the test. Since the half-life of aqueous Pitressin is extremely short, constant infusion is required to maintain adequate blood levels for the test. This complicates the test compared to the use of DDAVP. The question of secondary washout of medullary gradient is more germane to a concentration test performed with aqueous Pitressin during minutes compared to conducting a DDAVP test over a period of many hours. The DDAVP has activity in the dog for about 12 hours after mucosal application (Greene *et al.*, 1979).

The combined use of water deprivation and Pitressin in a single procedure has been advocated for the diagnosis of polyuria problems in both the human being and the dog (Mulnix *et al.*, 1976).

3. Methods of Conducting Urine Concentration Tests

The various tests for urine concentration probably all have merit if conducted carefully and interpreted properly. The tests subsequently described are those the author has found to be satisfactory in dogs and cats.

a. Abrupt Water Deprivation Test

This test is conducted so that a definite stimulus for ADH release is elicited prior to the conclusion of the test. In the past, the procedure involved withholding water for a specific number of hours and then determining the degree of urine concentration. This technique is inaccurate because of variation among patients in rate of dehydration following water deprivation. With this technique some patients may be dehydrated to dangerous degrees and others may not be challenged. The preferable end point is a specific degree of dehydration rather than a specified time period of water deprivation.

Prior to conducting the test, it is necessary to evaluate the animal's state of hydration. Performing a water deprivation test in a dehydrated animal is meaningless and dangerous. It is meaningless because clinically detectable dehydration is usually 5% or greater (Finco, 1972), and such an animal would already be secreting ADH and concentrating urine if capable. It is dangerous because imposing water deprivation on an animal that is already dehydrated may lead to complications of hypovolemia. Performing a water deprivation test in an azotemic animal is also contraindicated. The test gives no added information in cases of primary renal azotemia, and dehydration aggravates the azotemia by superimposing a prerenal factor on the underlying disease. Patients with prerenal azotemia are usually producing a concentrated urine spontaneously.

The stepwise procedure for conducting the abrupt water deprivation test in the dog or cat is the following:

1. While still providing water, withhold food for 4 hours.
2. After the fast, obtain a blood sample for measurement of packed cell volume (PCV), total plasma solids, and plasma osmolality if feasible. Obtain urine for refractometry and measurement of osmolality if feasible. Osmolality determinations should be deferred until the end of the test, when all samples can be analyzed at one time.
3. Weigh the animal with an accurate balance scale with the urinary bladder empty.
4. Remove all sources of drinking water. Fasting is preferable, but dry food may be given if the period of deprivation is prolonged.
5. Evaluate the patient at appropriate intervals for evidence of dehydration. Body weight measurements are the primary guide. Plasma total solids, PCV determinations, and clinical signs are less accurate and should be used only as secondary indices. Appropriate time intervals between observations vary considerably among patients; times can be chosen based on weight changes that occur during the early stages of the test. The first observation after initiating the test should be made at 14,400 seconds (4 hours). All body weight measurements should be made with the bladder empty, and consideration should be given to the weight changes that occur from eating, defecation, or other losses.

6. Terminate the test when 5–7% of body weight is lost or if undesirable signs develop during the test. Since urine produced during maximal dehydration should give the best indication of concentrating ability, it is desirable to empty the animal's bladder once sufficient weight loss has occurred and to wait for newly formed urine for analysis. Both plasma and urine are obtained for analysis (osmolality, refractometry) at the conclusion of the procedure. The interpretation of results of the test is discussed subsequently.

b. The 1-Deamino-8-D-Arginine Vasopressin (Desmopressin) Test

DDAVP is a synthetic vasopressin and it may be used in instances when it may be risky to deprive the patient of water. The test is conducted as follows:

1. Water need not be withheld for the test, but overnight fasting is preferable.
2. The same preinjection measurements listed for the abrupt water deprivation test are made.
3. The DDAVP is administered slowly intravenously at a dose of 3–10 μg, depending on the size of the dog or cat.
4. The animal is allowed water ad libitum during the study. Although not essential, comparison of water intake and urine volume for 24-hour periods before and after injection may aid in the interpretation of results.
5. Urine is obtained at 1, 2, 4, 6, 12, and 24 hours.

4. Interpretation of Results of Urine Concentration Tests

The same results would be anticipated whether exogenous or endogenous ADH were utilized, but some studies indicate that urine-concentrating ability is better after water deprivation than after injection of a long-acting Pitressin preparation (West *et al.*, 1955). Results with DDAVP would be expected to be comparable to the Pitressin preparation. Although not confirmed by controlled studies, it is the author's impression that the water deprivation test is a more reliable test than the DDAVP test. In the past, a urine specific gravity of 1.025 has been considered to be an adequate indication of concentrating ability for the dog and cat (Osborne *et al.*, 1972). This value was transposed from studies of human beings, whose maximal concentrating ability is about 1.040. Studies on normal beagle dogs indicated that 57,600 seconds (16 hours) or more of water deprivation resulted in specific gravity readings of 1.058 ± 0.008 (Balazs *et al.*, 1971). In another study of 20 dogs, mean concentrating ability was 1.062 ± 0.007 for specific gravity and 2289 ± 251 mOsm/kg for osmolality after a mean of 141,480 seconds (39.3 hours) of deprivation that resulted in 4–16% weight loss (Hardy and Osborne, 1979).

In studies of normal cats fed commercial dry catfood, water deprivation causing 5–8% loss of body weight resulted in urine osmolality of 2196 ± 533 mOsm/kg and urine specific gravity of 1.064 ± 0.015 (Ross and Finco, 1981). However, whether values obtained from abrupt deprivation of normal animals would be the same as values from normal animals that had polyuria prior to deprivation has not been established. Another problem is the influence of diet on concentrating ability, as mentioned in Section II.

Any guidelines to be used for differentiating normal from abnormal concentrating ability must be tentative until more information is collected. At present, for the dog and the cat with the use of the abrupt water deprivation test, urine specific gravity readings of 1.040 or above are considered evidence of normal concentrating ability. Readings between 1.030 and 1.040 are considered questionable and worthy of further investigation. Readings below 1.030 are considered abnormal. For the DDAVP test, values slightly lower (0.005) may be used.

If osmolality readings are made, pretest and post-test plasma samples may be compared for the water deprivation test in order to document the adequacy of water deprivation. Plasma osmolality should be higher in the post-test sample. Food ingestion seems to markedly alter plasma osmolality results, and thus at least a 4-hour fast is recommended prior to sampling. Post-test urine and plasma osmolality ratios may also be examined to establish the effectiveness of the renal concentrating mechanism.

C. Clearance Methods

The development of the clearance concept represented a major advancement in the measurement of renal function (Smith, 1951). Not only could specific renal functions be measured quantitatively, but a marked increase in sensitivity in detecting renal dysfunction was achieved. When performed properly, clearance procedures should detect a 20% decrement in renal function, compared to a 75% decrement required before BUN and SC change.

The clearance formula is expressed as follows

$$C = \frac{U_v U_c}{P_c}$$

where C is clearance; U_v, urine volume; U_c, urine concentration; and P_c, plasma concentration.

Physiology textbooks can be consulted for a more detailed description of the clearance concept and its application. Data have accumulated to indicate that inulin can be used to measure GFR, and *p*-

aminohippuric acid (PAHA) at low blood levels can be used to measure renal plasma flow. Although the clearance formula and inulin and PAHA clearances are standards by which other measures of renal function are judged, they are too time consuming for routine clinical use in veterinary medicine. Since both inulin and PAHA are foreign to the body, it is necessary to induce and maintain constant blood levels by giving priming doses followed by constant infusion of solutions. In research studies on dogs and cats, the determination of inulin and creatinine clearances requires several hours of human effort per animal.

1. *Importance of Hydration State*

Studies have demonstrated a significant effect of state of hydration on renal functions. In one study, creatinine clearance in clinically normal euhydrated dogs was increased by 14% when dogs received water (equal to 3% body weight) by gavage 40 minutes prior to clearance procedures. In the same dogs, clearance was decreased by 23% from the euhydrated state when dogs had dehydration induced (Tabaru *et al.*, 1993). Such changes in renal function according to the state of hydration probably affect scintigraphic and single-injection techniques of renal function evaluation as well as clearance procedures. Since clinical assessment of hydration state is insensitive, it is possible that many patients with marginal hydration yield spuriously low results from renal function tests. For short-term clearance determinations it is appropriate to administer water routinely by gavage (3% body weight) to avoid volume depletion during the procedure. Increased urine flow rate achieved by water administration also increases the reliability of the urine collections.

2. *Endogenous Creatinine Clearance*

In contrast to clearance methods previously mentioned, the endogenous creatinine clearance is feasible with clinic cases. Blood levels of creatinine are relatively constant over short intervals of time unless some factor acutely affects renal function. Thus, the blood level of creatinine can be measured once while an accurately timed collection of urine is made. Both 20-minute and 24-hour endogenous creatinine clearance values have been determined for the dog (Finco, 1971; Bovee and Joyce, 1979). Twenty-minute clearance determinations performed on 27 normal dogs of both sexes weighing from 5.6 to 31.3 kg gave values of 2.8 ± 0.96 ml/minute per kilogram of body weight or 60.0 ± 21.9 ml/minute per square meter of body surface area (Finco, 1971). Comparable values are obtained on 20-minute and 24-hour collections (Finco *et al.*, 1993). Discrepancies between laboratories have been noted and may be due to several factors. One important factor is the chromogen problem with creatinine measurement discussed in Section VI.A.5.

Because noncreatinine chromogens are present in plasma but absent in urine, endogenous creatinine clearance measurements underestimate the actual clearance of the compound. In one study, when endogenous and exogenous creatinine clearances were compared with inulin clearance in 10 healthy dogs, exogenous creatinine clearance was 1.03 times inulin clearance, but endogenous creatinine clearance was only 0.70 times inulin clearance (Finco *et al.*, 1981). This difference occurred despite the use of a kinetic method for creatinine analysis presumed to be specific for creatinine. Thus it is likely that values for endogenous creatinine clearance underestimate GFR in the dog, and probably other species that have insignificant tubular secretion of creatinine such as the cat and the pony.

Although endogenous creatinine clearance may not accurately measure GFR, it still has utility as a renal function test because it is a more sensitive indicator of renal function than BUN or SC measurements. However, meaningful interpretation depends on a knowledge of normal values for clearance with the method of creatinine analysis employed.

More recently, an enzymatic method of creatinine analysis was employed during clearance tests to determine if the error inherent in the Jaffe method could be eliminated (Finco *et al.*, 1993). With this method, values for inulin clearance and endogenous creatinine clearance in dogs were nearly identical (Fig 17.6). This study indicates that at least in dogs and possibly in other species that do not have tubular secretion of creatinine (cats, horses), endogenous creatinine clearance accu-

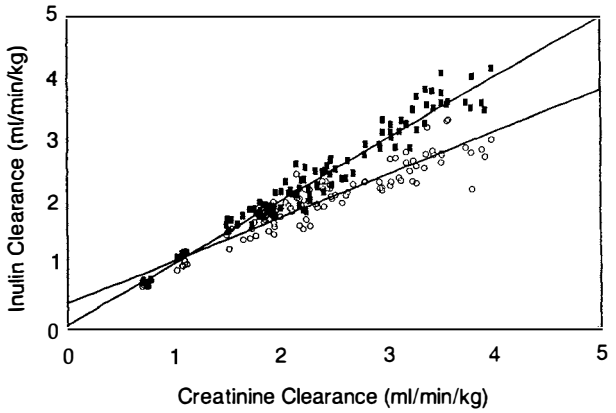

FIGURE 17.6 Relationship between inulin clearance and endogenous creatinine clearance in dogs with normal and impaired rena function. Analysis of creatinine by the Jaffe method (open circles gave clearance values less than inulin, whereas analysis by a specific enzymatic method for creatinine (solid squares) gave nearly identica results for creatinine and inulin.

rately measures GFR when specific (enzymatic) methods are used for creatinine analysis.

The technique for performing endogenous creatinine clearance is simple, but certain precautions are necessary. The test is dependent on total collection of urine during the time interval that is chosen. If urine is erroneously left in the bladder at the beginning of the test, creatinine will be measured that was not cleared from the blood during the test time chosen. Clearance values will be erroneously high. If all urine is not removed from the bladder at the termination of the test, not all creatinine cleared from the blood during the test period will be measured, and clearance values will be erroneously low. The precision required in emptying the bladder increases progressively as the time period for collection is decreased. When the 20-minute clearance test is performed, it is necessary to rinse the bladder several times with sterile saline both prior to initiating the test and at its conclusion. The rinses prior to the start are discarded; the rinses made prior to the conclusion of the test are added to the urine that is collected. The amount of creatinine excreted during the test period is the product of creatinine concentration of the rinse–urine mixture times its volume. Clearance is calculated by dividing urine creatinine excretion by plasma creatinine concentration.

3. *Exogenous Creatinine Clearance*

In dogs, cats, and horses, administration of creatinine to obtain constant, elevated blood levels is a proven way of accurately measuring GFR with the Jaffe method of creatinine analysis in normal animals (Smith, 1951) and in animals with renal dysfunction (Finco *et al.*, 1991, Fig. 17.7). By elevating plasma concentration of creatinine, the error due to noncreatinine chromogens becomes negligible. Since constant intravenous infusions make clearance procedures complicated, subcutaneous administration of creatinine has been employed (Finco *et al.*, 1981). Measurement of plasma creatinine concentration after subcutaneous injection revealed that levels were reasonably constant, and comparison of clearance values with those of inulin infused intravenously indicated that the creatinine clearance values were valid measures of GFR. Directions for application of this method to clinical practice have been published (Finco *et al.*, 1982).

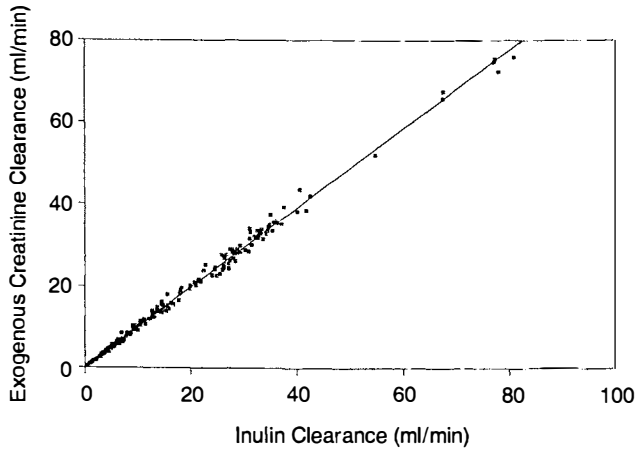

FIGURE 17.7 Relationship between inulin clearance and exogenous creatinine clearance in male and female dogs with subnormal to normal renal function. Exogenous creatinine clearance was the same as inulin clearance in both male and female dogs (Finco *et al.*, 1991).

D. Quantitative Renal Scintigraphy

Quantitative renal scintigraphy utilizes a strongly γ-emitting radioisotope, tagged to a compound handled by the kidney in a known manner. The compound is injected intravenously and the accumulation of the isotope in the kidneys is monitored with a detector placed over the kidneys. The detector simultaneously monitors plasma concentration of the isotope. The compound ^{99m}Tc-diethylenetriaminepentaacetic acid (DTPA) often is used to measure renal function by this technique. It is excreted by the kidney exclusively by glomerular filtration, and thus can be used to measure GFR. During the early phase of renal scintigraphy, accumulation of the isotope in the kidney is a function of glomerular filtration and plasma concentration of the isotope. Because both are being measured at many instants in time, values for GFR for each kidney can be generated, using classic clearance measurements of inulin for validation and calibration (Cowgill and Hornof, 1986 Krawiec *et al.*, 1986 Uribe *et al.*, 1992). In addition, information about kidney size can be obtained. A computer algorithm was developed for dogs to define kidney borders accurately (Cowgill and Hornof, 1986). This method of evaluating the kidneys has the advantages of rapid, noninvasive measurements, and assessment of both size and function of each kidney separately. In addition to use of DTPA for estimation of GFR in both the dog and cat, ^{99m}Tc-mercaptoacetyltriglycine has been used to estimate renal plasma flow (RPF) in the dog (Itkin *et al.*, 1994). Unfortunately, in some studies the correlation between these methods and classic clearance methods has not been impressive. In addition, cost of the equipment and isotope restriction are disadvantages.

E. Single-Injection Techniques

Following a single injection of a compound into the body, blood concentration is dictated by its distribution, metabolism, and excretion. For nonmetabolizable

materials excreted only by the kidneys, rate of disappearance of the material from the blood is related to renal function. This is the basis for single-injection techniques devised to measure renal function.

Several methods have been employed to analyze data from single-injection techniques. One method is to determine plasma half-life of the injected material, once its distribution in the body has occurred. Results from this method provide a value for half-life that cannot be converted to a numerical value for classical renal functions (GFR, RPF) but which may have clinical utility when compared to half-life values from normal animals. Compounds utilized in using this approach include sulfanilate and phenolsulfonphthalein (Rosenfeld, 1955 Mixner and Anderson, 1958 Brobst *et al.*, 1967 Carlson and Kaneko, 1971 Osbaldiston and Fuhrman, 1970).

Another approach to measuring renal function with a single injection of a test substance is to collect urine to determine what percent of the injected material has been excreted in a given amount of time. The urinary excretion of phenolsulfonphthalein in the 20-minute period after injection has been used in dogs to evaluate renal function (Finco, 1971). Such urine collection methods have the advantage over plasma decay methods of measuring only the renal contribution to removal of material from the blood, but have the disadvantage of requiring urinary catheterization and careful urine collection.

From data available, neither plasma half-life nor urine measurements following single injections of test substances seem as sensitive as classic clearance procedures for evaluating renal function.

In addition, pharmacokinetic modeling of plasma decay curves has been used to measure renal functions. Several models have been used and advocated, usually based on correlation between classic clearance values and clearances derived from the model computations. One study (Hall *et al.*, 1977) found that two methods advocated for calculation of GFR from single-injection decay curves (slope–intercept, two-compartment decay) gave spurious data, particularly when the volume of extracellular fluid was changed. In Hall's study, a third method (area under the curve) was devised using iodothalamate as the test substance. This method gave results that compared well with inulin clearance in 11 normal dogs and in 3 dogs with volume expansion. Similar methods have been used by others for both dogs and cats (Rogers *et al.*, 1991; Brown, 1994).

Some studies have used pharmacokinetic modeling to measure GFR, but failed to test the method by direct comparison with classic clearance techniques in normal animals, and in animals with abnormal extracellular fluid volumes (Powers *et al.*, 1977 Fettman *et al.*, 1985). A study in cats demonstrated a poor correlation between exogenous creatinine clearance and two pharmacokinetic models of plasma clearance of inulin (Rogers *et al.*, 1991). Validation of pharmacokinetic methods by comparison with classic clearance methods is required before such techniques can be considered acceptable measures of GFR.

Single-injection methods for measuring renal function have not had widespread use in veterinary practice because neither the test substances used nor their analysis for plasma concentration is routinely available. Iohexol is a nonmetabolizable radiocontrast medium that is excreted exclusively by glomerular filtration. It is readily available and has been used to determine GFR following a single injection into humans (Almen, 1994 Frennby *et al.*, 1994 Lindblad and Berg, 1994). An apparatus is commercially available which measures iohexol concentration and computes GFR from the measurements. Comparison of GFR measurements made by classic clearance methods with the single-injection method for iohexol gave good agreement (Brown *et al.*, 1995).

F. Urinary Enzymes

Increases in serum enzyme activity commonly are used to detect organ abnormalities. Such enzyme measurements are not true tests of function, but they are sensitive indicators of organ damage. Unfortunately, increases in serum enzyme activity that are specific for the kidney have not been documented secondary to renal damage.

The appearance of enzymes of renal origin in urine provides a unique opportunity for detection of renal injury. Studies on enzyme assays of urine for detection of renal injury have been reviewed (Mattenheimer, 1971, 1977 Raab, 1972 Dubach and Schmidt, 1978). Attention has been focused on enzymes present in the brush border of the proximal tubules and on enzymes in lysosomes. Factors complicating analysis are the presence of enzyme inhibitors and accelerators in urine that often must be removed prior to analysis. Of the domestic species, some results have been reported from the dog (Conzelman *et al.*, 1970 Ellis *et al.*, 1973 Greco *et al.*, 1985 Gossett *et al.*, 1987). However, results have not been encouraging for clinical application.

G. Single-Sample ("Spot") Fractional Excretion Determinations

As indicated in Section II.E., FE refers to the fraction of material filtered that appears in urine. The FE of any material reflects either the efforts of the kidney to

maintain homeostasis or defects in its ability to do so. Several examples demonstrate the clinical utility of FE measurements. In the normal animal, the FE of an ingested element that is well absorbed from the intestines (i.e., sodium) is expected to increase if dietary intake increases, in order for body balance to be maintained. If GFR is decreased but intestinal absorption is constant, the FE of sodium and phosphorus must be increased if body balance is to be maintained. The increase in FE is required because the filtered load (GFR × plasma concentration) is decreased, and thus a smaller percent of the filtered material need be reabsorbed to maintain body balance. An animal with a tubular absorption defect (i.e., Fanconi syndrome) is not able to respond to needs for homeostasis, and FE values in such animals will be higher than is appropriate for the diet being consumed.

Values for FE are determined by measuring GFR, plasma concentration, and urinary excretion of the substance in question. Values published as "normal" may be extremely misleading unless dietary intake and intestinal absorption of the material for which FE is being determined are defined.

Because determination of GFR is laborious, the "spot" method used for quantifying proteinuria (Section V.C.) has been applied to FE determinations of other materials (Traver *et al.*, 1977). This procedure may have merit in determining tubular homeostatic activity, but several qualifications must be imposed. The SC is not a valid marker of GFR because of plasma noncreatinine chromogens (Section VI.A.5) and because in some species it is secreted by the tubules. Consequently, values obtained are not equal to true FE values. Random samples of urine taken without regard to the time of food intake may not provide samples representative of 24-hour urinary excretion. In dogs, urinary sodium excretion is greatest during the first 6 hours after eating and diminishes substantially subsequently. Urinary potassium and phosphorus excretion are low soon after eating, but increase between 6 and 18 hours after eating (Groves *et al.*, 1987). Random samples of urine represent an accumulation over an unknown period of time, further complicating intake-related fluctuations in urinary excretion. Plasma concentrations of some electrolytes also are influenced by time of eating (Groves *et al.*, 1987). The presence of circadian rhythms in excretion of urinary components has been poorly studied in domestic animals but if present could complicate "spot" clearances as well as short-term FE measurements by classical techniques. The presence of renal dysfunction dictates an increase in FE to maintain homeostasis failure to account for level of renal function may lead to misinterpretation of results (Adams *et al.*, 1991).

The utility of "spot" FE measurements will be determined when the influence of these factors is determined in each species. It is possible that results will be found to be more reliable in herbivores than in carnivores because food intake is more constant in herbivores.

H. A Perspective on Renal Function Tests and Their Use

In veterinary medicine, the question of whether renal function is normal or abnormal is of frequent concern. The question should be answered reasonably quickly and at the least cost to the owner of the animal. This implies that the evaluation should be simple and quick to do.

The relative simplicity of performing BUN or SC measurements and determination of the specific gravity of a random sample of urine makes them logical choices for initial assessment of renal function. Normal values for BUN or SC and production of a concentrated urine indicate that at least one-third of renal mass is functional. This quantity of tissue is adequate for existence without signs of renal failure, and probably is sufficient for maintaining an animal through most surgical procedures. Clinical investigation is often discontinued at this point unless there is a specific reason to question the state of the kidneys. However, it must be recognized that normal values for these measurements could still mean loss of up to two-thirds of renal function.

Elevated levels for BUN or SC indicate that prerenal, renal, or postrenal azotemia exists. When azotemia is found, there is little if any additional information attained from more sensitive renal function tests. Renal function tests do not differentiate these categories, and other means must be used to distinguish one from the other.

Normal values for BUN or SC accompanied by a low specific gravity on a random sample of urine rule out uremia but introduce the question of the cause of low urine specific gravity. In euhydrated animals, water deprivation or ADH administration is helpful in determining whether concentrating ability is present. However, lack of concentrating ability is not specific for generalized renal dysfunction, and other means must be used to differentiate nonrenal causes from generalized renal failure.

Tests other than BUN, SC, and urine concentration are indicated under a variety of circumstances. One instance is when a urine-concentrating defect exists, but values for BUN or SC are normal or equivocal. Another example may be when a potentially nephro-

toxic drug is to be administered to an animal in which renal disease is suspected (glomerular proteinuria or urinary casts). The choice of the more sensitive test to be used in such instances depends on the use to be made of the data. If relative rather than absolute values for renal function are adequate, such tests as endogenous creatinine clearance or plasma decay curve half-life data may be adequate, as long as normal values are available for the hospital and laboratory in which they are to be used. When a specific measure of GFR is sought, creatinine clearance may be performed in the species in which it is valid (dog, cat, horse). Endogenous creatinine can be used if enzymatic methods of creatinine analysis are used; otherwise, exogenous creatinine clearance is required to overcome the error of the Jaffe method. Alternatives for GFR measurement are validated pharmacokinetic models or reliable renal scintigraphy.

CHAPTER

18

Fluid, Electrolyte, and Acid–Base Balance

GARY P. CARLSON

I. INTRODUCTION

The body fluids are arranged in dynamic but orderly functional compartments. Maintenance of these compartments in terms of volume and composition is essential for maintenance of normal physiologic and biochemical events. The electrolytes dissolved in body fluids fulfill vital roles in virtually all of life's processes. Transmembrane movements of electrolytes are responsible for the electrical events that result in nerve conduction and muscular contraction and also serve as essential cofactors in many enzymatically mediated metabolic reactions. The pH of body fluids is maintained within narrow limits. This is necessary for the maintenance of protein structure and function, which is an essential condition for normal progression of metabolic events. Virtually every organ system participates in the maintenance of fluid balance and/or is adversely affected by imbalances. In many disease states, impaired fluid intake, excessive fluid losses, or organ damage and dysfunction results in a state of

altered fluid and electrolyte balance. Regardless of whether fluid and electrolyte alterations are the primary problem or simply represent secondary manifestations of some other disease process, successful patient management depends on correct evaluation and appropriate therapy. To do this one must have a clear understanding of the anatomy and physiology of the body fluids, of the pathologic mechanisms by which normal processes become deranged, of the means by which these disturbances can be identified accurately, and finally the procedures that can be used to correct such disturbances in a prompt, safe, and effective manner (Tasker, 1980).

II. PHYSIOLOGY OF FLUID AND ELECTROLYTE BALANCE

A variety of different units have been used in the quantitative evaluation of biologic specimens. To avoid confusion, the units of measure that apply directly to the body fluids and electrolytes are described. An international standard for clinical chemistry units, the "Système Internationale d'Unites" (SI units), was developed to provide consistent terminology and usage. Although SI units are the international standard, they may not be familiar to all students or clinicians. All solute concentrations are expressed in moles or millimoles per liter, blood gas partial pressure in kilopascals, and osmolality in millikelvins of freezing point depression. See Appendix I for conversion tables.

Electrolytes are substances which exist as positive or negative charged particles in aqueous solution. The positively charged particles are *cations* and the negatively charged particles are *anions*. For univalent ions such as sodium, potassium, chloride, and bicarbonate, 1 mole equals 1 equivalent. For multivalent ions, 1 equivalent is equal to the molecular weight in grams (i.e., 1 mole) divided by the charge on the particle. The maintenance of electrical neutrality in biologic fluids requires that there be an equal number of equivalents or milliequivalents of anions and cations in solution. Electrolytes in solution combine equivalent for equivalent, not on a gram for gram or mole for mole basis.

The osmotic properties of a solute in solution are related to the number of particles in solution and not to its weight or its charge. One osmole of a nondissociable substance is equal to its molecular weight in grams. One osmole of any substance which dissociates in solution into two or more particles is equal to the molecular weight in grams divided by the number of particles into which each molecule dissociates. *Osmolarity* is defined as the number of osmoles per liter of final solution, whereas *osmolality* is the number of osmoles per kilogram of water. Although the expressions are very similar, osmolality more correctly describes the osmotic properties as measured in the clinical laboratory.

Most solutes in biologic fluids are present in relatively dilute concentrations and it is more convenient to express these concentrations as millimoles, milliequivalents, or milliosmoles. These simply represent one-thousandth of the standard unit. Conventional terms are milligrams per deciliter (mg/dl), millimole per liter (mmol/liter), milliequivalent/liter (mEq/liter) and milliosomole per kilogram of water (mOsm/kg). The concentrations of the principal anions and cations in plasma are presented in Table 18.1 as expressed in these conventional terms.

III. BODY FLUID COMPARTMENTS

Before proceeding with a discussion of the assessment of fluid deficits or imbalances, we need to consider the organization and composition of the fluid compartments from which these losses occur. An understanding of the forces which govern the relative volume and composition of the body fluid compartments is central to understanding both the clinical and clinicopathologic manifestations of altered fluid balance.

A. Total Body Water

Water is the most abundant compound in the body and all of life's essential processes take place in this aqueous environment. Although there is substantial variation, the total body water (TBW) of most domestic animals is approximately 60% of body weight (0.60 liter/kg). In a 500-kg horse this amounts to approximately 300 liters (Carlson, 1983b); in a 20-kg dog it amounts to just over 12 liters (Kohn and DiBartola, 1992).

Adipose tissue contains very little water and the amount of body fat has a major impact on the relative TBW. The average body water content of women is 0.45 to 0.50 liter/kg as compared to 0.55 to 0.60 liter/kg for men (Elkinton and Danowski, 1955; Edelman *et al.*, 1958). This is largely the result of the larger fat deposits in the adult woman and the larger muscle mass of the adult man (Elkinton and Danowski, 1955). Clear sex-associated differences in body fat are not appreciated in domestic animals. However, certain species of domestic animals such as fattened swine or sheep have a large amount of body fat. Although lighter sheep had a TBW of near 0.65 liter/kg (Wade and Sasser, 1970), the TBW of these fattened animals may be less than 0.50 liter/kg (Hansard, 1964; English,

TABLE 18.1 Plasma Electrolyte Concentrations Expressed in Different Units[a]

Plasma electrolyte	mg/dl	Normal concentration		
		mmol/liter	mEq/liter	mOsm/kg
Cations				
Sodium (Na^+)	326.6	142.0	142.0	142.0
Potassium (K^+)	16.8	4.3	4.3	4.3
Calcium (Ca^{2+})[b]	5.0	1.25	2.5	1.25
Magnesium (Mg^{3+})[b]	1.3	0.55	1.1	0.55
Total cations	349.7	148.1	149.9	148.1
Anions				
Chloride (Cl^-)	369.2	104.0	104.0	104.0
Bicarbonate (HCO_3^-)	146.4	24.0	24.0	24.0
Phosphate ($H2PO_4^-$, HPO_4^{2-})[c]	3.4	1.1	2.0	1.1
Proteins[c]	7000.0	2.5	14.0	2.5
Others (sulfate lactate, etc.)	—	5.5	5.9	5.5
Total anions	7519.0	135.5	149.9	137.0
Total milliosmoles from electrolytes				285.1

[a] From Tasker (1980).
[b] Only ionized calcium and magnesium have been considered here.
[c] Phosphate concentration is that of organic phosphorus. Since a variable equilibrium exists between $H_2PO_4^-$ and HPO_4^{2-}, the actual valence and milliequivalents must be estimated. The same variability is true of protein anions as well.

1966b), whereas the TBW of the athletic horse is generally greater than 0.65 liter/kg (Robb *et al.*, 1972; Dieterich and Holleman, 1973; Judson and Mooney, 1983). The relative water content of newborn animals is much higher than adults. Data in human infants, calves, foals, and lambs suggest a water content in excess of 75% of body weight at birth (Edelman and Leibman, 1959; Dalton, 1964; Phillips *et al.*, 1971; Pownall and Dalton, 1973; Bennett, 1975). The large TBW is primarily due to the very large extracellular fluid (ECF) volume, which exceeds 0.40 liter/kg at birth in most species (Tollertz, 1964; Bennett, 1975; Kami *et al.*, 1984; Spensley *et al.*, 1987). An initial rapid decline occurs during the first few days to weeks of life with TBW and ECF volumes approaching adult levels by 6 months of age (Spensley *et al.*, 1987).

The TBW consists of two major compartments, the intracellular fluid (ICF) volume and the ECF volume. The distribution of body water is illustrated in Fig. 18.1 indicating the normal fluid balance of a 450-kg horse. The ICF accounts for approximately one-half to two-thirds of the TBW and the ECF accounts for the remainder. Although these two compartments differ markedly in electrolyte composition, they are in osmotic equilibrium and water is freely diffusible between them. The relative volume distribution of water between these two compartments is largely governed by the number of osmotically active particles in each compartment. The ECF volume is determined by the ECF sodium content, and ICF volume is a function of ICF potassium content. The relationship between the exchangeable cation content (sodium in the ECF, potassium in the ICF) and the total body water was defined by Edelman *et al.*, (1958):

$$\text{Serum sodium mEq/liter } H_2O \approx \frac{\text{(Exchangeable sodium + potassium)}}{\text{Total body water}} \quad (18.1)$$

Since there are no major osmotic gradients between the ECF and the ICF, serum sodium concentration and osmolality reflect the osmolality of the ICF compartment as well as that of the ECF compartment (Edelman *et al.*, 1958; Scribner, 1969; Saxton and Seldin, 1986).

B. Extracellular Fluid Volume

The ECF should be viewed as a physiologic rather than a strictly definable anatomic space (Carlson *et al.*, 1979a). The ECF volume of adult animals ranges from 0.15 to 0.30 liter/kg body weight (Hix *et al.*, 1953; English, 1966b; Evans, 1972; Hankes *et al.*, 1973; Zweens *et al.*, 1975; Thornton and English, 1977; Carlson *et al.*, 1979a; Kohn, 1979; Spurlock *et al.*, 1985) depending on the species and the volume dilution procedure used. Regulation of ECF volume is a complex process in which a variety of factors interact. The ECF consists of all the fluids located outside the cells and includes the plasma (0.05 liter/kg), interstitial fluid and lymph (0.15 liter/kg), and the transcellular fluids (Edelman and Leibman, 1959; Rose, 1984; Saxton and Seldin, 1986). The transcellular fluids, which include the fluid content of the gastrointestinal tract, are generally con-

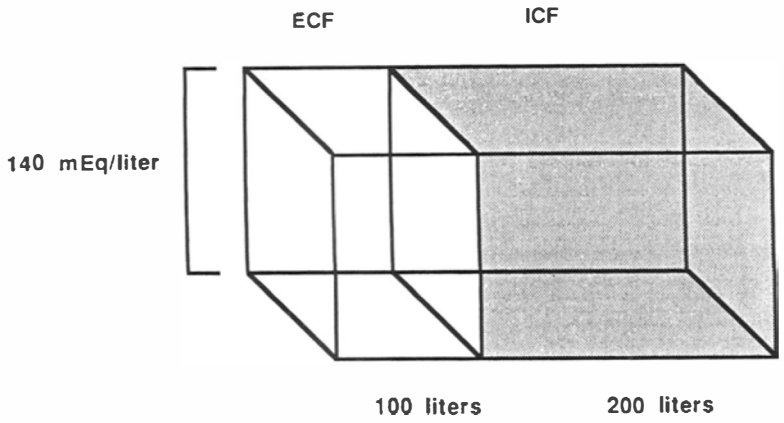

FIGURE 18.1 Body fluid compartments in a normal 450-kg horse. Serum sodium concentration is 140 mEq/liter (140 mmol/liter). Extracellular fluid (ECF) volume is 100 liters and intracellular fluid (ICF) volume is 200 liters.

sidered a subcomponent of the ECF. In small animal species the fluid content of the gastrointestinal tract is relatively small (Strombeck, 1979). In the large animal herbivore species, a substantial volume of fluid is normally present within the gastrointestinal tract. In the horse this may amount to 30–45 liters (Carlson, 1979b) and in cattle the forestomach may contain as much as 30–60 liters of fluid (Phillipson, 1977). During periods of water restriction and certain other forms of dehydration, this gastrointestinal fluid reservoir can be called on to help maintain effective circulating volume (McDougall *et al.*, 1974). All of the fluids of the ECF contain sodium in approximate concentrations of 130–150 mEq/liter H_2O. Sodium provides the osmotic skeleton for the ECF and the sodium content is the single most important determinant of ECF volume (Rose, 1984). Sodium deficits result in decreases in ECF volume, whereas sodium excess is most often associated with water retention and results in edema (McKeown, 1984; Rose, 1984).

C. Intracellular Fluid Volume

The ICF volume represents the fluid content within the body's cells. This volume cannot be measured directly, but is calculated as the difference between the measured TBW and the measured ECF volume. Potassium provides the osmotic skeleton for the ICF in much the same way that sodium provides the osmotic skeleton for the ECF. Because water is freely diffusible into and out of the cell, changes in the tonicity of the ECF are rapidly reflected by similar changes in ICF tonicity (Saxton and Seldin, 1986). This is largely the result of the movement of water across the cell membrane with resultant changes of ICF volume. Thus, although plasma sodium concentration decreases in response to water retention, ICF volume increases (Humes, 1984). On the other hand, with water depletion resulting in hypernatremia ICF volume decreases (Humes, 1984). Relatively little is known about the organization of intracellular water into the various subcellular compartments and organelles.

IV. REGULATION OF BODY FLUIDS AND ELECTROLYTES

A. Effective Circulating Volume

The effective circulating volume refers to that part of the ECF that is within the vascular space and is effectively perfusing the tissues (Rose, 1984). Effective circulating volume tends to vary with ECF volume and both parameters vary with the total body sodium stores (Rose, 1984). Sodium loading produces volume expansion, whereas sodium depletion leads to volume depletion.

Effective circulating volume is not a quantitatively measurable entity but refers to the rate of perfusion of the capillary circulation. Effective circulating volume is maintained by varying vascular resistance, cardiac output, and renal sodium and water excretion (Rose, 1984). Decreases in effective circulating volume result in decreased venous return, decreased cardiac output, and decreased blood pressure. Decreased volume and pressure are recognized by special volume receptors in the cardiopulmonary circulation and kidney which trigger increased sympathetic tone, resulting in increased arterial and venous constriction as well as increased cardiac contractility and heart rate. These responses tend to correct for the volume deficit by increasing cardiac output and systemic blood pressure.

Volume and pressure changes associated with decreases in effective circulating volume also result in activation of the renin–angiotensin system with subsequent enhancement of aldosterone secretion by the adrenal cortex (Brobst, 1984). Aldosterone acts to enhance renal sodium resorption, which is a critical factor in the restoration of effective circulating volume. Additional factors that influence sodium resorption in response to changes in fluid volume, include alterations in glomerular filtration rate, renal hemodynamics, atrial natriuretic factor, and plasma sodium concentration.

B. Antidiuretic Hormone

Antidiuretic hormone (ADH) plays a primary role in the regulation of the osmolality of the body fluids. Antidiuretic hormone is synthesized in the hypothalamus and released in response to changes in plasma osmolality. Because sodium concentration is the primary determinant of plasma osmolality, ADH release is closely correlated to plasma sodium concentration. Increases in plasma osmolality are recognized by special sensors in the hypothalamus and the normal response is increased thirst to enhance water intake and the release of ADH, which increases water reabsorption by the renal collecting tubules. Antidiuretic hormone exerts its activity on the collecting tubules by activating adenyl cyclase, which results in the generation of cyclic adenosine monophosphate (AMP) and protein kinases, which in turn alter the permeability of the tubules to water (Rose, 1984). Antidiuretic hormone also is released in response to decreases in effective circulating fluid volume although the renin–angiotensin system exerts primary control over volume changes. Antidiuretic hormone acts extrarenally as an arterial vasoconstrictor, thus increasing blood pressure. Plasma osmolality decreases in response to a water load and ADH release is inhibited. The resultant reduction in ADH-mediated reabsorption of water in the collecting tubules allows for appropriate renal excretion of the water load and a return of plasma osmolality toward normal. This highly sensitive system responds rapidly to small changes in osmolality and, as a result, plasma osmolality is normally maintained within a relatively narrow range.

C. Renin–Angiotensin

The renin–angiotensin system plays an important role in the maintenance of effective circulating fluid volume. Renin is a proteolytic enzyme produced by special juxtaglomerular cells of the glomerular afferent arteriole. Renin is released in response to reduced renal perfusion produced by hypotension, volume depletion, or increased sympathetic activity. Renin converts the circulating globulin angiotensinogen to angiotensin I, which is subsequently converted by an enzyme in the lung and vascular endothelial cells to the biologically active form, angiotensin II. Angiotensin II exerts a variety of systemic effects which tend to correct hypovolemia and hypotension. Angiotensin II increases renal retention of sodium and water by enhancing secretion of aldosterone from the adrenal cortex; it also has direct effects on the renal tubule. Angiotensin II exerts hemodynamic effects, which tend to increase blood pressure by inducing arteriolar vasoconstriction.

D. Aldosterone

Aldosterone plays a central role in the maintenance of effective circulating fluid volume and potassium balance largely through its effects on renal resorption of sodium in exchange for potassium and hydrogen ion. Aldosterone is produced in the adrenal cortex and exerts its effects on sensitive cells such as the renal collecting tubules by interacting with specific cytoplasmic receptors. The aldosterone receptor complexes subsequently enhance RNA-mediated production of specific proteins, which actually mediate the physiologic effects of the hormone. There is evidence for aldosterone-mediated effects on gastrointestinal sodium and potassium absorption as well as effects on sweat glands to alter the electrolyte composition of sweat in response to sodium depletion (Michell, 1974). Aldosterone secretion is enhanced by the renin–angiotensin system in response to changes in effective circulating fluid volume.

E. Atrial Natriuretic Factor

Atrial natriuretic factor (ANF), also known as atrial natriuretic peptide (ANP), exists as a group of diverse peptide hormones produced in the heart and released into the circulation in response to processes which increase central venous pressure and result in stretching of the atrial wall (Inagami, 1994). The actions of ANF, which tend to reduce cardiac output and systemic blood pressure, are mediated by transmembrane receptors which result in the production of cyclic guanidine monophosphate generated by quanylyl cyclase (Inagami, 1994). ANF results in natriuresis and diuresis by the kidneys. ANF also causes vasodilatation and fluid volume reduction by direct action on vascular smooth muscle and inhibition of the release of aldosterone from the adrenal cortex and norepinephrine from peripheral adrenergic neurons. Additionally, ANF has been found in the brain and centrally medicated effects on fluid volume regulation may be important. Elevated

plasma ANF has been noted in humans with a variety of diseases ranging from congestive heart failure to obstructive lung disease to chronic renal failure. However, the physiologic importance of ANF in these disease processes is not completely resolved. In humans, Bartter's syndrome and Gordon's syndrome are thought to be due to an excess or deficiency, respectively of ANF (Christensen, 1993). In horses, elevation of plasma ANF has been associated with treadmill exercise (McKeever *et al.*, 1991).

V. PHYSIOLOGY OF ACID–BASE BALANCE

The hydrogen ion concentration of the ECF is maintained within remarkably narrow limits, and is normally approximately 40 nmol/liter. This is 40×10^{-6} mmol/liter or roughly one-millionth the concentration of the other common electrolytes. Even at these extremely low concentrations, hydrogen ions have profound effects on metabolic events largely through interaction with cellular proteins. These interactions result in altered protein configuration and thus altered protein function. Most enzymatic reactions have a narrowly defined range of pH optimum, and changes in hydrogen ion concentration have direct effects on the rates of reaction and, thus, many basic biologic processes.

A. Definition of pH

Although the hydrogen ion concentration can be expressed in nanomoles per liter, a more useful expression is that of pH. The pH of a solution is equal to the negative logarithm of the hydrogen ion concentration.

$$\text{pH} = -\log[\text{H}^+] \tag{18.2}$$

It is important to remember that pH varies inversely with hydrogen ion concentration. When hydrogen concentration in the blood increases, pH decreases and the animal develops an acidosis. When the hydrogen ion concentration in the blood decreases, pH rises and the animal develops an alkalosis. The traditional view of acid–base balance involves the following:

1. Extracellular and intracellular buffering
2. Regulation of the rate of alveolar ventilation to control carbon dioxide concentration
3. Regulation of renal hydrogen excretion

B. Buffers

A buffer system consists of a weakly dissociated acid and the salt of that acid. The body buffers are able to take up or release hydrogen ion so that changes in hydrogen ion concentration are minimized. According to the law of mass action the dissociation of a weak acid, HA, into H^+ and A^- can be written

$$K_a = \frac{[\text{H}^+]\,[\text{A}^-]}{[\text{HA}]}, \tag{18.3}$$

where K_a is the dissociation constant for the reaction. The equation can be rewritten

$$[\text{H}^+] = K_a \frac{[\text{HA}]}{[\text{A}^-]} \quad \text{or} \quad [\text{H}^+] = K_a \frac{[\text{Acid}]}{[\text{Salt}]}. \tag{18.4}$$

Taking the negative logarithm of both sides of the equation yields

$$-\log[\text{H}^+] = -\log K_a - \log \frac{[\text{HA}]}{[\text{A}^-]}. \tag{18.5}$$

Substituting pH for $-\log[\text{H}^+]$, $+\log[\text{A}^-/\text{HA}]$ for $-\log[\text{HA}/\text{A}^-]$, and defining pK_a as $-\log K_a$, the formula now reads

$$\text{pH} = pK_a + \log \frac{[\text{A}^-]}{[\text{HA}]}. \tag{18.6}$$

This is the familiar Henderson–Hasselbalch equation for the dissociation of a weak acid. The buffering capacity of the body includes the extracellular buffers, intracellular buffers, and bone. The extracellular buffers include the bicarbonate (HCO_3^-/H_2CO_3) and phosphate ($HPO_4^=/H_2PO_4^-$) buffer pairs as well as the plasma proteins. The intracellular buffers include protein, organic and inorganic phosphates, and in the red cell hemoglobin. Cation exchange involving the intracellular movement of hydrogen ion in exchange for potassium and, to a much lesser extent, sodium is an additional and important means whereby cellular mechanisms buffer an acid load. The carbonate in bone provides a large and often overlooked buffer store. Although difficult to measure accurately, it has been estimated that bone carbonate may contribute up to 40% of the buffering capacity of an acute acid load. It is important to remember that a change in hydrogen ion concentration will affect all the body's buffer pairs. Thus, evaluation of any one buffer pair reflects the changes which occur in all of the buffer pairs.

1. Bicarbonate/Carbonic Acid Buffer System

Large amounts of carbon dioxide are produced by oxidative metabolism each day. Although carbon dioxide is not an acid, it combines with water as it is added to the bloodstream, resulting in the formation of carbonic acid. The enzyme carbonic anhydrase in the red cells facilitates this reaction:

$$\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{CO}_3 \rightleftarrows \text{H}^+ + \text{HCO}_3^-. \tag{18.7}$$

The ensuing elevation in the hydrogen concentration is

minimized because most of the excess H^+ ions combine with the intracellular buffers, particularly hemoglobin (Hb):

$$H_2CO_3 + Hb^- \rightleftarrows HHb + HCO_3^-. \quad (18.8)$$

The bicarbonate generated by this reaction then leaves the erythrocyte and enters the extracellular fluid in exchange for extracellular chloride ion. The net effect is that CO_2 is primarily carried in the venous circulation as HCO_3^- with little change in the extracellular pH. These processes are reversed in the alveoli. As HHb is oxygenated, H^+ is released and the H^+ combines with HCO_3^- to form H_2CO_3, which dissociates to CO_2 and H_2O. Carbon dioxide then is excreted by alveolar ventilation.

From a clinical and physiologic standpoint the bicarbonate–carbonic acid buffer pair is clearly the most important. Bicarbonate is present in relatively high concentrations, it is relatively easy to measure, and it is the buffer system over which the body has the greatest control. The Henderson–Hasselbalch equation applied to this buffer pair becomes

$$pH = 6.1 + \log \frac{[HCO_3^-]}{[H_2CO_3]}, \quad (18.9)$$

where 6.1 = pK for the HCO_3^-/H_2CO_3 buffer pair.

Plasma pH is determined by the concentration of bicarbonate and carbonic acid or, more importantly, the ratio between bicarbonate and carbonic acid. An equilibrium exists between the partial pressure of CO_2 in the alveolar air, the partial pressure of gaseous CO_2 dissolved in the blood, and the carbonic acid concentration of the blood. The conventional method of evaluating carbonic acid is the determination of the partial pressure of carbon dioxide (pCO_2) in the blood. The carbonic acid concentration can be calculated by multiplying pCO_2 by 0.03 (0.03 is the solubility constant for carbon dioxide in plasma). The Henderson–Hasselbalch equation for this buffer pair then becomes

$$pH = 6.10 + \log \frac{[HCO_3^-]}{0.03(pCO_2)}. \quad (18.10)$$

The four primary acid–base imbalances and their compensating responses are presented in Table 18.2.

TABLE 18.2 Acid–Base Imbalances and Compensating Responses

Disorder	pH	[H+]	Primary imbalance	Compensating response
Metabolic acidosis	↓	↑	↓ $[HCO_3^-]$	↓ pCO_2
Metabolic alkalosis	↑	↓	↑ $[HCO_3^-]$	↑ pCO_2
Respiratory acidosis	↓	↑	↑ pCO_2	↑ $[HCO_3^-]$
Respiratory alkalosis	↑	↓	↓ $[pCO_2$	↓ $[HCO_3^-]$

Acidosis is associated with a decrease in pH due to an increase in hydrogen ion concentration. Alkalosis is due to a decrease in hydrogen ion concentration, which is reflected by an increase in pH. In the metabolic disorders, the primary imbalance is due to changes in bicarbonate concentration. The compensating response is mediated by the respiratory system which, within limits, alters the pCO_2 so as to counterbalance the primary imbalance and to partially restore the pH toward normal. As the name implies, the primary imbalances of the respiratory disorders are related to alterations in alveolar ventilation, which result in increases in pCO_2 in respiratory acidosis and decreases in pCO_2 with respiratory alkalosis. The compensating responses for these primary respiratory imbalances are mediated by the kidney through alterations in the excretion or retention of hydrogen ions or bicarbonate.

Blood samples drawn for acid–base evaluation must be drawn anaerobically and sealed so as to avoid alteration in the blood gas tension. Heparin is the anticoagulant of choice. The rectal temperature of the patient should be taken so that appropriate temperature corrections can be made. For evaluation of blood gases during intense exercise, central blood temperature should be used for this correction because rectal temperature may not accurately reflect blood temperature under these non-steady-state conditions. The temperature correction usually has a greater impact on the pO_2 and pCO_2 than bicarbonate or base balance. Arterial blood samples are generally preferred and are essential for the evaluation of primary respiratory disorders or the patient's status under general anesthesia. Venous blood samples provide reliable data on metabolic acid–base abnormalities and because they are easier to obtain are routinely used. As a general rule blood gas determination should be made as soon after collection as possible. However, appropriately collected blood samples can be held in ice water for as long as 4 hours and still yield reliable results.

The effects of various sampling sites (arterial, venous, and capillary blood) on blood gas determination have been evaluated in dogs (van Sluijs *et al.*, 1983; Ilkiw *et al.*, 1991), horses (Littlejohn and Mitchell, 1969; Speirs, 1980), and swine (Hannon *et al.*, 1990). Consistent differences were demonstrated between arterial and venous blood. Arterial blood samples yield higher values for pH and lower values for pCO_2 and bicarbonate than venous blood, but the calculated base balance tends to be very similar for both arterial and venous blood samples. In horses, venous–arterial differences in bicarbonate can exceed 10 mEq/liter during intense exercise. The higher venous bicarbonate value reflects the important role of bicarbonate as a means of CO_2 transport in the venous circulation (Carlson, 1995). At

rest and during exercise, more than 70% of the CO_2 produced in the tissues is transported in the venous circulation to the lungs as bicarbonate. This process is greatly facilitated by erythrocyte carbonic anhydrase and the mechanism of the *chloride shift*. The effects of temperature on oxygen content of dog blood have been studied (Hedley-Whyte and Laver, 1964) as has the oxygen affinity and Bohr coefficient of dog blood (Reeves *et al.*, 1982). Recumbency in neonatal patients and body position during general anesthesia may have a significant impact on both arterial and mixed venous blood gas data (Steffey *et al.*, 1977; Mason *et al.*, 1987; Madigan *et al.*, 1992). Normograms have been developed relating the effects of temperature, CO_2 content, and hemoglobin saturation for dog blood (Rossing and Cain, 1966). The use of blood gas data for the evaluation of acid–base imbalances for clinical problems has been reviewed (DiBartola, 1992a, 1992b, 1992c; DiBartola and De Morais, 1992; De Morais, 1992a; George, 1994).

C. Acidosis

1. *Metabolic*

Metabolic acidosis is characterized by a decrease in pH and bicarbonate. Metabolic acidosis, as traditionally viewed, can be produced by the addition of hydrogen ions or a loss of bicarbonate ions. The initial buffering of an acid load is by the ECF buffers, primarily the bicarbonate–carbonic acid buffer pair (Rose, 1984). Intracellular buffers, particularly protein and phosphate, assist in the buffering process. The intracellular movement of hydrogen in exchange for potassium helps to prevent an excessive increase of the ECF hydrogen ion concentration in the face of an acid load. This exchange is called the *cation shift* and can result in hyperkalemia even though the total body potassium stores have been depleted due to renal or gastrointestinal losses.

a. Causes of Metabolic Acidosis

The most common causes include lactic acidosis, ketoacidosis, gastrointestinal loss of bicarbonate due to diarrhea, and renal failure, which may result in a decreased ability to excrete hydrogen and thus to retain bicarbonate (Emmett and Nairns, 1977). A profound metabolic acidosis without dehydration leading to depression, recumbency, and death has been described in goat kids (Tremblay *et al.*, 1991) and appears to be similar to reports in calves (Kasari and Naylor, 1984, 1986). The cause was undetermined, but the acidosis was usually associated with an increased anion gap. Sodium bicarbonate therapy, if initiated early in the course of the disease, was often curative. Additional causes of a metabolic acidosis include ingestion of certain medications or toxic compounds such as salicylate, methanol, ethylene glycol, or paraldehyde, which results in the accumulation of exogenous anions (DiBartola 1992b).

b. Compensation

A metabolic acidosis is recognized very quickly and the compensating respiratory response of increased ventilation will begin reduction of the pCO_2 within minutes. In dogs the anticipated respiratory response is a reduction of pCO_2 by 0.7 mm Hg for each mEq/liter decrease in bicarbonate (DeMorais, 1992a). This minimizes the fall in pH but the protective effects of the respiratory response are relatively short lived, lasting only a few days. Long-term correction of a metabolic acidosis requires renal bicarbonate retention and enhanced renal acid excretion primarily as ammonium ion since there is little ability to increase the titratible acidity, which consists primarily of phosphate buffers (Rose, 1984). Complete correction of a metabolic acidosis may be difficult in patients with intrinsic renal disease or diseases that would impair the kidney's ability to excrete acid or retain bicarbonate such as renal tubular acidosis.

2. *Respiratory*

A respiratory acidosis is characterized by a decrease in pH and an increase in pCO_2. Respiratory acidosis develops because of decreased effective alveolar ventilation. The initial buffering of the acid load produced by a respiratory acidosis is almost exclusively by the intracellular buffers. The principal ECF buffer, the bicarbonate–carbonic acid buffer pair, cannot buffer a respiratory acidosis. Carbon dioxide diffuses through the lung much more readily than O_2, thus, diseases that compromise ventilation normally result in decreases in pO_2 before significant increases in pCO_2 develop. The respiratory center is extremely sensitive to minor changes in pCO_2 and increased pCO_2 normally provides the major stimulus to ventilation (Rose, 1984). In contrast, hypoxemia does not begin to promote enhanced ventilation until the arterial pCO_2 is substantially decreased. If, however, the arterial pCO_2 is held at normal values or is elevated because of intrinsic lung disease, then ventilation begins to be enhanced as the arterial pO_2 falls below 70–80 mm Hg (Rose, 1984).

a. Causes of Respiratory Acidosis

Any disorder that interferes with normal effective ventilation may produce a respiratory acidosis. The most common causes are primary pulmonary diseases ranging from acute upper respiratory obstruction, to pneumonia, to pneumothorax, and chronic obstructive lung disease. Diseases or drugs that affect the central

nervous system may inhibit the medullary respiratory center and can produce a profound respiratory acidosis. An additional cause of special importance in veterinary medicine is general anesthesia with volatile agents using a closed system. Under these conditions ventilation may be seriously reduced without producing hypoxia. The high oxygen content of the gas mixture maintains high pO_2 in the blood but depression of the respiratory center may result in insufficient alveolar ventilation so that CO_2 accumulates. This problem can be overcome through the use of a positive pressure ventilatory apparatus and careful monitoring of arterial blood gases during general anesthesia.

b. Compensation

The compensating response for a respiratory acidosis is renal retention of bicarbonate. This response requires several days and, thus, the response is only seen in a chronic respiratory acidosis. In dogs with chronic respiratory acidosis, a compensating increase of 0.35 mEq/liter of bicarbonate is anticipated for each mm Hg increase in pCO_2 (De Morais, 1992a). The extent of the rise in the plasma bicarbonate concentration in chronic respiratory acidosis is determined by increased renal hydrogen secretion (Rose, 1984). Exogenous bicarbonate is unnecessary and should bicarbonate be administered to patients with a respiratory acidosis it would be excreted without affecting the final plasma bicarbonate concentration.

D. Alkalosis

1. Metabolic Alkalosis

Metabolic alkalosis is characterized by an increase in pH and bicarbonate. Metabolic alkalosis occurs with some frequency in domestic animals and is commonly seen in association with digestive disturbances in ruminants. The development of a metabolic alkalosis requires an initiating process capable of generating an alkalosis and then additional factors which are necessary for the continued maintenance of the alkalosis (Rose, 1984). Generation of a metabolic alkalosis can be due to excessive hydrogen loss, bicarbonate retention, or as a contraction alkalosis. A contraction alkalosis occurs with reduction of ECF fluid volume due to a loss or sequestration of sodium and chloride containing fluid without commensurate loss of bicarbonate (Garella *et al.*, 1975). Excessive hydrogen ion losses can result in a metabolic alkalosis.

a. Causes of Metabolic Alkalosis

The most common causes of increased hydrogen loss are gastrointestinal losses due to vomiting in small animals (Strombeck, 1979) or sequestration of chloride-rich fluid in the abomasum and forestomach of ruminants (Gingerich and Murdick, 1975b; McGuirk and Butler, 1980). Excessive renal hydrogen loss associated with mineralocorticoid excess, diuretic usage (particularly the loop diuretics such as furosemide), and low chloride intake may cause or contribute to the generation of a metabolic alkalosis (Rose, 1984). Most of these disorders are also associated with the development of significant sodium and chloride deficits and resultant decreases in effective circulating volume. These deficits and the responses that decreased effective circulating volume induce are central features of the processes which serve to maintain and perpetuate a metabolic alkalosis. Hydrogen loss from the ECF can also occur with hydrogen movement into the cells in response to potassium depletion (Irvine and Dow, 1968). Excessive bicarbonate administration is an additional potential cause of metabolic alkalosis. Most normal animals can tolerate large doses of bicarbonate and excesses are rapidly eliminated by renal excretion (Rumbaugh *et al.*, 1981). However, patients with decreases in effective circulating blood volume or with potassium or chloride deficits may not tolerate a bicarbonate load because renal clearance of excess bicarbonate is likely to be impaired.

The factors responsible for the maintenance of a metabolic alkalosis all impair renal bicarbonate excretion. These factors might include decreased glomerular filtration of bicarbonate seen in some types of renal failure. However, the most common factor is increased renal tubular bicarbonate resorption, which is associated with the renal response to decreases in the effective circulating fluid volume, potassium depletion, and/or chloride depletion (Rose, 1984). Sodium resorption is enhanced in response to hypovolemia in order to help restore normal effective circulating fluid volume. The maintenance of electroneutrality requires that sodium resorption in the proximal tubule be accompanied by a resorbable anion such as chloride, whereas in the distal tubule sodium resorption is associated with the secretion of a cation, usually hydrogen or, to a lesser extent, potassium. The only resorbable anion normally present in appreciable quantities in the proximal tubular fluid is chloride. In a metabolic alkalosis, plasma bicarbonate is increased and chloride concentration is generally decreased as the result of disproportionately high chloride losses due to vomiting, sequestration of gastric fluid (Whitlock *et al.*, 1975b), diuretic usage, or heavy sweat losses in exercising horses (Carlson, 1975, 1979a). The relative lack of the resorbable anion, chloride, in the proximal tubule thus allows a larger amount of sodium to reach the distal tubule where the action of aldosterone enhances hydrogen loss into the tubular lumen in exchange for sodium. The maintenance of effective circulating vol-

ume is so critical that the body chooses to maintain circulating volume by enhanced sodium resorption by whatever means necessary, even at the expense of extracellular pH. Renal hydrogen excretion is directly linked with bicarbonate resorption and thus it is not possible to eliminate the excess bicarbonate, and the metabolic alkalosis is maintained (Rose, 1984). This is the reason for the paradoxic acid urine seen in some patients with metabolic alkalosis (Gingerich and Murdick, 1975a, 1975b; McGuirk and Butler, 1980). Hypokalemia is another factor that contributes to the maintenance of a metabolic alkalosis. Hypokalemia is associated with an increase in intracellular hydrogen ion concentration. Increased renal tubular cell hydrogen ion concentration may enhance hydrogen secretion and thus bicarbonate reabsorption by the tubular cells.

b. Compensation

Chemoreceptors in the respiratory center sense the alkalosis and the respiratory response to a metabolic alkalosis is hypoventilation resulting in an increase in pCO_2. In dogs the expected compensating response is an increase of pCO_2 of 0.7 mm Hg for each mEq/liter increase in bicarbonate.

2. *Respiratory Alkalosis*

Respiratory alkalosis is associated with an increase in pH and a decrease in pCO_2.

a. Causes of Respiratory Alkalosis

Respiratory alkalosis is due to hyperventilation which may be stimulated by hypoxemia associated with pulmonary disease, congestive heart failure, or severe anemia. Hyperventilation may also be associated with psychogenic disturbances or neurologic disorders which stimulate the medullary respiratory center such as salicylate intoxication, or gram-negative sepsis. Respiratory alkalosis may be seen in animals in pain or under psychological stress. Hyperventilation may occur in dogs and other nonsweating animals because they employ respiratory evaporative processes for heat loss to prevent overheating (Tasker, 1980).

b. Compensation

The initial compensating response to an acute respiratory alkalosis is a modest decline in ECF bicarbonate concentration as the result of cellular buffering. Subsequent renal responses result in decreased ECF bicarbonate concentration through reduced renal bicarbonate reabsorption. These responses require 2 to 3 days for completion. The decline in bicarbonate is partially offset by chloride retention in order to retain electroneutrality. Thus, hyperchloremia and decreased pCO_2 may be associated with compensated respiratory alkalosis as well as compensated metabolic acidosis. Compensating responses for chronic respiratory alkalosis lasting several weeks may actually be sufficient to return pH to normal. In dogs anticipated renal compensation for a chronic respiratory alkalosis results in a decrease of bicarbonate of 0.55 mEq/liter for each mm Hg decrease in pCO_2 (DeMorais, 1992a).

E. Mixed Acid–Base Imbalances

Mixed acid–base disorders occur when several primary acid–base imbalances coexist (De Morais, 1992a). Metabolic acidosis and alkalosis can coexist and either or sometimes both of these metabolic abnormalities may occur with either respiratory acidosis or alkalosis (Nairns and Emmett, 1980; Wilson and Green, 1985). Evaluation of mixed acid–base abnormalities requires an understanding of the anion gap, the relationship between the change in serum sodium and chloride concentration, and the limits of compensation for the primary acid–base imbalances (Wilson and Green, 1985; Saxton and Seldin, 1986). Clinical findings and history are also necessary in order to define the factors that may contribute to the development of mixed acid–base disorders. The following are important considerations in evaluation of possible mixed acid–base disorders:

1. Compensating responses to primary acid–base disturbances do not result in overcompensation.
2. With the possible exception of chronic respiratory acidosis, compensating responses for primary acid–base disturbances rarely correct pH to normal. In patients with acid–base imbalances, a normal pH indicates a mixed acid–base disturbance.
3. A change in pH in the opposite direction to that predicted for a known primary disorder indicates a mixed disturbance.
4. With primary acid–base disturbances, bicarbonate and pCO_2 always deviate in the same direction. If these parameters deviate in opposite directions a mixed abnormality exists.

Although mixed acid–base abnormalities undoubtedly occur in animals and have been documented in the veterinary literature, they are often overlooked (Wilson and Green, 1985). An appreciation of the potential for the development of mixed abnormalities is essential for the correct interpretation of clinical and clinicopathologic data which would otherwise be confusing. Care should be taken when evaluating suspected mixed acid–base abnormalities that sufficient time has elapsed such that anticipated compensating responses could have occurred (DeMorais, 1992a).

F. Anion Gap

The anion gap can be calculated as the difference between the major cation (sodium) and the measured anions (chloride + bicarbonate) (Emmett and Nairns, 1977). Some investigators prefer to use the formula

$$\text{Anion gap} = (\text{Sodium} + \text{Potassium}) - (\text{Chloride} + \text{Bicarbonate}). \quad (18.11)$$

The addition of potassium to the equation, however, adds little to the diagnostic utility of this calculation (Emmett and Nairns, 1977; Man and Carroll, 1977; Epstein, 1984); the anion gap calculated with the inclusion of potassium concentration will be about 4 mEq/liter higher. Because most of the published data on the anion gap in animal species are the result of calculations using the second equation, this form is used in Table 18.4. Provided the component determinations are valid, the calculated anion gap provides an approximation of the so-called "unmeasured anions." Normally these unmeasured anions consist primarily of negatively charged plasma proteins, because the charges of the unmeasured cations (potassium, calcium, and magnesium) tend to balance out the charges of the unmeasured anions (phosphate, sulfate, and organic ions). The anion gap for most species of domestic animals appears to be similar to that defined for human subjects, i.e., approximately 10–20 mEq/liter (10 to 20 mmol/liter). However, there do appear to be significant differences in the normal range of the anion gap of different species as indicated in Table 18.4 (Adrogue *et al.*, 1978; Shull, 1978, 1981; Feldman and Rosenberg, 1981; Bristol, 1982; Polzin *et al.*, 1982; Gossett and French, 1983). Age-related changes in anion gap have been reported in horses (Gossett and French, 1983), with young foals having a significantly larger anion gap than adults. Further experimental data will be necessary to establish more clearly the normal range for the anion gap of animals under varying conditions.

TABLE 18.3 Causes of Alterations in Anion Gap

Decreased anion gap
Increased cationic protein
Polyclonal gammopathy (IgG)
Hypoalbuminemia
Hyperchloremic acidosis
Altered protein anionic equivalents
Laboratory error
Increased anion gap
Metabolic acidosis
Organic acids (lactic, keto acids)
Hypovolemic shock
Anaerobic exercise
Diabetes
Grain overload
Ketosis
Nonmetabolizable acids
Inorganic acids (sulfate, phosphate)
Uremic acidosis
Intoxication or poisoning
Salicylate
Paraldehyde
Metaldehyde
Methanol
Ethylene glycol
Laboratory error

This simple calculation (Eq. 18.11) can be extremely helpful in the categorization of acid–base disorders with regard to potential causal factors (Table 18.3) and may serve as a prognostic guide in a variety of circumstances (Shull, 1978; Bristol, 1982; Garry and Rings, 1987). Decreases in the anion gap can be seen with increases in cationic proteins associated with polyclonal gammopathy or multiple myeloma. Decreases in anion gap due to decreases in unmeasured anions occur most commonly with hypoalbuminemia and hyperchloremic metabolic acidosis, but also may be noted with overhydration. The causal factors associated with a hyperchloremic metabolic acidosis with a normal to low anion gap can often be differentiated based on the serum potassium concentration. Hyperchloremic metabolic acidosis associated with gastrointestinal fluid losses from diarrhea or renal causes such as renal tubular acidosis most often manifest a hypokalemia (Saxton and Seldin, 1986; Ziemer *et al.*, 1987a, 1987b). Hyperchloremic metabolic acidosis associated with decreased mineralocorticoid secretion or activity, such as that seen in Addison's disease or renal failure, generally presents with a hyperkalemia (Saxton and Seldin, 1986). There are indications that changes in hydrogen ion concentration may alter protein equivalency and thus alter the anion gap in either an acidosis or alkalosis (Adrogue *et al.*, 1978; Madias *et al.*, 1979).

Dehydration and alkalosis are potential but minor causes of increased anion gap. Most commonly, elevations of the anion gap are associated with the development of a metabolic acidosis in which there is an increase in anions which are not routinely measured in the clinical laboratory. This is called a *high anion gap acidosis* and may be associated with an accumulation of metabolizable acids as in a lactic acidosis associated with anaerobic exercise, grain overload, or hypovolemic shock or ketoacidosis due to diabetes or ketosis or with the accumulation of nonmetabolizable acids as in uremic acidosis or various intoxications (see Table 18.3). The presence of a metabolic acidosis with a high anion gap thus provides grounds to undertake a thorough investigation of disease processes capable of pro-

TABLE 18.4 Reference Values for Blood Gas and Electrolyte Determinations[a]

Electrolyte or gas	Dog	Cat	Horse	Ox	Sheep	Goat	Pig
Sodium (mEq/liter)	140–155	147–156	132–146	132–152	139–152	142–155	135–150
Potassium (mEq/liter)	3.7–5.8	4.0–5.3	2.6–5.0	3.9–5.8	3.9–5.4	3.5–6.7	4.4–6.7
Chloride (mEq/liter)	105–120	115–123	99–109	97–111	95–103	99–110	94–106
Calcium (mg/dl)	9.0–11.3	6.2–10.2	11.2–13.6	9.7–12.4	11.5–12.9	8.9–11.7	7.1–11.6
Magnesium (mg/dl)	1.8–2.4	2.2	2.2–2.8	1.8–2.3	2.2–2.8	2.8–3.6	2.7–3.7
Phosphorus (mg/dl)	2.6–6.2	4.5–8.1	3.1–5.6	5.6–6.5	5.0–7.3	6.5	5.3–9.6
Anion gap (mEq/liter)	15–25		6.6–14.7	13.9–20.2			
pH	7.31–7.42	7.24–7.40	7.32–7.44	7.35–7.50	7.32–7.54		7.39

Bicarbonate (mEq/liter)	17–24	17–24	24–30	20–30	20–25		25.6
Osmolality (mOsm/kg H_2O)	280–305	280–305	270–300	270–300			

[a] In part from Tasker (1980).

ducing an accumulation of these unmeasured anions. The anion gap also may be useful in the identification of mixed acid–base imbalances. When the change in the anion gap does not approximate the change in bicarbonate, a mixed metabolic acid–base imbalance should be suspected.

G. Bicarbonate and Total CO_2

If respiratory disturbances can be eliminated, the metabolic component of acid–base balance is indicated by the bicarbonate concentration. Bicarbonate is usually estimated by determination of the "CO_2 content" or "total CO_2" of plasma or serum samples.

Bicarbonate actually accounts for approximately 95% of the measured total CO_2 and thus the total CO_2 provides a measure of metabolic changes in acid–base balance. The bicarbonate determined in this fashion will be decreased in a metabolic acidosis and increased in a metabolic alkalosis. Estimates of bicarbonate are often provided in automated chemistry profiles. These determinations may provide an indication of the metabolic acid–base status. However, if acid–base abnormalities are suspected, a proper blood gas evaluation should be undertaken.

H. Buffer Base, Standard Bicarbonate, and Base Excess or Deficit

These values are mathematically derived from the measurements of blood pH and pCO_2 and provide an indication of the metabolic component of acid–base balance. Note that the metabolic changes indicated by these parameters do not always reflect the primary acid–base imbalances, but may represent compensating responses for primary respiratory disorders.

The *buffer base* provides an indication of the sum of all the buffer anions in blood under standardized conditions. The *standard bicarbonate* is the plasma bicarbonate concentration that would be found under specific conditions which eliminate respiratory influences on the values obtained. The *base excess*, which is sometimes considered to be the *base deficit* when the value is negative, indicates the deviation of the buffer base from normal. This derived value is often supplied in routine assessment of acid–base balance and is generally taken as an indication of the deviation of bicarbonate from normal. In an animal with a metabolic acidosis, the calculated base deficit provides a means of estimating the amount of bicarbonate required to correct the acid–base balance to normal. This estimate is calculated by multiplying the base deficit by the probable bicarbonate space (which is variably estimated from 0.25 to 0.55 liter/kg body weight). In newborn animals the bicarbonate may be even higher, 0.40–0.65 liter/kg body weight. The usual figure used is 0.3–0.4 liter/kg. For a 20-kg animal with a base deficit of 10 mmEq/liter (10 mmol/liter), the bicarbonate required would be calculated as

$$\text{Bicarbonate required} = 20\ \text{kg} \times 0.3\ \text{liter/kg} \times 10\ \text{mEq/liter} = 60\ \text{mEq}. \quad (18.12)$$

It should be appreciated that this calculation provides only a crude guide to bicarbonate requirements, but can be a useful step in the quantitative approach to correction of a serious primary metabolic acidosis.

I. Nontraditional Approach to Acid–Base Balance

Some years ago Peter Stewart developed a quantitative physiochemical approach to acid–base balance (Stewart, 1981, 1983). He recognized that the acid–base status of the aqueous solutions of the body was determined not only by the Henderson–Hasselbalch equa-

tion but also by a number of other relationships which could be represented by a series of simple equations, all of which must be satisfied simultaneously. In this approach, acid–base balance is determined by three independent variables: (1) strong ion difference, [SID], which for our purposes can be considered as (sodium + potassium) − (chloride); (2) the partial pressure of CO_2; and (3) the total concentration of nonvolatile weak acids, [Atot], the principal component of which is the plasma proteins but also includes inorganic phosphate. Bicarbonate and hydrogen ion concentration and, thus, pH are dependent variables determined solely by the independent variables listed. The appeal of Stewart's approach is the focus on factors which are causally related to acid–base balance, the independent variables. However, many of these concepts are not intuitively obvious. The interested reader is referred to Stewart's original work and to a number of papers that have attempted to adapt this approach for practical application (Fencil and Rossing, 1989, Jones, 1990; Fencil and Leith, 1993; De Morais, 1992b; Kowalchuck and Scheuermann, 1993; Gilfix *et al.*, 1993; Frischmeyer and Moon, 1994; Whitehair *et al.*, 1995).

It is useful to consider Stewart's three independent variables and how they relate to the more traditional view of acid–base balance. Strong electrolytes are completely dissociated in aqueous solution and chemically nonreactive. The [SID] is simply the difference between the total concentration of strong cations (sodium, potassium, and magnesium) and the total concentration of strong anions (chloride, sulphate, lactate, acedoacetate, and β-hydroxybutyrate). Since they are present in higher concentrations in the body fluids sodium, potassium and chloride are normally the principal determinants of [SID]. The [SID] is synonymous with buffer base as described by Singer and Hastings (1948), and as such can be considered to be roughly equivalent to the metabolic component of the traditional approach to acid–base balance. Abnormalities in pCO_2 are viewed in essentially the same manner in both the traditional and nontraditional approach to acid–base balance. Primary increases in pCO_2 result in a respiratory acidosis and decreases in pCO_2 result in a respiratory alkalosis. The contribution of plasma proteins to acid–base balance is not considered in the traditional approach to acid–base balance. The plasma proteins, or perhaps more correctly plasma albumen, make up the majority of [Atot], whereas inorganic phosphate normally accounts for less than 5% of [Atot]. The [Atot] in body fluids exist in both dissociated [A^-] and undissociated [HA] forms. A decrease in [Atot] due to hypoalbuminemia causes an alkalosis with an increase in bicarbonate; hyperalbuminemia has the opposite effect. Hypoalbuminemia is one of the most common causes of alkalosis in older human patients (McAuliffe *et al.*, 1986). Changes in A^- associated with changes in albumen concentration also have a direct, but often unrecognized, effect on anion gap. Increases in A^- result in an increase in anion gap, whereas decreases in A^- cause a decrease in anion gap (McAuliffe *et al.*, 1986). In some circumstances change in protein concentration will potentate or ameliorate the effects of alterations in [SID] on acid–base balance. As an example, in a vomiting dog the elevated protein associated with dehydration may reduce the bicarbonate increase anticipated for a given change in [SID].

Protein and inorganic phosphate often remain constant in the face of an acid–base disturbance and thus acid–base balance is largely controlled by changes in pCO_2 mediated by the respiratory system, whereas changes in [SID] are largely under the control of the kidneys. Compensating changes for increases in [SID] are brought about by alterations in pCO_2 via the respiratory tract; the reverse is true of primary respiratory disorders. Thus renal compensation for primary respiratory disorders and respiratory compensation for primary metabolic acid–base disturbances are similar in both the traditional and nontraditional approach. Precise quantitation of the anticipated compensating responses to primary acid–base disturbances based on change in [SID] has not yet been determined.

One might consider why such diverse conditions as vomiting in a dog, heavy sweat loss in an endurance horse, displaced abomasum in a cow, and the administration of the loop diuretic furosemide in a cat result in a similar acid–base disturbance. In each circumstance, we see a disproportionate loss of chloride relative to sodium, which results in a hypochloremia and an increase in [SID]. Correction of the alkalosis is not brought about by the administration of hydrogen ions, but by the provision of chloride, generally as sodium chloride or potassium chloride, which results in a decrease in [SID] and thus a return of the dependent variables, bicarbonate and hydrogen ion, toward normal. The data presented in Fig. 18.2 illustrate the close interrelationship between the relative balance of cations and anions in the normal animal and animals with metabolic acid–base disturbances. The horse with the lactic acidosis had just completed a race and in the traditional view the high anion gap metabolic acidosis was due to the high plasma lactate and a markedly decreased bicarbonate. From a nontraditional point of view, the principal reason for the acidosis was the marked increase in the strong anion, lactate, which resulted in decreased [SID]. Intense exercise caused profound but transient compartmental fluid shifts, which increase the concentration of sodium and potassium relative to chloride in the venous circulation.

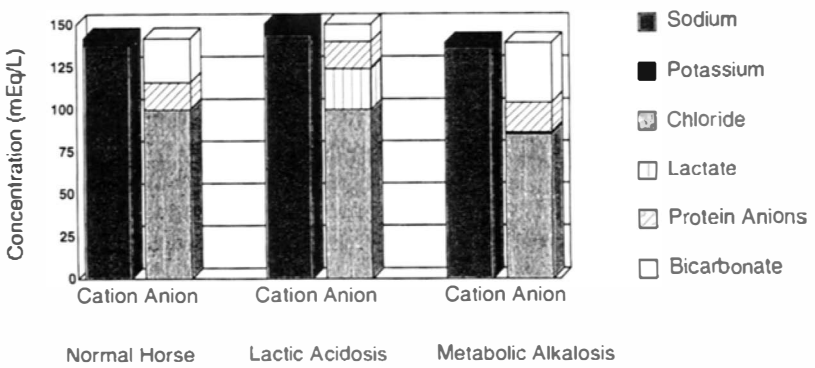

FIGURE 18.2 The cation–anion balance of three horses with differing acid–base status. The anion gap (AG) is calculated as (sodium + potassium) − (chloride + bicarbonate). In this figure AG is represented by the sum (protein anions + lactate). The [SID] is calculated as (sodium + potassium) - (chloride + lactate) and [SID] is equal to the sum (bicarbonate + protein anions).

This tends to ameliorate in part the decrease in [SID] brought about by the accumulation of the strong anion lactate (Carlson, 1995). The horse with the metabolic alkalosis had just completed an endurance race and was moderately dehydrated from heavy sweat losses. The disproportionately high loss of chloride in equine sweat was the principal reason for the hypochloremia with a resultant increase in [SID] and the development of a moderate metabolic alkalosis. The increase in [Atot] and A^- associated with elevated plasma proteins in this horse contributed to a modest increase in anion gap and blunted the increase in bicarbonate associated with the increased [SID]. In almost all circumstances there is a close correlation between bicarbonate and [SID]. In the cerebrospinal fluid where there is no appreciable protein, [SID] and bicarbonate concentration are essentially the same.

The nontraditional approach to acid–base balance has not replaced the traditional approach in routine medical matters. However, calculation of [SID] is simple and provides useful insight in patients with metabolic acid–base disturbances. Factors that influence [SID] range from changes in free water, to sodium–chloride imbalances resulting from excessive losses or disproportionate retention of sodium or chloride, to the accumulation of strong organic anions. Organic acidosis can be produced by the accumulation of exogenous as well as endogenous organic anions. Examples of exogenous anions include salicylate, glycolate, and formate associated with the ingestion of aspirin, ethylene glycol, and methanol, respectively. Many of these endogenous and exogenous organic anions are not routinely monitored in the diagnostic laboratory. This can create problems when calculating the [SID] because the presence of these unmeasured strong anions may not be appreciated. Although the anion gap can be helpful, it does not always accurately predict the presence of these compounds. More sophisticated mathematical methods have been suggested as a means for the detection of unmeasured anions for use in this calculation (Stewart, 1981). In animals with major changes in protein or albumen concentration, the primary concern must be a thorough investigation of the cause of the increase or decrease in protein. The acid–base consequences of change in protein and albumen concentration tend to be modest, but are a potential source of confusion when evaluating acid–base data.

With our present state of knowledge, the nontraditional approach to acid–base balance has had limited acceptance by the veterinary medical community. This limited acceptance is largely the result of our inability to translate this information effectively into the practical decision-making process. However, as we learn to harness its power, this approach has the potential to be extremely helpful for the evaluation of the interrelationship between fluid, electrolyte, and acid–base balance.

J. Dietary Factors in Acid–Base Balance

Dietary factors, particularly the dietary cation–anion balance (DCAB), have been extensively studied in cattle, swine, poultry, and horses. The calculation of the DCAB of a dry feed ration is remarkably similar to the calculation of [SID] for body fluids. The DCAB in mEq is generally represented as (sodium + potassium) − (chloride + sulfate) per kilogram of dry matter of the diet. Diets with a high DCAB, such as alfalfa hay, have an alkalinizing effect and are an important factor in the alkaline urine of most herbivores. High-grain rations tend to have a lower DCAB.

Manipulation of the DCAB has been employed to enhance milk yield in dairy cattle, to reduce the incidence and severity of gastric ulceration in swine, to decrease the incidence of milk fever in cattle, and to alter the urine pH and calcium balance in horses. The addition of sodium bicarbonate to the ration of dairy cattle to raise the DCAB from −100 to +200 mEq/kg diet DM resulted in increased milk production of more than 8%, which was due in part to more effective ruminal digestion (Block, 1984). On the other hand, supplementation of the diet of cattle with calcium chloride or ammonium chloride so as to lower the DCAB has an acidifying effect and has been shown to reduce the incidence of milk fever by enhancing the mobilization of calcium from the bone (Billig, 1984). As the application of these dietary practices become more widespread, we need to appreciate the implications of dietary factors and electrolyte supplementation on mineral metabolism and acid–base balance (Fredeen *et al.*, 1988).

Sodium bicarbonate supplementation has been used as a prerace ergogenic aid in race horses. Relatively large doses, 500 g or more of sodium bicarbonate, often mixed with sugar and water and referred to as "milk shakes," have been given via nasogastric tube and result in a marked metabolic alkalosis. Although experimental studies have often failed to detect a measurable performance benefit from sodium bicarbonate supplementation, practical experience suggests that some horses, particularly Standardbreds, show marked improvement in race times. Administration of any substance with intent to alter the performance is illegal in most racing jurisdictions. In many racing states, horses must meet specific guidelines for venous blood pH and bicarbonate or risk disqualification.

VI. EVALUATION OF IMBALANCES

It is important to understand the difference between volume regulation and osmoregulation. Osmoregulation is governed by osmoreceptors influencing ADH and thirst; volume disturbances are sensed by multiple volume receptors which activate effectors such as aldosterone. Antidiuretic hormone increases water resorption (and therefore urine osmolality), but does not affect sodium transport. Aldosterone enhances sodium reabsorption but not directly that of water. Thus, osmoregulation is achieved by changes in water balance and volume regulation primarily through changes in sodium balance.

Water balance is achieved when water intake from all sources is equal to water output by all routes. Water is available as drinking water, as water content of feedstuffs, and as metabolic water derived by oxidative metabolism. Oxidation of 1 g of fat, carbohydrate, or protein results in the production of 1.07, 0.06, or 0.41 g of water, respectively. Water is lost from the body by four basic routes: urine, feces, insensible respiration and cutaneous water loss, and as sensible perspiration or sweat in some animal species. Water intake and output may vary considerably from day to day, but normal animals are able to maintain water balance within remarkably narrow limits and at the same time maintain the critical interrelationship between water balance and electrolyte balance.

For human subjects, the normal values for water intake and output via various routes are well established. Although there is a substantial amount of data on water balance for many domestic animals (Leitch and Thomson, 1944; English, 1966a; Tasker, 1967a; Yoshida *et al.*, 1967; Fonnesbeck, 1968; Kamal *et al.*, 1972; Hinton, 1978; Sufit *et al.*, 1985), these data vary markedly from species to species and are only valid for the specific experimental conditions under which they were collected. Animals eat to meet their caloric requirements. The nursing or grazing animal may have a feed intake that is greater than 90% water as compared to animals on dry hay or dried prepared pet food, which may contain less than 10% water. Some desert rodents are so well adapted that they are able to maintain water balance without water intake and rely on the water content of feedstuffs and metabolic water derived from oxidative metabolism. The koala in its native state in Australia obtains virtually all of its water from the leaves of specific species of eucalyptus trees, which constitute its entire diet. Dehydration due to water restriction with and without heat stress has been studied widely in a variety of animal species (Elkinton and Taffel, 1942; Hix *et al.*, 1953; Bianca *et al.*, 1965; Tasker, 1967b; Kamal *et al.*, 1972; Schultze *et al.*, 1972; Rumsey and Bond, 1976; Carlson *et al.*, 1979a; Brobst and Bayly, 1982; Rumbaugh *et al.*, 1982; Genetzky *et al.*, 1987).

A. Water

1. Depletion—Dehydration

Dehydration is a relatively common problem in domestic animals. Dehydration results from inadequate fluid intake in the face of normal to increased fluid losses. When water losses occur with little or no electrolyte losses (i.e., panting or feed and water restriction), serum sodium concentration and osmolality increase. This is called *hypertonic dehydration* and occurs when water losses exceed losses of the exchangeable cations sodium and potassium (Carlson, 1987). This imbalance

between total body water and exchangeable cations is best characterized as a *relative water deficit* (Scribner, 1969). The effects of a pure water loss of 30 liters in a 450-kg horse are illustrated in Fig. 18.3. In this theoretical example, there has been a 10% loss of body water, but no change in electrolyte balance. Plasma sodium concentration has increased from a normal of 140 mEq/liter (140 mmol/liter) to 155 mEq/liter (155 mmol/liter). Fluid losses are shared proportionately by the ICF and ECF and few other clinical or clinicopathologic abnormalities will be noted until the fluid losses become more severe. Hypernatremia is associated with contraction of the ICF volume and shrinkage of the cells.

When water losses are associated with proportionate losses of exchangeable cations [i.e., 130–150 mEq (130–150 mmol) of sodium plus potassium per liter of water lost] an isotonic fluid volume contraction develops. The effects of an isotonic fluid loss of 30 liters of water, 1400 mEq (1400 mmol) of sodium, and 2800 mEq (2800 mmol) of potassium in a 450-kg horse are illustrated in Fig. 18.4. In this theoretical example there has been an approximate 10% loss of body water as well as a 10% loss of the exchangeable sodium and potassium. Despite these losses, the plasma sodium concentration and osmolality remain unchanged. The ECF and ICF share the fluid losses proportionally because the losses of sodium and potassium were proportional to the initial content in their respective fluid compartments.

In many instances isotonic dehydration may occur in which sodium loss exceeds potassium loss. This type of dehydration is seen with heavy sweat loss in horses, with acute diarrhea in most species, and with inappropriate diuretic administration. The effects of an isotonic fluid loss of 30 liters of water, 3800 mEq (3800 mmol) of sodium, and 400 mEq (400 mmol) of potassium in a 450-kg horse are illustrated in Fig. 18.5. With this type of isotonic fluid loss, plasma sodium concentration remains within normal limits despite the development of large sodium deficits. These animals manifest clinical signs of inadequate circulating fluid volume reflecting the sodium deficit and the associated decrease in plasma and ECF volume as has been shown in human subjects (McCance, 1937, 1938). When a substantial portion of the water deficit is replaced by water consumption or free water administration in these animals, the serum sodium concentration and osmolality decline and a hypotonic, hypovolemic dehydration can develop (Sufit *et al.*, 1985). The hyponatremia noted in this circumstance is best considered as an indication of a *relative water excess* (Scribner, 1969).

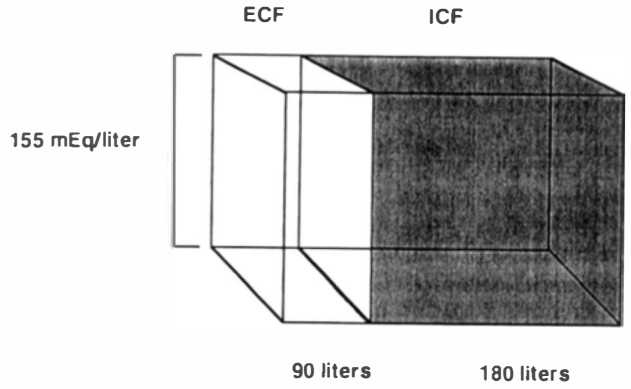

FIGURE 18.3 Body fluid compartments in a 450-kg horse with a pure water loss of 30 liters. Hypertonic fluid volume contraction is indicated by the increase in serum sodium concentration from 140 mEq/liter (140 mmol/liter) to 155 mEq/liter (155 mmol/liter). Fluid losses are shared by the extracellular fluid (ECF) volume and the intracellular fluid (ICF) volume.

2. *Water Excess — Overhydration*

The effects of the administration and retention of 30 liters of water in a 450-kg horse are illustrated in Fig. 18.6. In this example, total body water has been increased by 30 liters and there is an absolute as well as relative water excess. The primary effect of this water load is to dilute the electrolytes in the body fluids, producing a substantial decline in plasma sodium concentration and osmolality. These changes occur despite the fact that there has been no change in sodium or potassium balance. In this example the ECF and ICF share the water excess proportionately. The hyponatremia is associated with expansion of ICF and thus swelling of the cells.

Overhydration rarely occurs in normal individuals. The large water load described in Fig. 18.5, if administered to a normal animal, would produce only transient changes and the excess water would be eliminated by renal excretion. Even animals with psychogenic polydipsia ordinarily are able to maintain normal water balance through appropriate renal water excretion unless sodium depletion and renal medullary washout occur. However, overhydration can occur iatrogenically as the result of excessive fluid administration to patients with compromised renal function. If these fluids provide free water, as with 5% dextrose, plasma sodium concentration will decrease, reflecting the change in relative water balance. If these fluids consist of isotonic sodium-containing replacement fluids such as saline or lactated Ringer's solution, there will be no change in plasma sodium concentration (Cornelius *et al.*, 1978; Carlson and Rumbaugh, 1983), but there will be an increase in plasma and ECF volume with the potential for cardiovascular overload, pulmonary

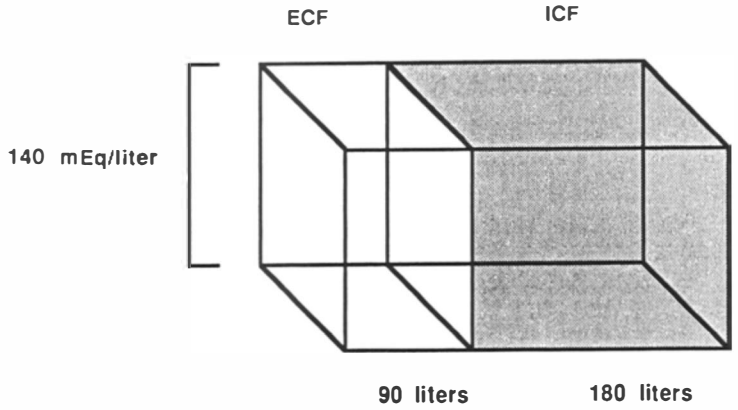

FIGURE 18.4 Isotonic fluid volume contraction. Body fluid compartments in a 450-kg horse with an isotonic fluid loss of 30 liters of water, 1400 mEq (1400 mmol) sodium, and 2800 mEq (2800 mmol) potassium. Serum sodium concentration remains unchanged at 140 mEq/liter (140 mmol/liter) and fluid losses are shared proportionately by the extracellular fluid (ECF) volume and intracellular fluid (ICF) volume.

edema, or generalized edema formation. In this instance, the primary problem is sodium retention and the changes in water balance are secondary.

B. Sodium

The ECF volume contains approximately one-half to two-thirds of the body's sodium. Most of the remaining sodium is bound in skeletal bone, relatively little of which is rapidly exchangeable (McKeown, 1984). The ECF volume thus contains essentially all of the body's readily available and exchangeable sodium. The exchangeable sodium content is the principal determinant of ECF volume, and sodium deficits are the principal causes of decreased ECF volume (Saxton and Seldin, 1986). Increases in sodium content result in expansion of ECF volume, which may lead to the development of hypertension or edema formation (McKeown, 1984; Dow *et al.*, 1987a). In either instance, the observed plasma sodium concentration will depend primarily on relative water balance. Because daily monitoring of electrolyte balance is difficult in most animal species, urinary fractional excretion or creatinine clearance ratios have been useful to provide and index of daily intake or potential deficits of sodium, potassium, chloride, and other electrolytes. Nor-

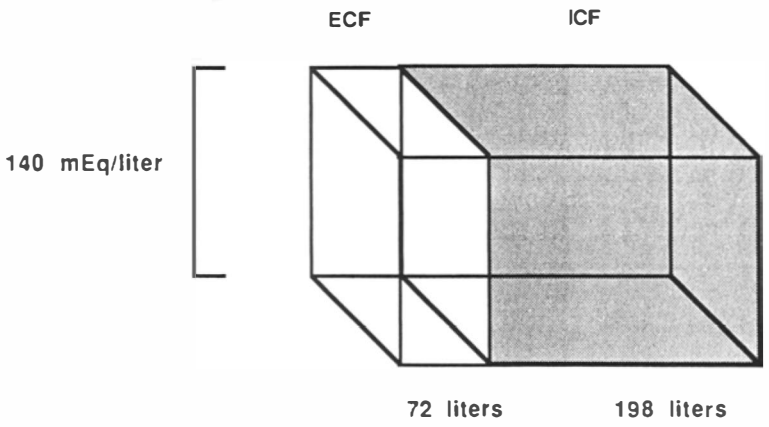

FIGURE 18.5 Isotonic fluid volume contraction sodium depletion. Body fluid compartments in a 450-kg horse with an isotonic fluid loss of 30 liters of water, 3800 mEq (3800 mmol) sodium, and 400 mEq (400 mmol) potassium. Serum sodium remains unchanged at 140 mEq/liter (140 mmol/liter) despite the development of the substantial sodium deficit. Fluid losses are borne primarily by the extracellular fluid (ECF) volume.

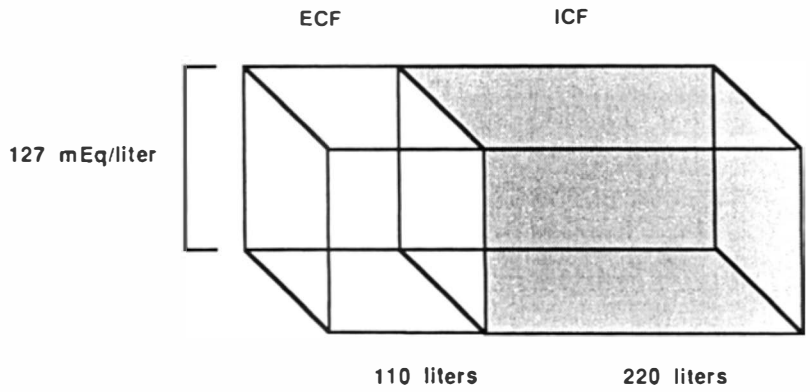

FIGURE 18.6 Hypotonic fluid volume expansion (relative water excess). Body fluid compartments in a 450-kg horse after administration and retention of 30 liters of water. Although no sodium or potassium losses have occurred, serum sodium concentration has declined from 140 mEq/liter (140 mmol/liter) to 127 mEq/liter (127 mmol/liter) reflecting a relative water excess. Water retention results in proportionate expansion of the extracellular fluid (ECF) volume and the intracellular fluid (ICF) volume.

mal values have been established for dogs and cats, horses (Morris *et al.*, 1984), and cattle (Fleming *et al.*, 1992).

1. Sodium Depletion

Sodium depletion is rarely the result of dietary sodium deficiency (Aitken, 1976). This is true even for herbivores whose feedstuffs are normally very low in sodium. Chronic sodium depletion has been reported in lactating dairy cows on a low-salt diet (Whitlock *et al.*, 1975a), but the sodium deficit was most probably the result of sodium losses in milk (Michell, 1985). Mastitis markedly enhances sodium loss in milk and could play a role in sodium depletion in lactating cows maintained on a low-salt diet (Michell, 1985). Sodium depletion is almost invariably associated with excessive losses of sodium-containing fluid (McKeown, 1984; Rose, 1984), most often occurring as the result of gastrointestinal losses through vomiting or diarrhea (Fisher and Martinez, 1976; Lakritz *et al.*, 1992). Excessive renal sodium losses can occur with intrinsic renal disease or as the result of diuretic therapy (Rose and Carter, 1979; Rose, 1984; Rose *et al.*, 1986). Cutaneous losses via sweating are very important in the exercising horse and may occur in any animal with extensive exfoliative dermatitis or burns. Salivary losses as the result of esophagostomy have been reported as a cause of sodium depletion in horses (Stick *et al.*, 1981b).

A history suggestive of excessive loss of sodium-containing fluid is thus an extremely important criteria for the diagnosis of sodium depletion in domestic animals. The foregoing discussion applies indirectly to the so-called "third space" problems associated with a sequestration or compartmentalization of a portion of the ECF volume (Rose, 1984). This can occur with obstructive bowel disease or with the sudden accumulation of fluid within the abdomen or thorax resulting from peritonitis, ruptured bladder, ascites, or pleural effusion. These fluids have an electrolyte composition similar to the ECF and initially are drawn from the plasma volume and interstitial fluids. The resultant changes in plasma volume and effective circulating fluid volume produce the same clinical and clinicopathologic changes as those observed with excessive external losses of sodium-containing fluid (Billig and Jordan, 1969). In these cases fluids have not been lost from the body, but there has been an internal sequestration of fluid which can be mobilized if treatment is effective.

2. Sodium Excess

Sodium excess occurs most often in association with an increase in body water leading to an isotonic expansion of ECF volume and the development of hypertension or generalized edema (Saxton and Seldin, 1986). Congestive heart failure, hypoalbuminemia, and hepatic fibrosis may lead to a failure to maintain effective circulating volume, which in turn results in compensating renal sodium retention (Rose, 1984). In these cases expanded ECF volume represents an attempt to restore effective circulating fluid volume, and, at least initially, plasma volume may be decreased while ECF volume expands. An expansion of ECF volume of 20–30% may be necessary before edema is first evident (Scribner, 1969). Sodium excess and edema can develop iatrogenically as the result of the excessive administration of

sodium-containing fluid to patients with severely compromised renal function.

Most domestic animals can tolerate a very large sodium intake provided they have adequate drinking water (Pierce, 1957; Aitken, 1976; Buck *et al.*, 1976). Excessive salt intake may occur when animals that had been on salt-restricted diets are first allowed free access to salt (Mitchell, 1985). Salt intoxication can occur in cattle that are feeding in reclaimed saltwater marshes or on pastures contaminated by oil field wastes when they are deprived of freshwater (Pierce, 1957; Aitken, 1976; Sandals, 1978; McCoy and Edwards, 1979; Michell, 1985). Salt poisoning in swine also occurs in association with water restriction followed by access to water (Aitken, 1976; Buck *et al.*, 1976). Salt intoxication is generally associated with increases in plasma and/or cerebrospinal fluid sodium concentrations. Neurologic signs associated with excessive salt consumption coupled with water restriction are related to development of cortical edema and in swine a characteristic eosinophilic meningoencephalitis (Aitken, 1976).

C. Potassium

Potassium is largely an intracellular ion with more than 98% of the exchangeable potassium located intracellularly (Strombeck, 1979; Brobst, 1986). This distribution of potassium is coupled with the active extrusion of sodium from the cells which is maintained by an energy-dependent sodium:potassium pump at the cell membrane (Tannen, 1984; Brobst, 1986). Potassium distribution across the cell membrane plays a critical role in the maintenance of cardiac and neuromuscular excitability. Changes in potassium concentration which alter the ratio of intracellular to extracellular potassium alter membrane potential (Tannen, 1984).

In general hypokalemia increases membrane potential, producing a hyperpolarization block resulting in weakness or paralysis. Hyperkalemia decreases membrane potential, causing hyperexcitability (Patrick, 1977). These features depend on the state of total body potassium content but are also dependent on the speed with which hypokalemia or hyperkalemia develops (Saxton and Seldin, 1986). As an example, acute potassium depletion may result in hypokalemia prior to the development of a marked change in intracellular potassium, producing a substantial alteration in the ratio of intracellular to extracellular potassium. Acute hypokalemia can produce a much greater alteration in membrane potential and thus more marked clinical signs than a gradually developing hypokalemia of the same magnitude (Saxton and Seldin, 1986). Potassium homeostasis involves regulation of internal balance (i.e., the distribution of potassium between the ECF and ICF) as well as external balance (i.e., the relation of potassium input to output) (Rose, 1984; Brobst, 1986). Internal potassium balance is influenced by changes in acid–base status, glucose and insulin administration, exercise, and catecholamine release and is discussed in greater detail in the section on factors which influence plasma potassium concentration.

1. Potassium Depletion

Potassium depletion is the result of altered external balance in which potassium losses by all routes exceed intake. Potassium is present in relatively high concentrations in most animal feeds. Therefore, dietary deficiency alone is not a common cause for potassium depletion (Tasker, 1980). However, dietary factors were associated with hypokalemia hospitalized cats, particularly when associated with diseases linked to increased potassium loss (Dow *et al.*, 1987b). Herbivores such as the horse fed an all-hay diet may have a daily potassium intake of 3000–4000 mEq (3000–4000 mmol) per day (Tasker, 1967a; Hintz and Schryver, 1976). Most of this potassium is absorbed in the small intestine and colon with subsequent renal excretion of more than 90% of the daily potassium intake (Hintz and Schryver, 1976). These animals are thus highly adept at excretion of a large daily potassium intake. However, renal compensation for deficient potassium intake is not very efficient and renal conservation of potassium may be delayed for several days when animals normally fed a high potassium diet are suddenly taken off feed or develop anorexia (Tasker, 1967b).

Potassium depletion most commonly develops as the result of gastrointestinal losses from vomiting or diarrhea. Excessive renal losses can occur as the result of diuretic usage, mineralocorticoid excess, renal tubular acidosis, and in the diuresis state which follows relief of urinary obstruction (Saxton and Seldin, 1986). Potassium depletion may result in decreased ICF volume, altered membrane potential, altered intracellular pH, and alterations of potassium-dependent enzymatically mediated reactions (Elkinton and Winkler, 1944). Clinical features include muscle weakness, ileus, cardiac arrhythmias, rhabdomyolysis, and renal dysfunction (Earley and Daugharty, 1969; Tannen, 1984; Dow *et al.*, 1987a, 1987b).

2. Potassium Excess

Potassium excess occurs relatively rarely and is generally a consequence of some alteration of renal excretion of potassium. Potassium excess may be associated with Addison's disease, some forms of renal disease, and clinical situations associated with hypovolemia

and renal shutdown (Rose, 1984; Weldon *et al.*, 1992). Care should be taken to avoid the rapid administration of large amounts of potassium salts orally or intravenously to patients with severely compromised renal function. Even normal animals can develop significant electrocardiographic abnormalities with potassium (Glazier *et al.*, 1982; Epstein, 1984; Dhein and Wardrop, 1995) or calcium infusions (Glazier *et al.*, 1979).

D. Chloride

Modest changes in hydration tend to produce roughly proportional changes in plasma sodium and chloride relative to sodium concentration. Acid–base alterations are associated with disproportionate changes in plasma chloride concentration (Saxton and Seldin, 1986). A disproportionate hyperchloremia is seen in association with a low to normal anion gap metabolic acidosis. Chloride concentration increases in this type of acidosis as the result of proportionately smaller losses of chloride than bicarbonate and enhanced renal chloride resorption in response to decreased bicarbonate (Saxton and Seldin, 1986). Disproportionate hypochloremia is a consistent feature of metabolic alkalosis (Rose, 1984). Chloride depletion develops in these animals due to excessive loss or sequestration of fluids with high chloride content. Changes in water balance can result in modest alterations in the relative concentrations of plasma sodium and chloride. A pure water deficit produces an increased sodium concentration which exceeds the increases in chloride. This contributes to the development of a contraction alkalosis with an increase in bicarbonate. A pure water excess has the opposite effect and can result in an expansion acidosis.

VII. CLINICAL FEATURES OF FLUID AND ELECTROLYTE BALANCE

It is convenient to discuss the theoretical ramifications of pure water loss or specific electrolyte deficits. However, in practical clinical situations the issue is almost never this clearly defined and most often there is a combination of fluid, electrolyte, and acid–base alterations. Many medical problems result in a consistent pattern of fluid and electrolyte loss with predictable changes in fluid volume, electrolyte concentration, and acid–base balance. A clear understanding of the interrelationships between specific deficits and their clinicopathologic consequences is essential if an appropriate initial diagnosis is to be made. Once treatment has been initiated, all clinical and clinicopathologic data will be influenced not only by the primary medical problem and compensating responses, but also by the effects of chemotherapeutic agents and fluid therapy as well. Therapeutic intervention may not be always appropriate, organ function may be impaired and, thus, the anticipated clinicopathologic responses become less predictable. These situations represent the bulk of clinical case material and laboratory data evaluated by clinicians and clinical pathologists. Under these circumstances, it is essential to understand the basic mechanisms which underlie changes in clinicopathologic data and how these changes relate to specific imbalances.

Rational fluid therapy depends on accurate evaluation of the fluid and electrolyte deficits, the associated acid–base alterations, and the primary disease processes which underlie these imbalances. Evaluation must include an accurate history, a complete physical examination, and, of course, laboratory evaluation of appropriate parameters.

A. History

An accurate history is absolutely essential for the evaluation and management of the patient with fluid and electrolyte imbalances. Basic signalment: age, sex, breed, pregnancy, and stage of lactation are important because these factors influence the incidence and severity of many disorders. The presence of a preexisting or coexisting disease process as well as an accurate drug history can be exceedingly important not only in the evaluation of fluid and electrolyte disorders but also in fluid selection and patient management. Of particular importance is the history of prior renal disease, diuretic usage, or exposure to potentially nephrotoxic drugs. Status of feed and water intake is exceedingly useful. Most animals that continue to eat and drink normally are able to maintain fluid balance even in the face of excessive fluid losses. However, reduced or restricted fluid intake in the face of normal to enhanced fluid losses can quickly result in dehydration. Inadequate fluid intake may result from neurologic disorders or traumatic injuries to the head or neck, and painful or obstructive lesions in the mouth, pharynx, or gastrointestinal tract may restrict feed and water intake. Inadequate water intake is often the result of management errors, broken or frozen water lines, etc. A history of polydipsia suggests that excessive fluid losses have occurred. Vomiting and diarrhea are obvious causes of fluid and electrolyte loss but these findings also reflect gastrointestinal disorders which may contribute to inadequate fluid and electrolyte intake or absorption.

Excessive fluid losses may be associated with vomiting, diarrhea, polyuria, excessive salivation, copious drainage from cutaneous wounds or burns, and as the result of heavy sweat losses in exercising horses. The water losses that occur in these situations are generally associated with significant sodium depletion and subsequent decreases in the effective circulating fluid volume. Vomiting in small animals (Clark, 1980), gastrointestinal stasis in ruminants (Gingerich and Murdick, 1975b), and excessive sweat losses in endurance horses (Carlson, 1983c) are associated with large losses or compartmentalization of chloride-rich fluids which contribute to the metabolic alkalosis that frequently accompanies these disorders.

B. Clinical Signs

Dehydration is defined as a loss of body water. Clinical signs of dehydration are said to be first apparent with fluid losses equivalent to 4–6% of body weight. Moderate dehydration is said to be present with fluid losses of 8–10% and severe dehydration when fluid losses are greater than 12% of body weight. It is important to realize that, although these guidelines have been clinically useful, there is relatively little documentation of this precise quantitative relationship in most animal species. Accurate measurement of fluid intake from all sources and output by all routes is not possible in most clinical situations. In acute situations, changes in body weight provide the most accurate guide to change in net water balance. Repeated measurement of body weight is a key component of the monitoring of patients on fluid therapy. The clinical signs of dehydration include weight loss, altered skin turgor, sunken eyes, and dry mucous membranes. If control of renal function in normal, urine volume is generally markedly reduced. The clinical consequences of dehydration depend much more on the pattern of electrolyte loss than the absolute water deficit.

Clinical signs associated with acute sodium deficits are largely related to hypovolemia and decreases in the effective circulating volume. These signs include increased pulse rate, decreased pulse pressure, delayed jugular distensibility, increased capillary refill time, and decreased blood pressure. Urine output is generally decreased and urine sodium and chloride concentrations are normally reduced. Decreases in ECF volume are always reflected by decreases in plasma volume, but the reverse is not always true. In the absence of blood or protein loss, the packed cell volume and total plasma protein concentration increase, reflecting the decrease in plasma and ECF volume, and are discussed more fully in section VIII.A.

VIII. CLINICOPATHOLOGIC INDICATORS OF FLUID AND ELECTROLYTE IMBALANCE

A. Packed Cell Volume and Total Plasma Protein

The packed cell volume (PCV) and total plasma protein (TPP) concentration are simple, convenient, and useful tools for the evaluation of acute fluid and electrolyte alterations. If we assume that there has been no gain or loss of erythrocytes or protein from the vascular compartment, changes in PCV and TPP reflect changes in plasma volume (Boyd, 1981). For the estimation of alterations in plasma volume in human subjects, the change in PCV or hemoglobin concentration is preferred over change in protein concentration (van Beaumont *et al.*, 1973). This is due to fluxes of protein both into and out of the plasma volume which may occur in certain rapidly changing clinical circumstances (Landis and Pappenheimer, 1963; Senay, 1970). There is a substantial extravascular protein pool and the volume distribution of both albumin and globulins is approximately two to three times that of the plasma volume (Landis and Pappenheimer, 1963; Mattheeuws *et al.*, 1966). This is one of the reasons why plasma transfusions have limited effects on the plasma protein concentration of hypoproteinemic patients.

In most animal species, there is a much wider range of normal for PCV than for TPP. In some of these species, most notably the horse, mobilization of erythrocytes from splenic reserves in response to excitement, pain, or catecholamine release can result in marked variability in PCV, erythrocyte count, or hemoglobin concentration (Persson, 1967; Persson, *et al.*, 1973; Carlson, 1987). For these reasons it has proven most useful to utilize the change in both PCV and TPP as a crude index of change in plasma volume in domestic animals. For these estimations to be valid, initial values for PCV and TPP must be known and there must have been no loss of blood or protein. The most common causes for decreases in plasma volume are the sequestration or loss of sodium-containing fluid such as occurs in obstructive bowel disease, diarrhea, vomiting, renal disease, or in heavily sweating horses. In these circumstances both PCV and TPP increase in relation to the change in plasma volume, but not necessarily in the same proportion (Boyd, 1981). The following example illustrates this point.

If we assume that the quantity of plasma proteins within the plasma volume remains constant (although this assumption is not always true), it is possible to calculate the percentage change in plasma volume based on protein concentration (Boyd, 1981):

$$\%PV = [(PP_1/PP_2) - 1]\ 100, \qquad (18.13)$$

where PV indicates plasma volume, PP_1 indicates initial plasma protein concentration, and PP_2 indicates final plasma protein concentration. It is also possible to calculate the change in plasma volume based on the change in PCV provided it is assumed that the number of erythrocytes within the circulating blood volume and the mean corpuscular volume remain constant (Boyd, 1981)

$$\%PV = \left(\frac{PCV_1\ (1 - PCV_2)}{PCV_2\ (1 - PCV_1)} - 1\right)100, \qquad (18.14)$$

where PV again indicates plasma volume, PCV_1 indicates the initial PCV, and PCV_2 indicates the final PCV. Using this approach, the calculated increase of PCV and plasma protein concentration associated with a progressive reduction in plasma volume in a 20-kg dog is presented in Fig. 18.7. In this example the dog was assumed to have had an initial plasma volume of 5% of body weight (0.05 liter/kg), an initial PCV of 40% (0.4 liter/liter), and an initial TPP concentration of 6.5 gm/dl (65 g/liter). A 50% reduction in plasma volume results in a 100% increase in TPP from 6.5 to 13.0 gm/dl, whereas PCV only increased from 40 to 55% (Fig. 18.8). It will be noted that as plasma volume declines the percentage change in PCV is always less than the percentage change in plasma protein concentration. This is true whether the changes are due to an increase or decrease in plasma volume.

In most clinical situations the initial PCV and plasma protein concentration are not known. To make these estimates, we must assume that these values were within the normal range prior to dehydration. A large disparity in the change in PCV and TPP concentration in the face of a history of loss of sodium-containing fluid and clinical evidence of reduced effective circulating volume suggests that either erythrocytes or protein have been lost from the circulation. Marked increases in PCV with normal to low plasma proteins are frequently encountered in animals with acute toxic enteritis due to losses of protein into the gastrointestinal tract (Merritt *et al.*, 1977). This finding suggests erosive bowel disease but also could be seen in animals with low protein due to preexisting renal or hepatic disease. Increases in plasma protein with little or no change in PCV are seldom seen in dehydrated animals, but could occur with a preexisting anemia or hyperproteinemia. Blood loss generally results in a decrease in both PCV and TPP concentration.

Sodium deficits result in decreases in ECF volume, which are usually reflected by changes in plasma volume (Hopper *et al.*, 1959; Saxton and Seldin, 1986). As plasma volume decreases, the PCV and TPP concentration increase. Changes in PCV and TPP are, thus, particularly useful in evaluating the need for and the response to sodium-containing replacement fluid (Carlson, 1983a). When sodium-containing fluids are administered to dehydrated volume-depleted subjects, plasma volume reexpansion is reflected by the return of PCV and TPP toward the normal range (Hayter *et al.*, 1962). Declining PCV and TPP in response to fluid therapy are the two most useful laboratory indicators of return of effective circulating fluid volume and

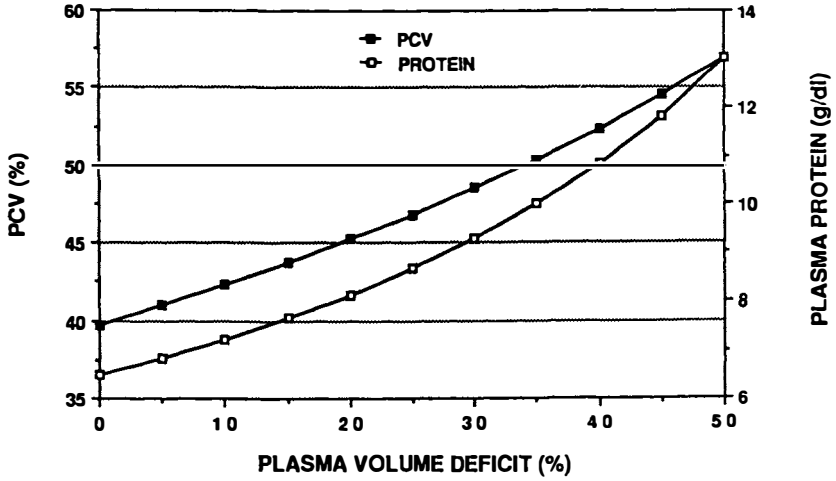

FIGURE 18.7 Effects of decreasing plasma volume on PCV and plasma protein concentration as calculated using Eqs. (18.13) and (18.14).

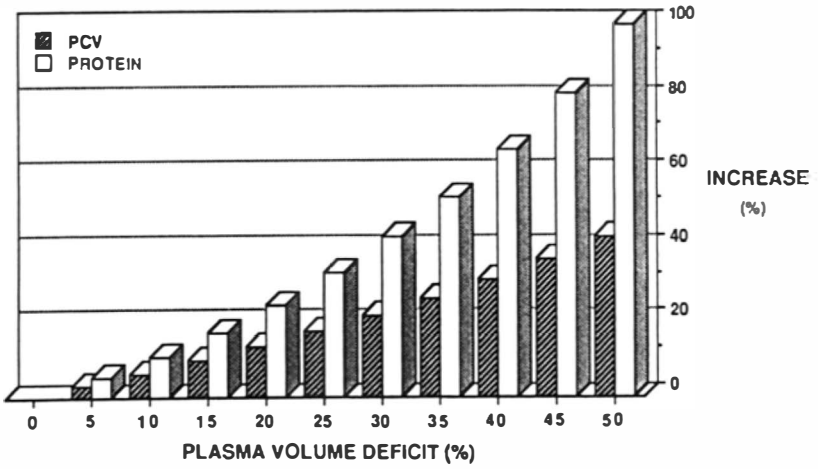

FIGURE 18.8 Calculated effects of plasma volume depletion. Percentage increase in PCV and plasma protein concentration with progressive plasma volume deficits.

should be correlated with clinical evidence such as return of normal pulse pressure, capillary refill time, and jugular distensibility.

B. Serum Sodium

Serum sodium concentration varies within relatively narrow limits in the normal individual but there is substantial interspecies variation in the normal range of sodium, chloride, and osmolality as indicated in Table 18.4. A serum sodium concentration of 134 mEq/liter (134 mmol/liter), while quite normal for a horse or cow, represents a significant hyponatremia in a dog or cat.

Before proceeding with a discussion of the significance of alterations of sodium concentration, some comment on the methods used for electrolyte determination is appropriate. Flame photometry for many years had been the standard method for the determination of both sodium and potassium. Recently, methods employing ion-specific electrodes have achieved wider use. Although both procedures yield accurate and reproducible results, there may be consistent differences between the two procedures. Flame photometry yields results in mEq or mmol/liter of plasma or serum, whereas the ion-specific electrodes are generally considered to measure the electrolyte concentration only in the aqueous phase of the sample. The water content of serum or plasma samples is normally between 93 and 94%, with most of the remaining volume occupied by protein. For this reason, electrolyte determinations performed by flame photometry tend to be 6–7% lower than those obtained using ion-specific electrodes. Interestingly, ion-specific electrode instruments that dilute samples tend to yield values which are very similar to values reported from the flame photometer. This may be a function of the mathematical algorithm employed in these devices to convert changes in electric potential to electrolyte concentration. There may be interfering substances in the urine of some animal species which render urine potassium determinations inaccurate when assessed by ion-specific potentiometry (Brooks *et al.*, 1988) The relationship between protein concentration and serum or plasma water content has been determined for man and the horse (Eiseman *et al.*, 1936; Carlson and Harrold, 1977; Harris *et al.*, 1987). This relationship can be used to correct serum or plasma electrolyte concentration determined by flame photometry for the effects of variation in protein concentration and thus water content. Electrolyte concentration then can be expressed per liter of serum or plasma water.

$$\text{Sodium mEq/liter } H_2O = \frac{\text{Measured sodium (mEq/liter)}}{\text{\% Water}} \times 100 \qquad (18.15)$$

1. Hyponatremia

The common causes of hyponatremia are listed in Table 18.5. A falsely low sodium concentration may be noted when there is marked hyperlipemia or hyperproteinemia. Large quantities of lipid or protein occupy a significant volume in a serum or plasma sample and because electrolytes are dissolved only in the aqueous phase the measured concentrations will be falsely low. The presence of obvious lipemia or markedly elevated serum protein concentration should alert the clinician to the probable cause of an accompanying hypo-

TABLE 18.5 Causes of Hyponatremia

  - Renal disease
  - Inappropriate ADH secretion

natremia. Should this information not be available, the presence of a false hyponatremia can be determined by comparison of the measured serum osmolality and the calculated osmolality based on sodium, glucose, and urea concentration as explained in Section VIII.E. This potential cause for confusion in interpretation of hyponatremia can be avoided if ion-specific electrodes are used for electrolyte determination.

Marked hyperglycemia associated with diabetes mellitus or the administration of glucose at an excessive rate generally produces a hyponatremia. As glucose concentration increases in the ECF, osmotic forces are generated that result in the movement of cellular water into the ECF, diluting serum sodium concentration. The actual mechanics of this process are complicated by the fact that cells and tissues are variably permeable to glucose and, thus, the glucose space clearly exceeds the ECF volume. For practical purposes, we can anticipate that serum sodium concentration will decline 1.6 mEq/liter (1.6 mmol/liter) for each 100 mg/dl (5.55 mmol/liter) increase in glucose concentration (Saxton and Seldin, 1986). Serum osmolality may be increased by hyperglycemia but this should not cause a large disparity between the measured and calculated serum osmolality.

Changes in water balance are principally responsible for changes in serum sodium concentration (Leaf, 1962). Hyponatremia should be considered an indication of a *relative water excess* (Scribner, 1969). Hyponatremia is often but not invariably associated with conditions which cause sodium depletion and resultant decreases in effective circulating volume. These conditions include vomiting, diarrhea, excessive sweat losses, and adrenal insufficiency. Dehydration and volume depletion induce neurohormonal responses that result in increased water consumption via increased thirst and enhanced renal conservation of water as well as sodium (Rose, 1984). Fluid losses in these forms of dehydration are most often hypotonic or isotonic and initial fluid and electrolyte deficits do not result in hyponatremia until water intake and/or renal water retention disturb the balance between the remaining exchangeable cations and the total body water. Thus, while substantial sodium and potassium deficits are associated with these conditions, plasma sodium concentration does not always reflect these deficits and diagnosis of sodium depletion should be based on other grounds (Scribner, 1969).

The accumulation of sodium-containing fluid within body cavities as a result of ascites, peritonitis, or a ruptured bladder is referred to as a *third space problem* (Rose, 1984). The fluid that accumulates in the "third space" has a composition similar to the ECF. When this accumulation of fluid occurs rapidly, plasma volume is reduced and serum sodium concentration then may decrease as the compensating responses result in water retention. A classic example of this situation is the marked hyponatremia associated with ruptured bladder in neonatal foals. As the dilute urine of the neonate accumulates in the abdomen, osmotic equilibrium is established first with the ECF and then with all of the body fluid compartments. Sodium and chloride as well as other ions are drawn from the rest of the ECF into this progressively expanding fluid compartment and hyponatremia develops despite the fact that there has been no appreciable loss of sodium from the body. The severe neurologic signs associated with ruptured bladder in foals are related in large part to the effects of the sudden and marked hypotonic hyponatremia on the central nervous system. Hyponatremia associated with excessive retention of water also can occur without the development of significant sodium depletion or decreases in effective circulating fluid volume. Hyponatremia may be observed with psychogenic polydipsia if the rate of water consumption exceeds renal capacity for free water clearance due to intrinsic renal disease or renal medullary washout (Tyler *et al.*, 1987). This also may occur in patients with impaired free water clearance due to renal disease or when under the influence of inappropriate release of ADH (McKeown, 1984). Hyponatremia and associated

neurologic disturbances can develop with naturally occurring disease (Lakritz *et al.*, 1992) or iatrogenically if excessive amounts of free water are administered to patients with altered renal function (Arieff, 1986; Sterns *et al.*, 1986).

Urine sodium concentration can be useful in the differentiation of the causes of hyponatremia as indicated in Fig. 18.9. Renal adaptive responses normally result in sodium retention and production of urine with very low sodium concentration in patients with sodium depletion resulting from vomiting, diarrhea, excessive sweat loss, or third space problems (Rose, 1984). Hyponatremia and hypokalemia of adrenal insufficiency are generally associated with a relatively high urine sodium concentration (Rose, 1984). With the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), urine sodium tends to be high in the presence of hyponatremia, whereas urine sodium concentration tends to be low in animals with psychogenic polydipsia. Urine sodium concentration in animals with renal failure can be quite variable.

A form of moderate to pronounced hyponatremia associated with elevated levels of ADH which develops in the absence of an appropriate osmotic or volume stimuli has been well recognized in human subjects. This syndrome has been associated with several systemic disorders including malignant neoplasms which produce an ADH-like material, with a variety of brain diseases which apparently stimulate synthesis and release of ADH, or in association with certain pulmonary diseases which may result in abnormal neural inputs from the lung that trigger the inappropriate ADH release from the pituitary.

The diagnosis of SIADH in the absence of readily available procedures for ADH determination is dependent on ruling out a number of other potential causes for persistent hyponatremia. The diagnostic criterion for SIADH for human subjects include the following (McKeown, 1984):

1. Demonstration of a hypotonic hyponatremia without hypovolemia or edema
2. Normal renal, adrenal, and thyroid function
3. Inappropriately elevated urine osmolality relative to plasma osmolality
4. Relatively high urine sodium concentration
5. Correction of the hyponatremia by strict fluid restriction

SIADH has been reported in the dog (Breitschwerdt and Root, 1979; Giger and Gorman, 1984; Houston *et al.*, 1989; Crow and Stockham, 1985), but the incidence and importance of this problem in other animal species is uncertain. A variant of SIADH has been described in certain chronically ill and malnourished human sub-

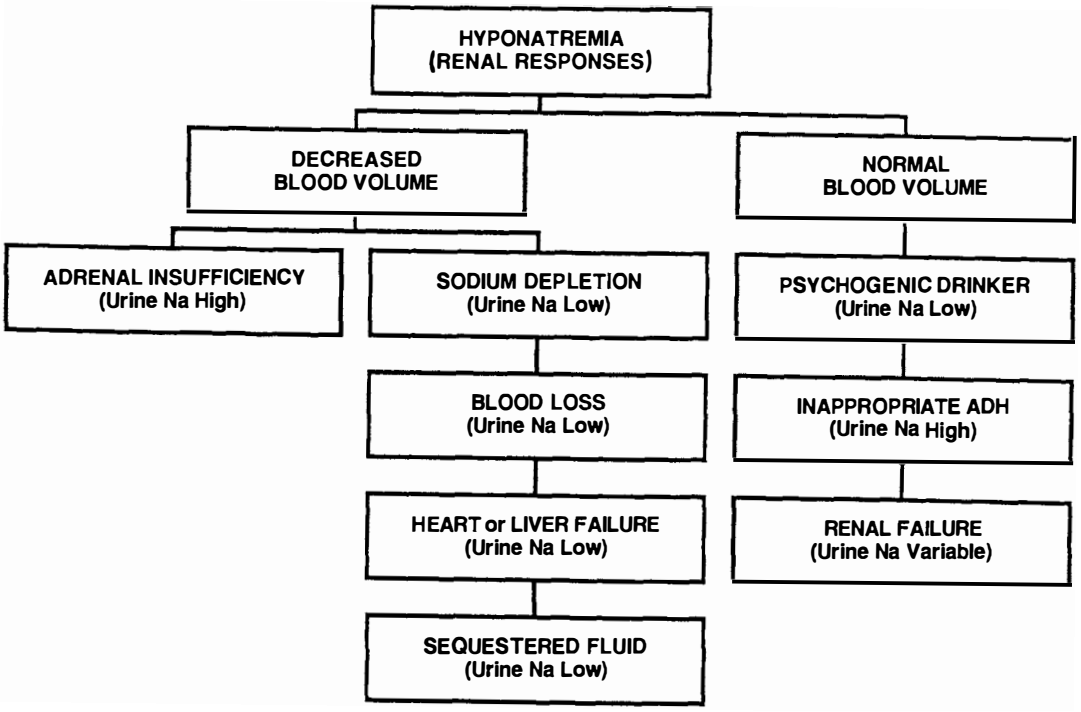

FIGURE 18.9 The urinary sodium concentration as an aid in the differentiation of possible causes of hyponatremia. Urinary electrolyte concentration is also influenced by dietary intake.

jects that maintain a mild but persistent hyponatremia. In these individuals ADH secretion remains under osmotic control but it would appear that the osmoreceptor threshold functions at a lower value than normal (McKeown, 1984). Thus, it is the resetting of the osmostat which results in persistent chronic hyponatremia. Resolution of the underlying medical problem usually results in correction of this variant form of SIADH.

2. *Hypernatremia*

Hypernatremia almost always is associated with elevation of serum osmolality. Hypernatremia occurs in dehydrated subjects when water losses exceed losses of sodium and potassium and should be considered as an indication of a *relative water deficit* (Scribner, 1969). This can occur in the initial stages of diarrhea, vomiting, or renal disease if losses of water exceed the electrolytes lost (Saxton and Seldin, 1986). Common causes of hypernatremia are listed in Table 18.6. As water losses are replaced by increased water consumption and/or enhanced renal water retention, serum sodium concentration tends to decline into or below the normal range. Hypernatremia also develops as the result of an essentially pure water loss, such as the evaporative respiratory water loss in panting animals (Tasker, 1980). Hypernatremia is associated with excessive renal free water loss with either central or nephrogenic diabetes insipidus if water intake is restricted (Breukink *et al.*, 1983). Food and water deprivation in normal individuals is associated with substantial reduction of renal and fecal output (Tasker, 1967b; Carlson *et al.*, 1979b; Brobst and Bayly, 1982; Genetzky *et al.*, 1987). However, continued cutaneous and respiratory insensible water loss may result in hypernatremia (Elkinton and Taffel, 1942; Rumsey and Bond, 1976; Carlson *et al.*, 1979b; Genetzky *et al.*, 1987).

Abnormal thirst mechanisms with resultant hypernatremia have been reported in young dogs (Crawford *et al.*, 1984; Hoskins and Rothschmitt, 1984). Hypernatremia may occur transiently following administration of hypertonic saline or sodium bicarbonate if water intake is restricted or impaired. The hypernatremia observed with salt poisoning in cattle and swine is, in fact, triggered by water restriction in animals with a high salt intake (Padovan, 1980; Pearson and Kallfelz, 1982). As long as adequate water is available, salt poisoning does not occur. In human subjects, hypernatremia is reported with mineralocorticoid excess (McKeown, 1984).

C. Serum Potassium

Serum potassium concentration does not always reflect potassium balance but is influenced by factors which alter internal balance, that is, the distribution of potassium across the cell membrane between the ECF and ICF as well as factors which change external balance, that is, potassium intake and output (Patrick, 1977; Rose, 1984; Brobst, 1986). The effective adjustment of external and internal balance in normal individuals in response to either large potassium loads or excessive potassium losses usually maintains serum potassium concentration within normal limits. However, changes in potassium concentration occur in a wide variety of clinical circumstances and have profound neuromuscular effects largely due to changes in cell membrane potential (Brobst, 1986). The compensating responses to change in circulating fluid volume distribution and acid–base balance can result in confusing and contradictory findings. As an example, calves with acute diarrhea may develop significant depletion of body potassium stores due to excessive losses and inadequate intake (Phillips and Knox, 1969). However, the serum potassium concentration in these calves may actually be normal to increased as the result of renal shutdown and the metabolic acidosis induced by dehydration and sodium depletion with resultant decreases in the effective circulating fluid volume. Electrolyte replacement fluids given to these calves should include potassium (Fettman *et al.*, 1986). Correct interpretation of serum potassium concentration thus requires a knowledge of probable intake and sources

of excessive loss as well as the status of renal function and acid–base balance. Measurement of erythrocyte potassium concentration has been suggested as an aid in the assessment of the potassium status of horses with exercise-related myopathy (Muylle *et al.*, 1984a, 1984b; Bain and Merritt, 1990). However, experimental studies have failed to demonstrate a close correlation between erythrocyte potassium concentration and potassium depletion.

1. *Hypokalemia*

Hypokalemia occurs relatively frequently in domestic animals and may result from depletion of the body's potassium stores or from a redistribution of potassium from the ECF into the ICF space (Brobst, 1986), as indicated in Table 18.7. Hypokalemia most often is associated with excessive potassium losses from the gastrointestinal tract as the result of vomiting or diarrhea (Tasker, 1967c). Excessive renal loss of potassium results from the action of mineralocorticoid excess, the action of certain diuretics, and as the result of altered renal tubular function in animals with renal tubular acidosis or postobstructive states. Chronic dietary potassium deficiency eventually can lead to modest hypokalemia even in normal individuals (Aitken, 1976; Dow *et al.*, 1987b). A rapidly developing and profound hypokalemia can develop in animals with reduced dietary intake due to anorexia when coupled with other causes of excessive potassium loss (Tasker, 1980).

Hypokalemia may develop without potassium depletion as the result of intracellular movement of potassium from the ECF space. This occurs with an acute alkalosis (Burnell *et al.*, 1966) and in patients treated with insulin and glucose infusions (Tannen, 1984). In fact, medical management of severe life-threatening hyperkalemia often involves the administration of glucose, insulin, and in some circumstances bicarbonate in an effort to shift potassium intracellularly. Catecholamines exert a biphasic effect on potassium concentration (Tannen, 1984). The initial response to catecholamine administration is a modest transient increase in potassium as the result of α-adrenergic stimulation followed by hypokalemia as the result of β-adrenergic receptor responses (Clausen *et al.*, 1980; Bendheim *et al.*, 1985; Williams *et al.*, 1985). Beta-adrenergic agents have been used for the treatment of hyperkalemic periodic paralysis (Bendheim *et al.*, 1985). The relationship between catecholamine release, receptor stimulation, and potassium balance may play a significant role in the development of exertional fatigue in human and equine athletes (Sjogaard *et al.*, 1985; Carlson, 1987).

2. *Hyperkalemia*

Hyperkalemia can be produced iatrogenically by the excessive administration of potassium salts but does not usually result from high dietary intake in individuals with normal renal function (Aitken, 1976). The three major causes of hyperkalemia are indicated in Table 18.8. Hyperkalemia may develop *in vitro* in blood sample containers due to hemolysis or prolonged storage of blood samples prior to the separation of serum or plasma from erythrocytes in the sample. This leakage of erythrocyte potassium can result in significant errors in those species with a high potassium content in their erythrocytes; the horse, pig, and most cattle (Tasker, 1980). The erythrocytes of cats and most dogs have a high sodium content and relatively low potassium. Slight hemolysis will have little effect on serum or plasma potassium concentration in these

TABLE 18.7 Causes of Hypokalemia

Hypokalemia due to altered external balance
Gastrointestinal losses
Vomiting
Diarrhea
Renal losses
Mineralocorticoid excess
Diuretics
Renal tubular acidosis
Postobstruction diuresis
Hypokalemic nephropathy in cats
Dietary deficiency
Hypokalemia due to altered internal balance
Excessively rapid bicarbonate administration
Insulin with glucose administration
Catecholamine release
Hypokalemic periodic paralysis

TABLE 18.8 Causes of Hyperkalemia

False hyperkalemia
Hemolysis
Markedly elevated leukocyte or platelet count
Hyperkalemia due to altered external balance
Addison's disease
Renal disease
Ruptured bladder
Urethral obstruction
Hypovolemia with renal shutdown
Hyperkalemia due to altered internal balance
Metabolic acidosis
Diabetes
Tissue necrosis
Hyperkalemic periodic paralysis
Vigorous exercise

species. Polymorphism however, occurs in intracellular cation content of certain breeds of sheep, cattle, and dogs which relate to sodium–potassium ATPase activity of mature erythrocytes. Release of potassium from leukocytes or platelets into the serum following clot formation in the sample collection vial is a potential cause of hyperkalemia in subjects with a marked leukocytosis or thrombocytosis (Mandell *et. al.*, 1988; Degan, 1986).

Hyperkalemia may be associated with excessive renal potassium retention in conditions such as Addison's disease, acute renal failure, and renal shutdown secondary to inadequate effective circulatory fluid volume. Hyperkalemia results, in a number of circumstances, from the movement of intracellular potassium into the ECF without change in external potassium balance. Hyperkalemia develops in association with a metabolic acidosis, particularly when the acidosis results from volume depletion complicated by renal shutdown. Hyperkalemia may be noted in patients with diabetes or transiently in animals with massive muscle necrosis. Interestingly, most horses with exertional rhabdomyolysis do not develop hyperkalemia or a metabolic acidosis (Koterba and Carlson, 1982). Vigorous short-term exercise at high intensity results in a profound hyperkalemia in horses. Serum potassium as high as 9–10 mEq/liter (9–10 mmol/liter) has been observed transiently in horses exercising at maximal intensity on a high-performance treadmill (Harris and Snow, 1986). Muscular exhaustion in these horses appeared to be related to the hyperkalemia and the profound lactic acidosis seen in the immediate postexercise state (Kryzwanek, 1974; Kryzwanek *et al.*, 1976; Milne *et al.*, 1976; Carlson, 1987). An interesting and unusual condition of episodic hyperkalemia and muscular weakness has been recognized in the dog (Jezyk, 1982) and certain quarterhorses (Cox, 1985; Steiss and Naylor, 1986; Spier *et al.*, 1990, 1993; Pickar *et al.*, 1991). In the horse the condition closely resembles the heritable disease hyperkalemic periodic paralysis, which has been reported in human subjects, and is due to an alteration in the voltage regulated sodium channel (Rudolph *et al.*, 1992a, 1992b). Sudden marked increases in serum potassium concentration result from the transcellular movement of potassium. Serum potassium concentration can reach 8–9 mEq/liter (8–9 mmol/liter) and is associated with profound electrocardiographic abnormalities and fluid shifts which result in marked increases in PCV and protein concentration. The disease is inherited as an autosomal dominant and all affected horses can be traced back to a common ancestor. A DNA test which can detect the single base pair substitution responsible for this disease has been developed (Rudolph *et al.*, 1992a). Using this procedure it is possible to identify individuals which are heterozygous or homozygous for this trait.

D. Serum Chloride

It long has been assumed that the anion chloride which combines with sodium to form common salt simply follows sodium in the physiologic processes which regulate body fluid and electrolyte balance. It is becoming increasingly apparent that this may not always be true and that some of the problems ascribed to sodium retention do not occur unless chloride is present in excess as well (Kurtz *et al.*, 1987). Causes of alterations in chloride concentration are given in Table 18.9. The hyperchloremia and hypochloremia which are normally seen in association with roughly proportional changes in sodium concentration are due to changes in body water balance.

Changes in chloride concentration which are not associated with a similar change in sodium concentration are usually associated with acid–base imbalances (Divers *et al.*, 1986). Chloride concentration tends to vary inversely with bicarbonate concentration. A disproportionate increase in chloride most commonly is associated with a normal to low anion gap hyperchloremic metabolic acidosis, and may be seen as a compensating response for a primary respiratory alkalosis (Saxton and Seldin, 1986). Disproportionate decreases in chloride characteristically are seen in a metabolic alkalosis but also may be seen as part of the compensating response for a chronic primary respiratory acidosis (Saxton and Seldin, 1986).

E. Osmolality

It has been demonstrated that the concentration of sodium in serum water is closely correlated with the serum osmolality over an extremely wide range

TABLE 18.9 Causes of Alterations in Chloride Concentration

Hyperchloremia
With proportional increase in sodium
Dehydration (relative water deficit)
Without proportional increase in sodium
Hyperchloremic metabolic acidosis
Compensation for respiratory alkalosis
Hypochloremia
With proportional decrease in sodium
Overhydration (relative water excess)
Without proportional decrease in sodium
Hypochloremic metabolic alkalosis
Compensation for respiratory acidosis

of physiologic and pathologic states provided appropriate corrections are made for the contributions made by variations in glucose and urea concentrations (Edelman *et al.*, 1958). The measurement of serum osmolality has two specific and very useful purposes (Gennari, 1984). First, to determine whether serum water content deviates widely from normal, and second to screen for the presence of foreign low-molecular-weight substances in the blood. Interpretation of serum osmolality for these purposes requires simultaneous comparison of the measured osmolality and the calculated osmolality as determined from the measured concentrations of the major solutes in serum (sodium, glucose, and urea). The difference between the measured and the calculated osmolality is sometimes referred to as the *osmolal gap* (Feldman and Rosenberg, 1981; Shull, 1978, 1981).

Sodium is the principal cation in serum and sodium is balanced by a number of different anions (chloride, bicarbonate, protein, sulphate, and phosphate). Sodium concentration thus provides a reasonable estimate of the total electrolyte concentration (anions and cations) in the sample, and in this calculation is usually multiplied by a factor of 2. As has been mentioned earlier the water content of serum samples is approximately 94%. Correction for the water content of serum is not necessary since, fortuitously, it is counterbalanced by the fact that sodium chloride does not dissociate completely and has an osmotic coefficient of 0.93 in serum (Wolf, 1966; Dahms *et al.*, 1968; Rose, 1984). The osmolality can thus be calculated using the measured sodium concentration and the concentration of the two nonelectrolyte components of serum which are normally present in amounts sufficient to influence osmolality:

$$\text{mOsm/kg } H_2O = 2 \times \text{Sodium} + \text{Glucose} + \text{Urea}. \quad (18.16)$$

This calculation is valid if concentrations of sodium, glucose, and urea are expressed in mmol/liter. Conversion of glucose concentration from mg/dl to mmol/liter requires division by 18, whereas urea concentration in mg/dl can be converted to mmol/liter by dividing by 2.8.

Decreases in osmolar gap indicate laboratory error. Increases in osmolar gap (>10 mOsm/kg) could also represent laboratory error but generally result from one of two circumstances: either a decrease in serum water content or the addition of low-molecular-weight substances in serum. Decreases in serum water content occur with marked hyperlipidemia or hyperproteinemia and the calculated osmolality will exceed the measured osmolality. This is the cause of the false hyponatremia discussed in Section VI.B. The presence of a similar disparity between the measured and calculated osmolality in the absence of hyperlipidemia or hyperproteinemia should prompt an alert for the presence of exogenous substances in abnormally high concentrations in the serum. These substances could include a variety of exogenous and potentially toxic compounds such as mannitol, ethanol, methanol, ethylene glycol, isopropanol, ethyl ether, acetone, trichlorethane, and paraldehyde (Saxton and Seldin, 1986).

CHAPTER

19

Pituitary Function

JAN A. MOL AND AD RIJNBERK

I. HYPOTHALAMUS–PITUITARY SYSTEM

The hypothalamus–pituitary system is a preeminent example of integration of neural and endocrine control. It consists of three major systems: (1) a neuroendocrine system connected to an endocrine system by a portal circulation, (2) a neurosecretory pathway, and (3) a direct neural regulation of endocrine secretion (Fig. 19.1).

The neuroendocrine system involves clusters of peptide- and monoamine-secreting cells in the anterior and midportion of the ventral hypothalamus. Their products reach the median eminence by axonal transport. From there they are released into the capillary vessels of the hypothalamus–pituitary portal system and transported to the pituitary to regulate the secretion of hormones from the anterior lobe (AL) of the adenohypophysis.

The neurosecretory pathway runs from the anterior hypothalamus, traverses the floor of the ventral hypothalamus, and terminates in the neural lobe (NL) of the neurohypophysis on fenestrated blood vessels (Page, 1986). The system is involved in osmoregulation through the production and release of vasopressin, and in parturition and nursing through the secretion of oxytocin.

In the intermediate lobe (IL) the secretory activity is regulated via direct neuronal inhibitory and stimulatory influences (Tilders *et al.*, 1985). In amphibians (Verburg-van Kemenade *et al.*, 1986) and reptiles (Dores *et al.*, 1987) the IL plays an important role in adaptation to background color. The function of IL cells in mammals has not been fully established, but they may play a role in opioid-regulated functions.

A. Anatomical Considerations

The hypothalamus and pituitary control vital functions such as growth, reproduction, lactation, basal metabolism, stress response, parameters of immune function, and the state of hydration. Understanding of the complicated functional relationship of the hypothalamus to the pituitary requires an appreciation of the anatomical relationships.

1. Hypothalamus

Hypophysiotropic neurohormones are produced in several areas of the hypothalamus. For example, in an immunofluorescence study of hypothalami of dogs, the majority of cell bodies with immunoreactivity to corticotropin-releasing hormone (CRH) were found in

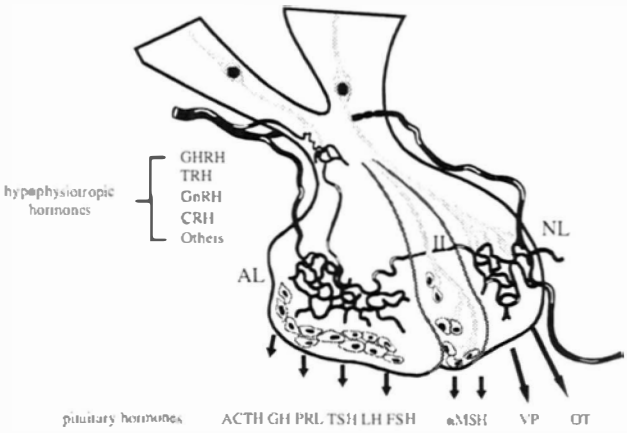

FIGURE 19.1 Schematic representation of the relationship between the hypothalamus and the pituitary in a generalized mammal. The hypothalamus exerts control over the anterior lobe (AL) by releasing and inhibiting factors. These hormones reach the AL cells via capillaries of the pituitary portal system. The neural lobe (NL) of the pituitary is a downward projection of the hypothalamus. The intermediate lobe (IL) is under direct neurotransmitter control.

the region of the periventricular and paraventricular nuclei, but they were also found in the supraoptic and suprachiasmatic area as well as craniodorsal to the mamillary bodies (Stolp *et al.*, 1987).

The cell bodies of the neurohormone-producing neurons that project to the median eminence are in part intermingled with cell bodies that also synthesize these neurohormones but project to other brain areas. The majority of the neurons that project to the median eminence are found in the preoptic and suprachiasmatic region of the hypothalamus. Axons containing the same neurohormone may have synaptic contacts that enable regulation of cellular function between these neurons.

The neurohormone-producing cells receive a complex neural input from a variety of chemical messengers, such as neurotransmitters and other neurohormones. Not only the neurohormones CRH and arginine vasopressin (AVP), but in general the combination of a neurohormone and another chemical messenger, may colocalize within a single neuron.

The neurons of the neurohypophyseal system represent a more anatomically distinct entity, with cell bodies located in the paraventricular and supraoptic hypothalamic nuclei (Sawchenko and Swanson, 1983). However, within these areas there are also neurons producing a variety of other neuropeptides.

2. *Neurotransmitter Systems*

The major neurotransmitter systems for intercellular communication within the central nervous system consist of monoamines and peptides. These chemical messengers regulate the biosynthesis and release of the hypophysiotropic neurohormones. Through a network of axodendritic and axoaxonic contacts, these neurons are connected to the neurohormone-producing cells. In addition, many monoamines and peptides are found within the hypophysiotropic hormone-producing cells, where they are released together with the neurohormones into the portal system and modify the effect of hypothalamic hormones on the pituitary.

The biogenic amine neurotransmitters, known to play a regulating/modulating role in the hypothalamus–pituitary system, include catecholamines (dopamine, noradrenalin, adrenalin), indolamines (serotonin, melatonin), acetylcholine, γ-aminobutyric acid (GABA), and histamine. Neuropharmacologic agents can be used to alter neurotransmitter effects and, as a consequence, hypothalamic and pituitary hormone release.

Many of the peptides with potential effects on hypophysiotropic hormone release are widely distributed in hypothalamic and extrahypothalamic areas of the brain. They include, among many others, peptides common to the gastrointestinal tract, such as gastrin, cholecystokinin, and pancreatic polypeptide, as well as bombesin, angiotensin II, galanin, substance P, neurotensin, enkephalins, neuropeptide Y, natriuretic peptide, and, from a common precursor, the vasoactive intestinal peptide (VIP) and the peptide histidine isoleucine (PHI). The last three peptides may, through vasoconstriction and vasodilatation activities, play an important role in the control of the portal blood flow.

3. *Vascular System*

The releasing and inhibiting hormones are stored in nerve terminals in the median eminence, where their concentrations are 10 to 100 times as great as elsewhere in the hypothalamus. The uniquely organized capillary plexus (see Page, 1986) of the median eminence is in close proximity to nerve terminals of the hypophysiotropic neurons. In contrast to other brain regions, the blood–brain barrier in the area of the median eminence is incomplete, permitting protein and peptide hormones as well as other charged particles to move to the intercapillary spaces and the nerve terminals contained therein. These terminals respond to humoral and neuronal stimuli by secreting releasing and inhibiting factors into the portal system.

The portal capillaries coalesce into a series of vessels that descend through the pituitary stalk and form a second capillary plexus that surrounds the AL cells (Fig. 19.1).

Inferior hypophyseal arteries supply the neurohypophysis. From the primary plexus of the neural lobe

(NL), blood flows not only to the systemic circulation but also to the AL and the hypothalamus. There is evidence for some degree of circulatory flow within the pituitary, that is, from the AL to the NL, from there to the infundibulum, and then back to the AL. The primary capillary plexus of the NL appears to be well positioned in the mini-circulatory system, controlling all of the afferent vascular events and many of the efferent vascular events in the pituitary (Page, 1986).

The vascularization of the intermediate lobe is closely linked to that of the neurohypophysis. However, in spite of the rich blood supply of the NL, the IL is a poorly vascularized structure.

4. *Pituitary*

During embryogenesis the adenohypophysis develops from Rathke's pouch, which arises from the primitive roof of the mouth in contact with the base of the brain. Rathke's pouch subsequently separates by constriction from the oral cavity. The anterior wall thickens and forms the anterior lobe of the adenohypophysis. This largest portion of the adenohypophysis remains separated from the intermediate lobe by the hypophyseal cleft, which is the residual lumen of Rathke's pouch. In several species (Fig. 19.2) the adenohypophysis also extends into a pars tuberalis that forms a cuff or collar around the proximal neurohypophysis and may even envelop part of the median eminence (Hullinger, 1979; Batten and Ingleton, 1987).

The posterior wall of Rathke's pouch is closely opposed to the neural tissue of the NL, thereby forming the intermediate lobe (IL), which is well developed in most mammals, but not in man and birds (Fig. 19.2). In man only during fetal life is a distinct IL found (Visser and Swaab, 1979), whereas there is some debate about the view that in adults "invading" cells of the posterior lobe are homologous with the IL cells of lower vertebrates (Coates *et al.*, 1986; McNicol, 1986; Lamberts, 1987).

The pituitary stalk (infundibulum) and the neurohypophysis (posterior lobe, neural lobe) develop from the basal outgrowth of the diencephalon in connection with the development of Rathke's pouch. The cells of the diencephalic outgrowth later develop into glial cells (pituicytes), whereas nerve fibers from the supraoptic and paraventricular nuclei grow into the NL.

5. *Cells of the Anterior Lobe*

The peptide hormones secreted by the AL can be divided into three categories: (1) the somatomammotropic hormones growth hormone (GH) and prolactin (PRL), (2) the glycoprotein hormones thyrotropin (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH), and (3) the corticomelanotropins, which include α-melanotropin (MSH), adrenocorticotropin (ACTH), β-endorphin (β-END), and β-lipotropin (β-LPH).

Over the years identification of the adenohypophyseal cells has been developed by histochemical staining techniques, immunocytological methods, and ultrastructural studies. Staining and immune reactions de-

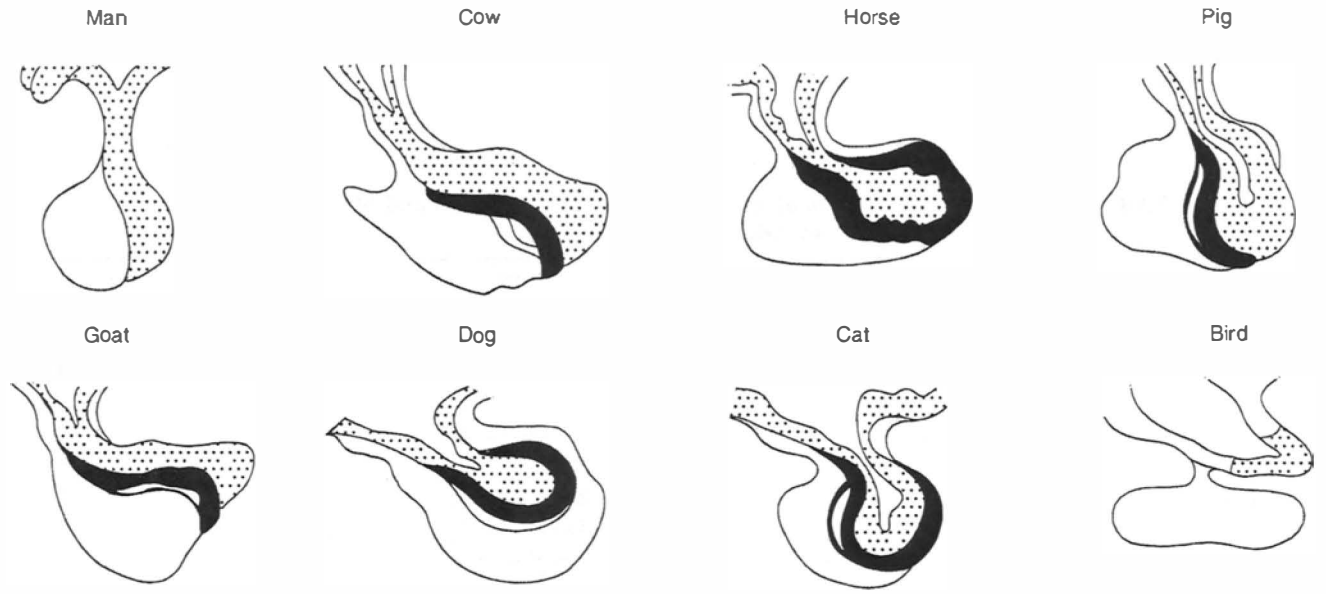

FIGURE 19.2 Schematic illustration of median sections through mammalian and avian pituitaries. Key □, anterior lobe; ■, intermediate lobe; ⊡ neural lobe. Redrawn from Seiferle (1975) and Batten and Ingleton (1987).

pend on the chemical nature of the hormones that are stored in granules within the cytoplasm. Special stains allow histochemical identification of particular cell types. A general identification of adenohypophyseal cells, as derived from Baker (1974), Bentley (1976), and Batten and Ingleton (1987), is given in Table 19.1, although it must be realized that the various cell types do not always give exactly the same staining reaction in different animal species.

As far as ultrastructural features are concerned, the adenohypohyseal cells have the typical cytoplasmic organelles for peptide synthesis and release. Characteristics such as the form and location of the various organelles and the size and shape of the cells allow identification of adenohypophyseal cells at the ultrastructural level (Mikami, 1986; Batten and Ingleton, 1987).

In the embryonic development of the cells of the AL, two main lineages arise from a progenitor cell, the acidophilic (A) cells that result in the mammasomatotropic cells and the basophilic (B) cells that differentiate into gonadotrope, thyrotrope, and corticotrope. During the fetal development of the mouse AL the expression of the α-subunit of the glycoproteins is among the first that becomes apparent. Then hormone biosynthesis is found in the corticotropes and then in the gonadotropes. The differentiation of the thyrotropes and somatomammotropes depends on the expression of a specific transcription factor called Pit-1 or GHF-1. Mutations in the Pit-1 gene may result in the complete absence of TSH-, GH-, and PRL-producing cells in the pituitary.

The concept of one type of pituitary cell producing one hormone now appears to be an oversimplification. Not only are the majority of gonadotropes and somatomammotropes multihormonal cells that contain LH and FSH or GH and PRL, respectively, but other combinations such as gonadotrope hormones and ACTH or TSH and ACTH have been described. As already has been discussed for the hypothalamus, the hormone-producing AL cells, or the so-called "folliculostellate" cells, also may synthesize a variety of chemical messengers, intrapituitary growth factors, and cytokines that exert local paracrine effects on cell function and proliferation (Denef, 1994).

6. *Cells of the Intermediate Lobe*

The predominant IL cell in mammals is the melanotrope, a cell with immunoreactivity for α-MSH, which is very sparse in the AL (Halmi and Krieger, 1983). In some species, including the dog (Halmi *et al.*, 1981) and the horse (Amann *et al.*, 1987), the IL is cytologically heterogeneous. ACTH-containing cells (B cells) have been found to be dispersed among the predominant melanotropes (A cells). In the dog the immunoreactive ACTH content of the IL even exceeds that in the AL (Halmi *et al.*, 1981). In agreement with the previously mentioned direct neural regulation of IL secretory activity, the presence of neural elements was demonstrated in the bovine IL (Boyd, 1987). Evidence is accumulating that the cells of the intermediate lobe are also involved in the biosynthesis and release of a yet-unknown prolactin-releasing factor. The blood supply of the IL is very poor, and therefore the peptides released from the IL are thought to act mainly by diffusion in a paracrine manner.

7. *Cells of the Neural Lobe*

The NL contains axonal nerve fibers, often swollen by being packed with neurosecretory granules. These nerve fibers and the glial cells (pituicytes) have synap-

TABLE 19.1 Molecular Weights of Adenohypophyseal Hormones and Staining Properties of Adenohypophyseal Cells

Cell type	Hormone	MW[a]	Subunits	Staining	Orange G	PAS[b]	Color[c]
Somatotrope	GH	22,000	—	Acidophil	+	−	Yellow

toid contacts. The pituicytes appear to play an intermediary role in the regulation of the release of vasopressin and oxytocin (Van Leeuwen and De Vries, 1983).

B. Regulation of Pituitary Functions

For the regulation of each of the five major adenohypophyseal hormone systems (ACTH, LH and FSH, TSH, GH, and PRL) there is a feedback (closed-loop) system. AL hormone and hypophysiotropic hormone secretion are suppressed by the products of target endocrine glands such as the thyroid, adrenal, and gonad. Apart from this long-loop feedback, some hormones (e.g., PRL) regulate their own secretion directly by acting on the hypothalamus (short-loop feedback). On this powerful feedback control with primarily blood-borne signals, other signals are superimposed. These may originate within the central nervous system (open loop) and can be mediated through neurotransmitters and hypophysiotropic hormones. Thus, influences are exerted that represent the environment (temperature, light–dark), stress (pain, fear), and intrinsic rhythmicity.

These regulatory factors influence peptide synthesis and/or release in adenohypophyseal cells, where each of the steps in hormone synthesis and ultimate secretion represents a potential control point in the regulation of circulating hormone levels.

1. Hypophysiotropic Hormones

The main hypothalamic neurohormones may stimulate or inhibit the release of a single hormone, or affect several hormone-producing cells (Fig. 19.3). The predominant influence of the hypothalamic hormones on the pituitary is stimulatory. Interference with the integrity of the hypothalamus–pituitary connections results in decreased secretion of pituitary hormones. The exception is PRL, the secretion of which is increased when hypothalamic influence is removed.

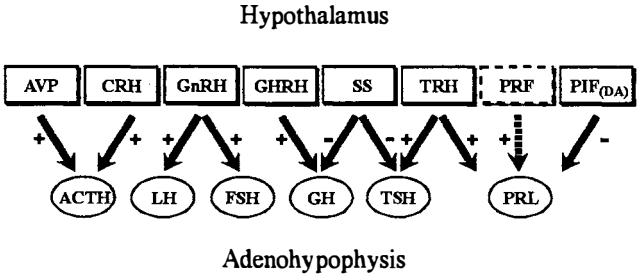

FIGURE 19.3 Hypophysiotropic regulation of the secretion of pituitary hormones. Solid lines denote hormones whose structures have been determined. Dashed lines indicate a factor whose identity is still unknown.

As the complexity of the peptide structure of the hypophysiotropic hormones increases, species variation in sequence may occur. Whereas the structures of TRH, GnRH, and SS (3, 10, and 14 amino acids, respectively) are identical in all mammals, those of GHRH and CRH (44 and 41 amino acids) exhibit species specificity. The one nonpeptide hypophysiotropic hormone is dopamine. In addition to its major role as a neurotransmitter, dopamine is the most important inhibitor of PRL.

2. Regulation of Gene Expression

The developments in recombinant DNA technology have provided better understanding of the genes encoding pituitary hormones and the regulatory elements involved in gene transcription. The main elements regulating the gene transcription will be mentioned briefly (Fig. 19.4). Eukaryotic genes encoding peptide hormones consist of a promoter (regulatory) unit and a transcription unit encoding the primary transcript that after appropriate processing will form the messenger RNA (mRNA).

The promoter unit is the upstream (5′) part of the gene. The promoter has specific DNA sequences (response elements) permitting the binding of transcription factors that enhance or inhibit gene expression by changes in the stability of the RNA polymerase–TATA box factors complex at the constitutive promoter. At a greater distance from the gene, specific enhancer elements may also regulate gene transcription. The highly specialized hormone production is also regulated by tissue-specific silencers and enhancers that are mandatory for gene expression.

Specific binding of hypothalamic neurohormones to membrane receptors of individual AL cells will result in changes in second messenger concentrations of, for instance, cyclic AMP or inositol triphosphate within the cell, a process called signal transduction. These changes will result in differences in phosphorylation of transcription factors that bind to a cAMP response element (CRE) or tetradecanoylphorbol acetate response element (TRE) in the promotor unit. Complexes of steroid hormones, thyroid hormone, or the retinoids with their respective receptors may also bind to specific areas of the promoter. For example, a glucocorticoid response element (GRE) in the promoter of the gene encoding pro-opiomelanocortin binds the glucocorticoid–receptor complex, resulting in inhibition of gene transcription (negative GRE). Transcription is thus regulated by responses to extracellular signals, but tissue-specific intracellular transcription factors also play a crucial role in determining gene expression.

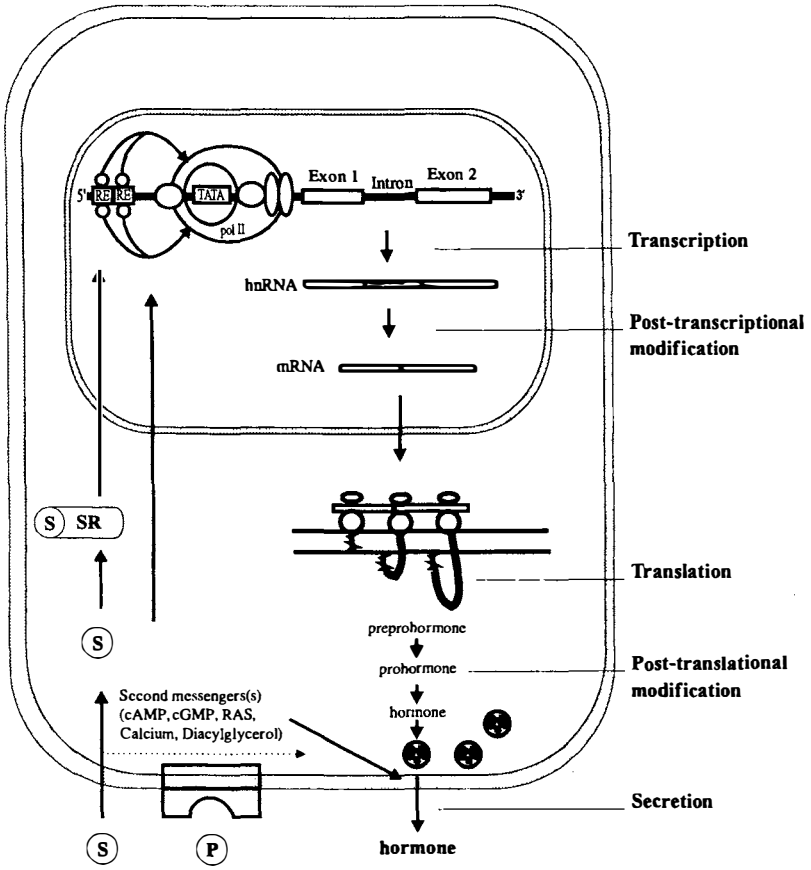

FIGURE 19.4 Schematic representation of potential control points in pituitary hormone synthesis and secretion.

After initiation of transcription a primary transcript is made, which contains an RNA copy of the entire transcription unit, the heteronuclear RNA (hnRNA). After excision of the intron areas, a process called splicing, the formation of a 7-methylguanine cap at the 5′ end, and the addition of a poly(A) tail at the 3′ end, a mature mRNA is formed. Through alternative splicing reactions, length variants of the mRNA may ultimately result in variation of the coding sequence (see section on growth hormone) or changes in mRNA stability as found for the insulin-like growth factors (IGFs). Through differences in exon coupling, even completely different peptides can be obtained from a single gene, as in the case of the gene encoding calcitonin.

3. Prohormone Biosynthesis, Processing, and Release

The process of peptide synthesis occurs principally on the rough endoplasmatic reticulum (rER). mRNA, encoded by nuclear DNA, passes to cytosolic ribosomes, and by sequential processing of transfer RNAs (tRNA) with their attached amino acids, the translation process of mRNA to a peptide starts. The beginning of the growing peptide forms a specific signal peptide that facilitates the attachment of the translation complex to the rER and enables the passage into the lumen of the rER. The signal sequence of the pre-prohormone is cleaved and the remaining prohormone undergoes several modifications such as disulfide formation and glycosylation. The peptide passes along the rER lumen into the Golgi complex, where peptides are packaged and released into the cytoplasm as membrane-bound granules. During storage of these granules the prohormone is further processed by specific proteolytic cleavage, C-terminal amidation, or N-terminal carboxylation. Characteristic proteolytic cleavage sites are pairs of the basic amino acids arginine and lysine. The granules are stored until the hormone is released by exocytosis. This process involves fusion of the granule membrane with the cell membrane.

II. ANTERIOR LOBE AND INTERMEDIATE LOBE

A. Proopiomelanocortin-Derived Peptides

The corticotropic cells of the AL and the melanotropic cells of the IL are both able to synthesize proopiomelanocortin (POMC), the common prohormone for ACTH, α-MSH, β-LPH, and a family of β-END-related peptides (Fig. 19.5).

1. *ACTH/α-MSH*

a. Gene Expression

The gene encoding POMC contains three exon areas. Exon 1 encodes a 5′ untranslated region (5′-UTR) and exon 2 encodes the signal peptide and the N-terminal part of the POMC prohormone. The majority of the prohormone, including γ-MSH, is encoded by exon 3. After the splicing process a mRNA of approximately 1100 nucleotides is formed in the pituitary of most species, including the dog (Mol *et al.*, 1991). By alternative splicing of the intron A sequence a longer transcript is found in the hypothalamus. Ectopic human ACTH-producing tumors contain shorter POMC mRNA sequences (Jacobson and Drouin, 1994).

The expression of the POMC gene in corticotropes and melanotropes is regulated by the same promoter elements, as shown by experiments with transgenic mice. Synergistic stimulation of gene expression requires binding of yet partially characterized transcription factors in the distal and central part of the POMC promoter. Binding of corticotropin-releasing hormone mediates the activation of the corticotrope in the AL, resulting in increased cAMP production within the cell (Jacobson and Drouin, 1994). The sequence of CRH appears to be very homologous among species. The peptide sequence CRH in the dog is identical to that in the human, rat, and horse (Mol *et al.*, 1994), and there are only small differences in CRH in cattle and sheep. Glucocorticoids inhibit POMC gene expression via type II glucocorticoid receptors in the AL corticotrope.

POMC expression in the IL melanotrope is also stimulated by cAMP. *In vitro* experiments in various species point to a possibility that CRH activates this signal transduction system. However, chronic infusion of CRH stimulates the POMC mRNA concentration in the AL, but inhibits mRNA concentration in the IL (Höllt and Haarmann, 1984). The POMC gene expression in the IL is inhibited by dopaminergic and GABAergic compounds (Chronwall *et al.*, 1987; Loeffler *et al.*, 1986), but not by glucocorticoids.

b. (Pro)hormone

POMC prohormone sequences are known for a variety of species and share a common structure (Fig. 19.5). Among species a high sequence homology is found between the N-terminal site (N-POC) of the prohormone (including γ-MSH), the ACTH region, and the β-endorphin region. In contrast, the regions between γ-MSH and ACTH and the first part of β-lipotropin are rather heterogeneous (Numa and Imura, 1985; Mol *et al.*, 1991). Species differences in the sequence of ACTH occur only in the N-terminal part (Fig. 19.6), whereas the ACTH(1-24) sequence, necessary for full biological activity, is identical among mammals.

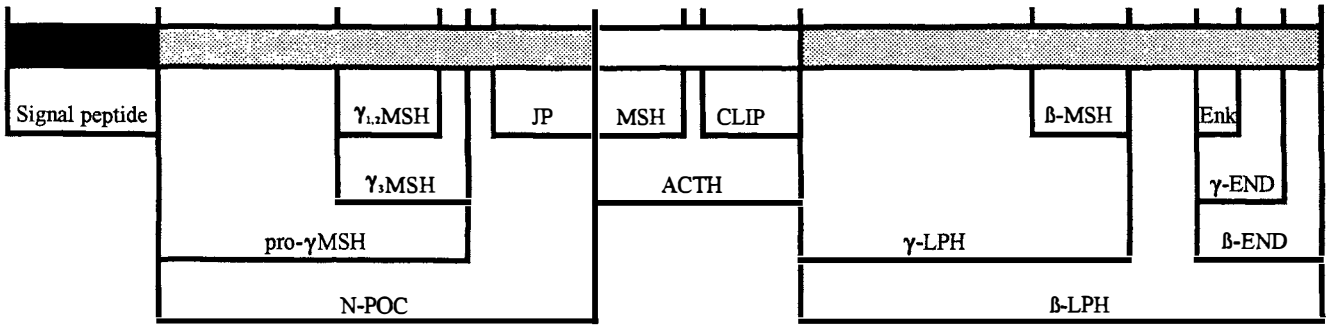

FIGURE 19.5 Schematic representation of preproopiomelanocortin (horizontal bar), with four main domains: the signal peptide, which is cleaved after entrance to the lumen of the RER; the N-terminal peptide (N-POC), containing the (pro-)γMSH sequences and the joining peptide (JP); the ACTH domain, from which MSH and corticotropin-like intermediate lobe peptide (CLIP) can be generated; and the β-lipotropin (β-LPH) domain, including the endorphin (END) family of peptides and a metenkephalin sequence (Enk). Pairs of basic amino acid residues are indicated with vertical lines, representing potential sites of proteolytic cleavage. In the anterior lobe, major cleavage products are N-POC, ACTH, and β-LPH. In the intermediate lobe, the major products are N-POC, γ-MSH, α-MSH, and β-endorphin.

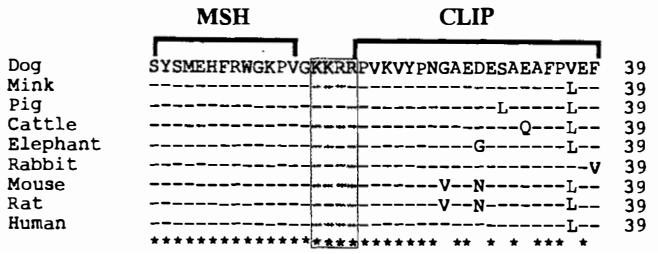

FIGURE 19.6 Comparison of the ACTH(1–39) sequence from various species using the one-letter code for amino acids. Identical amino acids are given by a single line (-). The asterisk (*) means an identical sequence for all species. The shaded box indicates the two pairs of basic amino acids prone to proteolytic cleavage.

The proteolytic enzymes PC1/PC3 and PC2 are involved in the processing of prohormones in neuroendocrine cells. They cleave the precursor at pairs of basic amino acids, resulting in the formation of biologically active hormones. The PC1/PC3 enzyme present in the AL cleaves POMC to ACTH and β-LPH. PC2 generates the ACTH(1–13) fragment in both AL and IL. The combination of both enzymes is present in the IL.

C-Terminal amidation and N-terminal acetylation of ACTH(1–13) results in α-MSH. Various degrees of acetylation of MSH result in the storage of desacetyl-, monoacetyl-, and diacetyl-α-MSH in secretory granules (Eipper and Mains, 1980; Krieger, 1980). The desacetyl form is predominant in the AL. In the rat the IL contains diacetyl-α-MSH, whereas the canine IL contains predominantly the monoacetyl-α-MSH (Young *et al.*, 1992).

c. Secretion by the AL

ACTH is released in frequent pulses, as demonstrated in the pituitary venous effluent of the horse (Redekopp *et al.*, 1986a,b). By measurements in peripheral blood, Kemppainen and Sartin (1984) documented episodic secretion of ACTH in dogs, with an average of nine peaks per 24-hour period.

The release of ACTH by the AL is influenced by many factors (Table 19.2). A number of these factors modulate the release of CRH and AVP, which are considered to be the predominant stimulating neurohormones *in vivo* (Antoni, 1986; Keller-Wood and Dallman, 1984). The relative contribution of CRH and AVP to ACTH release varies among species and circumstances. In dogs (Van Wijk *et al.*, 1994) and pigs (Minton and Parsons, 1993) both exogenously administered CRH and LVP induce comparably high plasma ACTH concentrations. In sheep, AVP is the predominant ACTH-releasing factor. In the rat the stimulation of ACTH release by CRH and AVP is synergistic, meaning that the response to CRH + AVP is greater than the sum of the reactions to CRH and AVP separately (Buckingham, 1987).

The basal release of ACTH is regulated by the occupancy of type I or mineralocorticoid receptors (MR) in the hippocampus (Jacobson and Sapolsky, 1991). Decreases in brain MR binding capacity of the dog during aging results in enhanced basal activity of the hypothalamus–pituitary–adrenal axis (Rothuizen *et al.*, 1993). In sheep, basal ACTH release is inhibited by active immunization against CRH (Guillaume *et al.*, 1992a) but not by immunization against AVP (Guillaume *et al.*, 1992b).

Exercise and insulin-induced hypoglycemia stimulate ACTH release. In the horse, exercise-induced ACTH release is accompanied by increased AVP concentration in pituitary venous blood without changes in CRH concentrations (Alexander *et al.*, 1991). In sheep, mild hypoglycemia is accompanied by increases in AVP and CRH concentrations in portal blood, but in severe hypoglycemia the AVP secretion is relatively much higher than the CRH release (Caraty *et al.*, 1990). AVP also regulates the ACTH response on hypoglycemia in the neonatal rat (Muret *et al.*, 1992).

Hypotension induced by nitroprusside (Kemppainen and Sartin, 1987) or by hemorrhage (Lilly *et al.*, 1983) causes ACTH release in the dog, together with large increases in plasma AVP derived from the NL (Raff *et al.*, 1988). Selective neurohypophysectomy results in greatly attenuated ACTH and AVP responses to hypotension and angiotensin II, whereas the ACTH response to CRH injection remains unchanged. By substitution with adequate AVP infusion, the ACTH response to hypotension can be restored (Raff *et al.*, 1992). In sheep, chronic absence of ovarian hormones after ovariectomy reduces the ACTH response to hypotension also, but not to CRH, AVP, or hypoglycemia (Pecins-Thompson and Keller-Wood, 1994).

TABLE 19.2 Factors Modulating ACTH Release from the Adenohypophysis

	Stimulating	Inhibiting

Horse	β-END		(18.3 ± 4.4)	Orth *et al.* (1982)
Horse	ACTH		3.5–15.0	Hodson *et al.* (1986)
Sheep	ACTH	10.00	(116 ± 19)	Clarke *et al.* (1986)
Sheep	α-MSH	10.00	0–4.2	Clarke *et al.* (1986)

[a] Most of the values have been converted to SI units. 1 ng ACTH/liter = 0.22 pmol/liter; 1 ng α-MSH/liter = 0.60 pmol/liter; 1 ng β-END/liter = 0.29 pmol/liter.

In the dog the release of ACTH is stimulated by β-adrenergic agonists (isoproteronol), dopaminergic antagonists (haloperidol), and serotoninergic agonists (quipazine maleate). TRH and GnRH stimulate the release of cortisol, probably by stimulating ACTH release (Stolp *et al.*, 1982). Although direct stimulatory effects of catecholamines on the *in vitro* release of ACTH from ovine pituitary cells has been found, central stimulation of predominantly noradrenergic, but also adrenergic, pathways evokes the highest ACTH response (Liu *et al.*, 1991).

Endogenous opiates (metenkephalin, dynorphin, and β-endorphin) inhibit the release of ACTH in man (Besser *et al.*, 1987). Conflicting results have been reported on the effect of metenkephalin in the rat, but β-endorphin and dynorphin may exert tonic inhibition of CRH release (Plotsky, 1986). The metenkephalin agonist DAMME stimulates the release of ACTH in the dog (Meij *et al.*, 1990).

Activation of the immune system by infections results in the enhanced production of the cytokine interleukin-1 (IL-1β), which has the ability to stimulate CRH secretion from the hypothalamus and thus activates the hypothalamus–pituitary–adrenal axis. The biosynthesis and release of IL-6 has been found in the folliculostellate cells of the AL. IL-6 also stimulates the HPA-axis, at both the hypothalamic and the pituitary level (Sweep *et al.*, 1991).

Endogenous corticosteroids inhibit ACTH release predominantly at hypothalamic sites. Synthetic steroids such as dexamethasone may act primarily at the pituitary level (De Kloet *et al.*, 1974). In a review on corticosteroid-mediated feedback, Keller-Wood and Dallman (1984) suggested three different time schedules: a fast feedback that acts on the corticotropic cell but may not be related to nuclear receptor binding, an intermediate feedback that probably acts by inhibition of CRH release, and a slow feedback that acts by a decrease in mRNA encoding POMC in the pituitary gland. The delay in inhibiting ACTH production may be caused by the high stability of the mRNA encoding POMC and not by the absence of direct inhibition of the transcription. Dexamethasone inhibits gene transcription *in vivo* within 30 minutes in the rat (Fremeau *et al.*, 1986). In the dog the intermediate-delayed feedback is determined by the mean change in corticosteroid concentration over time (Keller-Wood, 1989). Acute lowering of plasma cortisol in the horse by inhi-

bition of the synthesis in the adrenal gland resulted first in an increased ratio of ACTH:CRH in pituitary venous blood before CRH concentrations started to rise (Alexander *et al.*, 1993), indicating that the first effect is the opposite of the fast feedback and is mediated by increased sensitivity of the corticotrope.

d. Secretion by the IL

The release of POMC-derived peptides by the IL is under direct neural control. The rat and the mouse have been the mammals in which most studies on the regulation and processing of POMC in the IL have been carried out thus far. In the rat the release of POMC-derived peptides is regulated predominantly via tonic dopaminergic inhibition and β-adrenergic stimulation (Berkenbosch *et al.*, 1981; Tilders *et al.*, 1985), although GABAergic innervation of the IL has also been demonstrated (Oertel *et al.*, 1982). In addition, Proulx-Ferland *et al.* (1982) demonstrated that CRH is a potent stimulator of α-MSH secretion by the IL. In line with the absence of a glucocorticoid receptor in the IL (Antakly *et al.*, 1985), the α-MSH response to CRH could not be suppressed by dexamethasone administration. The expression of the glucocorticoid receptor in the IL is suppressed by dopamine (Antakly *et al.*, 1987), whereas the CRH receptor content of the rat IL is stimulated by dopamine (Shiver *et al.*, 1992).

In the dog, *in vitro* studies (Mol *et al.*, 1987) and *in vivo* and immunocytochemical observations (Middleton *et al.*, 1987a) have revealed the IL to be resistant to glucocorticoid suppression. There is also evidence from *in vivo* studies that dopaminergic pathways play a regulatory role in canine IL function (Kemppainen and Sartin, 1986). However, in other respects the situation in the dog is different from that in the rat with regard not only to the heterogeneous cytology (see Section I.A.5), but also to some of the regulation characteristics. Despite the fact that CRH-immunoreactive fibers have been identified in the canine neurointermediate lobe (Stolp *et al.*, 1987) and although *in vitro* CRH stimulates ACTH release from the neurointermediate lobe (Mol *et al.*, 1987), there is no convincing evidence that CRH can stimulate release of ACTH from the IL *in vivo* (Kemppainen and Sartin, 1986, 1987; Middleton *et al.*, 1987b), whereas no (Kemppainen and Sartin, 1986) or a very small (Rijnberk *et al.*, 1987) α-MSH response to CRH stimulation has been observed. In contrast with a significant increase of plasma MSH concentrations after administration of the dopamine antagonist haloperidol, even after administration of dexamethasone to inhibit the contribution of the AL, no release of IL ACTH is observed after haloperidol.

In the cat as well, no stimulation of MSH occurs after CRH administration (Willemse and Mol, 1994). However, cats undergoing handling and skin testing without anesthesia show significant increases in plasma MSH concentrations (Willemse *et al.*, 1993). *In vitro* experiments revealed the sensitivity of feline IL MSH release to dopaminergic inhibition (Willemse and Mol, 1994).

In fetal and newborn lambs and in adult sheep (Newman *et al.*, 1987) the administration of a dopamine-receptor antagonist results in α-MSH release. Elimination of the inhibitory hypothalamic control in sheep by hypothalamus–pituitary disconnection results in increased α-MSH release (Clarke *et al.*, 1986). The dopamine inhibition of ACTH secretion in the hyperadrenocorticoid horse (Wilson *et al.*, 1982) suggests that in the normal horse the IL is under dopaminergic control. In the rabbit the dopaminergic control of the IL is absent (Schimchowitsch *et al.*, 1986).

e. Action

The predominant action of ACTH is stimulation of steroidogenesis and corticosteroid release from the adrenals (see the chapter on adrenal function). ACTH also exerts a growth-stimulating effect on the adrenal cortex. Moreover, non-ACTH portions of POMC, that is, N-terminal POMC peptides, are involved in adrenocortical growth (Lowry *et al.*, 1987). In pharmacological dosages ACTH may promote lipolysis in fat cells and amino acid uptake in muscle. The role of ACTH produced in hypothalamic neurons projecting to higher brain centers remains to be elucidated. Distribution patterns have been reported for the cat (Rao *et al.*, 1986).

The biological effect of α-MSH in mammals remains uncertain, although the presence of specific α-MSH receptors in many tissues suggests that this peptide may affect the function of several organs (Tatro and Reichlin, 1987). Stimulation of nerve regeneration by α-MSH has been reported (Verhaagen *et al.*, 1987; De Koning and Gispen, 1987). The C-terminal fragment of ACTH(18–39), called corticotropin-like intermediate lobe peptide (CLIP), has been found to be a potent stimulator of *in vitro* adrenal DNA synthesis (Wulffraat *et al.*, 1987). α-MSH is present in the fetal pituitary of all species studied, and there is evidence that it may play a role in the regulation of intrauterine growth (Mulchahey *et al.*, 1987).

f. Disease

Lesions at the hypothalamic and pituitary level may result in altered synthesis and release of POMC-derived peptides. There have been no reports of the occurrence of isolated ACTH deficiency in domestic animals. There are a few reports of dogs with tumorous (supra)hypophyseal lesions, with indirect evidence for multiple adenohypophyseal and neurohypophyseal

deficits (Rijnberk, 1971; Eigenmann *et al.*, 1983a), and one dog reported to have secondary hypoadrenocorticism without information about other pituitary functions (Peterson *et al.*, 1992).

In contrast to the few descriptions of ACTH deficiency, pituitary-dependent hyperadrenocorticism is a common disorder in the dog (Peterson, 1987a), in which the adenomas producing the ACTH excess may originate in the AL or the IL (Capen *et al.*, 1967; Peterson *et al.*, 1986). From the significantly lower CRH concentrations in cerebrospinal fluid of dogs with pituitary-dependent hyperadrenocorticism as compared to control dogs, it is concluded that the excessive ACTH secretion is not caused by chronic hyperstimulation with CRH (Van Wijk *et al.*, 1992). The ACTH secretion appeared also to be less sensitive to stimulation with CRH than with LVP (Van Wijk *et al.*, 1994). Evidence for a genetic involvement in tumorigenesis was found in a family of Dandie Dinmont terriers (Scholten-Sloof *et al.*, 1992). In the horse the disease originates primarily in the IL (Wilson *et al.*, 1982; Orth *et al.*, 1982). In agreement with the characteristics described earlier for the secretion of POMC-derived peptides by the IL, ACTH release by tumors of IL origin in both the dog and the horse tends to be strongly resistant to suppression by dexamethasone (Orth *et al.*, 1982; Peterson *et al.*, 1986). In dogs the highest plasma α-MSH concentrations are found in individuals with dexamethasone-resistant ACTH secretion. This suggests an IL origin of the disease, although there is evidence that the pituitary lesions do not always maintain the characteristics of the lobe of origin (Rijnberk *et al.*, 1988b). A dog with diabetes insipidus has been described, in which the pituitary tumor released primarily biologically inactive POMC-derived peptides (Goossens *et al.*, 1995). In contrast with the equine IL tumors, these tumors in dogs respond poorly to administration of dopamine agonists in terms of diminished ACTH secretion (Rijnberk *et al.*, 1988b).

For details on clinical manifestations, laboratory findings, diagnostics, and treatment of these diseases, including iatrogenic hypoadrenocorticism due to corticosteroid therapy, the reader is referred to textbooks (Feldman and Nelson, 1996; Rijnberk, 1996) and the chapter on adrenocortical function in this volume.

g. Tests

Basal levels of circulating POMC-derived peptides are measured for diagnostic purposes in situations of suspected hypo- as well as hypersecretion. ACTH values below or just within the reference range (Table 19.3) may be found in cases of hypothalamus–pituitary disease, as well as in situations in which endogenous or exogenous glucocorticoid excess suppresses hormone synthesis in the corticotropic cells. This makes the measurement of basal ACTH levels a useful tool in the differentiation between pituitary-dependent hyperadrenocorticism and hyperadrenocorticism due to adrenocortical tumor (Feldman, 1983; Peterson, 1986). In pituitary-dependent hyperadrenocorticism, ACTH values exceeding the reference range may be found, but there is considerable overlap. Basal MSH concentrations have been found to be elevated in horses (Orth *et al.*, 1982) and dogs (Peterson *et al.*, 1986; Rijnberk *et al.*, 1987) with pituitary-dependent hyperadrenocorticism of IL origin.

Of the dynamic tests, the dexamethasone suppression tests (see chapter on adrenocortical function) are still the best for the diagnosis and differential diagnosis of excessive ACTH and glucocorticoid secretion. In animals suspected of having pituitary–adrenocortical insufficiency, the secretory capacity for POMC-derived peptides can be measured by provocative testing.

CRH and AVP are also used in the differentiation between pituitary-dependent hyperadrenocorticism and hyperadrenocorticism due to adrenocortical tumor. The chronically suppressed corticotropic cells are presumed to be unresponsive to these stimuli. However, Meijer *et al.* (1978) found considerable overlap in plasma cortisol values in the AVP test, whereas much less is claimed to occur in the CRH test (Peterson, 1986). It has been demonstrated that LVP stimulates cortisol release by adrenal tumors in a direct way (Van Wijk *et al.*, 1994).

It has been shown that dogs with pituitary-dependent hyperadrenocorticsm usually do not respond supranormally to CRH administration (Rijnberk *et al.*, 1987). The cells of these pituitary lesions were found to be less responsive to CRH *in vitro* than were normal corticotropes (Mol *et al.*, 1987).

As far as the possibility for manipulation of canine IL function is concerned, of the substances tested only the dopamine agonist haloperidol (Kemppainen and Sartin, 1986; Rijnberk *et al.*, 1987) caused significant increases in circulating α-MSH. More detailed information pertaining to some of these tests is presented in Section IV of this chapter and in Table 19.4.

2. *β-Endorphin/β-Lipotropin*

a. Gene Expression and Biosynthesis

β-Lipotropin (β-LPH) consists of the 91 C-terminal amino acids of the POMC precursor. It is synthesized in the corticotropic cells of both the AL and IL. The C-terminal sequence (36–91) is remarkably similar in human, porcine, and ovine pituitaries, whereas the N-terminal sequence (1–36) is rather heterogeneous. β-

MSH (sequence 37–58) appears to be an extraction artifact and plays no physiological role.

By proteolytic cleavage at amino acid 61, γ-LPH (β-LPH(1-61)) and a family of endorphins is formed. Through specific deletion of C-terminal amino acids and N-terminal acetylations, various β-END-related peptides are formed. The three main compounds are β-END(61–91), γ-END(61–77), and α-END(61–76). The corticotropic cells of the AL synthesize approximately equal or higher concentrations of β-LPH than of β-END(1–31) in most species. The equine AL, however, contains primarily β-END(1–31) and N-acetyl-β-END(1–27) (Millington *et al.*, 1992). The corticotropic/melanotropic cells of the IL produce relatively more β-END and related peptides. In the IL of the normal dog the ratio β-LPH/β-END is less than 0.1 (Krieger, 1983). β-END(1–27) is the most abundant form in the canine IL, followed in decreasing order of concentration by the nonacetylated β-END(1–31) and (1–26) forms, and the N-acetyl (1–27), (1–26), and (1–31) forms (Young and Kemppainen, 1994).

b. Secretion

The stimuli that induce ACTH or α-MSH release from either AL or IL cells also cause a release of the β-LPH-related peptides from the same cell. The cellular subset of specific proteolytic, amidating, and acetylating enzymes present in the secretory vesicles define the ultimate composition of POMC-derived peptides that are secreted into the blood.

c. Action

The main action of β-LPH is to mobilize fat from adipose tissues, as demonstrated in the rabbit. Its biological function in man and other species has not been fully elucidated. Brain tissue can break down β-LPH to form β-END-related peptides. However, it is questionable whether these pituitary peptides are involved in brain function; in conscious sheep, hemorrhagic stress elevates β-END concentrations in plasma but not in cerebrospinal fluid (Smith *et al.*, 1986).

β-END is an endogenous opiate with a potent morphinomimetic action. It is also produced in the hypothalamus where the entire POMC precursor is present. Brain and pituitary endorphin are probably part of separate systems. The role of β-END and other opioid peptides in the secretion of pituitary hormones is has been studied with long-acting analogues, opiates, and opioid receptor antagonists (Besser, 1987; Van Wimersma Greidanus, 1987). It appears that there are opioid mechanisms in the hypothalamus and that stimulation, for example, causes secretion of PRL (Grossman *et al.*, 1981; Delitala *et al.*, 1982) and inhibition of the release of oxytocin, whereas the release of vasopressin is differentially affected (van Wimersma Greidanus, 1987; Hellebrekers *et al.*, 1987). Cross-species studies have revealed marked differences in the amount of hypothalamic opiate receptors of the various subtypes of opioid peptides.

d. Disease/Tests

Hypersecretion of β-END is associated with the ACTH hypersecretion of IL tumors in both equine and canine pituitary-dependent hyperadrenocorticism (Orth *et al.*, 1982; Peterson *et al.*, 1986; Rijnberk *et al.*, 1987). As the regulation of the secretion of β-END is similar to that of other POMC-derived peptides from the AL and IL, testing procedures can be applied as mentioned in the section on ACTH and MSH. Elevation of plasma β-END has been documented in horses following running and shipping (Li and Chen, 1987) and in sheep during electroimmobilization and shearing procedures (Jephcott *et al.*, 1987). Treadmill exercise of Thoroughbred horses induces a variable response in plasma β-END concentration (Art *et al.*, 1994). Elevated plasma β-END concentrations are found in dogs with congestive heart failure (Himura *et al.*, 1994) and are further elevated after naloxone treatment.

B. Glycoprotein Hormones

The gonadotropes and thyrotropes synthesize the hormones LH, FSH, and TSH, each of which consists of two different peptide chains, termed the α- and β-subunits. The amino acid sequence of the α-subunit is identical for LH, FSH, and TSH within a species, as it is for placental chorionic gonadotropin. The β-subunits have unique structures and determine the hormone specificity. Carbohydrate substituents account for 10–20% of the molecular weights of these hormones.

1. α-Subunit

a. Gene Expression

The gene encoding the α-subunit varies between 8 and 16.5 kb among the species and contains four exons. The α-subunit comes to expression in a variety of cells such as thyrotropes, gonadotropes, and syncytiotrophoblasts. Its promotor sequence contains a cAMP response element (CRE), a negative thyroid hormone response element (nTRE), a negative glucocorticoid response element (nGRE), and thyrotrope-specific and GnRH/TRH response sites.

b. (Pro)hormone

Translation of the mRNA results in the formation of a precursor peptide with a molecular weight of approximately 13,500. The α-subunit has a high degree of homology among species (Fig. 19.7). The human sequence contains 92 amino acids, rather than 96 as found in all other species studied thus far. The shorter human sequence is due to a deletion of 12 nucleotides at the beginning of exon 3. After cleavage of the signal peptide, five disulfide bridges are formed. Two asparagine residues are prone to N-glycosylation, but there is also a putative O-glycosylation site (Fig. 19.7). The α-subunit is produced in excess of the β-subunit that determines the hormone specificity. The β-subunit formation is rate limiting in the formation of the hetero αβ dimer.

1. TSH

The thyrotropic cells of the anterior pituitary produce thyroid-stimulating hormone (TSH), which stimulates both the synthesis and secretion of thyroid hormone.

a. Gene Expression

The rat and human TSH gene consists of three exons, whereas the mouse gene has five exons. The most prominent stimulator of gene transcription is the hypothalamic thyrotropin-releasing hormone (TRH). TRH activates the thyrotrope via a signal transduction process that is mediated by activation of the phospholipase C pathway. At least two ultimately activated transcription factors are known. The first is Pit-1 / GHF-1, which is essential for cells producing TSH, GH, and PRL. Secondly, heterodimers of *c-fos/c-jun* forming an AP-1 complex activate the TSH-β gene. Both α-subunit and TSH-β-subunit expression are strongly inhibited by a negative thyroid hormone response element (nTRE) in the pituitary thyrotrope. The α and β types of the thyroid hormone receptor may form homodimers, and heterodimers, or even form heterodimers with the retinoic acid receptors RAR and RXR. Which forms are

important for negative feedback is the subject of current research.

b. (Pro)hormone

The TSH-β chain consists of 118 amino acids and forms six intrachain disulfide bonds (Fig. 19.8). The TSH-β of the species in this figure share 74% identical amino acids. There are no free cysteine residues, consistent with the fact that subunits form heterodimers noncovalently. The β-chain of TSH has one putative N-glycosylation site.

c. Secretion

The release of TSH is stimulated by the hypothalamic TRH. Somatostatin (SS) has an inhibitory effect on TSH release. Thyroid hormone exerts a long-loop negative feedback. Thus, secretion of TSH is regulated by the interplay of TRH, SS, and thyroid hormone feedback (Reichlin, 1982). Although this feedback depends on 3,3',5-triiodothyronine (T_3) binding to the nuclear receptor of the thyrotrope, plasma TSH correlates better with the thyroxine (T_4) plasma concentration (Larsen, 1982). A specific 5'-deiodinating enzyme is responsible for T_3 generation in the thyrotropic cell.

d. Action

TSH stimulates both synthesis and secretion of thyroid hormones. After receptor binding, TSH stimulates the production of cAMP, which acts as a second messenger. In addition, intracellular Ca^{2+} may modulate the biological effect of TSH via the phosphoinositol pathway. As a result of receptor activation, T_4, and to a much lesser extent T_3, are secreted into the blood. Prolonged stimulation of the thyroid with TSH results not only in hypersecretion of thyroid hormone, but also in enlargement of the thyroid gland.

e. Disease/Tests

Sensitive TSH assays became available in 1995 (Klingler *et al.*, 1995; Nachreiner *et al.*, 1995). At the time this chapter was written, the first clinical evaluations were encouraging for the usefulness of one of these assays for the diagnosis of primary hypothyroidism (Williams *et al.*, 1996).

Long-term glucocorticoid excess reduces T_4 levels in dogs (Belshaw, 1983; Peterson *et al.*, 1984). As in man, this may be the result of diminished pituitary sensitivity to TRH (Visser and Lamberts, 1981) or to inhibited TRH release. However, in dogs there is some indirect evidence for intact TSH release, whereas it has been postulated that glucocorticoids interfere with basal T_4 secretion by inhibiting lysosomal hydrolysis of colloid in the thyroid follicular cell (Kemppainen *et al.*, 1983). Low plasma thyroxine values may also be due to decreased plasma TBG concentrations. Also, the use of certain drugs, such as antiepileptics, results in low plasma total thyroxine concentrations in the dog.

In the dog hypothyroidism is most often due to a primary defect in the thyroid gland. Secondary hypothyroidism may be caused by a pituitary tumor (Rijnberk, 1971; Chastain *et al.*, 1979; Dunbar and Ward, 1982) or panhypopituitarism caused by a suprasellar tumor (Eigenmann *et al.*, 1983a). Low plasma thyroxine values in combination with low TSH values may thus be caused by either secondary hypothyroidism or hyperadrenocorticism and certain drugs. In the first circumstance a true hypothyroidism exists, whereas in the latter cases the dogs should be essentially euthyroid. Unfortunately, free thyroxine measurements in the dog have not been found to discriminate between these circumstances, and thus true secondary hypothyroidism due to impaired TSH secretion should be docu-

mented by performing a TRH test and measurement of TSH secretion. For further details the reader is referred to the chapter on thyroid function.

2. LH and FSH

Luteinizing hormone (LH), which is identical to the interstitial-cell stimulating hormone, and follicle-stimulating hormone (FSH) are produced by the gonadotropic cells of the AL.

a. Gene Expression

In primates multiple copies of LHβ-related genes have been identified, the chorionic gonadotropins (CG), which are expressed in the placenta. The horse is the only known nonprimate in which a CGβ protein is formed in the placenta for the maintenance of early pregnancy. In the horse this CGβ in the placenta is derived from the same gene that encodes pituitary LHβ. Pulsatile GnRH and castration both stimulate the LHβ mRNA levels in the pituitary. Pulsatile treatment with GnRH also increases the length of the polyadenylation of the LHβ mRNA. The consequences for mRNA stability or translation efficiency are unknown. In the horse three transcription start sites have been found (Sherman *et al.*, 1992).

The gene encoding FSHβ contains three exons and two introns. Exon 1 encodes only untranslated mRNA sequences, exon 2 encodes the signal peptide and the first 18 amino acids of the prohormone, and exon 3 encodes the remaining amino acids of the prohormone and a 3'-untranslated region (3'UTR) that is long relative to other β-subunits. The bovine gene is transcribed into a single mRNA, whereas in humans there are several transcripts of different lengths as the result of alternative splicing in exon 1 or variations in the polyadenylation length.

Little is known about the response elements in the FSHβ-promoter. However, it has been demonstrated that GnRH, activin, inhibin, and gonadal steroids regulate the gene expression.

b. (Pro)hormone

After cleavage of the signal peptide, LHβ proteins are formed with a variation in amino acid content among the species of 115 to 121 amino acids (Fig. 19.9). The mature FSHβ chain contains 111 amino acids in most species, except in the horse, in which it contains 118 amino acids (Fig. 19.10). Both subunits contain six intrachain disulfide bridges. LHβ has a single N-glycosylation site, whereas FSHβ has two N-glycosylation sites. The carbohydrate chain formed by the glycosylation of LHβ is sulfated, in contrast to FSHβ, in which a sialic acid residue is added to the carbohydrate chain. This difference may play a role in the hormone sorting within the gonadotrope and certainly results in prolonged plasma half-life of FSH.

c. Secretion and Action

As with other pituitary hormones, the gonadotropins are released in a pulsatile fashion, stimulated by the hypothalamic gonadotropin-releasing hormone GnRH. The pulsatile secretion of GnRH has been demonstrated in sheep (Clarke and Cummins, 1982) and the horse (Irvine and Alexander, 1986). Continuous infusion of GnRH in rhesus monkeys switched off gonadotropin secretion (Belchetz *et al.*, 1978) because of down regulation of GnRH receptors (Naor *et al.*, 1984). In the female, FSH stimulates follicle development and

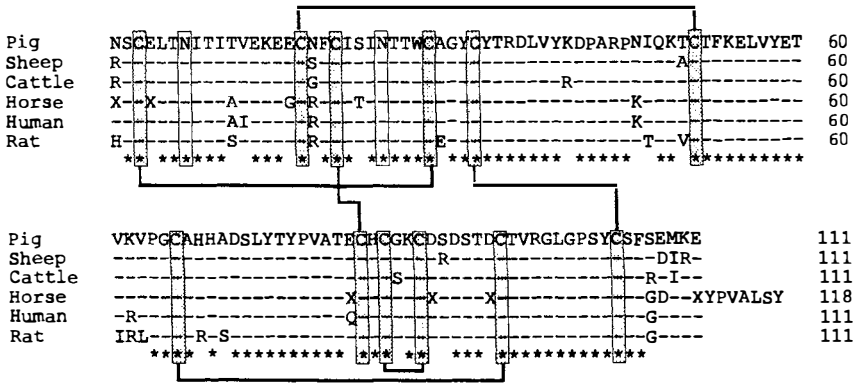

FIGURE 19.10 Sequence comparison of the β-subunit for follicle-stimulating hormone (FSH). Lines between shaded boxes represent intrachain disulfide bridges. The open boxes indicate potential glycosylation sites. See legend to Fig. 19.6.

ripening in the ovaries. Within the theca interna, LH stimulates the production of androstenedione that is converted, by FSH stimulation, into estradiol-17β. Estradiol stimulates the pulse frequency of the GnRH release. Above a threshold level of estradiol, a massive LH surge is stimulated by a hypothalamic GnRH surge, resulting in initiation of ovulation. Administration of PMSG in cows results in increased follicular growth. The increased number of preovulatory follicles severely suppresses endogenous FSH secretion (Bevers *et al.*, 1989).

After ovulation, LH stimulates the formation of a corpus luteum in the ovary, and this secretes high concentrations of progesterone into the plasma. This progesterone inhibits the release of gonadotropins by decreasing the pulse frequency of GnRH release, or by decreasing the sensitivity of the gonadotrope to stimulation with GnRH. During the course of early to late anestrus, the sensitivity of pituitary LH release of the female dog to stimulation with GnRH increases (Van Haaften *et al.*, 1994).

The ovaries also synthesize a nonsteroidal factor that attenuates or inhibits the midcycle gonadotropin surge. After partial purification by which all detectable inhibin and follistatin activity (see later discussion) was removed, the so-called "gonadotropin surge inhibiting factor" (GnSIF) appeared to inhibit the GnRH-stimulated LH secretion *in vitro* without affecting the basal FSH release (Danforth and Cheng, 1993).

In the male animal, LH stimulates the synthesis and release of testosterone in the Leydig cells of the testis, which may in turn exert a negative feedback on LH secretion. This feedback may depend upon aromatization of testosterone to estradiol in the brain. In the male dog both testosterone and estradiol are the major inhibitors of LH and FSH release (Winter *et al.*, 1982). The opioid agonist bremazocine exerts a stimulatory effect on the LH peak level, but not on the peak frequency during the follicular phase of the estrous cycle of heifers. Both peak height and frequency are decreased after administration of an opioid antagonist. In pigs and sheep there are also reports on the role of opioid control in various reproductive states (Short *et al.*, 1987).

FSH secretion is also stimulated by GnRH. The LH surge is accompanied by an FSH surge. The release of FSH can be selectively inhibited *in vitro* by inhibin, a glycoprotein hormone produced in the Sertoli cells of the testis and the granulosa cells of the ovary (De Jong, 1979). A simple bioassay has been developed for inhibin-like activity using ovariectomized ewes. Injection of follicular fluid, which is rich in inhibin activity, resulted in a selective lowering of the plasma FSH (Miller and Bolt, 1987). FSH in turn has been found to increase inhibin secretion by cultured Sertoli cells and granulosa cells (Ultee-Van Gessel and De Jong, 1987). The amino acid sequences of bovine and porcine inhibin have been elucidated (Forage *et al.*, 1986). In dogs with Sertoli-cell tumors, increased inhibin bioactivity and mRNA for the α- and βB-subunits is found in tumor tissue. The increased inhibin concentrations in plasma are likely to be the cause of the suppressed FSH plasma concentrations, although plasma LH and testosterone concentrations were also suppressed (Grootenhuis *et al.*, 1990).

The activins are formed in the pituitary gonadotrope. Originally these proteins, consisting of homo- and heterodimers of activin-A and activin-B, were purified from ovarian follicular fluid. Within the pituitary the activin-B homodimer stimulates FSH synthesis without affecting LH synthesis. The action of the activins is antagonized by the glycoprotein follistatin, which is also produced both in folliculostellate cells and in gonadotropes of the pituitary.

d. Tests

Plasma LH can be detected by heterologous radioimmunoassays. Using a β-unit-specific monoclonal antibody against equine LH, parallel displacement curves have been reported for LH preparations from the horse, sheep, pig, cow, dog, cat, rabbit, rat, and kangaroo (Matteri *et al.*, 1987). Cross reactivity ranged from 45 to 265% for LH of these species, but there was only 15% cross reactivity for human LH. For details readers are referred to the chapter on reproduction.

C. Somatomammotropic Hormones

Growth hormone (GH), prolactin (PRL), and placental lactogen show homology in amino acid composition and some biological activities, and thus may be grouped together as a family of somatolactotropic hormones. There is increasing evidence that these hormones evolved from a single ancestral gene (Wallis, 1984; Seo, 1985).

1. GH

The somatotropic cells, producing GH, are the most abundant cells of the anterior lobe.

a. Gene Expression

In primates multiplication of the GH gene has resulted in a cluster of five GH-related genes. The GH-N gene is expressed in the pituitary and the other four, consisting of the chorionic somatomammotropins (so-called "placental lactogens") and a variant gene (GH-V), are expressed in the placenta during pregnancy. In nonprimates a single gene encodes GH, but a family of PRL-like genes (also including placental lactogens) are present.

The Pit-1 (also called GHF-1) transcription factor is essential for the development of pituitary cells producing GH, PRL, and TSH. Within the somatotrope the Pit-1 gene expression is stimulated by the hypothalamic growth-hormone-releasing hormone (GHRH) and inhibited by somatostatin (SS). Both neurohormones modulate GH gene transcription by stimulation or inhibition, respectively, of the adenylate cyclase activity. The activins as formed by the gonatropes may also inhibit the expression of the GH gene. This effect is additive to the inhibition by SS.

A synergistic stimulation of GH gene transcription is mediated by retinoic acid and by both thyroid hormone and glucocorticoids. The retinoic acid receptor (RAR) and the thyroid hormone receptor (TRα or TRβ) may form heterodimers with the 9-*cis* retinoic acid receptor (RXR) and thus strongly promote GH gene transcription. The glucocorticoid-mediated gene transcription does not result in enhanced plasma GH concentrations *in vivo*, because glucocorticoids also stimulate the release of somatostatin from the hypothalamus and thus inhibit GH release from the pituitary.

The gene encoding GH-N contains five exon areas. By alternative splicing, the 5′ part of exon 3 is missing in a minority of pituitary transcripts, and this results in the formation of a GH protein missing 15 amino acids in the N-terminal part of the molecule (Baumann, 1991).

b. (Pro)hormone

GH is a single-chain polypeptide. It contains two intrachain disulfide bridges and has a molecular weight of approximately 22,000. The amino acid sequence of GH belongs to the best-known sequences of pituitary hormones among species (Fig. 19.11). Using DNA technology the cDNAs for human and bovine GH have been cloned in bacteria and brought to expression, leading to the production of recombinant GH (Olson *et al.*, 1981), which is used to stimulate human growth and to enhance bovine milk production (Bauman *et al.*, 1985).

In cattle a polymorphism in the GH gene exists resulting in four GH variants that can arise from two possible N-terminal amino acids (phenylalanine or alanine) and two amino acids in position 127 (leucine or valine). The transmission of the trait of high milk production was greater for homozygous leucine-127 in Holstein cows and valine-127 in Jersey cows (Lucy *et al.*, 1993).

c. Secretion

A variety of factors modulate the release of GH (Table 19.5). The integration of all of these factors results in pulsatile release of GH with pulse intervals of 4–6 hours, as shown in the dog (Watson *et al.*, 1987; French *et al.*, 1987). The hypothalamic neurohormones GHRH and SS play a central role in the pulsatile GH release, where bursts of GHRH result in the episodic release of GH and the intervening troughs in GH secretion are maintained by SS (Fig. 19.12).

GHRH was first isolated from human pancreatic islet cell tumors (Rivier *et al.*, 1982; Guillemin *et al.*, 1982). Using this knowledge, the amino acid sequence of hypothalamic GHRH of various species was elucidated. A GHRH(1–44)NH_2 and a GHRH(1–40)OH form is found in the hypothalamus; both have GH-releasing capacity because the biologic activity resides in the 1–31 sequence. Outside the central nervous system, GHRH mRNA or immunoreactivity is found in leukocytes, testis, ovary, and placenta. Continuous infusion of a high dose of GHRH results in elevated GH levels, followed by a decline to low values due to

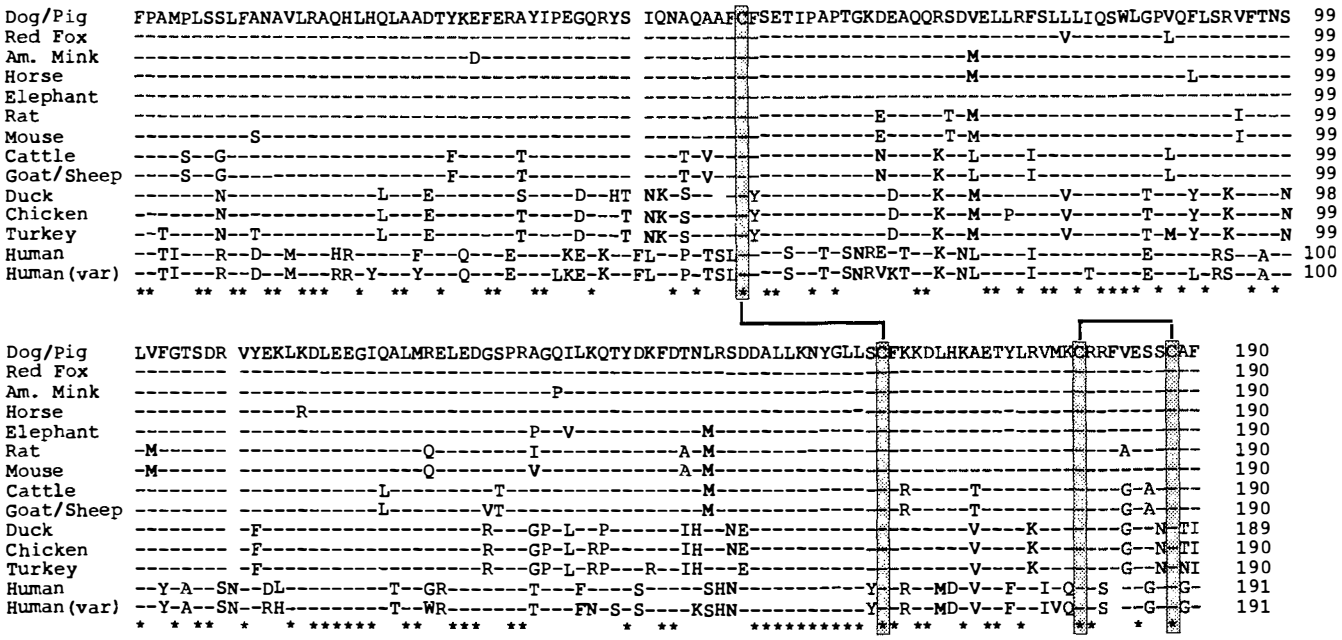

FIGURE 19.11 Sequence comparison of growth hormone (GH). Lines between shaded boxes represent intrachain disulfide bridges. See legend to Fig. 19.6.

desensitization of the somatotropic cell as a result of down regulation of GHRH binding sites. This phenomenon is a time- and concentration-dependent process (Bilezikjian *et al.*, 1986). The GHRH-induced GH release is potentiated by protein kinase C activation, indicating that the phosphoinositol system also plays a role in the GH release. A candidate for this activation is the yet unknown endogenous counterpart of the synthetic GH-releasing peptide (GHRP-6) that stimulates GH release *in vivo* in a variety of species, including the dog (Muruais *et al.*, 1993). TheTRH effect on GH release is more complex. In healthy mammals, including the dog (Rutteman *et al.*, 1987a), TRH does not stimulate GH release (Scanes *et al.*, 1986). In cattle, TRH induces some GH release, but when used together with GHRH these two releasing hormones act in strong synergy (Lapierre *et al.*, 1987) (see also Table 19.7).

Somatostatin (SS) denotes a family of peptides including the 14-amino-acid-containing S-14 and the N-terminal-extended S-28 (Reichlin, 1982). Passive immunization of chickens with SS antiserum increases the basal plasma GH concentrations and augments TRH-induced GH secretion (Harvey *et al.*, 1986). In compari-

son with that of S-14, the suppressive effect of S-28 on GH release is much longer. SS appears mainly to inhibit GH release and to have little effect on the synthesis of GH. The apparent ineffectiveness of SS in some studies may be due to its extremely short half-life (Harvey and Scanes, 1987), which was found to be 1.82 minutes in the dog (Schusdziarra *et al.*, 1979). However, in dogs, GH pulsatile secretion could also not be inhibited by the administration of the long-acting SS analogue SMS 201–995 in a dose of 1 μg/kg (Watson *et al.*, 1987). Continuous infusion of SS in a dose of 0.15 μg/kg/min abolished the secretory bursts, but no effect was seen on basal secretion rates (Cowan *et al.*, 1984). In the chicken, bolus injections of SS also failed to inhibit basal GH release (Harvey *et al.*, 1986).

The pulsatile GH secretion is age and gender related. Although there are conflicting reports on the effect of aging on basal GH release, it is generally assumed that the pulse height of GH decreases with age in man. This age-related decline has been confirmed in domestic fowl (Harvey *et al.*, 1987) and cattle (Verde and Trenkle, 1987). In the rat there is a gender-related pattern of GH secretion. The male rat has high pulses and a very low trough, whereas the female rat has lower bursts but higher basal levels (see also Section II.C.1.e.).

There are also indirect neuronal influences that modulate GH secretion (see also Table 19.5) (Hall *et al.*, 1986). The main physiological stimuli for GH secretion are sleep, physical exercise, stress, fasting, catecholamines, hypoglycemia, and certain amino acids, but not all apply to all species. For example, GH secretion in dogs is not related to sleep or day–night cycles, although GH peaks may occur after forced wakefulness at the onset of sleep (Takahashi *et al.*, 1981). Insulin-induced hypoglycemia and arginine administration do not consistently result in GH release in the dog (Eigenmann and Eigenmann, 1981a). Of the neurotransmitter systems involved, adrenergic systems seem to play a major role. α_2-Adrenergic agonists promote GH secretion, whereas β-adrenergic agonists are inhibitory. Thus, clonidine, a central α_2-adrenergic agonist, is also an effective stimulator of GH secretion in the dog (Eigenmann and Eigenmann, 1981a).

There is increasing evidence that the GH-stimulated release of insulin-like growth factor I (IGF-I) exerts a negative long-loop feedback on pituitary GH release. IGF-I stimulates the release of somatostatin by the hypothalamus and also inhibits pituitary GH release directly (Ceda *et al.*, 1987). In the domestic fowl, injection of IGF-I results in decreased GH responses to stimulation with TRH and GHRH (Buonomo *et al.*, 1987). The elevated GH levels in fasting dogs have also been explained as the result of impaired feedback inhibition due to low IGF-I levels in plasma (Eigenmann *et al.*, 1985). A low level of feeding also results in reduced plasma IGF-I concentrations and significantly increased plasma GH concentrations in steers (Breier *et al.*, 1986). GH responsiveness of the liver appears to change under different nutritional conditions through changes in receptor number, thereby having a dominant influence on the regulation of GH release.

After secretion, GH may circulate in the blood partially bound to specific GH-binding proteins. One of these binding proteins appears to be identical to the amino acid sequence of the extracellular domain of the GH receptor, whereas the other seems to be unrelated to the GH receptor (Bingham *et al.*, 1994). There was no difference in the binding of ^{125}I-labeled hGH to serum proteins of poodles differing considerably in body size, but binding to serum of dwarf pigs was reduced in comparison to binding to serum of normal pigs (Lauteriq *et al.*, 1988).

d. Action

The effects of growth hormone can be divided into two main categories: rapid or metabolic actions and slow or hypertrophic actions. The (acute) metabolic responses are due to direct interaction of growth hormone with the target cell, whereas the slow hypertrophic effects, or those on cartilage, bone, and other tissues, are indirect. The direct effects of GH result in enhanced lipolysis and restricted glucose transport due to insulin resistance (Eigenmann, 1984). Administration of recombinant-DNA-derived human GH induces glucose intolerance in the dog (Shaar *et al.*, 1986). Treatment of pigs for 7 days with purified pituitary GH or recombinant-DNA GH causes insulin resistance together with decreases in insulin- and IGF-I-stimulated lipogenesis of adipose tissue (Walton *et al.*, 1987). The GH responsiveness of adipose tissue is less dependent on nutrition than that of the liver, which may explain the reduced adiposity in the absence of growth enhancement in GH-treated ruminants (Breier *et al.*, 1986).

In contrast to these direct catabolic effects, the indirect actions are anabolic and appear to be mediated by the insulin-like growth factors, IGF-I and IGF-II (Daughaday *et al.*, 1987). In their chemical structure the IGFs have approximately 50% homology with insulin/proinsulin, suggesting they have evolved from a common ancestral molecule. The IGFs are bound to a family of six different IGF binding proteins (IGFBP). The main IGFBP in plasma is IGFBP-3, which is formed and released by the liver upon stimulation with GH. The IGF–IGFBP complex binds in plasma to an acid-labile subunit, resulting in a 150-kDa complex. As a consequence of this binding the IGFs have a very long plasma half-life, which is consistent with their long-term growth-promoting action. Insulin and IGF seem to complement each other, insulin being the acute and IGF the long-term regulator of anabolic processes (for

a review, see Eigenmann, 1987). The other IGFBPs play a more local role in the modulation of the IGF effects in specific tissues. These effects may be inhibitory as well as stimulatory.

Competitive binding experiments have revealed that IGF receptors are distinct from insulin receptors and that there are two subtypes of IGF receptors (type I and type II), which differ in their affinity for IGF-I and IGF-II. These two subtypes of IGF receptors have been characterized in terms of structure, phosphorylation, and regulation (Rechler and Nissley, 1985).

There is increasing evidence that the action of GH cannot be categorized by two opposing biological activities in such absolute terms as described earlier. GH exerts its growth-promoting effect not only via IGF-I produced in the liver, but also by a direct effect on cells in the growth plate. It has been proposed that GH stimulates cell differentiation directly and clonal expansion indirectly through the local production of insulin-like growth factors (Nilsson *et al.*, 1986).

Circulating IGF-I concentrations appear to be associated with body size. In a study in different breeds of dogs the IGF levels were found to correlate with body size (Eigenmann *et al.*, 1984a). By studying genetic subgroups within one breed, i.e., standard, miniature, and toy poodles, Eigenmann *et al.* (1984b) found IGF-I levels (and not GH) to parallel body size. Dwarf chickens also have relatively low circulating levels of this growth factor (Huybrechts *et al.*, 1987).

e. Extrapituitary GH Synthesis

In dogs, endogenous progesterone and exogenous progestins may induce considerable rises in plasma growth hormone levels, resulting in acromegalic changes and insulin resistance with the possibility of development of frank diabetes mellitus (Eigenmann and Rijnberk, 1981; Eigenmann *et al.*, 1983b; Selman *et al.*, 1994b). GH excess has only been found to occur in intact female dogs during diestrus (progesterone phase) or in dogs treated with progestins (Concannon *et al.*, 1980; Rijnberk *et al.*, 1980; Eigenmann and Rijnberk, 1981). Estradiol priming may enhance the effect of exogenous progestins in inducing GH overproduction (Eigenmann and Eigenmann, 1981b). Progestin withdrawal and/or ovariohysterectomy results in a reduction of the elevated plasma GH and IGF-I concentrations (Eigenmann *et al.*, 1984a) and reversal of the soft-tissue changes and the insulin resistance (Eigenmann *et al.*, 1983b). A decrease in the plasma GH levels has also been achieved by administration of a synthetic antiprogestin (Watson *et al.*, 1987).

Selman *et al.* (1991) made progress in the characterization of this phenomenon. Progestin-induced GH excess was insensitive to stimulation with GHRH or clonidine and also insensitive to inhibition with the SS analogue SMS 201-995, whereas the dosage SMS used inhibited the GHRH- and clonidine-stimulated GH release in healthy male dogs (Selman *et al.*, 1991). Taken together these observations strongly supported the autonomous character of the progestin-induced GH secretion. Hypophysectomy of progestin-treated ovariohysterectomized female dogs did not result in decreases in plasma GH concentrations (Selman *et al.*, 1994a), supporting an autonomous, nonpituitary production. Analyses of various tissues revealed the highest immunoreactive GH concentrations in the mammary gland. The mammary origin of elevated plasma GH was then confirmed by an arteriovenous gradient across the mammary gland, a rapid decrease and normalization of plasma GH concentrations after complete mammectomy (Selman *et al.*, 1994a), and the presence of GH mRNA in the canine mammary gland by reverse transcriptase PCR (Mol *et al.*, 1995a). From the sequence identity between the pituitary and the mammary PCR product it was concluded that a single gene encodes pituitary and mammary GH in the dog.

Until recently, the progestin-induced GH synthesis was only found in the dog. In cats Peterson (1987b) found no significant rise in plasma GH concentrations during 12 months of treatment with megestrol acetate. However, it was demonstrated recently that in cats with progestin-induced fibroadenomatous changes of the mammary gland the GH mRNA is also present in these tissues (Mol *et al.*, 1995a). Moreover, GH mRNA has now been demonstrated in the normal and neoplastic human mammary gland as well (Mol *et al.*, 1995b, 1996).

In normal cyclic female dogs, significantly higher basal plasma concentration of GH and IGF-I are found during the progesterone-dominated metestrus than during anestrus. This increased basal concentration is accompanied by a decreased responsiveness to stimulation with GHRH or clonidine (Rutteman *et al.*, 1987b; Selman *et al.*, 1991). In the light of the progesterone-induced synthesis in mammary tissue, it is possible that these changes during metestrus are caused by a contribution of the mammary gland to the circulating plasma GH concentrations. Whether extrapituitary GH synthesis is also the cause of gender-related differences in GH secretion in other species remains to be elucidated.

f. Disease

Inadequate GH secretion at an early age causes retardation of growth. Apart from occasional reports on dwarfism in dogs and cats, GH-deficiency dwarfism seems to occur primarily as a genetically transmitted condition in the German shepherd (Andresen *et al.*,

1974) and in the Carelian bear dog (Andresen and Willeberg, 1976). The abnormality has been documented as a primary GH deficiency (Scott *et al.*, 1978; Eigenmann, 1981) with low levels of circulating IGF-I (Eigenmann *et al.*, 1984c) and seems to be due to pressure atrophy of the adenohypophysis by cysts of Rathke's pouch (Müller-Peddinghaus *et al.*, 1980).

In adults, GH deficiency causes much less impressive changes. The clinical features remain confined to the skin and coat. Affected dogs present with alopecia and hyperpigmentation of the skin (Parker and Scott, 1980; Eigenmann and Patterson, 1984). The skin problems may improve by treatment with heterologous GH, although the administration of hGH to the dog is not effective and gives rise to GH antibody formation (Van Herpen *et al.*, 1993). The condition is not well defined and may be an isolated GH deficiency. It has been suggested that in some cases of alopecia the low basal GH levels and the absence of response to stimulation by clonidine or GHRH were due to enhanced somatostatin release as a result of mild and fluctuating hyperadrenocorticism (Rijnberk *et al.*, 1993).

In cats, as in man (Melmed *et al.*, 1983), excessive amounts of growth hormone may be secreted by a pituitary tumor. Since the publication of Gembardt and Loppnow (1976) on adenohypophyseal adenomas in diabetic cats, there has been growing awareness that GH hypersecretion may be involved in the pathogenesis of diabetes mellitus (Peterson et al., 1990).

Hypothyroidism leads to a markedly reduced growth-hormone secretion, with lack of response to provocative stimuli (Chernausek *et al.*, 1983). Apart from low serum GH levels, hypothyroidism is associated with low GHBP, IGF-I, and IGFBP-3 concentrations (Rodriguez-Arnao *et al.*, 1993).

In hyperadrenocorticism, GH secretion is decreased and the response to provocative stimuli is impaired. In hyperadrenocorticoid dogs this proved to be reversible when normocorticism was achieved, suggesting that the impaired GH secretion is the result of hypercorticism per se (Peterson and Altszuler, 1981) and mediated by glucocorticoid-induced increase of the hypothalamic SS tone (Takahashi *et al.*, 1992).

g. Tests

As GH secretion is pulsatile, single values are of no great diagnostic value. In healthy individuals, resting plasma GH concentrations (Table 19.6) may be very low, even below the detection limit of the assay. Hence when GH deficiency is suspected, a stimulation test is needed. In the dog, stimulation with clonidine, xylazine, or GHRH has proven to be reliable for this purpose,

TABLE 19.6 Basal GH and IGF-I Concentrations in Plasma of Healthy Animals[a]

Species (*n*)	Age, breed (condition)	Range (μg/liter) (mean ± SEM)	Reference
GH			
Dog (63)	Adult	(1.9 ± 0.1)	Eigenmann and Eigenmann (1981a)
Dog (5)	7 weeks, Great Dane	(13.7 ± 2.2)	Nap *et al.* (1993)
Dog (5)	27 weeks, Great Dane	(0.7 ± 0.4)	Nap *et al.* (1993)
Dog (6)	Beagle (anestrous)	(0.5 ± 0.1)	Selman *et al.* (1991)
Dog (6)	Beagle (metestrous)	(2.2 ± 0.4)	Selman *et al.* (1991)
Cat (25)	Adult	(3.2 ± 0.7)	Eigenmann *et al.* (1984d)
Mare (12)	7–11 year, Selle Français	(2.8 ± 0.7)	Davicco *et al.* (1994)
Calf (6)	3 days	(11.0 ± 1.8)	Coxam *et al.* (1987)
Steer (6)	267–303 days	15.3–32.6	Wheaton *et al.* (1986)
Pig (4)	5 days	(9.0 ± 1.4)	Lee *et al.* (1993a)
Pig (4)	170 days	(1.5 ± 0.1)	Lee *et al.* (1993a)
Sheep (6)		(3.0 ± 0.2)	Krysl *et al.* (1987)
IGF-I			
Dog (8)	Cocker spaniel	36 ± 27	Eigenmann *et al.* (1984a)
Dog (10)	Beagle	87 ± 33	Eigenmann *et al.* (1984a)
Dog (10)	Keeshond	117 ± 34	Eigenmann *et al.* (1984a)
Dog (13)	German shepherd	280 ± 23	Eigenmann *et al.* (1984a)
Mare (12)	7–11 year, Selle Français	154–318	Davicco *et al.* (1994)
Pig (4)	170 days	(182 ± 30)	Lee *et al.* (1993a)
IGF-II			
Dog (8)	7 ± 0.5 year, beagle	(390 ± 55)	Mol *et al.* (1997)
Pig (4)	170 days	(326 ± 19)	Lee *et al.* (1993a)

[a] The values can be converted to SI units: 1 μg GH/liter = 0.0455 nmol/liter; 1 μg IGF/liter = 0.133 nmol/liter.
[b] Means of determinations in samples collected at 15-min intervals for 24 hours.

TABLE 19.7 Maximal Plasma Concentrations of GH Following Intravenous Administration of a Variety of Stimulants[a]

Species (*n*)	Substance	Dose	Range (μg/liter) (mean ± SEM)	Reference
Dog (6)	Clonidine	10 μg/kg	(19.2 ± 6.2)	Selman *et al.* (1991)
Dog (6)	GHRH	1 μg/kg	(10.0 ± 5.1)	Selman *et al.* (1991)
Cow (4)	GHRH	0.4 μg/kg	16.5	Enright *et al.* (1987)
Calf (4)	GHRH	0.4 μg/kg	(107 ± 55)	Enright *et al.* (1987)
Cow (6)	GHRH	3.3 μg/kg	20.4	Lapierre *et al.* (1987)
Cow (6)	TRH	1.1 μg/kg	4.0	Lapierre *et al.* (1987)
Cow (6)	TRH + GHRH	1.1 μg/kg each	71.4	Lapierre *et al.* (1987)
Lamb	GHRH	0.5 μg/kg	(50.1 ± 19.1)	Barenton *et al.* (1987)

[a] See also footnote to Table 19.6.

whereas in calves and lambs GHRH stimulation has been used (Table 19.7).

Elevated GH values are not definitive proof of acromegaly, not only because of the pulsatile nature of the GH secretion but also because environmental factors may cause sharp increases. Although hypersecretion should be tested by an inhibition test, in the case of progestin-induced GH secretion a blunted stimulation of high basal GH concentrations may support the diagnosis, together with elevated plasma IGF-I concentrations (Selman *et al.*, 1991). It should be kept in mind that the reference values for the IGF-I concentrations in the dog are breed (= body size) dependent.

2. *Prolactin*

a. Gene Expression

Prolactin (PRL) is encoded by a single gene in the human genome. In nonprimates such as cattle, however, a family of PRL-related genes is found, and only one gene encodes GH. The PRL-related genes of the rat can be divided into the lactogens (placental lactogen I, II, I-variant, and the decidual luteotropin) and the nonlactogens (PRL-like protein (PLP) A, PLP-B, PLP-C, and the proliferin-1 and -2 proteins).

The appearance of specific PRL-producing lactotropes is one of the latest events in pituitary development. It has been proposed that most, if not all, lactotropes are derived from presomatotropes under the influence of the lactotrope-specific transcription factor (LSF-1). In humans and rats the majority of PRL-producing cells are also capable of synthesizing GH and are called mammosomatotropes. Even in adulthood the balance between somatotropes and lactotropes may change in the direction of PRL-producing cells under the influence of chronic stimulation with GnRH (Cooke, 1995). It is not clear whether this is due to conversion of somatotropes to lactotropes or whether new lactotropes are generated from pituitary stem cells.

The Pit-1 transcription factor is a prerequisite for the expression of PRL, as it is for expression of GH and TSH. The Pit-1 factor appears to interact with the estrogen response element (ERE) located on a more distal enhancer site, resulting in augmented transcription. More specific for the PRL promoter is the binding of the LSF-1 transcription factor. Glucocorticoids may inhibit PRL gene expression by a negative GRE.

The PRL gene, like the GH gene, has five exon areas. In the extrapituitary expression of PRL in decidua and lymphocytes, a different promoter and exon 1 are used, located upstream to the pituitary promotor.

b. (Pro)hormone

Prolactin (PRL) is synthesized as a single polypeptide that, after cleavage of the signal peptide, has a molecular weight of approximately 22,500 and three intrachain disulfide bridges. There is a good deal of variability in the sequences of PRLs of different species (Fig. 19.13). A minority of prolactin molecules may be present in the pituitary in a glycosylated form. This form has a decreased potency in receptor binding and biological assays.

Expression of the PRL gene within the hypothalamus–neurohypophyseal system results in full-length PRL mRNA. After translation the hormone is processed differently from the AL by specific proteolytic enzymes that generate a 16- or 14-kDa N-terminal fragment. This fragment is able to inhibit angiogenesis by a specific receptor (Clapp *et al.*, 1994).

c. Secretion

For two reasons PRL has a unique place among the AL hormones. First, it is the only hormone that is under tonic inhibition by the hypothalamus. After transplan-

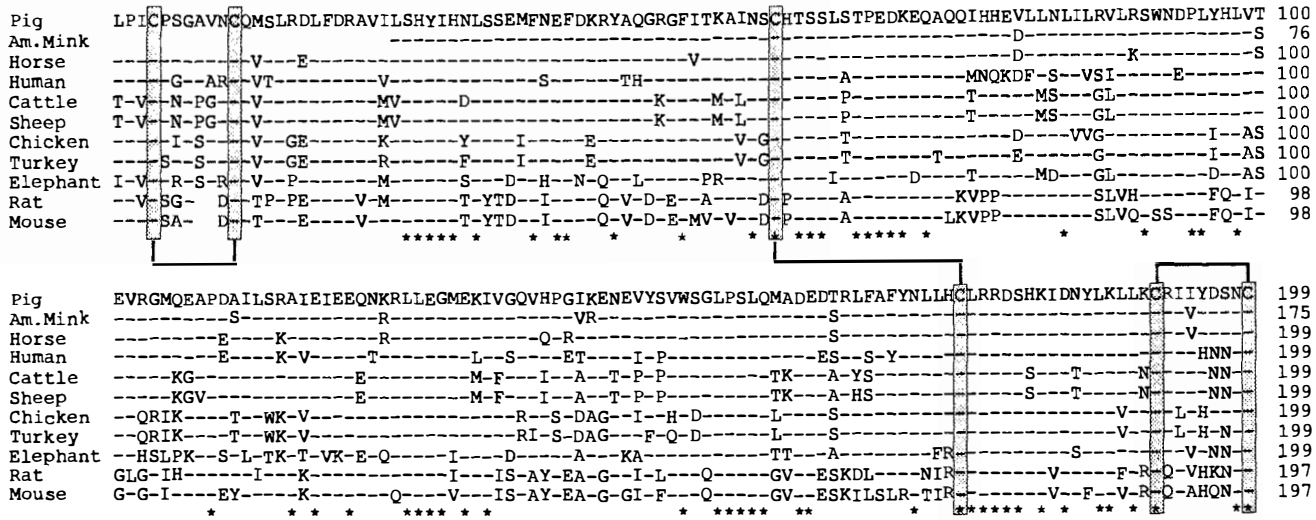

FIGURE 19.13 Sequence comparison of prolactin (PRL). Lines between shaded boxes represent intrachain disulfide bridges. See legend to Fig. 19.6.

tation of the pituitary under the kidney capsule, PRL synthesis is remarkably enhanced. Secondly, PRL lacks a specific target organ that produces factors exerting negative feedback.

The main hypothalamic prolactin-inhibiting factor (PIF) is dopamine. After the release in the median eminence, it may reach the lactotrope via the portal vasculature or by diffusion from the synaptic contact of dopaminergic terminals that end on the melanotropes of the IL. The relative contribution of these systems is not clear. Several isoforms of the endothelins, known for their vasoconstrictor properties, are potent inhibitors of PRL release *in vitro*, but no effect has been demonstrated *in vivo*. Both basal and TRH-induced PRL secretion is also inhibited by calcitonin *in vitro*.

The suckling-, stress-, or estrogen-induced PRL surge cannot be explained by changes in dopaminergic inhibition alone. Therefore, the presence of a prolactin-releasing factor (PRF) has been suggested. Several candidates for PRF have been proposed. One of the components of hypothalamic extracts known to have a stimulatory effect on PRL release is TRH. This was demonstrated in several mammalian species, including the pig (Bevers and Willemse, 1982). However, TRH is probably neither the sole nor the major physiological PRF. Another strong candidate for PRF is vasoactive intestinal peptide (VIP) (Shimatsu *et al.*, 1985).

The rat posterior pituitary was found to contain a potent PRF (Hyde *et al.*, 1987). Further analysis demonstrated that two compounds, oxytocin from the NL and an unidentified peptide from the IL, could function as PRF. The low potency of oxytocin made it a less likely candidate for the physiological regulation of PRL release. The PRF from the IL appeared to be a small peptide that is present in the posterior pituitary of many species. Its chemical nature remains to be determined.

Like other pituitary hormones, PRL is released in a pulsatile manner, with fluctuations during different stages of the reproductive cycle. Apart from an increase around the time of ovulation (McNeilly *et al.*, 1982), PRL concentrations in plasma tend to increase in the luteal phase of the sexual cycle in dogs (DeCoster *et al.*, 1983; Okkens *et al.*, 1985) and cows (Dieleman *et al.*, 1986), but not in cats (Banks *et al.*, 1983). During lactation very high PRL concentrations have been found in the sow by Bevers *et al.* (1978) and in the dog by Concannon *et al.* (1978). In addition, distinct increases in PRL concentration have been found in relation to parturition (Taverne *et al.*, 1978/1979; Concannon *et al.*, 1978). The effect of the lighting regime on PRL secretion in rams is thought to be a direct effect of melatonin on the pituitary gland (Lincoln and Clarke, 1994).

Important modulating factors in the control of PRL secretion are estrogens, especially 17-β-estradiol. Estrogens modulate the TRH receptor levels in the pituitary (DeLean *et al.*, 1977) and cause a biphasic increase in transcription of the prolactin gene (Gorski *et al.*, 1985). From experiments in rats, Deis and Alonso (1985) concluded that progesterone may also stimulate the release of PRL. Rutteman *et al.* (1987a) found that estradiol rapidly induces an enhanced PRL response

to TRH in dogs, without changing basal PRL levels. Subsequent administration of medroxyprogesterone acetate did not further affect these findings.

Neurogenic factors also influence PRL secretion. Milking and suckling are almost immediately followed by PRL release. Removal of litters from their dams, for example, piglets from sows (Bevers *et al.*, 1978), results in a rapid decline in PRL levels in plasma. Following return of the litters, PRL concentrations rise again.

d. Action

The most familiar role of PRL in mammals is stimulation of mammary gland growth and lactation. PRL increases mitosis of mammary gland epithelial cells not only during development, but also during pregnancy and lactation. It has been relatively difficult to demonstrate *in vitro* effects of PRL on cell proliferation in mammary glands (Friesen *et al.*, 1985). This can be explained by the increasing evidence that the growth-promoting effect of PRL has much in common with that of GH, i.e., intermediate factors comparable to IGF are required for effects on cell proliferation (Nicoll *et al.*, 1985).

PRL has a wide variety of other physiological actions among vertebrates. It may affect water and electrolyte balance, metabolism, gonadal function, and behavior. Of these, the effect on the ovary has received much attention. PRL has a luteotrophic effect in some animals, such as rodents, sheep, and ferrets (see the review by McNeilly *et al.*, 1982), but not in the cow (Bevers and Dieleman, 1987). Bovine follicles do not bind (ovine) PRL (Bevers *et al.*, 1987).

The reciprocal relationship between PRL and LH has been well demonstrated in several species, including the sow (Bevers *et al.*, 1983) and the cow (Dieleman *et al.*, 1986). This can explain the reduced fertility during lactation that is known in many species. It has been suggested that PRL may also interfere directly at the ovarian level (McNeilly, 1982). These effects of PRL also appear to play a role in the maintenance of the long interestrous interval in the bitch. Treatment of bitches with the dopamine agonist bromocriptine results in considerable shortening of the interestrous interval (Okkens *et al.*, 1985).

Mammalian maternal behavior in several species consists of nest building and caring for offspring. Prolactin-induced maternal behavior has been demonstrated in some animals. However, the primary role of PRL in inducing mammalian maternal behavior has been questioned (Scapagnini *et al.*, 1985). There appears to be diversity in the hormonal basis of maternal behavior, and in some species estrogens and progesterone play a crucial role (Rosenblatt, 1984).

e. Disease

The prolactinoma is the most frequently diagnosed functioning pituitary tumor in man. Mixed GH–PRL adenomas are known to occur in a substantial number of patients with acromegaly, and the concomitant production and secretion of PRL by corticotrope adenomas is not unusual (Ishibashi and Yamaji, 1985). There have been no well-documented reports on the occurrence of prolactinomas in animals, although in dogs with pituitary-dependent hyperadrenocorticism (PDH) Stolp *et al.* (1986) found PRL concentrations in plasma to be higher than those in healthy control dogs and in dogs with hyperadrenocorticism due to adrenocortical tumor. Moreover, the PRL concentrations in dogs with PDH responded supranormally to stimulation with TRH. This suggests that the pituitary lesions of dogs with PDH contain prolactin cells.

Thus, there do not seem to be pathological hyperprolactinemic states in domestic animals that require treatment with dopaminergic drugs. These drugs are nevertheless often used, the main application being in a physiological condition in the bitch called pseudopregnancy (Arbeiter and Windig, 1977; Janssens, 1981; Mialot *et al.*, 1981). Administration of the dopamine agonist bromocriptine results in rapid disappearance of the signs suggesting impending parturition. As treatment with bromocriptine lowers PRL concentrations in plasma (Okkens *et al.*, 1985; Stolp *et al.*, 1986), it is likely that the lactation and maternal behavior of the diestrual bitch are PRL dependent.

f. Tests

Despite the variations in amino acid sequences of PRLs from different species, plasma concentrations can be measured in heterologous assays, for example, employing labeled porcine PRL with an antibody against ovine PRL in an assay for canine PRL (Stolp *et al.*, 1986). PRL levels in the blood may vary during the reproductive cycle, but the basal levels in both male and anestrous female dogs are within similar narrow limits (Stolp *et al.*, 1986). Reference values are presented in Table 19.8.

When there is a suspicion of prolactin deficiency, the secretory capacity can be tested with TRH. In healthy dogs intravenous administration of 10 μg TRH per kg body weight resulted in PRL increments of 13.1–42.5 μg/liter (Rutteman *et al.*, 1987a). In cats, 75 μg TRH caused PRL elevation to seven times the basal levels (Banks *et al.*, 1983). Prolactin concentrations can be suppressed with the dopamine agonist bromocriptine. Both 20 μg/kg intravenously (Stolp *et al.*, 1986) and 10 μg/kg orally (Rijnberk *et al.*, 1987) resulted in protracted decreases lasting at least 8 hours after administration.

TABLE 19.8 Concentrations of PRL in Plasma of Healthy Animals[a]

Species (*n*)	Condition	Range (ug/liter) (mean ± SEM)	Reference
Dog	Anestrous female	(9.1 ± 1.2)	Knight *et al.* (1977)
Dog (6)	1.5 weeks of lactation	(86 ± 19)	Concannon *et al.* (1978)
Dog (6)	8–32 hours prepartum	(117 ± 24)	Concannon *et al.* (1978)
Dog (23)	Males + anestrous females	(0.9 ± 10.5)[b]	Stolp *et al.* (1986)
Dog (5)	Ovariectomized females	7.9–11.5	Rutteman *et al.* (1987a)
Cat (8)	Early gestation	(7.0 ± 0.3)	Banks *et al.* (1983)
Cat (8)	End of gestation	(43.5 ± 4.5)	Banks *et al.* (1983)
Cat (8)	4 weeks post partum	(40.6 ± 7.2)	Banks *et al.* (1983)
Cow (5)	Luteal phase	(23.3 ± 4.8)	Dieleman *et al.* (1986)
Cow (5)	Follicular phase	(15.8 ± 2.7)	Dieleman *et al.* (1986)
Sow (3)	2nd week of lactation	(9.1 ± 1.4–26.1 ± 5.0)[c]	Bevers *et al.* (1978)
Sow (3)	Piglets removed	(1.4 ± 0.3–1.9 ± 0.1)[c]	Bevers *et al.* (1978)
Sheep (8)	Males	68.6 ± 15.3	Matthews and Parrott (1992)

III. NEUROHYPOPHYSIS

A. Vasopressin

1. *Gene Expression*

Although there is considerable homology between the genes for vasopressin (VP) and oxytocin (OT), each of the relevant hypothalamic neurons produces only one hormone, either VP or OT. The VP gene consists of three exons. Exon 1 encodes the signal peptide, the nonapeptide VP, and the N-terminal part of neurophysin II (NP-II). Exon 2 encodes the central part of NP-II, and exon 3 encodes the C-terminal part of NP-II and a glycoprotein (GP). The major factor that regulates VP synthesis is osmotic stimulation. Rats given hypertonic saline chronically have increased VP and OT mRNA concentrations in the magnocellular neurons in the hypothalamus. Similar increases in VP mRNA are observed in hypovolemic conditions. Acute increases in plasma osmolality or hypovolemia result in a rapid lengthening of the poly(A) tail of the mRNA, followed by a slow increase in mRNA abundance.

2. *(Pro)hormone*

After cleavage of the signal peptide, the GP moiety of the VP prohormone is glycosylated, disulfide bonds are generated, and then the prohormone is packaged into a secretory vesicle. The correct sorting of the prohormone into the secretory pathway requires the formation of aggregates. Specific association of VP and NP-II results in dimeric and tetrameric units, which is essential for sorting (De Bree and Burbach, 1994). The secretory vesicles are axonally transported to the axon endings in the posterior pituitary. Studies in the dog suggest that approximately 1.5 hours are required from the time of synthesis to possible release of the nonapeptide (Richter and Ivell, 1985). During this transport the neurophysin II, VP, and glyprotein are liberated by proteolytic cleavage. The C-terminal glycine residue of the VP molecule is finally amidated. The mature VP nonapeptide has a disulfide bridge between cysteine residues at positions 1 and 6 (Fig. 19.14).

In most mammals VP contains an arginine residue at position 8 (arginine vasopressin, AVP). In the members of the pig family, VP contains a lysine residue at position 8. This lysine vasopressin (LVP) is the only form present in the domestic pig. Heterozygotic peccaries, warthogs, and hippopotami may possess both AVP and LVP. Substitution of the phenylalanine residue at position 3 by isoleucine leads to arginine vasotocin (AVT). This peptide has been identified as a uniquely nonmammalian substance and is probably the most primitive and certainly the most commonly occurring neurohypophyseal peptide. Neurohypophysis of some strains of chickens (but not ducks or turkeys) contain not only AVT but also AVP (Choy and Watkins, 1986).

In the rat and the calf the cDNAs encoding the neurophysins of AVP and oxytocin have a high degree of homology. Amino acid analysis of the AVP- and oxytocin-related neurophysins also shows a strong homology for bovine, porcine, and equine neurophysin.

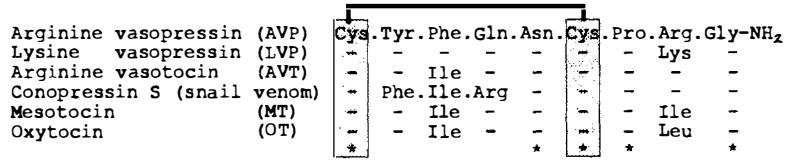

FIGURE 19.14 Sequence comparison of vasopressin (VP) and oxytocin (OT). Lines between shaded boxes represent intrachain disulfide bridges. See legend to Fig. 19.6.

The glycoprotein sequence appears to be highly conserved among various species, but its physiological role remains to be clarified (Majzoub, 1985).

3. *Secretion*

The major determinant in the release of VP is plasma osmolality. Below a certain plasma osmolality threshold, which may vary considerably between individuals, plasma VP concentration is suppressed to levels that allow maximal free water clearance (Wade *et al.*, 1982). Once plasma osmolality rises to the threshold, the pituitary secretes VP. Although the concentration of plasma VP causing maximal antidiuresis is about 5–10 pmol/liter, the release of VP is related to plasma osmolality over a much broader range (Robertson, 1983). Biewenga *et al.* (1987) developed a nomogram for this relationship in the dog, which allows analysis of the osmoregulation of VP secretion in terms of sensitivity and threshold.

Apart from the influence of osmolality, a significant decrease in circulating blood volume may also cause enhanced VP secretion. The decrease in left atrial pressure triggers receptors. Denervation of these receptors prevents the hypovolemia-mediated VP release. The functional properties of this regulatory system differ from those of the osmoregulatory system. Although the relationship between plasma osmolality and VP appears to be linear, the relationship between blood volume and plasma VP is best described by an exponential function (Vokes and Robertson, 1985a).

Under ordinary circumstances, changes in VP levels are not observed until blood volume decreases by 5–10%. With further decreases, plasma VP rises exponentially. The relative insensitivity of VP to modest changes in blood volume means that this regulatory mechanism plays little or no role in the physiological control of water balance. Under ordinary circumstances, total body water rarely changes by more than 1–2%, an amount far too small to affect VP secretion through hemodynamic influences (Wang and Goetz, 1985). In dogs, 24 hours of fluid deprivation increases plasma VP because of changes in both extracellular volume and tonicity, but the increase in tonicity plays a greater role than the reduction in volume (Wade *et al.*, 1983).

It has been proposed that hemodynamic influences modulate VP secretion by raising or lowering the osmostat (Robertson, 1978). According to this concept, a decrease in plasma volume and/or pressure will permit normal osmoregulation of VP, but the threshold for release will be lowered by an amount proportional to the degree of hypovolemia or hypotension, associated with increased sensitivity of the VP response to rising plasma osmolality. Conversely, hypervolemia or hypertension increases the threshold and decreases the sensitivity of release (Quillen and Cowley, 1983).

There are numerous other factors that may influence VP secretion. Of these, nausea/vomiting (Raschler *et al.*, 1986) and insulin-induced hypoglycemia (Vokes and Robertson, 1985b) are the most potent. The effects of opiates and opioid peptides on VP secretion have been studied for many years and have been the subject of some controversy. Both stimulatory and inhibitory effects have been reported. Apart from the substances, doses, and routes of administration used, the animal species is an important factor (Van Wimersma Greidanus, 1987). Intracerebroventricular administration of β-END in conscious rats decreases basal and stimulated VP release (ten Haaf *et al.*, 1986). An opioid inhibition of dehydration-induced VP release has been reported in dogs (Wade, 1985). However, Hellebrekers *et al.* (1988) could not confirm this endogenous opioid modulation of osmolality-regulated VP release in conscious dogs subjected to hypertonic saline infusion. In contrast, sharp increases in plasma VP have been found in conscious dogs after intravenous administration of the μ-type opiate receptor agonist methadone (Hellebrekers *et al.*, 1987).

4. *Action*

The major role of VP is to regulate body fluid homeostasis by affecting water resorption. An increase in plasma VP results in increased water retention, which maintains plasma osmolality between narrow limits. The antidiuretic effect is achieved by promoting the reabsorption of solute-free water in the distal and col-

lecting tubules of the kidney. In the absence of VP, this portion of the nephron is not permeable to water and the hypotonic filtrate of the ascending limb of Henle's loop passes unmodified through the distal tubule and collecting duct. In this condition urine osmolality decreases to around 80 mOsm/kg. The action of VP on the tubular cells is mediated by V2 receptors that, after VP binding, activate a signal transduction system leading to an intracellular increase in cAMP (Jard, 1983).

Besides this well-known role in the regulation of fluid homeostasis, VP exerts a large variety of effects. Among these is the vasopressor effect, which is mediated by V1 receptors (Liard, 1986). In addition, VP increases glucogenolysis by liver cells, increases ACTH release by adenohypophysis (Lowry *et al.*, 1987), and has several effects on animal behavior (De Wied and Versteeg, 1979). The extrarenal effects on hepatocytes and vascular smooth muscle are exerted through cAMP-independent, calcium-dependent V1 receptors (Jard, 1983).

There is some evidence that in birds AVT, apart from its established antidiuretic action, also has oxytocic properties and participates in normal oviposition (Shimada *et al.*, 1986, 1987). MT does not seem to function in oviposition, and its release was found to be negatively correlated with plasma osmolality (Koike *et al.*, 1986).

5. *Disease*

Disorders of the hypothalamic–neurohypophyseal system resulting in deficiency or excess of VP are known to occur in domestic animals. Deficient VP release causes the syndrome of diabetes insipidus, which is characterized by persistent inappropriately dilute urine in the presence of strong osmotic stimuli for VP release. The disease is not uncommon in the dog and cat (see Feldman and Nelson, 1996; Rijnberk, 1996) and rare in other species.

VP excess is known as the syndrome of inappropriate ADH (SIADH) secretion or the Schwartz–Bartter syndrome. The VP release is inappropriately high in relation to the plasma osmolality. The resulting defect in water excretion causes hyponatremia, which is the hallmark of SIADH. This condition has been documented as a disease of the dog, and at the same time studies of the threshold and sensitivity of VP secretion revealed that it occurred in two forms (Rijnberk *et al.*, 1988; Houston *et al.*, 1989).

The glucocorticoid excess in Cushing's syndrome is accompanied by (mild) polyuria in the dog. A marked impairment of the osmolality-regulated AVP release at the pituitary level may, in concert with a partial AVP resistance at the kidney level, be the cause of this corticosteroid-induced polyuria (Biewenga *et al.*, 1991). Chronic liver disease is accompanied by both enhanced activity of the pituitary–adrenocortical axis and disturbances in sodium and water homeostasis. Also in these cases a profoundly impaired osmoregulation of AVP release was found (Rothuizen *et al.*, 1995). In dogs with spontaneous pericardial effusion, moderately elevated plasma AVP levels declined rapidly after pericardiocentesis (Stokhof *et al.*, 1994).

6. *Tests*

The diagnosis of VP deficiency requires that it be differentiated from other causes of water diuresis. Following exclusion of conditions such as hyperadrenocorticism, hyperthyroidism, and hypercalcemia, both nephrogenic diabetes insipidus and primary polydipsia remain as the main differential diagnoses. Slightly elevated plasma osmolality may suggest neurogenic or nephrogenic diabetes insipidus, whereas low plasma osmolality may be observed in primary polydipsia. However, in many cases this parameter is not conclusive.

The procedure that is widely used to differentiate these disorders is the modified water deprivation test, as introduced for the dog by Mulnix *et al.* (1976). In this test maximal urine concentration is induced by several hours of dehydration. Once a plateau in urine osmolality is reached, the effect of an injection with VP is investigated. A further increase in urine osmolality by 50% or more is regarded as diagnostic for VP deficiency.

Although these indirect criteria for VP secretion can usually differentiate between complete neurogenic and complete nephrogenic diabetes insipidus, they cannot differentiate among partial neurogenic, partial nephrogenic, and dipsogenic polyurias. In these situations, direct measurements of plasma VP during hypertonic saline infusion are required (Biewenga *et al.*, 1989).

Hypersecretion of VP can only be diagnosed by measurements of the circulating concentrations of the hormone (Table 19.9). The basic criterion is the presence of "inappropriately" high VP concentrations in relation to the hypoosmolality of the extracellular fluid. The type of osmoregulatory defect can best be judged by repeatedly measuring plasma osmolality and VP during administration of hypertonic saline (Rijnberk *et al.*, 1988). Details of this test are given in Section IV of this chapter.

B. Oxytocin

1. *Gene Expression*

The oxytocin (OT) gene expression is predominantly found in the hypothalamic supraoptic nucleus and paraventricular nucleus (Ivell, 1986). The neurons proj-

TABLE 19.9 Concentrations of Neurohypophyseal Hormones in Plasma of Healthy Animals[a]

Species (*n*)	Peptide	Condition	Range (pmol/liter) (mean ± SEM)	Reference
Dog (5)	AVP	Basal	0.5–2.9	Dogterom *et al.* (1978)
Dog (12)	AVP	Basal	(3.3 ± 0.4)	Simon-Oppermann *et al.* (1983)
Dog (9)	AVP	24 hours dehydration	(7.7 ± 1.5)	Szczepanska-Sadowska *et al.* (1983)
Dog (25)	AVP	Basal	0.9–6.0	Biewenga *et al.* (1987)
Dog (10)	OT	First week of lactation	15–66	Eriksson *et al.* (1987)
Cow (334)	OT	Before milking	(1.6 ± 0.6)	Schams (1983)
Sow (9)	OT	6–12 days postpartum	<10	Porter *et al.* (1992)
Sow (9)	OT	idem, suckling	24.9–74.6	Porter *et al.* (1992)
Sheep (12)	OT	Spontaneous pulse height	(18.3 ± 9.5)	Payne and Cooke (1993)
Goat	AVP	Basal	(1.3 ± 0.2)	Thornton *et al.* (1986)
Goat	OT	Basal	(4.5 ± 1.0)	Thornton *et al.* (1986)
Calf (16)	AVP	Basal	(1.3 ± 0.2)[b]	Doris and Bell (1984)
Calf (16)	AVP	4 days dehydration	(16.9 ± 1.9)[b]	Doris and Bell (1984)
Hen	AVT	Basal	(3.3 ± 0.3)[b]	Shimada *et al.* (1986)
Hen	AVT	Oviposition	(14.8 ± 0.6)[b]	Shimada *et al.* (1986)

[a] When necessary the values were converted to SI units: 1 ng/liter AVP = 0.932 pmol/liter; 1 ng/liter AVT = 0.953 pmol/liter; 1 ng/liter OT = 0.994 pmol/liter.
[b] In μU/ml.

ect mainly to the posterior pituitary, where OT is secreted for endocrine stimulation of parturition and lactation, whereas other neurons project to higher brain centers, where OT may be converted by brain peptidases and exert an effect as a neurotransmitter or neuromodulator (Burbach, 1986). Central-nervous OT may attenuate learning and memory processes, and it may function in maternal behavior (Kovács, 1986). OT has also been demonstrated in the placenta, ovary, corpus luteum, testis, and adrenal gland. At least in the bovine corpus luteum, OT is synthetized locally (Ivell *et al.*, 1985) and acts as a paracrine compound by influencing the prostaglandin-mediated regression of the corpus luteum (Flint and Sheldrick, 1982).

The organization of the OT gene closely resembles that of the VP gene. The exon–intron organization is similar, with the exception that exon 3 lacks a glycoprotein domain. In the cow, among 194 bases of the 3′ part of exon 2, no single base is different from the corresponding one in the VP exon 2. Exon 3 has the least homology between the VP and OT genes (Ivell and Richter, 1985).

Apart from an identical increase in OT and VP mRNA after hyperosmotic or hypovolemic stimulation, differences exist between the expression of both genes. The OT gene expression increases in estrus, whereas VP gene expression is not cycle dependent. In the suprachiasmatic nucleus there is a circadian rhythm in VP expression, but not in OT mRNA. During pregnancy and lactation an increased poly(A) tail of the OT mRNA is observed. The length of the poly(A) tail is considered to be related to stability of mRNA or may stimulate the translation efficiency.

2. *(Pro)hormone*

After translation of the mRNA, OT is cleaved from neurophysin I by proteolytic enzymes and a C-terminal amidation of OT occurs. This posttranslational processing is time dependent, as for the biotransformation of the VP prohormone (Ivell, 1986).

3. *Secretion*

The release of OT is most abundant during parturition and the lactation period. The main stimuli for the release of OT from the posterior pituitary therefore arise either from the nipples during milking (Wachs *et al.*, 1984) or suckling, or from vaginal and cervical distension. The suckling-related release of OT has been documented in the dog (Eriksson *et al.*, 1987). The neural regulation of OT release is complex. Both dopamine and opioid peptides (enkephalin and β-endorphin) modulate OT release at the nerve terminals in the NL (Forsling, 1986). This interaction may be mediated by opioid effects on posterior pituitary pituicytes. There is some evidence that OT is released in response to osmotic challenge in the rat and some carnivores, but not in primates or ungulates (Thornton *et al.*, 1987).

Plasma OT levels may also vary during the reproductive cycle. Generally, a similar secretion pattern is found among domestic animals. Plasma levels increase after the preovulatory LH surge and decrease at the time of luteal regression, in the cow, goat, and sheep (Schams, 1983). In the mare, plasma OT levels are lower in the midluteal phase than on day 2 of estrus and day 5 after ovulation (Burns *et al.*, 1981). The latter is closer to the pattern of OT release in man. The high OT content of the corpus luteum of the sheep and the cow may mean that the majority of the circulating OT is derived from the ovary in these species.

Ovarian estrogen may enhance pituitary OT release, whereas progesterone inhibits it. In male animals, mating may be a stimulatory factor. Nonreproductive factors such as stress and plasma osmolality may also influence OT release (Forsling, 1986).

4. Action

OT causes contraction of the myoepithelial elements of the excretory ducts of the mammary glands, resulting in milk ejection. In addition, it exerts a constricting effect on the uterine muscle. Estrogens increase the response of the uterus to OT, whereas progesterone inhibits it. During pregnancy, the sensitivity of the uterus to OT is greatly reduced. However, during delivery and immediately thereafter, the uterus is particularly sensitive to OT. In birds, AVT is far more active in stimulating the contraction of the oviduct than is OT (Bentley, 1971).

5. Disease/Tests

To our knowledge no pituitary dysfunction concerning OT release in domestic animals has been reported. Basal plasma levels of OT are in approximately the same range as plasma VP concentrations (Table 19.9). In man and the goat (Thornton *et al.*, 1986), OT release cannot be stimulated by hypertonic saline infusion, but does increase in response to insulin-induced hypoglycemia (Nussey *et al.*, 1986). In the rat, nausea-producing chemical agents and cholecystokinin cause a dose-dependent increase in OT (Verbalis *et al.*, 1986).

IV. ASSESSMENT OF PITUITARY FUNCTION

Endocrine studies in animals with suspected hypothalamus–pituitary disease may be carried out for three reasons: (1) documentation of specific endocrine deficits, (2) insight into the type, size, and progression of the lesion, and (3) characterization of hyperfunction. Specific diagnostic tests for several of the pituitary hormones have been described in the previous sections. Here the discussion will be concentrated on a more general approach, in an attempt to determine the extent of involvement of AL, IL, and/or NL.

A. Adenohypophysis

1. Anterior Lobe

The species specificity of some of the AL hormones precludes their measurement in several animal species with the assays now available. For many other hormones, however, homologous or heterologous assays are available, allowing assessment of AL function.

Although baseline hormone levels can provide much information, the pulsatile nature of AL hormone secretion often makes interpretation difficult. It is particularly difficult to distinguish between normal and low levels of these hormones. For this reason provocative tests should be used to examine hypothalamus–pituitary adequacy. Now that hypothalamic-releasing hormones have become available and are applicable in most species (Tables 19.4–19.8), appropriate testing of AL function is possible.

In all instances blood samples are collected at −15, 0, 10, 20, 30, and 60 minutes for measurement of the pituitary hormones. At time zero the test substance is injected intravenously. It may be one of the following:

1. 1 μg GHRH/kg or 10 μg clonidine/kg to test GH secretory capacity (see also Table 19.7).
2. 1 μg CRH/kg or 0.6 μg lysine vasopressin/kg to test ACTH secretory capacity (see also Table 19.5).
3. 10 μg TRH/kg to test PRL secretion (see Section II.C.2 of this chapter)

Because of the rapid proteolytic degradation of some pituitary hormones, blood samples should always be chilled on ice as soon as possible and stored at ≤20°C (see also Section V.E of the chapter on adrenocortical function).

Combined function tests are coming into use in man. The anterior pituitary is stimulated with four hypothalamic releasing hormones in a single procedure. Despite the fact that there is some interaction of the different releasing hormones, combined administration of releasing hormones seems to be a useful test for the assessment of pituitary function (Schopohl *et al.*, 1986). Such a combined function test has been introduced for the dog. In this test the anterior pituitary is stimulated with four hypothalamic releasing hormones (CRH, GHRH, TRH and GnRH) with measurements of ACTH (+cortisol), GH, PRL and LH (Meij *et al.*, 1996). Compared with the single administration of these secretagogues, there is little interference in this test, except

for the LH response, which is lower in the combined test then following single GnRH administration.

2. *Intermediate Lobe*

α-MSH is secreted specifically by the IL. Its release can be stimulated with dopamine agonists such as haloperidol (Table 19.5). The times of sampling can be as for the tests of adenohypophyseal function (see Section IV.A.1 of this chapter).

B. Neurophypohysis

As explained in Section III.B of this chapter, VP secretion can be examined indirectly by means of a modified water-deprivation test and directly by measuring plasma VP during hypertonic saline infusion. Both procedures are described here in detail, as they have been developed for use in the dog (Mulnix *et al.*, 1976; Biewenga *et al.*, 1987). It should be noted that because of interference of plasma proteins, the radioimmunoassays for AVP and OT require prior extraction of the peptide. Antisera against AVP may possess 100% cross reactivity with AVT (Choy and Watkins, 1986; Hellebrekers *et al.*, 1987).

1. *Modified Water Deprivation Test*

a. *Indication*

Differentiation between neurogenic and nephrogenic diabetes insipidus, when the administration of DDAVP (Minrin) has not resolved the diagnosis.

b. *Procedure*

Following 12 hours of fasting, water is withheld and plasma and urine are collected every hour or every 2 hours, depending on the severity of the polyuria. Osmolality is measured in both samples. At each collection the animal is weighed. When the weight loss approaches 5% of initial body weight, the test should be stopped.

When, in the presence of an adequate osmotic stimulus (Posm > 305 mOsm/kg), urine concentration is maximal (less than 5% increase in Uosm between consecutive collections), 2 IU of lysine vasopressin are administered subcutaneously. Uosm is measured again 1 hour later.

c. *Interpretation*

In both nephrogenic diabetes insipidus and neurogenic diabetes insipidus, Uosm will remain low during water deprivation. In neurogenic diabetes insipidus Uosm will rise by 50% or more following the injection of vasopressin, whereas in nephrogenic diabetes insipidus there will be little or no rise in Uosm. However, as mentioned earlier, in some cases the outcome may not be conclusive and erroneous results may also occur.

2. *AVP Measurements during Hypertonic Saline Infusion*

a. *Indications*

Differential diagnosis of polyuric conditions and suspicion of inappropriate VP secretion.

b. *Procedure*

The euhydrated animal is infused for 2 hours via the jugular vein with 20% NaCl solution at a rate of 0.03 ml/kg body weight per minute. Samples for plasma AVP and Posm are obtained at 20-minute intervals. Especially in the severely polyuric animal, there is a risk of inducing critical hypertonicity. In these cases the samples collected at 0, 40, and 80 minutes should be checked for Posm immediately.

c. *Interpretation*

The slope of the regression line for Posm and PAVP is used as a measure of the sensitivity of the osmoregulatory system. In the nomogram developed by Biewenga *et al.* (1987), the 90% range for sensitivity was 0.24–2.47 (pg/ml)/(mOsm/kg). The 90% range for the threshold of the system was 276–309 mOsm/kg.

Acknowledgments

The authors gratefully acknowledge the contribution to the manuscript of Dr. B. E. Belshaw.

CHAPTER

20

Adrenocortical Function

AD RIJNBERK AND JAN A. MOL

I. INTRODUCTION

In their daily activities the authors of this chapter are not involved with livestock or with experimental animals. They have accepted the invitation of the editor to contribute to this book on clinical biochemistry under the condition that they could confine themselves largely to companion animals. This seems justified, as most of the clinical problems of the adrenal cortex are seen in these species. Other species are covered in terms of general comparative aspects of mammals and birds and with the presentation of some additional species-specific data.

II. ANATOMICAL CONSIDERATIONS

In mammals the adrenal glands are bilateral structures located craniomedial to the kidneys. The adrenal is, in fact, made up of two glands of different embryological origin. The center of the gland, the medulla, comprises coalesced chromaffin cells of neuroectodermal origin that secrete epinephrine and/or norepinephrine. The surrounding adrenal cortex arises from mesoderm and can be divided histologically into three zones: (1) zona glomerulosa (or arcuata), (2) zona fasciculata, and (3) zona reticularis. The cells of the zona glomerulosa are arranged in ovoid groups immediately inside the connective tissue capsule. The region may be particularly obvious (e.g., sheep) or difficult to discern (e.g., small rodents). The zona fasciculata accounts for most of the adrenal cortex (>60%) and appears histologically in radial lines. The inner zona reticularis comprises networks of cell cords surrounding the large blood sinuses.

In birds the adrenal glands are also separate, encapsulated organs. The glands lie cranial to the kidney, often wholly or partly covered by the gonads. The adrenocortical and chromaffin tissues are intermingled to varying degrees, depending on the species. The basic unit of avian adrenocortical tissue is a cord of a double row of parenchymal cells, with their long axes in the transverse plane of the strand. The cords radiate from

the center of the gland, branch, and anastomose frequently. Groups of chromaffin cells lie between the cords and also ensheathed within the connective tissue reticulum (Chester-Jones, 1987).

Blood flow of the adrenals is centripetal. In species with separated medulla and cortex, this results in high medullary corticoid concentrations that induce an enzyme in the chromaffin cells, converting norepinephrine to epinephrine. Therefore, species with anatomically separated medulla and cortex predominantly secrete epinephrine, and species with intermingled chromaffin and adrenocortical tissue secrete predominantly norepinephrine (Marks, 1983).

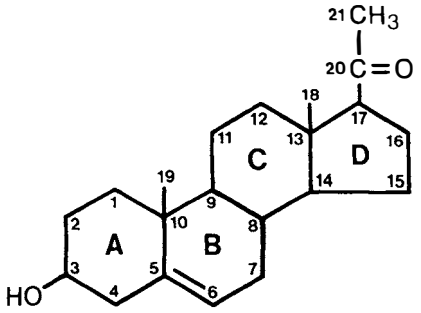

FIGURE 20.1 The numbers of the carbon atoms and the letters designating the rings of the pregnenolone molecule [recommendations of the International Union of Pure and Applied Chemistry; IUPAC-IUB 1967 (1968)].

III. PHYSIOLOGY OF ADRENOCORTICAL HORMONES

The secretion of the mammalian adrenal cortex comprises three main categories of hormones, which can be related to some extent to the anatomical zonation just described. The zona glomerulosa produces mineralocorticoids (aldosterone and deoxycorticosterone), which maintain salt balance. The cells of the zona fasciculata secrete glucocorticoids (cortisol and corticosterone), which are primarily involved in carbohydrate metabolism. The third category of adrenocorticol hormones, the androgens (e.g., androstenedione), are produced in the zona reticularis. This zone to a minor degree also secretes glucocorticoids and other hormones such as progesterone and estrogens.

In birds aldosterone and corticosterone are the main corticosteroids secreted. Zonation of the avian adrenal is less clear than in the mammalian adrenal. However, the outer subcapsular cells, looping in a manner similar to the zona glomerulosa, appear to be the predominant aldosterone secretors. The cells reaching toward the central part of the gland form corticosterone (Kime, 1987).

A. Steroid Nomenclature

The adrenal steroids contain as their basic structure a cyclopentanoperhydrophenanthrene nucleus consisting of three six-carbon rings (A, B, and C) and a single five-carbon ring (D). The letter designations for the carbon rings and the numbers of the carbon atoms are shown for pregnenolone (Fig. 20.1), a key biosynthetic intermediate. The Greek letter Δ indicates a double bond, as does the suffix -ene. The position of a substituent below or above the plane of the steroid ring is indicated by α and β, respectively. The α-substituent is drawn with a broken line (e.g., --OH), and the β-substituent with a solid line (e.g., —OH). The C_{18} steroids, which are devoid of a side chain at C-17 and have a substituent at C-18, are estrogens. The C_{19} steroids, which have substituent methyl groups at positions C-18 and C-19, are androgens (see also Fig. 20.2).

Steroids that have a ketone group at C-17 are termed 17-ketosteroids. The C_{21} steroids, the corticosteroids and progestagens, are those that have a two-carbon side chain (C-20 and C-21) attached at C-17 and, in addition, have substituent methyl groups at C-18 and C-19. The C_{21} steroids that also possess a hydroxyl group at position 17 are termed 17-hydroxycorticosteroids and may have predominantly glucocorticoid properties.

B. Biosynthesis

Cholesterol, derived from food and from endogenous synthesis via acetate (Fig. 20.2), is the principal starting compound in steroidogenesis. The adrenal gland is enriched in receptors that internalize low- and high-density lipoproteins. This uptake mechanism is increased when the adrenal is stimulated and provides the major cholesterol source. Subsequent steps occur in the mitochondrion or endoplasmic reticulum.

The zonal difference in adrenocortical hormone production is due to two steroidogenic enzyme systems. The mithochondrial cytochrome $P450_{CMO}$ (corticosterone methyloxidase), which converts corticosterone to aldosterone, is found only in the zona glomerulosa. The characteristic enzyme of the inner zones is the microsomal cytochrome $P450_{17\alpha}$ (17-hydroxylase/lyase), which catalyzes the 17α-hydroxylation of pregnenolone and progesterone as well as the side-chain fission of 17α-hydroxy C_{21} steroids. The other steroidogenic enzymes occur in all the three zones of the adrenal cortex (Müller, 1986).

The characteristic 11β- and 21-hydroxylations appear to have developed at a very early stage of evolu-

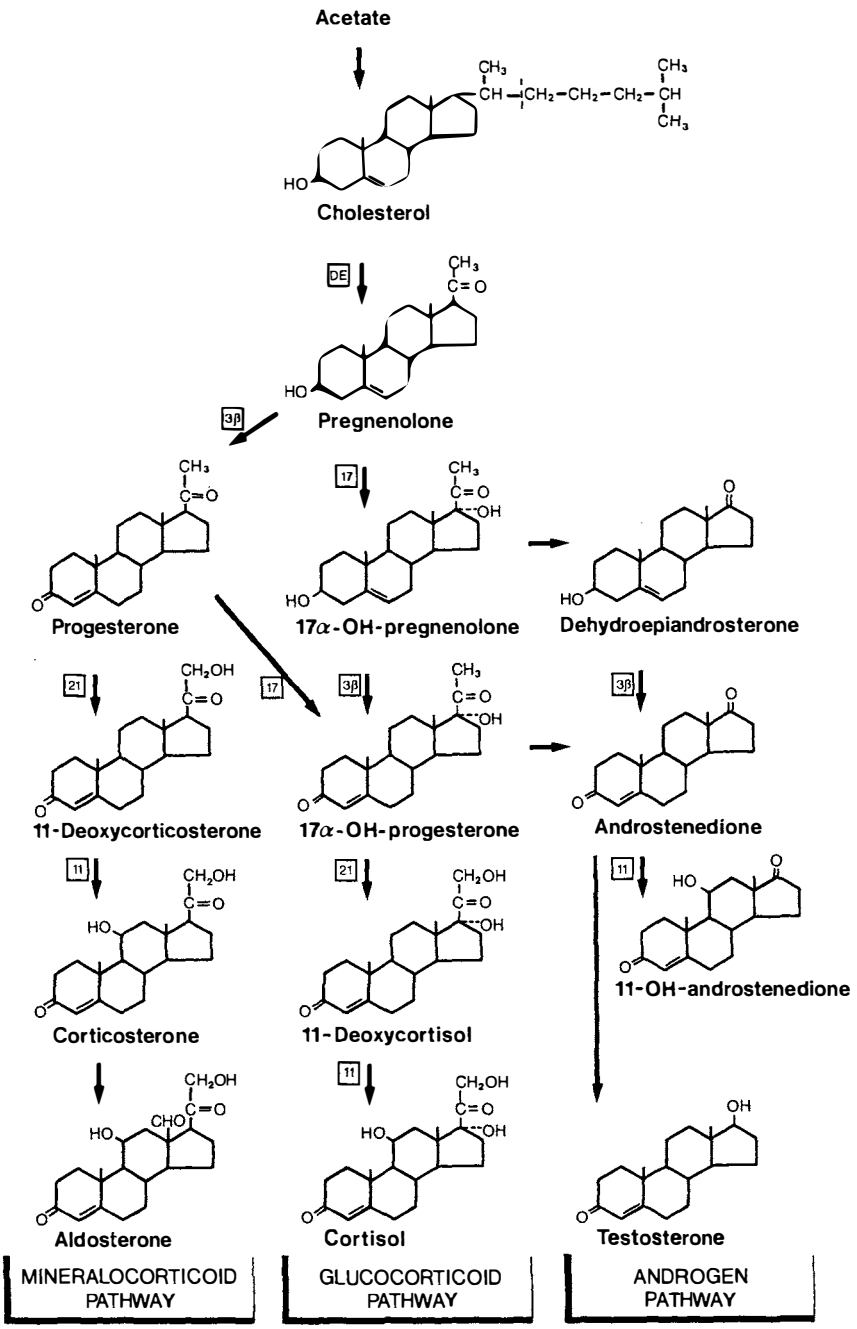

FIGURE 20.2 Biosynthetic pathways for adrenal steroid production. Letters and numbers by arrows denote specific enzymes: DE, debranching enzyme; 3β, 3β-ol-dehydrogenase with Δ4,5-isomerase; 11, C-11 hydroxylase; 17, C-17 hydroxylase; 21, C-21 hydroxylase.

tion and are present in all vertebrates. The 18-oxygenated corticosteroids also retain their importance as mineralocorticoids in all vertebrates. For the 17α-hydroxylase potential, the situation is different. Most mammals secrete cortisol as the predominant glucocorticoid. However, rodents and also birds secrete predominantly 17-deoxycorticosteroids such as corticosterone.

In line with this, steroid determinations in adrenal venous blood of dogs (Hirose *et al.*, 1977) have revealed cortisol/corticosterone ratios that range from about 3 to 7. Dor *et al.* (1973) have found ratios of secretion rates ranging from 1.2 to 2.7 and corticosterone/aldosterone secretion ratios ranging from 7 to 25. With HPLC analysis in peripheral blood of ACTH-stimulated dogs, the cortisol/corticosterone ratios ranged from 2.4 to 9.7

with a mean of 5.0 (Lothrop and Oliver, 1984). In addition to glucocorticoids and aldosterone, adrenal-vein blood of dogs and pigs contains androstenedione, 11-hydroxyandrostenedione, androsterone, pregnenolone, progesterone, and 11-hydroxyprogesterone (Heap *et al.*, 1966; Holzbauer and Newport, 1969) as well as very small amounts of estradiol and estrone (Dor *et al.*, 1973).

In cats the cortisol/corticosterone ratio has been estimated to range from 1.6 to 12.4, whereas in kittens the ratio is less than unity (Ilett and Lockett, 1969). In peripheral blood of horses, higher cortisol/corticosterone ratios (16:0.5 and 7:0.5) have been reported (Zolovick *et al.*, 1966; James *et al.*, 1970).

In birds, corticosterone, a glucocorticoid with minor mineralocorticoid properties, is by far the main adrenal secretory product. In the peripheral blood of adult birds no cortisol could be demonstrated with radioimmunoassay (Zenoble *et al.*, 1985; Walsch *et al.*, 1985) or HPLC analysis (Lumeij *et al.*, 1987). In chickens the 17α-hydrolyase activity is present in embryonic life but decreases after hatching (Nakamura *et al.*, 1978; Carsia *et al.*, 1987).

C. Transport

At normal concentrations, only about 10% of the total blood cortisol and corticosterone is in the free form, that is, susceptible to ultrafiltration. At body temperature, 70% of the plasma cortisol is bound to a globulin called transcortin or corticosteroid-binding globulin (CBG). Transcortin has a high affinity for cortisol and corticosterone, but its binding capacity is limited. Another 20% of plasma cortisol is bound to albumin, although its affinity for cortisol is much less than that of transcortin. In line with these percentages, in the dog the free fraction has been estimated to range from 5 to 12% (Kemppainen *et al.*, 1991; Meyer and Rothuizen, 1993).

Transcortin is ubiquitous in mammals, but plasma concentrations vary considerably, resulting in species differences in total cortisol concentration. Most domestic animals have little corticosteroid-binding activity compared to that of humans (Rosner, 1969). As the free rather than the protein-bound steroid is biologically active, methods have been developed to measure free cortisol. By employing the combination of ultrafiltration and equilibrium dialysis, Meyer and Rothuizen (1994) demonstrated that in dogs with portosystemic encephalopathy the associated hyperadrenocorticism is characterized not only by an increased total cortisol concentration in plasma, but also by an increase in the free fraction of plasma cortisol.

Unbound steroids readily diffuse into the salivary glands. Because of the close relationship between free cortisol in blood and saliva (Riad-Fahmy *et al.*, 1982), techniques have been developed for the collection of saliva from cattle (Murphy and Connell, 1970), sheep (Fell *et al.*, 1985), and dogs (Phillips *et al.*, 1983). Detailed background information on steroid hormones in saliva is available in Ferguson (1984). In cow's milk, about 60% of the cortisol is present in the ultafiltrate. Following parturition, the percentage of unbound cortisol (in colostrum) decreases to 40% (Shutt and Fell, 1985) owing to the higher concentrations of CBG-like protein.

The physiological significance of protein binding probably lies in a buffering effect, which prevents rapid variations of the plasma cortisol level. Transcortin restrains the active cortisol from reaching the target organ and also protects it from rapid inactivation by the liver and excretion through the kidneys.

Plasma aldosterone is predominantly bound to albumin, which has a low affinity. The relatively low degree of protein binding of plasma aldosterone partially explains the very low plasma concentration and the short biological half-life of this hormone.

D. Metabolic Breakdown and Excretion

Only unbound cortisol and its metabolites are filterable at the glomerulus. Most of this filtered cortisol is reabsorbed, whereby a tubular maximum is only achieved at very high filtered loads of free cortisol (Boonayathap and Marotta, 1974). Less than 20% of the filtered cortisol is excreted unchanged in the urine. Nevertheless, in most mammals the kidneys account for 50–80% of the excretion of the metabolized steroids. The remainder is lost via the gut. To render them suitable for renal elimination, the steroids are inactivated and made more water soluble through enzymatic modifications. The liver is the major organ responsible for steroid inactivation and conjugation to form water-soluble compounds, although in the dog—in contrast to the situation in humans—the kidney and the gastrointestinal tract also contribute to the metabolic clearance of cortisol (McCormick *et al.*, 1974). In the canine kidney, cortisol glucuronide is both secreted and reabsorbed, without a tubular maximum or a plasma threshold (Boonayathrap and Marotta, 1974).

Cortisol is cleared from the plasma with a half-life of 60 minutes or less. For pigs, the metabolic clearance rate of cortisol was calculated to be about 11 $hour^{-1}$ kg^{-1} (Hennesy *et al.*, 1986). In dogs about 60% of infused cortisol is eliminated within 24 hours in the urine (Rijnberk *et al.*, 1968). The 11β-hydroxyl group of cortisol can be oxidized to the ketone, forming

cortisone (Fig. 20.3). the reaction is reversible, and in general the equilibrium is shifted to favor the 11β-hydroxyl group. However, because the adrenal cortex produces much more cortisol than cortisone (if any), there is substantial cortisol-to-cortisone conversion. These two steroids have similar subsequent metabolic fates.

Apart from this 11β-hydroxylation, cortisol metabolism in the dog involves the following: (i) reduction of ring A to tetrahydro derivatives, (ii) reduction of the 20-keto group to a hydroxyl, and (iii) conjugation with glucuronic acid to form glucuronidates (Gold, 1961). In addition, unconjugated 20-hydroxycortisol / cortisone has been found in canine urine.

In the total glucuronide fraction of urinary corticoids in dogs, at least 60% is represented by steroids reduced at C-20. This is of prime importance when it comes to assessment of adrenocortical function by measuring urinary cortisol metabolites. Measurements directed at steroids containing a 17α, 21-dihydroxy, 20-keto arrangement, i.e., the Porter–Silber reaction, will detect only a small part of the cortisol metabolites and therefore have limited value (Siegel, 1965). Instead, preferably, measurements are preformed involving reduction of the urine metabolites at C-20, followed by oxidation to 17-ketosteroids, which are then quantitated. Further details on this measurement of "total 17-hydroxycorticosteroids" are given in Section V.

Aldosterone is converted not only to tetrahydroaldosterone-3-glucuronide, but also to aldosterne-18-glucuronide. Most aldosterone metabolism takes place in the liver and kidney, but the intestine and spleen might also contribute to a minor degree (Balikian, 1971).

In domestic animals, the catabolism of androgens has not been studied in any detail. For the dog it is known that very little of the secreted androgens can be measured as 17-ketosteroids in urine (Siegel, 1967; Rijnberk *et al.*, 1968a). Probably most of the excretion occurs via the bile (J. Van der Vies, personal communication, 1968).

In the cat glucocorticoid excretion is also largely biliary (Taylor, 1971; Rivas and Borrell, 1971). Feline liver function has several specific features, including a relatively low glucuronyl-transferase activity. Hence, formation of glucuronide conjugates is low and the conjugates are mainly sulfates, which are mostly excreted via the biliary route. Despite this low urinary excretion of metabolites and conjugates, it was recently shown that renal excretion of free cortisol is sufficient for diagnostic purposes (Goossens *et al.*, 1995) (see also Section V.B of this chapter).

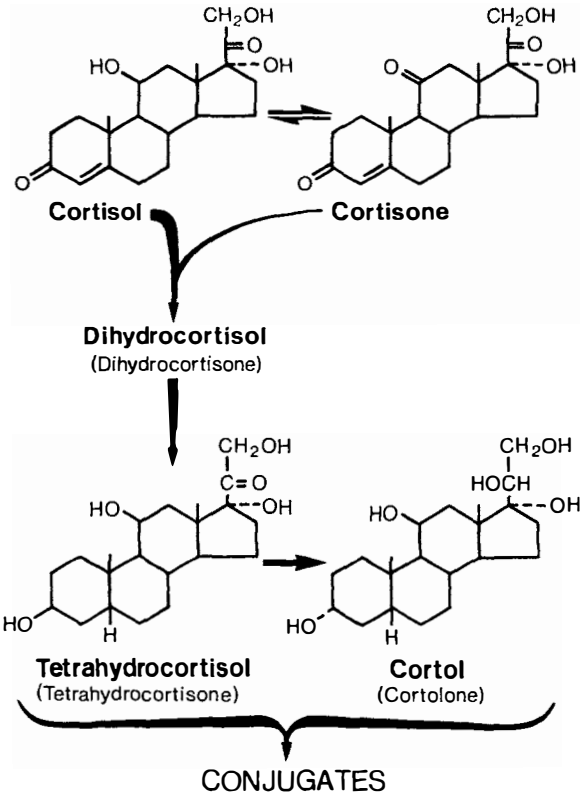

FIGURE 20.3 Metabolism of cortisol in the dog (simplified).

E. Regulation of Secretion

The steroidogenic activity of the two inner zones of the adrenal cortex is almost exclusively controlled by the pituitary hormone ACTH. The production of aldosterone in the zona glomerulosa is adapted to the sodium and potassium status of the organism by a complex, multifactorial, and mainly extrapituitary control system. For details on the secretion of ACTH by the pituitary and its regulation, readers are referred to Chapter 19, this volume. In puppies the feedback control of the hypothalamic-pituitary-adrenal axis is already operative at the time of birth (Muelheims *et al.*, 1969), although up to the age of 8 weeks, basal plasma cortisol concentrations are lower than in mature dogs. There is indirect evidence that this is related to low binding to transport proteins (Randolph *et al.*, 1995).

The action of ACTH on the adrenal gland is rapid; within minutes of its release, there is an increased concentration of steroids in the adrenal venous blood. The most likely mechanism by which ACTH stimulates steroidogenesis is via activation of membrane-bound adenylate cyclase. This increases the level of cyclic adenosine 3′,5′-monophosphate (cAMP), which activates adrenocortical protein kinases. This results in the phosphorylation of enzymes that enhance the rate of conversion of cholesterol to pregnenolone.

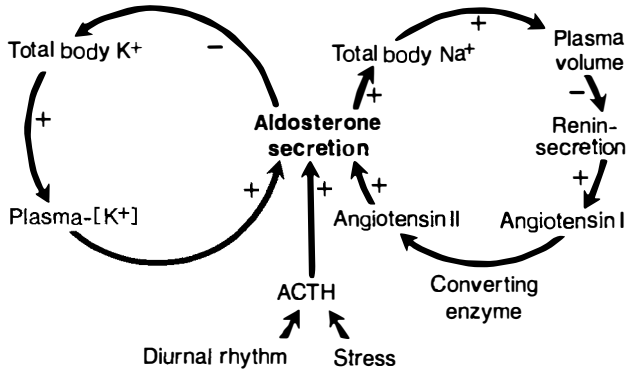

FIGURE 20.4 Physiological control of aldosterone seretion. After Müller and Labhart (1986).

In the regulation of aldosterone secretion, the two most important effectors are the peptide hormone angiotensin and the extracellular potassium concentrations. Regulation of aldosterone secretion by the potassium status is direct and rather simple (Fig. 20.4). The second loop, which adapts aldosterone secretion to the sodium balance, is much more complex. Apart from this renin–angiotensin system and potassium, a number of known, unknown, or poorly defined stimulators and inhibitors may contribute to the regulation of aldosterone biosynthesis and secretion. ACTH also belongs to a group of substances with short-term stimulatory effects on aldosterone biosynthesis.

F. Actions

1. Glucocorticoids

Of the naturally occurring glucocorticoids (cortisol, cortisone, and corticosterone), cortisol is the most potent. Several of the synthetic analogs of cortisol are more potent than cortisol itself (Table 20.1). The structural features that determine glucocorticoid potency are illustrated in Fig. 20.5.

TABLE 20.1 Relative Potencies of Corticosteroids

Corticosteroid	Mineralocorticoid activity	Glucocorticoid activity
Cortisol	1	1
Cortisone	0.7	0.7
Corticosterone	0.2	2
11-Deoxycorticosterone (DOC)	0.0	20
Aldosterone	0.1	400
9α-Fluorocortisone	10	400
Prednisone	4	0.7
Prednisolone	4	0.7
Dexamethasone	30	2
Triamcinolone	3	0.0
6α-Methylprednisolone	5	0.5

In their target organ cells, glucocorticoids act in the same manner as other steroid hormones: diffusion through the cell membrane; binding to the cytoplasmic, glucocorticoid (GR), and mineralocorticoid (MR) receptors; translocation of the hormonereceptor complex to the nucleus; and subsequent stimulation of the synthesis of specific RNAs, leading to synthesis of specific enzymes. The latter include key enzymes in gluconeogenesis such as fructose-1,6-disphosphatase, glucose-6-phosphatase, and pyruvate carboxylase. In the dog, corticosteroid excess also results in induction of an isoenzyme of alkaline phosphatase. This corticosteroid-induced form of alkaline phosphatase has not yet been found in other species. The marked stability at 65°C allows easy quantitation in plasma as a diagnostic screening tool for cases of suspected hyperadrenocorticism (Teske *et al.*, 1986, 1989).

Glucocorticoids may also act in a different manner mediated via a glucocorticoid receptor in the plasma membranes. The receptor seems to play a role in the cellular response in lymphoid tissues, exerting immunosuppressive effects. Ultimately, this may result in cytolysis, a property that has important therapeutic implications (Gametchu, 1987).

The overall effect of glucocorticoids on metabolism is to supply glucose to the organism by the transformation of proteins. This occurs via the just-mentioned induction of gluconeogenic enzymes in the liver. Thus, glucocorticoids divert metabolism from a phase of growth and storage toward increased physical activity and energy consumption, whereas chronic excess leads to catabolic effects such as muscle wasting, skin atrophy, and osteoporosis. The tendency to hyperglycemia is opposed by increased secretion of insulin, which in turn tends to enchance fat synthesis. This along with the increased food intake owing to central appetite stimulation (Debons *et al.*, 1986) explains the (centripe-

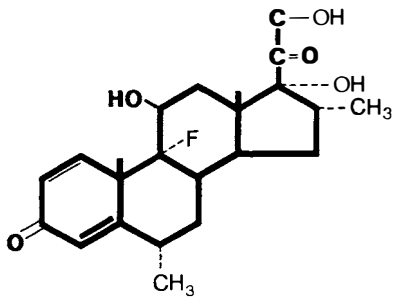

FIGURE 20.5 Structure–function relationships of corticosteroids. The bold lines and letters indicate the structure common to all glucocorticoids. Substituents that may enhance glucocorticoid activity are represented by light lines and letters.

tal) fat deposition, manifested by abdominal enlargement.

In situations of glucocorticoid deficiency, water excretion is impaired, whereas glucocorticoid excess may result in polyuria, being most pronounced in the dog. This is in part due to antagonism of cortisol to the action of vasopressin. In addition, glucocorticoid excess decreases the sensitivity of the osmoregulation of vasopressin release (Biewenga *et al.*, 1991). Even physiological increases in cortisol may inhibit basal vasopressin release in dogs (Papanek and Raff, 1994).

Glucocorticoids have long been known to have effects on blood cells, including a reduction in the numbers of eosinophils and lymphocytes and an increase in the number of neutrophils and hence in the total number of leukocytes. Glucocorticoid deficiency leads to normochromic, normocytic anemia.

As far as effects on other endocrine glands are concerned, Peterson and Altszuler (1981) demonstrated that canine hyperadrenocorticism results in reversible suppression of growth-hormone secretion. The frequently observed lowering of circulating thyroxine concentrations has been ascribed to changes in the thyroid hormone binding capacity of the plasma and to inhibition of lysosomal hydrolysis of colloid in the thyroid follicular cell (Kemppainen *et al.*, 1983; Woltz *et al.*, 1983). Glucocorticoids have multiple effects on peripheral transfer, distribution, and metabolism (Kaptein *et al.*, 1992), but thyroid function does not seem to be affected (Rijnberk, 1995). The glucocorticoid prednisone was found to inhibit LH secretion in male dogs, leading to reduced testosterone concentrations (Kemppainen *et al.*, 1983).

2. *Adrenal Androgens*

In health, adrenocortical production of androgens is trivial in comparison with the production of these hormones by the gonads. However, a pathological excess of adrenal androgens might induce virilization, that is, the development of masculine secondary sex characteristics, which would be most noticeable in the female or immature male. So far, no virilization as a consequence of enzyme deficiency has been reported in domestic animals, but in equine hyperadrenocorticism, hirsutism is a common feature (Pauli *et al.*, 1974; Van der Kolk *et al.*, 1993).

3. *Mineralocorticoids*

The widespread MR have equal affinity for aldosterone and the glucocorticoids cortisol and corticosterone, whereas the latter two hormones circulate at much higher concentrations than does aldosterone. However, in the classical aldosterone targets (kidney, colon, salivary gland) the enzyme 11β-hydroxysteroid dehydrogenase converts cortisol and corticosterone (but not aldosterone!) to the 11-keto analogs. These analogs cannot bind to MR, thereby enabling aldosterone to occupy this receptor (Funder *et al.*, 1988). Thus, not the receptor but a prereceptor modification provides the tissue specificity. The synthetic steroid 9α-fluorocortisone (Table 20.1) binds tightly to mineralocorticoid receptors and is used for mineralocorticoid replacement therapy, because it is more stable than aldosterone after oral administration. Mineralocorticoid antagonists such as spironolactone bind to these receptors and in this way block aldosterone action. Aldosterone controls the volume and the cationic composition of the extracellular fluid by regulating sodium and potassium balance. Its main action is on the tubular apparatus of the kidneys, but aldosterone receptors are also found in the gut, the salivary glands, and the sweat glands.

In the kidney the effect of aldosterone on the distal tubule consists almost entirely of an exchange of sodium with potassium and hydrogen ions. Aldosterone also promotes the excretion of magnesium and ammonium ions.

G. Physiological Variation, Stress, and the Immune System

In the absence of extraordinary stress, the plasma cortisol concentration of healthy animals varies within certain limits, although adrenocortical secretion does not occur evenly throughout the day, but rather in bursts. In humans, most of the secretory bursts occur between midnight and early morning, leading to a diurnal rhythm of circulating cortisol levels. The temporal coincidence between secretory bursts and plasma ACTH concentrations indicates neuroendocrine control.

In domestic animals and certainly in the dog, initially there has been some controversy as to the occurrence of circadian variation in cortisol concentrations. Later, Kemppainen and Sartin (1984b) presented definite evidence for episodic but not circadian fluctuations in plasma cortisol concentrations in dogs. In the horse (Dybdal *et al.*, 1994) and the pig (Bottoms *et al.*, 1972; Larsson *et al.*, 1979; Benson *et al.*, 1986; Janssens *et al.*, 1995c), as well as in sheep (Fulkerson and Tang, 1979), bulls (Thun *et al.*, 1981), pigeons (Joseph and Meier, 1973; Westerhof *et al.*, 1994a), and chickens (Lauber *et al.*, 1987), the occurrence of circadian variations is generally acknowledged. Also, in the cat there have been reports of the occurence of an (opposite) diurnal rhythm. However, in later reports this was not confirmed (Johnston and Mather, 1979; Leyva *et al.*, 1984).

As in the dog, the secretion is episodic without evidence for a diurnal rhythm (Peterson and Randolph, 1989). Apart from relatively short-term changes such as episodic secretion and diurnal variation, plasma cortisol concentration may change with age and during the estrus cycle, during pregnancy, and around the time of parturition. For example—as mentioned in Section III.E of this chapter—basal cortisol concentrations in puppies 8 weeks of age or younger are lower than in mature dogs, most probably a result of reduced binding to plasma proteins rather than of an altered secretion pattern (Randolph *et al.*, 1995). In gilts a discrete cortisol peak occurs during the early follicular phase of the sexual cycle, coinciding with the decline in plasma progesterone levels, that is, at 4 days prior to the plasma LH surge (Janssens *et al.*, 1995a). Plasma cortisol concentrations of pregnant cows decrease significantly during the fourth month of pregnancy. Thereafter, they remain fairly constant until the sixth and fifth day before parturition, when a sharp rise is seen. Also, at around 24 hours before parturition, plasma corticoids increase again (Eissa and El-Belely, 1990).

Independent of these physiological variations, it is clear that stress may activate the pituitary–adrenocortical system. Factors such as housing (Koelkebeck and Cain, 1984; Carlstead *et al.*, 1993; Cockram *et al.*, 1994), lactation (Gwazdauskas *et al.*, 1986), exercise (Foss *et al.*, 1971; Dybdal *et al.*, 1980; Rossdale *et al.*, 1982), surgery (Robertson *et al.*, 1994), anesthesia, heat (Gould and Siegel, 1985), emotional strain (James *et al.*, 1970; Kirkpatrick *et al.*, 1977; Bobek *et al.*, 1986), food deprivation (Messer *et al.*, 1995), and anticipation of feeding (Murayama *et al.*, 1986) all lead to increased corticosteroid secretion. Guthrie *et al.* (1980, 1982) demonstrated in the horse that during exercise increased plasma renin activity results in a considerable rise in aldosterone secretion. From the lack of any increase in plasma corticosterone in homing pigeons during flight, Viswanathan *et al.* (1987) concluded that the animals were not under serious stress.

With chronic stress, such as during prolonged tethered housing of pigs, an increased responsiveness of the adrenal cortex to ACTH is induced, whereas the sensitivity of the pituitary to stimulation with CRH and/or vasopressin remains unaltered and the challenge (nose sling)-induced ACTH response is lower than in loosely housed pigs. This indicates that during chronic stress, mitigating mechanisms become operational, most probably mediated by endogenous opioids (Janssens, 1995b).

According to Selye's theory of general adaptation, corticosteroids are needed for the (metabolic and circulatory) defense reaction. Administration of cortisol to improve nonspecific resistance is indicated in established pituitary or adrenal insufficiency. From an immunological point of view, stress suppresses defense reactions. Stress-induced glucocorticoid secretion prevents the overshooting of the animal's reactions to stress. The glucocorticoids modulate the mediators of the immune system such as the various lymphokines and mediators of the inflammatory reactions: prostaglandins, leukotrienes, kinins, serotonin, and histamine (Munck *et al.*, 1984).

It is now well established that the interaction of the neuroendocrine system and the immune system is not a one-way but a bidirectional communication. Tissue injury or inflammation elicits production of immunoregulatory cytokines (lymphokines and monokines) by macrophages and monocytes. These cytokines also activate the pituitary–adrenal axis and increase glucocorticoid concentrations, whereas the production and action of these immune mediators are inhibited by glucocorticoids. Thus, there is strong evidence for the existence of a feedback circuit, in which immunoregulatory cytokines act as afferent and ACTH and glucocorticoids as efferent hormonal signals (Woloski *et al.*, 1985; Besedovsky *et al.*, 1986). The regulatory actions of the cytokines are exerted at the level of the hypothalamus, where CRH is the major mediator of the response (Berkenbosch *et al.*, 1987), although cytokines also exert an influence at the level of the pituitary and the adrenals (Gaillard, 1994).

IV. ADRENOCORTICAL DISEASES

As this chapter is not meant to cope with clinical and pathological details, discussion of adrenocortical diseases is confined to definitions, short statements on occurrence in species, and referral to key references. In textbooks on endocrine diseases of companion animals (Drazner, 1994; Rijnberk, 1995; Feldman and Nelson, 1996) the adrenocortical diseases of the dog and the cat are described in detail.

A. Hypoadrenocorticism

Adrenocortical hypofunction includes all conditions in which the secretion of adrenal steroid hormones falls below the requirements of the animal. It may be divided into two categories:

1. Primary hypoadrenocorticism or Addison's disease is the result of deficiency of both glucocorticoid and mineralocorticoid secretion from the adrenal cortices (primary adrenocortical failure). "Idiopathic" or immune-mediated

atrophy (Schaer *et al.*, 1986) of all zones is the most frequently observed histopathologic lesion, although the lymphocytic adrenalitis may be confined to the zona fasciculata and zona reticularis (Kooistra *et al.*, 1995). It is well known in the dog and rare in the cat (Peterson and Randolph, 1989).

2. Secondary hypoadrenocorticism is the result of pituitary ACTH deficiency, causing decreased glucocorticoid secretion. Because of the almost unaltered aldosterone secretion, it will usually remain unnoticed. It is observed occasionally in dogs as a result of a destructive (neoplastic) pituitary lesion.

Animals receiving long-term corticosteroid treatment, despite physical and biochemical hyperadrenocorticoid–changes, develop secondary adrenocortical insufficiency because of prolonged hypothalamo–pituitary suppression. Atrophy of the two inner zones of the adrenal cortex results from the loss of endogenous ACTH stimulation. This is observed in the species in which corticosteroid therapy is common practice, that is, the dog (Greco and Behrend, 1995; Rijnberk, 1996) and the horse (Hoffsis and Murdock, 1970; Toutain and Brandon, 1983). It has also been observed in dogs and cats treated with progestagens, owing to the glucocorticoid activity that is intrinsic to these drugs (Chastain *et al.*, 1981; Mansfield *et al.*, 1986; Middleton *et al.*, 1987; Selman *et al.*, 1994).

B. Hyperadrenocorticism

In principle the adrenal cortex of animals might, as in humans, give rise to three distinct clinical syndromes of hyperfunction, that is, mineralocorticoid excess (Conn's syndrome), glucocorticoid excess (Cushing's syndrome), and androgen excess (adrenogenital syndrome). In animals, thus far only the occurrence of glucocorticoid excess has been reported. This form of hyperadrenocorticism is common in the dog while rare in the cat and the horse.

In about 15% of hyperadrenocorticoid dogs, the disease is due to a primary adrenocortical tumor. In the other 85% of cases, the disease is associated with a pituitary lesion, producing excess ACTH. The pituitary hyperplasias and neoplasias may reside in either the anterior lobe or the intermediate lobe (Peterson *et al.*, 1982; Kemppainen and Peterson, 1994). In cats the disease may also be either primary adrenocortical or pituitary dependent (Meijer *et al.*, 1978b; Peterson and Randolph, 1989). In the horse the disease originates almost invariably in the intermediate lobe of the pituitary (Orth *et al.*, 1982). In domestic ferrets hyperadrenocorticism is quite common, and it is primarily associated with adrenocortical tumor or nodular adrenocortical hyperplasia (Rosenthal *et al.*, 1993a).

V. ASSESSMENT OF ADRENOCORTICAL FUNCTION

A. Routine Laboratory Diagnostics

In both hypoadrenocorticism and hyperadrenocorticism, a number of abnormal laboratory findings are more common than in other diseases. Many of these abnormalities can be derived from the action of glucocorticoids and mineralocorticoids (described in Section III.F). The essentials are summarized here.

In primary hypoadrenocorticism the decreased aldosterone production results in hyponatremia and hyperkalemia. The associated hypovolemia leads to prerenal uremia, which is suggested when the ratio of urea to creatinine in plasma (both expressed in micromoles per liter) exeeds 150. In hyperadrenocorticism the classic hematologic abnormality is eosinopenia, which may be associated with lymphopenia and occasionally with leukocytosis and erythrocytosis. A very common biochemical abnormality is the elevated plasma concentration of alkaline phosphatase (Eckersall and Nash, 1983) that may occur in conjunction with mild elevation of alanine aminotransferase. In addition, hyperglycemia, hyperlipidemia, and low thyroxine concentrations may be observed. Urine specific gravity is usually low, and in 5–10% of cases glucosuria is found.

Of these abnormalities the elevated alkaline phosphatase (AP) concentration is the most common laboratory abnormality in dogs with corticosteroid excess (either exogenous or endogenous). This increase is due to the induction of a specific isoenzyme, which has greater heat stability at 65°C than other AP isoenzymes (Teske *et al.*, 1986) and is therefore easily measured by a routine laboratory procedure. An abnormally elevated AP-65°C value may point to hyperadrenocorticism, but it is unsuitable as a diagnostic test because of its low specificity (Teske *et al.*, 1989). The low thyroxine (T_4) concentrations in plasma that may be observed in hyperadrenocorticism seem to be a consequence of altered transport, distribution, and metabolism of T_4, rather than of hyposecretion (Rijnberk, 1996).

There may be other conditions causing these abnormalities, however; in addition, some cases do not present with typical routine laboratory characteristics. Therefore, a detailed understanding of the specific laboratory tests commonly used to investigate adrenocortical function is essential. In addition, the spontaneous forms of hyperadrenocorticism may arise from pitu-

itary ACTH overproduction or from autonomously hypersecreting adrenocortical tumors. Each of these requires a different mode of treatment, and therefore insight into the tests used in the differential diagnosis is of prime importance.

B. Tests of Basal Adrenocortical Function

The availability of highly specific radioimmunoassays has greatly enhanced and simplified assessment of adrenocortical function. Some of the older (chemical) methods, which are now seldom used, are mentioned briefly. Methods in common use are described in more detail, which applies especially to the dynamic tests, part of which is used in the differential diagnosis (Section V.C).

1. Cortisol Production Rate

In the radionuclide dilution method, the rate of cortisol production is determined through administration of radiolabeled cortisol and isolation of cortisol metabolites from urine that is collected over at least 24 hours. The specific activities of labeled cortisol and tetrahydrocortisol (or tetrahydrocortisone) are compared. Some preliminary work (Rijnberk *et al.*, 1968a) indicated that this test worked for the dog and might potentially be very useful. However, the laborious character of the procedure rules out general availability.

2. Plasma Corticoids

Plasma corticoid levels are subject to considerable variation owing to the pulsatile nature of the secretion, physiological variation (see Section III.G of this chapter), and alterations in transport proteins (Meyer and Rothuizen, 1994). Therefore, single determinations are of little diagnostic value in assessing hypo- or hyperadrenocorticism. Nevertheless, in a considerable percentage of cases resting values outside the reference ranges may be found. There are few data on sex and breed differences, and they are not dealt with in Table 20.2. Nevertheless there is evidence that they should be taken into account. In dogs circulating cortisol concentrations do not differ between males and females, but in small dogs higher values are found than in large-breed dogs (Reimers *et al.*, 1990).

3. Urinary Corticoids

With measurements of urinary corticoids and/or their metabolites, an integrated reflection of corticoid production over a period of time is obtained, thereby adjusting for the fluctuations in the plasma levels. Indeed, in dogs measurements of 17-hydroxycorticosteroids in 24-hour urine samples were found to have a high discriminatory power (Table 20.3; Rijnberk *et al.*, 1968b). However, the method has been abandoned because of the complicated and time-consuming chemical analysis, in combination with the difficulty of accurate collection of 24-hour urine samples.

Meanwhile, for the dog, another measurement reflecting cortisol secretion over a period of time has been introduced by Stolp *et al.* (1983). In this approach the 24-hour urine collection has been replaced by morning samples. The urinary corticoids (largely cortisol) are measured by radioimmunoassay and related to the creatinine concentration. In an assessment (Rijnberk *et al.*, 1988), the corticoid/creatinine ratios were found to have a higher accuracy in the diagnosis of hyperadrenocorticism than the commonly used dexamethasone screening test (see Section V.C.3).

The method has also been introduced for diagnostic use in the cat (Goossens *et al.*, 1995) and the ferret (Gould *et al.*, 1995). Also, for these species the determination of the urinary corticoid/creatinine ratio appears to be valuable for the diagnosis of hyperadrenocorticism.

4. Salivary Cortisol

In saliva, the "free" (biologically active) fraction rather than the "total" cortisol (Section III.C) is measured. Thus far in animals, salivary collection devices have been used primarily for research purposes. In the past a disadvantage has been the anesthesia involved, although it does not inhibit salivary flow (Phillips *et al.*, 1983).

In recent years there has been renewed interest in the approach, especially now that a technique has been introduced for saliva collection in unrestrained animals. Cortisol measurements in saliva may serve as a noninvasive indicator of stress in animals. When dogs are allowed to chew on large wads of cotton for up to 30 seconds, adequate saliva samples can be obtained (Vincent and Michell, 1992). The same method has been used succesfully in pigs (Parrott and Misson, 1989) and sheep (Cooper *et al.*, 1989). It does not seem to be advisable to increase saliva flow by pilocarpine (Blackshaw and Blackshaw, 1989). It has also been reported that in calves (Fell and Shutt, 1986) and goats (Greenwood and Shutt, 1992) saliva can be aspirated from the side of the mouth with minimum restraint.

5. Cortisol in Milk

Monitoring adrenocortical activity by measurements in milk may be of value in searching for stressors in the livestock industry (Stephens, 1980). Some of the results of cortisol measurements in milk have been incorporated in Table 20.2.

TABLE 20.2 Basal Corticosteroid Concentrations in Healthy Animals[a]

Species (*n*)	Hormone (fluid)[b]	Time of sampling	Range (nmol/l) (mean ± SEM)	Reference
Dog (6)	Cortisol (p)	8 samples/24 hr	<8–214	Johnston and Mather (1978)
Dog (21)	Cortisol (p)	8.00 hr	27–188	Meijer *et al.* (1979)
Dog	Aldosterone (p)		0.08–0.94	Willard *et al.* (1987)
Dog (24)	Cortisol (p)	9.30 hr	42–205	Hansen *et al.* (1994)
Cat (12)	Cortisol (p)	8.00 hr	9–71	Kemppainen *et al.* (1984)
Cat (6)	Cortisol (p)	8.00 hr	(87 ± 16)	Willemse *et al.* (1993)
Cat (100)	Cortisol (p)	9.00 hr	5–140	Peterson *et al.* (1994)
Cat (6)	Cortisol (p)		(30 ± 14)	Peterson and Kemppainen (1993)
Horse (11)	Cortisol (p)	11.00 hr	36–81	Hodson *et al.* (1986)
Horse (6)	Cortisol (p)	8.00 hr	(153 ± 18)	Messer *et al.* (1995)
Horse (7)	Cortisol (p)	09.00 hr	103–217	Van der Kolk *et al.* (1993)
Cow (23)	Cortisol (p)	5.00 hr	(17 ± 2)[c]	Gwazdauskas *et al.* (1986)
Cow (11)	Cortisol (s)	Milking time	(12 ± 2)	Shutt and Fell (1985)
Cow (11)	Cortisol (m)	Milking time	(1 ± 0.2)	Shutt and Fell (1985)
Cow (8)	Cortisol (c)	Day 1 postpartum	(46 ± 4)	Shutt and Fell (1985)
Calf (8)	Cortisol (sa)	Afternoon	(3.3 ± .5)	Cooper *et al.* (1989)
Calf (19)	Cortisol (sa)		0.3–3.4	Fell and Shutt (1986)
Pig (8)	Cortisol (s)	8.00 hr	(82 ± 3)	Becker *et al.* (1985)
Pig (8)	Free cortisol	Hourly	(5 ± 0.5)	Hemsworth *et al.* (1986)
Pig (6)	Cortisol (p)	10.00 hr	(49 ± 8)	Janssens *et al.* (1995b)
Pig (6)	Cortisol (p)	18.00 hr	(20 ± 4)	Janssens *et al.* (1995b)
Sow (20)	Cortisol (p)	10.00 hr	(29 ± 5)	Von Borrell and Hurnik (1991)
Sheep (11)	Cortisol		(62 ± 10)	Jephcott *et al.* (1986)
Sheep (6)	Cortisol (sa)	07.00 hr	(3.1 ± 1.6)	Cooper *et al.* (1989)
Goat (5)	Cortisol (p)		(65 ± 8)	Frandsen (1987)
Goat (6)	Cortisol (sa)		(3.0 ± 1.3)	Greenwood and Shutt (1992)
Pigeon (30)	Corticosterone (p)	11.30 hr	<5–34	Lumeij *et al.* (1987)
Pigeon (14)	Corticosterone (p)	04.00 hr	(13 ± 3)	Westerhof *et al.* (1994a)
White leghorn (9)	Corticosterone (p)	19.30–22.0 hr	(5 ± 2)	Craig and Craig (1985)
White plymouth (20)	Aldosterone		0.06–0.07	Rice *et al.* (1985)
Ferret (8)	Cortisol (p)		26–235	Rosenthal *et al.* (1993b)
Ferret (8)	Corticosterone (p)		2–47	Rosenthal *et al.* (1993b)

[a] Values have been converted to SI units when necessary.
[b] p, plasma; s, serum; m, milk; c, colostrum; sa, saliva.
[c] Two days after drying off.

6. Plasma ACTH

Determinations of resting plasma ACTH concentrations are not very useful in the diagnosis of hyperadrenocorticism because of the overlapping values for normal dogs and dogs with hyperadrenocorticism. Their value lies mainly in the differential diagnosis of hyperadrenocorticism (see later discussion). In animals with primary adrenocortical failure, plasma ACTH concentrations are usually extremely high. However, in most cases such a determination is primarily of academic interest, as the diagnosis can be made with the more practical ACTH stimulation test (see Section V.C.1). Plasma ACTH measurements are useful to resolve doubt about a primary or secondary adrenocortical insufficiency (Kooistra *et al.*, 1995).

C. Dynamic Tests

Apart from the just-described measurements of reflections of basal adrenocortical secretions, various maneuvers have been introduced to test the physiology

TABLE 20.3 Urinary Corticoids

Method	Species (*n*)	Range (mean ± SD)	Reference
17-Hydroxycorticoids			
Appleby *et al.* (1955)	Dog (21)	0.06–0.32 mg kg^{-1}/24 hr	Rijnberk *et al.* (1968a)
Siegel (1965)	Dog	2.13–6.98 mg/24 hr	Siegel (1968)
Metcalf (1963)	Dog	(2.3 ± 0.7) mg/24 hr	Bell *et al.* (1971)
Corticoids (radioimmunoassay)			
Stolp *et al.* (1983)	Dog (20)	0.3–3.6 nmol kg^{-1}/24 hr	Stolp *et al.* (1983)
Corticoid/creatinine ratio			
	Dog (28)	$1.2–6.9 \times 10^{-6}$	Stolp *et al.* (1983)
	Dog (12)	$(9 \pm 4 \times 10^{-6})$	Jones *et al.* (1990)
	Dog (20)	$0.5–17.7 \times 10^{-6}$	Feldman and Mack (1992)
	Dog (31)	$0.1–31.2 \times 10^{-6}$	Smiley and Peterson (1993)
	Cat (42)	$2–36 \times 10^{-6}$	Goossens *et al.* (1995)
	Ferret (51)	$0.04–1.66 \times 10^{-6}$	Gould *et al.* (1995)

of the hypothalamic–pituitary–adrenocortical axis. As in other areas of endocrinology, stimulation tests are used when hypofunction is suspected, and suppression tests are used when hyperfunction is suspected.

1. *Tests of Adrenocortical Reserve*

There are a number of modifications of the test for adrenal reserve, including intramuscular (IM) injection of ACTH rather than intravenous (IV) (Table 20.4). The critical feature of the test, however, is that a substantial increase in plasma (and/or urinary) corticoids must occur in response to ACTH if one is to prove the existence of adrenal reserve. One method is described in detail in Section V.F.

In veterinary medicine, ACTH stimulation has also been used for confirmation of adrenocortical hyperfunction. This is based on the assumption that hyperplastic adrenal cortices have abnormally large cortisol reserves. Indeed, hyperresponsiveness to ACTH or lysine–vasopressin (Meijer *et al.*, 1978a) stimulation is found in pituitary-dependent hyperadrenocorticism, but there is considerable overlap with normal dogs. Over the years, several modifications/combinations of the ACTH stimulation test (Eiler and Oliver, 1980; Eiler *et al.*, 1984; Feldman, 1985, 1986) for the diagnosis of hyperadrenocorticism have been used, but it still appears to be a dynamic test with less diagnostic accuracy than the low-dose dexamethasone suppression test (LDDST) (Feldman, 1986; Peterson, 1986). This seems to hold true for the horse as well (Dybdal *et al.*, 1994), although the ACTH stimulation test is recommended for the diagnosis of equine hyperadrenocorticism (Van der Kolk *et al.*, 1993). The value of the ACTH stimulation test lies in the diagnosis of hypoadrenocorticism (see Section V.F). When the test is used for the diagnosis of hyperadrenocorticism, combining it with a dexamethasone suppression test is not at all desirable, as doses of ≥0.1 mg of dexamethasone/kg can alter the results of the ACTH-stimulation test for at least three days (Kemppainen *et al.*, 1989).

2. *Tests of Pituitary (ACTH) Reserve*

In animals with adrenals responsive to ACTH, administration of the 11β-hydroxylase inhibitor metyrapone decreases cortisol secretion and consequently increases ACTH secretion. As a result, cortisol precursor synthesis increases, which can be measured as urinary 17-hydroxycorticosteroids. Although effective in the dog (Siegel, 1968), the procedure is cumbersome, which has prohibited its wider use in veterinary medicine. At present, pituitary ACTH reserve is tested by use of physiological suprapituitary stimuli, that is, vasopressin or CRH (see Chapter 19). Such tests are mainly useful in differential diagnosis, whereby it should be noted that vasopressin is the least useful for this purpose, as it can exert a direct stimulatory effect on cortisol release by adrenocortical tumors (Van Wijk *et al.*, 1994).

3. *Tests of Pituitary–Adrenocortical Suppressibility*

The integrity of the feedback system can be tested by giving a potent glucocorticoid and judging suppression of ACTH secretion by measuring either steroids excreted in urine or plasma cortisol levels. A potent glucocorticoid such as dexamethasone is used, so that the administered compound can be given in small amounts that will not contribute significantly to the steroids to be analyzed. In pituitary-dependent hyperadrenocorticism, there is loss of normal sensitivity to suppression, and as a result higher values are found than in normal individuals following dexamethasone administration (Table 20.5).

TABLE 20.4 Plasma Corticoids (nmol/liter) Following ACTH Stimulation

Species (*n*)	ACTH preparation	Dose and route	Time of sampling (min)	Range (mean ± SEM)	Reference
Cortisol					
Dog (6)	ACTH gel	2.2 IU/kg IM	60–120	188–308	Johnston and Mather (1978)
Dog (21)	ACTH (1–24)	250 μg IV	90	120–620	Meijer *et al.* (1978c)

Horse (9)	ACTH gel	1 U/kg IV	4 hr	(455 ± 110)	Dybdal *et al.* (1994)
Goat (5)	pACTH	0.35 IU/kg	120	(96 ± 19)	Frandsen (1987)
Ferret (8)	ACTH (1–24)	1 μg/kg IV	60	143–308	Rosenthal *et al.* (1993b)
Corticosterone					
Ferret (8)	ACTH (1–24)	1 μg/kg IV	60	30–72	Rosenthal *et al.* (1993b)
Pigeon	ACTH (1–24)	125 μg IM	30–120	80–419	Lumeij *et al.* (1987)
Psittac (35)	ACTH gel	16 IU IM	60	(73 ± 26)	Lothrop *et al.* (1985)
Eagle (12)	ACTH (1–24)	125 μg IM	60	298–541	Zenoble *et al.* (1985)
Condor (6)	ACTH (1–24)	125 μg IM	60	243–365	Zenoble *et al.* (1985)
White leghorn (9)	pACTH	50 IU IM	30	(40 ± 5)	Craig and Craig (1985)
Broiler chick (11)	ACTH (1–24)	4 IU/kg	30	(7 ± 1)	Van Mourik *et al.* (1986)
Aldosterone					
Dog (9)	ACTH gel	2.2 IU/kg IM	60	0.48–1.59	Willard *et al.* (1987)

[a] Two days in dry period.

In the dog the most frequently used test is still the low-dose dexamethasone suppression test (LDDST) introduced by Meijer *et al.* (1978a). In this test, 0.01 mg of dexamethasone/kg of body weight is administered intravenously and a plasma sample for cortisol determination is taken after 8 hours. In healthy dogs at this time the plasma cortisol concentrations are still depressed (Kemppainen and Sartin, 1984a). This test is described in detail in Section V.F. Others recommend intramuscular administration of 0.015 mg of dexamethasone/kg and the collection of plasma samples for cortisol determination 2, 4, 6, and 8 hours after injection (Peterson, 1984). Although not necessary for the diagnosis, the results of a 3- or 4-hour sample may be informative for differential diagnosis (see Sections V.D and V.F).

TABLE 20.5 Upper Reference Values for Post-dexamethasone Cortisol Concentrations in the Low-Dose Dexamethasone Suppression Test

Species	Dose and route	Time of sampling	Plasma cortisol (nmol/liter)	Reference
Dog	10 μg/kg iv	8 h	<40	Meijer *et al.* (1979)
Dog	15 μg/kg im	2, 4, 6, 8 h	<28	Peterson (1986)
Cat	10 μg/kg iv	8 h	<36	Smith and Feldman (1987)
Cat	15 μg/kg iv	8 h	<14	Peterson and Graves (1988)
Horse	40 μg/kg iv	15 h	<30	Dybdal *et al.* (1994)
Pigeon	0.5 μg/kg iv	4 h	<5	Westerhof *et al.* (1994b)

D. Tests for Differential Diagnosis

In animals with primary hypoadrenocorticism, the physical and biochemical features are very much determined by the electrolyte disturbances caused by the insufficient mineralocorticoid secretion. In secondary hypoadrenocorticism, mineralocorticoid secretion is practically unchanged, and the presenting signs are usually completely different. Thus only very rarely is there a need for additional tests to distinguish between these two forms of hypoadrenocorticism. However, when doubt exists about the background of the hyporesponsiveness to exogenous ACTH, plasma ACTH concentrations should be measured (see also Section V.B.6) and/or the pituitary should be tested for ACTH reserve (see Section V.C).

For hyperadrenocorticism, the situation is completely different. Once the diagnosis of hyperadrenocorticism has been made by either a basal test or a dynamic test, it is necessary to distinguish between pituitary-dependent hyperadrenocorticism and hyperadrenocorticism arising from an adrenocortical tumor. In principle these forms of the disease require different modes of treatment. Probably owing to the additional secretion of steroids with mineralocorticoid activity by adrenocortical tumors, a higher incidence of hypokalemia is found than in animals with pituitary-dependent hyperadrenocorticism (Meijer, 1980). However, this sign is not specific enough to allow differentiation between the two forms. As there are no further signs that may be helpful to distinguish the two entities, specific tests are needed. The two most helpful procedures are the measurement of basal plasma ACTH levels an the high-dose dexamethasone suppression test (HDDST). A test of pituitary ACTH reserve may also be helpful.

Normal to high plasma ACTH concentrations ($\geq$40 pg/ml) in hyperadrenocorticoid dogs usually indicate ACTH excess of pituitary origin. Low to undetectable concentrations of ACTH are found in dogs with hyperadrenocorticism arising from an adrenocortical tumor in which the feedback control of pituitary ACTH secretion is undisturbed. ACTH concentration may not be low when both disease entities occur simultaneously (Nothelfer and Weinhold, 1992; Van Sluijs *et al.*, 1995). However useful this measurement may be, in practice it is not the first choice when it comes to the differential diagnosis of hyperadrenocorticism because of the requirements for collecting and handling the samples and the technically difficult assay (see also Section V.E).

In contrast to the determination of endogenous ACTH, the HDDST is readily available. Despite a decreased sensitivity to the suppression by glucocorticoids, the ACTH secretion of most animals with pituitary-dependent hyperadrenocorticism can be suppressed with a 10-fold dose of dexamethasone, resulting in a decrease of the adrenocortical secretion. The autonomous hypersecretion by adrenocortical tumors will not be influenced by the high dose of dexamethasone.

Two procedures are used in the dog, one employing plasma cortisol as a reflection of adrenocortical secretion (Meijer *et al.*, 1979) and the other using urinary corticoid/creatinine ratios (Rijnberk *et al.*, 1987, 1988). In both, a greater than 50% decline from baseline values is regarded as diagnostic for pituitary-dependent hyperadrenocorticism (see Section V.F). When suppression is less than 50%, the hyperadrenocorticism may be due to either an adrenocortical tumor or a pituitary ACTH excess that is extremely resistant to dexamethasone suppression. For the differentiation between these two forms, the measurement of endogenous ACTH may be necessary, or a CRH test may be performed. In dogs with pituitary-dependent hyperadrenocorticism, CRH administration (1 μg/kg IV) results in elevations of both plasma ACTH and cortisol, whereas no such rise is seen in dogs with hyperadrenocorticism caused by adrenocortical tumors (Van Wijk *et al.*, 1994). The high cost of the commercially available powder preparation and the necessary pharmaceutical preparation prohibit general use of CRH.

E. Collection and Handling of Samples

It has become common practice for clinicians to perform endocrine function studies and to mail samples to a laboratory for measurement of cortisol. It is therefore important to rule out nonpathological factors that can alter hormone concentrations. Apart from stress (see Section V.B), the nutritional state of the animal may also play a role. Reimers *et al.* (1986) found that mean serum concentrations of cortisol in dogs fasted 12 or 24 hours were lower than those in dogs that were not fasted. The concentrations were not further affected by continued fasting for 36 hours.

Olson *et al.* (1981) studied several aspects of sample handling, such as uncentrifuged storage and storage time. They concluded that either serum or plasma of dogs is suitable for radioimmunoassay of cortisol and that samples (with and without added anticoagulants) may be left uncentrifuged at 4°C for up to 40 hours without cortisol degradation. However, prolonged storage of serum at room temperature is detrimental, particularly for samples having large concentrations of cortisol. Samples allowed to defrost and sit for more than 3 days en route to a laboratory may have a lower cortisol concentration than at the time of collection.

The peptide ACTH is readily inactivated at room temperature. Therefore, blood for ACTH measurements should be collected in EDTA-coated tubes

placed in ice, and the blood should be centrifuged at 4°C. The plasma should then be placed in polypropylene tubes and kept frozen until assayed. These requirements are most easily fulfilled when the samples are collected in a clinic with the necessary facilities. If the samples have to be transported, it is imperative that they be kept frozen with dry ice in a Styrofoam container.

It has become clear that these strict rules can be alleviated to some extent by adding a protease inhibitor (aprotinin) to the collection tubes. Kemppainen *et al.* (1994) have found that aprotinin-containing plasma samples shipped (second-day delivery) unfrozen in an insulated container with frozen refrigerant packs are not affected by transport.

F. Protocols

The protocols presented in this section are applicable to the dog. With the data presented in some of the tables, extrapolation to other species may be possible.

1. The ACTH Stimulation Test

a. Indications

The ACTH stimulation test is performed when there is suspicion of decreased adrenocortical reserve capacity: (1) primary adrenocortical insufficiency (Addison's disease) and (2) (iatrogenic) secondary adrenocortical insufficiency.

b. Performance

Blood for cortisol measurements is collected immediately before and 90 minutes after intravenous administration of 0.25 mg synthetic ACTH (Cortrosyn [Organon]). In cases in which treatment for adrenocortical insufficiency was already started, on the morning of the test the cortisone administration is postponed until after completion of the test.

c. Interpretation

In healthy dogs, the cortisol concentrations rise to 270–690 nmol/liter. In Addison's disease, the control value is usually low and does not increase following ACTH administration. In animals with secondary adrenocortical insufficiency the basal cortisol values may be low as well, and, depending on the severity (duration) of the ACTH deficiency, the cortisol rise is subnormal or absent.

2. The Low-Dose Dexamethasone Suppression Test

a. Indication

The low-dose dexamethasone suppression test is used when hyperadrenocorticism (Cushing's syndrome) is suspected.

b. Performance

In the morning 0.01 mg dexamethasone per kg body weight is administered intravenously. Blood for cortisol measurements is collected immediately before and at 3 and 8 hours after dexamethasone administration.

c. Interpretation

A plasma cortisol concentration exceeding 40 nmol/liter at 8 hours after dexamethasone administration can be regarded as diagnostic for hyperadrenocorticism with a diagnostic accuracy of 0.83 (95% confidence limits 0.76–0.88) (Rijnberk *et al.*, 1988). The measurements at 0 and 3 hours are not needed for the diagnosis of hyperadrenocorticism, but may be informative in the differential diagnosis. Quite commonly the high value at 8 hours is preceded by a lower value at 3 hours. Thus, at 8 hours the pituitary–adrenocortical system escapes from suppression by dexamethasone. If the value at 3 hours is at least 50% lower than the basal value, the desease may be regarded as pituitary dependent.

3. The High-Dose Dexamethasone Suppression Test

a. Indication

Differentiation between pituitary-dependent hyperadrenocorticism and hypercorticism arising from adrenocortical tumors is possible with the high-dose dexamethasone suppression test.

b. Performance

Blood for cortisol determination is collected immediately before and 3 hours after administration of 0.1 mg dexamethasone per kg body weight.

c. Interpretation

If the plasma cortisol declines by more than 50%, the diagnosis of pituitary-dependent hyperadrenocorticism is justified. A decrease of less than 50% can be due either to an adrenocortical tumor or to dexamethasone-resistant pituitary-dependent hyperadrenocorticism. Differentiation between these two forms requires additional tests (see Section V.D).

4. The Corticoid/Creatinine Ratios (with High-Dose Dexamethasone Test)

a. Indication

Determination of corticoid/creatinine ratios can be performed when hyperadrenocorticism is suspected.

b. Performance

The owner is asked to collect morning urine samples at set times (e.g., 7 A.M.) on three consecutive days. On the preceding evenings the animal should have its last

walk at identical times (e.g., 11 P.M.). After collection of the second urine sample oral administration of dexamethasone is begun. At 8-hour intervals the owner administers 0.1 mg dexamethasone per kg body weight.

c. Interpretation

Corticoid/creatinine ratios exceeding 10×10^{-6} can be regarded as compatible with hyperadrenocorticism with a diagnostic accuracy of 0.91 (95% confidence limits 0.85–0.95) (Rijnberk *et al.*, 1988). When the ratio of the third urine sample is 50% lower than the mean of the first two ratios, the diagnosis of a pituitary-dependent hyperadrenocorticism is justified. A lesser decrease may be due to either adrenocortical tumors or dexamethasone-resistant pituitary-dependent hyperadrenocorticism (for differentiation, see Section V.D).

d. Comment

This test is now generally regarded as a sensitive screening test for the diagnosis of hyperadrenocorticism (Feldman, 1995). There has been some debate on its specificity (Rijnberk and Teske, 1992; Feldman, 1992), and it has been stated that the test lacks specificity (Feldman, 1995). Indeed, as with other screening tests the specificity is not 100% (Smiley and Peterson, 1993; Kaplan *et al.*, 1995) and in conditions that are associated with increased adrenocortical function, such as hepatic encephalopathy (Rothuizen *et al.*, 1995), elevated ratios can be found.

In this discussion two points remain somewhat underexposed. First, a high sensitivity and not a high specificity is essential for a screening test. The predictive value of a positive test result is dependent on the sensitivity of the test and also on the prevalence of the disease in the population studied. When the testing is limited to dogs suspected of the disease, the population under study will have a high prevalence of disease and as a result the predictive value of a positive test result will be high. Secondly, as always, the diagnostic accuracy of a test also depends on the quality of the test procedure. In this respect it should be mentioned that easily elevated C/C ratios can be obtained when the urines are collected under stressful conditions, such as in the hospital. This will increase the number of false positive test results, i.e., lower the specificity.

When C/C ratios are measured in a population suspected of hyperadrenocorticism, with urine collections at home, not only is the sensitivity of the test high, but also the specificity (0.77) is comparable to that of the low-dose dexamethasone suppression test (0.73) (Rijnberk *et al.*, 1988).

CHAPTER

21

Thyroid Function

J. JERRY KANEKO

I. INTRODUCTION

Disorders of the thyroid gland are the most common endocrine disorders in humans, and an extensive historical and scientific literature is available. Among the domestic animals, thyroid function and its diseases are well known in companion animals but less so in livestock. In livestock, nutritional iodine deficiencies have been of greater importance than thyroid-gland diseases, particularly in the iodine-deficient areas of the world. The importance of thyroid function and its diseases has also become progressively more important as the longevity of companion animals such as the dog and cat has increased.

Advances in thyroid physiology, the pathogenesis of its diseases, and the continued development and refinement of methods of testing thyroid function have added impetus to the study of thyroid disease in all animals. This chapter reviews the anatomy and physiology of the thyroid gland and its diseases as a corollary to understanding the pathophysiology of the thyroid gland in disease. The physiological bases of a variety of thyroid function tests, most of which are now readily available to the veterinary clinician, are emphasized.

II. ANATOMICAL CONSIDERATIONS

The thyroid gland of animals is a bilobed structure that overlays the trachea at a point just below the larynx. Anatomical variations of the gland are quite marked between species and, to some extent, within a given species. The isthmus connecting the two lobes

of the thyroid is the region that varies most markedly between species. Humans and the pig have a large discrete isthmus that forms a pyramidal lobe connecting the two lateral lobes. The cow has a fairly wide band of glandular tissue that forms the connecting isthmus. In the horse, sheep, goat, cat, and dog, the isthmus is a narrow remnant of tissue and may be nonexistent. The size of the gland relative to body weight is extremely small in all animals, approximating 0.20% of body weight. The size of the gland varies and may be enlarged in iodine deficiency, ingestion of goitrogenic toxins, tumors, or hyperactivity. In primary hypothyroidism, the gland may be reduced to fibrotic and inactive remnants of thyroid tissue.

Accessory or extrathyroidal tissue is quite commonly seen in the dog, particularly near the thoracic inlet, though it may be found anywhere along the esophagus. This tissue is fully functional physiologically, synthesizes hormone, and can be located by its uptake of radionuclides.

The thyroid gland is a highly vascularized tissue with a large blood flow. The functional unit of the thyroid gland is the thyroid follicle, a spherical structure composed of an outer monolayer of follicular cells surrounding an inner core of colloid, the thyroglobulin–hormone complex, which is the storage reservoir of thyroid hormone. The colloid stored in the lumen is a clear, viscous fluid. The individual follicular cells vary from 5 to 10 μm in height and the entire follicle may vary from 25 to 250 μm in diameter. The size of the follicles and the height of their cells vary according to the functional state of the gland. The cells may vary from an inactive squamous cell to the highly active, tall columnar cell. Interspersed between the follicles are the thyroid C cells, the source of calcitonin, the hypocalcemic hormone associated with calcium metabolism. A third type of hormonal tissue, the parathyroid, is embedded within the thyroid or located in close proximity. The parathyroids are the source of parathormone, the hypercalcemic hormone. Removal of the parathyroids is virtually unavoidable during surgical thyroidectomies, so that postsurgical hypocalcemias are important consequences to be considered.

III. NUTRITIONAL REQUIREMENTS

The thyroid gland is unique among the endocrine glands in that an integral part of its hormone, L-thyroxine (T_4), is a trace mineral, iodine, that is available to the animal in only limited amounts. Marine plants are known to be good sources of iodine, but on land, iodine is limited and many regions of the world are known to be iodine deficient. The minimum daily iodine requirement of the adult beagle dog is 140 μg (1103 nmol) (Belshaw *et al.*, 1975), and the recommended daily requirement is 35 μg/kg bw (276 nmol/kg bw) for the adult dog and 70 μg/kg bw (551.6 nmol/kg bw) for the growing puppy. Milk is a very poor source of hormonal iodide, contributing only about 4–7% of the maintenance requirements for hormone (Akasha and Anderson, 1984).

The very small requirements are compensated for by a very efficient intestinal absorption mechanism and by conservation and recycling of internal iodine. Very little iodine is lost from the body by the various excretory routes such as urine, saliva, tears, milk, sweat, and feces. Also, although most endocrine glands store little of their hormones, the thyroid manages to store large quantities of hormone, sufficient for 1 to 3 weeks depending upon the species. The thyroid gland contains about 20% of the total body iodine. Its iodine content and size varies with iodine intake and the state of thyroid function but it usually contains 10–40 mg (78.8–315.2 μmol) iodine/100 g tissue or 4–16 mg (31.5–126.1 μmol) iodine in a 20-kg dog.

IV. IODINE METABOLISM

Iodine can be absorbed in any of its soluble chemical forms, but in the intestines it is usually absorbed in the form of iodides (I^-) or iodates (IO_4^-), or as the hormonal forms. Iodides may be absorbed from any moist body surface, including the mucous membranes, and is absorbed easily through broken epithelia. Normally, the chief route of entry into the general circulation is by absorption through the mucosal cells of the small intestine. The I^- in the circulation is trapped almost exclusively by the thyroid gland; small amounts are trapped by the salivary gland and minimal amounts by the gastric mucosa, placenta, and mammary gland. In the ruminant, 70–80% of an oral dose is absorbed in the rumen and 10% in the omasum (Barua *et al.*, 1964).

The main route of excretion of I^- is by the kidneys, through which almost all the I^- that was not trapped by the thyroid is lost in the urine. A small but significant amount is lost in the saliva, and minimal amounts are lost in tears, feces, sweat, and milk. In ruminants, a significant amount may be lost in the feces as well (Bustad *et al.*, 1957). A minute amount of free hormone, that fraction not bound to serum proteins, is also lost in the urine. These routes of excretion are especially important considerations when patients are being treated with radioiodine.

V. FUNCTIONS OF THE THYROID GLAND

The main functions of the thyroid gland are the trapping of I^- and the synthesis, storage and release of thyroid hormones (Fig. 21.1), and these activities are under the control of thyrotrophic or thyroid-stimulating hormone (TSH). Although all steps in hormonogenesis are stimulated by TSH, the trapping of I^- and the release of hormone are the two major sites of its action.

A. The Thyroid Hormones

The principal thyroid hormones elaborated by the thyroid are the two active hormones, 3,5,3′,5′-tetraiodothyronine (T_4) and 3,5,3′-triiodothyronine (T_3), and the inactive hormone, 3,3′,5′-triiodothyronine (reverse T_3 or rT_3). rT_3 is the inner deiodination product of T_4. The structures of the individual hormones are given in Fig. 21.2. The T_4 molecule contains 65.3% iodine and the T_3 molecule contains 58.5% iodine. T_3 is the active hormone in the target cell. T_4 functions as the transport form and as the feedback regulator of the thyroid gland.

B. Hormonogenesis and Release

1. *Trapping of Iodide*

The I^- in the general circulation is taken up by the thyroid follicular cells by a highly efficient trapping and concentrating mechanism. It does this against a large concentration gradient, which can be from 1 : 20 to 1 : 500 across the thyroid cell membrane and is stimulated by TSH. The trapping process is catalyzed by a trapping enzyme, requires oxygen, and is an active transport or "pump" mechanism catalyzed by a Na^+–K^+-ATPase and dependent upon ATP. It is the high efficiency of this trapping system that concentrates virtually all of the body iodine in the thyroid gland. It also accounts for the microgram nutrient requirement for iodine. In addition, the thyroid follicular cells have a high capability for compensatory hypertrophy when there is a scarcity of iodine; hence the development of iodine-deficiency goiters. The efficiency of I^- trapping is also the basis for the radioactive iodine uptake (^{131}I uptake) test of thyroid function, ^{131}I thyroid imaging, and ^{131}I thyroid therapy. The trapping of I^- is stimulated by TSH and blocked by goitrogenic agents such as thiocyanate (SCN^-) and perchlorate (ClO_4^-) and by large amounts of I^-. The sites of these and other blocks in the thyroxine biosynthetic pathway are also shown in Fig. 21.1. Other compounds are trapped by the thyroid gland; a clinically useful one is ^{99m}Tc-pertechnetate, which is used for thyroid imaging.

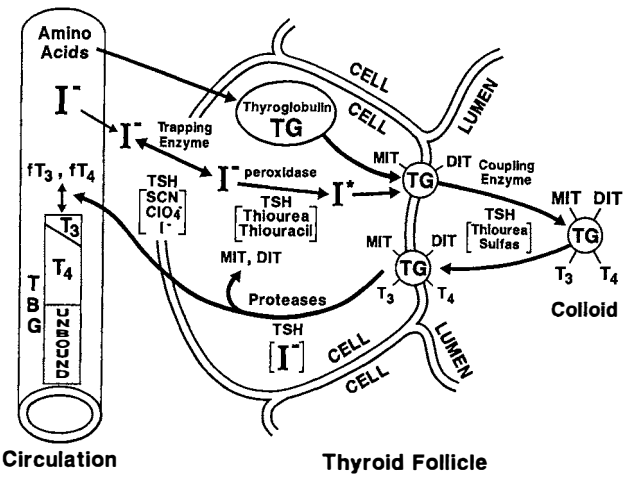

FIGURE 21.1 Pathways of iodine metabolism and thyroid hormone synthesis. Goitrogenic blocking agents are shown in brackets.

2. *Synthesis of Thyroid Hormones*

After trapping, there is an oxidation of I^- catalyzed by a peroxidase, and the product is a highly active form of iodine, most likely a free radical, I*. This reaction is inhibited by thyrotoxic agents such as the thiouracils or thioureas and stimulated by TSH. Propylthiouracil is commonly used in the treatment of hyperthyroidism. The I* almost instantaneously binds to the phenyl groups of the tyrosine moieties of thyroglobulin at the 3 and / or 5 position to form a monoiodotyrosine (MIT) or a diiodotyrosine (DIT). This iodination occurs while the tyrosines remain in polypeptide linkage within the thyroglobulin molecule. Next, the iodinated phenyl groups of the tyrosines are coupled by the oxidative condensation of an iodinated phenyl group of one DIT to another DIT to form T_4, or of an MIT group to a DIT to form T_3. These iodination reactions occur mainly at the follicular cell membrane–colloid interface. These iodination reactions are energy requiring and are sensitive to blocking by sulfa drugs, thioureas, and *para*-aminobenzoic acid (PABA).

3. *Storage of Hormone*

Thyroglobulin is the thyroidal glycoprotein of high molecular weight (660,000) synthesized exclusively by the thyroidal follicular cells. After synthesis, it moves to the cell membrane, where the iodinations occur and the iodinated thyroglobulin, or colloid, is released into the lumen of the follicle where it is stored. The amount stored can be quite large, as evidenced by the mass of protein contained within a normal follicle.

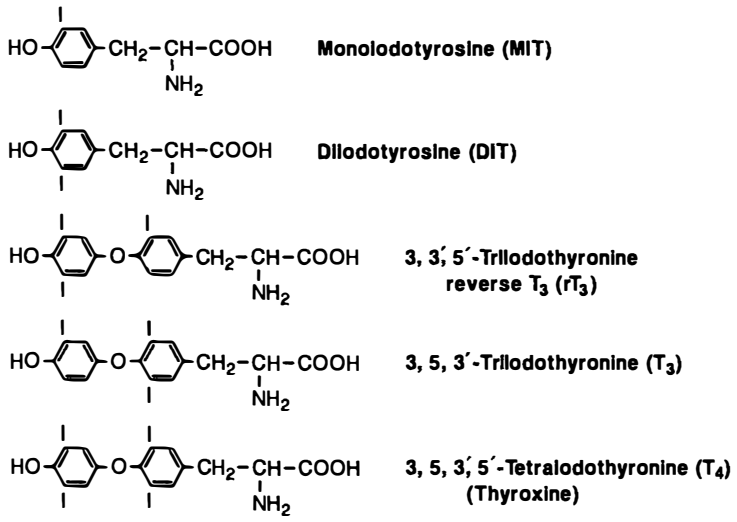

FIGURE 21.2 Chemical structures of the major iodinated compounds of the thyroid gland.

4. Release of Hormone

Although all steps in the hormonogenesis and release process are stimulated by TSH, TSH stimulus of the release of hormones is the second of its two principal sites of action. Within a few minutes after giving TSH, small packets of colloid are taken up by the follicular cell membrane, and vesicles are formed and taken into the cell by endocytosis. The vesicles merge with lysosomes in the cell, and the lysosomal proteases hydrolyze the colloid and release their MIT, DIT, T_3, and T_4. The released MIT and DIT are enzymatically degraded by microsomal tyrosine deiodinases and their iodine is recycled within the gland. The T_4 and T_3 are released into the circulation by a simple diffusion process. Of the total hormone released, about 90% is T_4 and 10% is T_3. Within the gland, there is also some deiodination of the T_4 of the inner phenyl group to form rT_3 but most of this deiodonation occurs in the peripheral tissues. This rT_3 is the inactive form of thyroid hormone and is on a degradation pathway.

VI. TRANSPORT OF HORMONE: PROTEIN BINDING

The thyroid hormones in the circulation are T_4, T_3, and rT_3. Immediately on entering the circulation, these hormones are bound to transport proteins, mainly to thyroxine binding globulin (TBG) and in lesser amounts to thyroxine binding prealbumin (TBPA) and to albumin. There is a wide spectrum of species variation in hormone binding by serum proteins (Table 21.1). TBPA is present in all species, in contrast to earlier reports indicating that TBPA was present only in humans and in rhesus monkey, horse, cat, rabbit, pigeon and chicken. The early work was based on electrophoretic migration (Tanabe *et al.*, 1969; Refetoff *et al.*, 1970), but later work was based on chemical properties that identified TBPA or its analogs at different migration sites (Larsson *et al.*, 1985). The differences in migration are probably due to the amino acid composition of these proteins among the various species. By chemical criteria, all species have TBPA.

TBG is the major binding protein for hormone, but not all species have TBG. In those species without TBG, albumin is the major binding protein. The binding constant of TBG for T_4 is about 10^{10} liter/mol so that some 99.97% of the plasma T_4 is bound to TBG and only 0.03% is free or unbound (fT_4). The binding constant for T_3 is about 10^9 liter/mol so that about 99.7% of the plasma T_3 is bound to TBG and 0.3% is free. Therefore, TBG or albumin transport most of the hormones.

In the cat, rabbit, rat, mouse, Guinea pig, pigeon, or chicken, TBG is absent and most of the hormone is transported by albumin. The albumin binding constant is about 10^5 liter/mole for T_4 or T_3, but with an unlimited binding capacity. In these species without TBG, albumin transports 50–80% of the hormones. T_3 (and likely rT_3) appears to bind to these transport proteins in parallel with T_4 binding.

Protein binding has several functions. It serves to solubilize these lipid-soluble hormones for transport in the aqueous plasma. The bound forms also do not readily pass through the renal glomerular membrane,

TABLE 21.1 Thyroxine-Binding Proteins of Various Species, Their Electrophoretic Migration, and Their Relative Thyroxine Binding[a]

Species	Electrophoretic migration position		
	α-Globulin	Albumin	Prealbumin
Human	TBG (73)	ALB (10)	TBPA (17)
Rhesus monkey	TBG (59)	ALB (8)	TBPA (33)
Cattle[b]	TBG (60) TBPA (20)	ALB (20)	
Sheep	TBG (86)	TBPA (14)	
Goat	TBG (63)	TBPA (37)	
Water buffalo	TBG (78)	TBPA (22)	
Horse	TBG (61)	ALB (17) TBPA (22)	
Pig	TBPA (0) TBG (93)	ALB (7)	
Dog	TBG (60) TBPA (17) α-G (11)	ALB (12)	
Cat[b]	TBPA (39)	ALB (61)	
Rabbit[b]	TBPA (73)	ALB (27)	
Rat[b]		ALB (80) TBPA (20)	
Mouse[b]		ALB (80) TBPA (20)	
Guinea pig[b]		ALB (81) TBPA (19)	
Chicken	TBPA (10)	ALB (75) TBPA (15)	
Pigeon[b]		ALB (50)	TBPA (50)

[a] TBG, thyroxine-binding globulin; ALB, albumin; TBPA, thyroxine-binding prealbumin; α-G, α-globulin. Positioned as shown relative to the albumin position in each species. Numbers in parentheses are % thyroxine binding. Constructed from the data of Tanabe *et al.* (1969), Refetoff *et al.* (1970), and Larsson *et al.* (1985).
[b] Approximation.

so they minimize urinary loss of hormones; the free hormones pass and are lost. The bound forms also serve as a large and readily accessible reservoir of the active hormones for delivery to the target organs and cells. Finally, the protein binding equilibrium is the fundamental basis for protein- or immunoprotein-binding assays of hormone, indirect assay of TBG, and the free thyroxine index (FTI) tests of thyroid function.

VII. MECHANISM OF THYROID HORMONE ACTION

A. General Effects of Thyroid Hormones

After the administration of thyroid extracts or T_4, the first physiological effects are noted in 24–28 hours and maximal effects are noted in 7–10 days (Table 21.2). The T_4 requirements for these effects varies. The requirement for T_3 also varies; less is required for equivalent activity and it acts more quickly. T_3 is now recognized as the active form of the thyroid hormone within the target cell. The T_4 that is transported into the target cell is rapidly deiodinated to the active T_3. However, rT_3, which is also produced in the cell, is an inactive form of thyroid hormone.

B. Molecular Basis of Thyroid-Hormone Action

The molecular basis of thyroid-hormone action at the cellular level has been frequently reviewed and a multifaceted concept of its action has evolved (Stanbury and Dumont, 1983). For many years, the mitochondrion was considered to be the site of thyroid-hormone action. Uncoupling of oxidative phosphorylation (ox-phos) in the mitochondria was a viable hypothesis for many years. Under normal conditions, 3 mol of ATP (P) are synthesized per atom of oxygen ($\frac{1}{2}O_2 = O$) used in the cytochrome oxidase system; hence, the P:O ratio equals 3. If less than 3 mol ATP are formed per unit O in a system in the presence of a compound such as the thyroid hormone, the system is said to be uncoupled, that is, the P:O ratio is less than 3. In this event, more O_2 would need to be utilized to generate an equivalent amount of ATP, and O_2 consumption would increase. T_4 has repeatedly been shown to uncouple oxidative phosphorylation in

TABLE 21.2 Effects of Thyroid Hormone

Category	Effect
Clinical	Tremors, nervousness, exophthalmos, hyperactivity, weight loss
Physiological	Increase temperature, heart function
Calorigenic	Increase in basal metabolic rate (O_2 consumption)
Carbohydrate metabolism	Increased glucose turnover, absorption
Protein metabolism	Anabolic, positive N balance
Lipid metabolism	Decrease in blood cholesterol
Development	Stimulation of growth and maturation
Reproductive	Fertility, pregnancy, ovulation
Hematological	Erythropoiesis

in vitro systems, but it does so only in large, unphysiological amounts. These findings were extended to the whole animal to explain the increased oxygen consumption by T_4. The large amounts of oxidative energy not incorporated into ATP increased body temperature and was dissipated as heat. Thus, T_4 action was theorized to be the result of the uncoupling of oxidative phosphorylation.

Another now well-known effect of thyroid hormone is the stimulation of cellular protein synthesis (Tata *et al.*, 1963; Tapley, 1964). This occurs during the latent period when the calorigenic effect of thyroid hormone occurs. T_3 is now known to stimulate messenger RNA (mRNA) transcription, increasing translation and protein synthesis and accounting for the anabolic effects of thyroid hormones. This also means that the site of action is at the cell nucleus.

Another action of thyroid hormone is to stimulate the "sodium pump" (Na–K-ATPase) at the cell membrane, an action that would increase O_2 consumption (Edelman, 1974). Oubain, an inhibitor of Na–K-ATPase, also inhibits the increased O_2 consumption induced by T_4 or T_3. Thus, stimulation of the sodium pump is an important way in which thyroid hormones stimulate increased oxygen consumption and accounts for almost half of the increase.

A direct effect of thyroid hormones on cell membrane transport has also been suggested from studies on 2-deoxyglucose uptake (Segal *et al.*, 1977). Pliam and Goldfine (1977) proposed that T_3 binds to receptors on the cell membrane and is transported by carriers into the cell.

A combination of the preceding mechanisms is the most likely explanation of the mechanism of action of thyroid hormone. Stanbury and Dumont (1983) describe a model patterned after the generalized steroid hormone model in which (1) T_3 is bound to a receptor site on the plasma membrane; (2) T_3 is transported across the membrane into the cell by carrier protein; (3) T_3 in the cell is again bound to a carrier protein; (4) T3 rapidly exchanges between receptor sites on the mitochondrion or nucleus; and (5) T3 interacts in metabolic processes and protein synthesis.

VIII. CATABOLISM AND EXCRETION OF THYROID HORMONES

The thyroid hormones undergo deiodination, conjugation, or oxidative reactions. The deiodination reaction occurs widely in peripheral tissues and is catalyzed by deiodinases specific for each iodine position, and the released iodine is returned to the iodine pool. The details of the specific reactions, however, are yet not known. The deiodinase that catalyzes the deiodination of T_4 to T_3 in target cells is actually participating in an activation reaction. Deiodination at the 3 position of T_4 gives rT_3, the inactive form on the degradation pathway. Within a cell, therefore, some of the T_4 is converted to its active form and some is converted to its inactive form for degradation. Some of the thyroid hormones are conjugated in the liver and excreted in the bile either as glucuronides or as sulfates. Also, the thyroid hormones, being amino acids, are deaminated and decarboxylated in the liver to form corresponding tetraiodoacetic acid and triiodoacetic acid, which are excreted. The small amounts of free hormones in the blood are also excreted by the kidney.

IX. REGULATION OF THE THYROID GLAND

A. Production and Regulation of Thyroid-Stimulating Hormone

The thyroid gland is under the control of thyroid-stimulating hormone, secreted by the anterior pituitary gland, which in turn is mediated through the hypothalamus and its thyrotrophin-releasing factor (TRF). TRF is synthesized in the anterior hypothalamus by neurosecretory cells and then transported down axonic processes to the anterior pituitary. There, TRF stimulates the thyrotrophic cells to synthesize TSH. The secretion of TSH is regulated by a classic negative-feedback control system based on the product of the target gland, thyroxine. A high plasma concentration of free hormone, fT_4, depresses TSH secretion by the pituitary and to some extent, the TRF from the hypothalamus.

The pituitary, with its direct inhibition by increased fT_4, is the faster-responding of the two tissues. At low concentrations of fT_4, however, the hypothalamus responds quickly by increasing its synthesis and release of TRF, which in turn increases the synthesis and release of pituitary TSH. In consequence, this regulatory mechanism, which is sensitive to either high or low concentrations of fT_4, maintains the circulatory hormone concentrations at the normal homeostatic level for that species.

B. Action of Thyroid-Stimulating Hormone on the Thyroid Gland

TSH has a number of direct effects on the thyroid gland: The gland increases in size, the height of the follicular cell increases, and there is a loss of colloid. The response of the thyroid gland to TSH is modified by the intake of stable iodine. When iodine intake is high, the action of TSH is suppressed and the height, size, and activity of the follicular cells are decreased. When iodine intake is low, there is a compensatory hypertrophy of the gland with an increase in number, height, and size of the follicular cells. This is characteristic of iodine-deficiency goiters or nontoxic goiters.

C. Action of Thyroid-Stimulating Hormone on Hormonogenesis

The effects of TSH upon hormone synthesis by the thyroid follicle are outlined in Fig. 21.1 and discussed in Section V. TSH affects every reaction in the hormone synthetic pathway, beginning with the uptake of iodine, its activation, tyrosine iodination, coupling of the iodinated phenyls, and hydrolysis of colloid. The two most important sites of TSH action are the initial uptake of iodine and the final hydrolysis of colloid to release hormones into the circulation.

D. Long-Acting Thyroid Stimulators

A second thyroid stimulatory factor has been identified in the serum of human patients with Graves' disease. This factor appears to be closely involved in the mechanism of thyrotoxicosis (Adams, 1958; McKenzie, 1958). It differs from TSH in that it is cleared from the blood more slowly and produces its thyroid stimulating effects many hours (8–24) after that of TSH. It is therefore referred to as long-acting thyroid stimulator, or LATS. Studies of LATS have been largely in humans, where it has been closely correlated with hyperthyroidism (Lipman, 1967). Since the initial observations, many other forms of delayed-acting thyroid stimulators have been found, and all, including LATS, are now known to be immunoglobulins of the IgG class. These thyroid-stimulating immunoglobulins (TSI) or thyroid-stimulating antibodies (TSAb) do not appear to have a role in normal thyroid physiology, nor have corresponding stimulators been found in animals.

X. THYROID FUNCTION TESTS

The diagnosis of thyroid disease is usually obscured by the very nonspecific nature and variety of clinical signs. A thorough physical examination is essential for the detection of a potential thyroid disease and as a rationale for laboratory tests of thyroid function. Initial routine laboratory tests such as hematology or urinalysis are of limited value. The initial parallel biochemical screen is also limited except for hypercholesterolemia. In consequence, the specific tests of thyroid function are of great importance in the diagnosis of thyroid disease. Fortunately, improvements of standard tests and the development of new tests have made several specific and direct tests of thyroid function readily available to the veterinary clinician.

A. Indirect Tests of Thyroid Function

1. Hematology

A moderate normocytic normochromic anemia is sometimes associated with clinical hypothyroidism in the dog. This anemia has also been observed in human hypothyroidism and in experimental animals and is known to be of a depression type or the anemia of chronic disease (Cline and Berlin, 1963). The stained blood smear characteristically has little or no evidence of active erythrogenesis such as anisocytosis, polychromasia, or nucleated red cells. Leptocytosis may be prominent in some cases. The hemogram, therefore, is characteristic of the nonresponsive anemia of chronic diseases such as neoplasia or chronic infection. This anemia is not diagnostic for hypothyroidism, but conversely, in cases of unexplained hypoplastic or nonresponsive anemia, hypothyroidism is an important differential diagnosis.

2. The Basal Metabolic Rate

The basal metabolic rate (BMR) measures the O_2 consumption of an animal under rigidly standardized basal conditions and is the classical test of thyroid function in humans. The test is based upon the decreased O_2 consumption in hypothyroidism and the increased O_2 consumption found in hyperthyroidism. The BMR has found little application in clinical veterinary medicine because of the difficulty of maintaining

animals under basal conditions. Even under anesthesia, basal conditions are seldom maintained.

3. *Cholesterol*

The serum cholesterol generally varies inversely with thyroid activity. The net effect of thyroid hormone on cholesterol metabolism is to increase the rate of its catabolism by the liver (Koppers and Palumbo, 1972), thereby lowering the cholesterol. In hypothyroidism, the net effect is a decrease in cholesterol catabolism and an increase in cholesterol.

The cholesterol is carried in dog plasma equally by the low-density lipoproteins (LDL-Chol) and the high-density lipoproteins (HDL-Chol) (Mahley and Weisgraber, 1974). In humans, cholesterol is carried mainly by the LDL-Chol and only about 20% by the HDL-Chol. This partitioning of cholesterol is important because increased LDL-Chol is associated with atherosclerosis, whereas increased HDL-Chol is associated with a reduced risk for heart disease. A detailed discussion of cholesterol metabolism and its association in various diseases is given in a separate chapter. Table 21.3 gives the normal cholesterol reference ranges of a number of domestic animals.

Early on, increased cholesterol was often the only index of thyroid function used because the protein-bound iodine (PBI) was unreliable. Cholesterol alone is also of limited value because hypercholesterolemia can result from a variety of causes unrelated to thyroid activity. These include the diet, nephrotic syndrome, hepatic function, biliary obstruction, and diabetes mellitus. The diagnostic accuracy of serum cholesterol for hypothyroidism in the dog is about 66%. However, when the concentrations are very high, >500 mg/dl (>12.9 mmol/liter), and diabetes mellitus is eliminated, serum cholesterol's diagnostic accuracy is greatly increased. Therefore, increased cholesterol is a signal for further investigation of thyroid disease. Recently, cholesterol used in conjunction with the fT_4 was found to have the highest predictive value among a battery of thyroid function tests (Larsson, 1988).

Similarly, hypocholesterolemia has little value as an index of hyperthyroidism. On the other hand, cholesterol decreases consistently in response to thyroxine replacement therapy, so it has value as a guide to

TABLE 21.3 Serum Cholesterol Concentration in Various Species

Species	Total (mg/dl)	Free (mg/dl)	Ester (mg/dl)	Reference
Cat	95–130			Kritchevsky (1958)
	93 ± 24	30 ± 10	63 ± 23	Boyd (1942)
	98 ± 7.3			Morris and Courtice (1955)
Cow	80–120			Kritchevsky (1958)
Pregnant, nonlactating	110 ± 32	37 ± 15	73 ± 15	Boyd (1942)
Lactating, nonpregnant	241.9			Lennon and Mixner (1957)
Heifer, 15–18 months	96.1			Lennon and Mixner (1957)
Calves	105.6			Lennon and Mixner (1957)
	123			Lennon and Mixner (1957)
Dog	125–250			Kaneko (1980)
	110–135			Kritchevsky (1958)
	110 ± 28	51 ± 20	59 ± 19	Boyd (1944)
	194 ± 35			Morris and Courtice (1955)
Low-fat diet	140			Boyd and Oliver (1958)
High-fat diet	280			Boyd and Oliver (1958)
Fowl (chicken, ducks, geese)	100–200			Kritchevsky (1958)
Cockerel	100 ± 23	34 ± 9	66 ± 19	Boyd (1942)
Nonlaying hens	116 ± 2–152 ± 2			Leveille *et al.* (1957)
Laying hens	208 ± 15–285 ± 24			Leveille *et al.* (1957)
Goat	80–130			Kritchevsky (1958)
Horse	83–140			Kritchevsky (1958)
	96.8 ± 2.8	15.7	81.1	Norcia and Furman (1959)
	128 ± 12			Morris and Courtice (1955)
Rabbit	30–70			Kritchevsky (1958)
	45 ± 18	22 ± 13	23 ± 12	Boyd (1942)
Sheep	70			Boyd and Oliver (1958)
	64 ± 12			Morris and Courtice (1955)
Swine (low-fat diet)	35.6 ± 53.7	5.7–10.9	28–48	Reiser *et al.* (1959)

therapeutic response. In thyroidectomized horses with clinical evidence of hypothyroidism, Lowe *et al.* (1974) demonstrated a 50% decrease in serum cholesterol shortly after feeding iodinated casein.

B. Direct Tests of Thyroid Function

A direct approach to thyroid evaluation is to measure the amount of the hormones in the blood. Because there are thyroid inhibitory effects among a wide variety of iodine-containing compounds, it is critical that any form of iodine-containing medication, including thyroid hormones, be uncovered in the history of the patient. As a general rule, any iodine-containing medication or thyroid hormones being given to the patient should be withdrawn for at least 2 weeks before any thyroid function tests are undertaken.

1. Serum Protein-Bound Iodine

The classic protein-bound iodine test measured all the precipitable protein-bound hormonal forms (T_4, T_3, rT_3) plus all coprecipitable iodine. Clearly, this method overestimated the amounts of hormone, but it was a useful index of thyroidal activity because the PBI is proportional to the amount of thyroid hormones. Because most of the iodine bound to plasma protein is hormonal iodine, the PBI mainly represents hormone concentration. The partitioning between hormonal and nonhormonal forms is quite constant, so that the PBI is directly proportional to the amount of thyroid hormone.

The PBI method is fraught with logistical and technical difficulties and, though useful in its time, is no longer used. The sample and the chemical procedure are readily contaminated by any source of iodine: antiseptics, internal or external iodine-containing medicaments, iodinated radiographic contrast media, and thyroid medications (Table 21.4). Reliability is improved by prior extraction of the thyroid hormones from the serum with butanol (butanol-extractable iodine, BEI). A further refinement was to separate the hormones by column chromatography (Pilleggi *et al.*, 1961; Fisher *et al.*, 1965). Automation of the iodine assay increased its reliability, but immunoassays for thyroid hormones are now the tests of choice. Reference ranges for animals are given in Table 21.5; note that these ranges are considerably lower than in humans.

2. Competitive Protein-Binding Assays

The elucidation of the protein-binding equilibrium and the competition between labeled and nonlabeled hormones for binding sites on the proteins provided the basis for the determination of T_4, and indirectly, the TBG and fT_4:

$$\text{TBG–T}_4 \xrightarrow{k} \text{TBG} + \text{fT}_4. \tag{21.1}$$

Since the TBG–T_4 is the total T_4, one can substitute and reformulate Eq. (21.1):

$$\text{fT}_4 = k\frac{\text{T}_4}{\text{TBG}}. \tag{21.2}$$

It can be seen that the amount of fT_4 is directly proportional to the amount of T_4 and inversely proportional to the amount of TBG, and that knowing these two factors permits the calculation of fT_4. The calculated fT_4 is expressed as the free thyroxine index (FTI), but it is not valid for animals. T_4 is now measured directly by competitive protein binding (CPB) assay, by radioimmunoassay (RIA), or by enzyme-labeled immunoassay (EIA). The TBG is measured indirectly by competitive binding of labeled T_3 to a secondary binding agent such as red cells, resins, charcoal, or hemoglobin. TBG can also be assayed directly by immunoassay.

a. Thyroxine by Competitive Protein Binding

The competitive protein binding (T_4-CPB) method was the forerunner of all the competitive protein binding methods for T_4 and does not depend on the colorimetric determination of iodine (Murphy and Pattee, 1964). The method is based on the competitive binding of TBG for patient T_4 and ^{131}I-labeled T_4. The labeled T_4 and patient T_4 bind to the TBG in proportion to their concentrations, so that labeled T_4 binding is inversely proportional to patient T_4 concentration. The use of TBG has been replaced by immunoglobulins as the binding proteins, so CPB is now seldom used. Reference values in animals are given in Table 21.6.

There is minimal interference from diphenylhydantoin and salicylates when given in large amounts (Sparagana *et al.*, 1969), so T_4-CPB is a reliable method (Lucis *et al.*, 1969). Comparisons with T_4-RIA indicated no significant difference (Kaneko *et al.*, 1975). Also, in horses, T4-CPB decreased dramatically to almost zero at 2 days after thyroidectomy (Lowe *et al.*, 1974). Feeding of iodinated casein to these horses resulted in a rapid rise of T_4 to above normal. Iodinated casein contains about 2.5 μg (3.85 nmol) T_4 and 1.25 μg (1.61 nmol) T_3 per gram (Kaneko, 1979).

b. Thyroxine by Radioimmunoassay

Thyroxine by radioimmunoassay (T_4-RIA) is a typical immunoassay method in which an antibody is used as the binding protein. Owing to their high specificities, antibodies are useful for the assay of proteins, polypeptides, and haptens, including most of the hormones.

TABLE 21.4 Some Drugs Affecting Thyroid Function Tests

Compound	Effect on ^{131}I uptake	Effect on PBI	Effect on T_3 uptake	Duration of effect (average period)
Iodides				
Lugol's, cough syrup, vitamin preparations	Decrease	Increase	None	10–30 days
Iodine antiseptics	Decrease	Increase	None	10–30 days
Iodine-containing drugs	Decrease	Increase	None	10–30 days
X-Ray contrast media				
Iodoalphionic acid (pheniodal)	Decrease	Increase	None	3–12 months
Iodopyracet (Diodrast)	Decrease	Increase	None	2–7 days
Iodized oil (oleum iodatum)	Decrease	Increase	None	0.5–3 years
Most iv contrast media	Decrease	Increase	None	2–6 weeks
Most gallbladder media	Decrease	Increase	None	3 weeks–3 mo
Hormones				
Thyroid extract	Decrease	Increase	Increase	4–6 weeks
Triiodothyronine	Decrease	Decrease	Decrease	2–4 weeks
ACTH	Decrease	None	Increase	2 weeks
Estrogens	None	Increase	None	—
Oral contraceptives	None	Increase	None	—
Androgens	None	None	Increase	—
Thiocarbamide compounds				
Thiouracil	Decrease	Decrease	None	5–7 days
Propylthiouracil	Decrease	Decrease	None	5–7 days
Thiocyanate	Decrease	Decrease	None	14–21 days
Phenylbutazone	Decrease	None	Increase	14 days
Bromides	Decrease	None	—	10–30 days
Antihistamines	Decrease	None	—	7 days
Diphenylhydantoin (dilantin)	None	Decrease	Increase	7–10 days
Salicylates	None	None	Increase[a]	—

[a] Effect depends on the method.

The principles and details of radioimmunoassay are described in the chapter on clinical enzymology. Polyclonal antibodies give accurate results and are usually used for these hormone assays. Reference values in animals are given in Table 21.6. Belshaw and Rijnberk (1979) report that other than in hypothyroidism of dogs, only diphenylhydantoin, corticosteroids, or Cushing's disease result in very low concentrations of either T_4-RIA or T_3-RIA. This further emphasizes the need for a careful history of the patient prior to assay for thyroid hormones. The mean normal T_4-RIA in dogs is 2.3 ± 0.8 μg/dl (29.6 ± 10.3 nmol/liter) with an observed range of 0.6–3.6 μg/dl (7.7–46.3 nmol/liter) (Kaneko *et al.*, 1978), which is comparable to the 1.5–3.6 μg/dl (19.3–46.3 nmol/liter) of Sims *et al.* (1977) and Belshaw and Rijnberk (1979). T_4-RIA is now widely used in cats because of the high prevalence of hyperthyroidism in this species. The reference range for cats is 0.1–2.5 μg/dl (1.3–32.3 nmol/liter). In the horse, T_4-RIA is also quite low, 0.9–2.8 μg/dl (11.6–36.0 nmol/liter). Messer *et al.* (1995) report a similar finding, a mean T_4-RIA of 21.42 ± 3.46 nmol/liter in 12 adult horses.

c. Thyroxine by Enzyme-Labeled Immunoassay

An important advance in hormone assay is the development of an enzyme-labeled immunoassay (EIA) test comparable in every way to radioimmunoassay except that the labeling is by an enzyme rather than radioiodine. This method has some obvious advantages in that there is no need to use radioactivity and the enzyme can be assayed in any laboratory. One system labels T_4 with malate dehydrogenase (MD), which, in competition with unlabeled T_4, binds to antibody. This method has the acronym EMIT, for enzyme multiplied immunosorbent test.[1] This method has another advantage in that the labeled and unlabeled fractions need not be separated. The MD is inactive when bound to T_4; when it binds to the immunoglobulin, it is activated. The activity of malate dehydrogenase is assayed by standard enzyme methodology, and the T_4 is read from a standard curve as in a radioimmunoassay.

Another system uses two separate recombinant fragments of the enzyme β-galactosidase (Horn *et al.*,

Goat, miniature	4 (2–5)	Ragan *et al.* (1966)

[a] Values are means with their standard deviations, if available. Ranges are given in parentheses.

1991). The individual fragments, enzyme donor (ED) and enzyme acceptor (EA), are inactive, but when they recombine, they form the active enzyme. Thyroxine is bound to ED. In the presence of thyroxine antibody, the thyroxine–ED–antibody complex inhibits recombination with EA and no active β-galactosidase is formed. When sample thyroxine and a standard amount of thyroxine–ED are mixed, they compete for a standard amount of antibodies. Thus, unbound thyroxine–ED accumulates in direct proportion to the amount of sample thyroxine. The unbound thyroxine–ED is free to bind with EA to form the active β-galactosidase. In this case, enzyme activity is directly proportional to the amount of thyroxine. This method had a very high correlation coefficient compared to that of an RIA (r = 0.969), an EIA (r = 0.966), and a fluorescence polarization immunoassay (FPIA, r = 0.939).

Another variation of the nonisotopic immunoassay is the fluorescence immunoassay, in which a fluorochrome is tagged to the T_4. The T_4 concentration is inversely proportional to the fluorescence, as in the RIA. This is also a very sensitive test, but it requires a sensitive spectrofluorometer for the assay.

Enzyme immunoassays have not replaced radioimmunoassays for hormones, but the principle is now widely used for antigen or antibody assays using horseradish peroxidase (HRP) as the enzyme label. The procedure is popularly known as the enzyme-labeled immunoadsorbent assay, or by its acronym, ELISA. This procedure has been adapted for T_4 by labeling T_4 with HRP, then coupling the HRP to a dye that indicates enzyme activity and hence T_4 concentration.

d. Triiodothyronine by Radioimmunoassay

Triiodothyronine is assayed by radioimmunoassay (T_3-RIA), and reference values in animals are given in Table 21.6. In the dog, the mean normal T_3-RIA is 107 ± 18 ng/dl (1.6 ± 0.3 nmol/liter) with an observed range of 82–138 ng/dl (1.26–2.12 nmol/liter) (Kaneko, 1980). It closely parallels T_4-RIA in the dog, so that the simultaneous determination of T_4-RIA and T_3-RIA will increase the diagnostic accuracy of either one alone. In cats, T_3-RIA is less widely used than T_4-RIA. The reference range for cats is 15–50 ng/dl (0.23–0.77 nmol/liter). In the horse, Messer *et al.* (1995) report a mean T_3-RIA of 0.85 ± 0.52 nmol/liter.

3. *"Free" Thyroxine and "Free" Triiodothyronine*

"Free" thyroxine (fT_4) is the unbound fraction of the total circulating T_4, and its concentration is controlled by the equilibrium between TBG and TBG-T_4 (Section III). Equilibrium dialysis or ultrafiltration are the best methods for determining the free hormones, but they are too labor intensive for use in most clinical

TABLE 21.6 Serum Thyroxine and Triiodothyronine Concentrations in Animals[a]

Species	T_4 CPB (μg/dl)	T_4 RIA (μg/dl)	T_3 RIA (ng/dl)	Reference
Dog	0.3–2.3 (1.3 ± 0.5)			Kaneko (1980)
		0.6–3.6 (2.3 ± 0.8)		Kaneko *et al.* (1978)
		0.74–4.1 (2.48 ± 0.52)	45–175 (94 ± 24)	Belshaw and Rijnberk (1979)
			82–138 (107 ± 18)	Kaneko (1980)
	1.13–4.71 (3.1 ± 1.1)			Kallfelz (1973)
		1.4–3.6	45.4–117.5	Larsson (1988)
Cat	0.1–2.5 (0.1 ± 0.5)			Kaneko (1980)
Male	1.0–3.6 (1.7 ± 0.5)			Bigler (1976)
Female	0.8–3.7 (2.1 ± 0.6)			Bigler (1976)
	(0.95 ± 0.5)			Ling *et al.* (1974)
		0.8–3.8 (2.1 ± 0.1)	15–104 (52.3 ± 1.8)	Peterson *et al.* (1983)
Horse	0.9–2.8 (1.9)			Kaneko (1980)
	1.46–3.38 (2.57 ± 0.71)			Kallfelz and Lowe (1970)
	(2.70)			Thomas and Adams (1978) Irvine and Evans (1975)
		(1.55 ± 0.27)	(55.34 ± 33.85)	Messer *et al.* (1995)
Foal		2.0–3.3 (2.67 ± 0.50)	110–130 (117 ± 12)	Osame and Ichijo (1994)
Weanling		2.1–2.8	48–62	Glade and Luba (1987)
Cow	4.2–8.6 (6.3 ± 1.0)			McCrady *et al.* (1973)
	(5.10 ± 1.30)			Kallfelz and Erali (1973)
Pig	(2.10 ± 0.42)			Kallfelz and Erali (1973)
Goat	(5.25 ± 2.08)			Kallfelz and Erali (1973)
Sheep	(6.05 ± 1.64)			Kallfelz and Erali (1973)
Monkey (*Macaca mulata*)		(4.1 ± 0.6)	(160 ± 34)	Belchetz *et al.* (1978)
Baboon		(9.9 ± 2.2)	(121 ± 18)	Maul *et al.* (1982)

[a] Observed ranges; means ± SD in parentheses.

laboratories. An equilibrium dialysis method for free thyroxine has recently become commercially available. Other methods for free thyroid hormone assay have been reviewed by Wilke (1986). Labeled thyroxine-analog methods of determining free T_4 are inaccurate and should not be used (Alexander, 1986). Free T_4 as determined by RIA (fT_4-RIA), however, is accurate and ought to be more widely used in conjunction with the T_4-RIA and T_3-RIA.

The fT_4 concentration for dogs is 0.52–2.7 ng/dl (6.7–34.7 pmol/liter) (Larsson, 1988) and for the beagle dog is 3.53 ± 0.34 ng/dl (45.4 ± 4.4 pmol/liter) (Michaelson, 1969). Eckersall and Williams (1983) found the total T_4-RIA by a commercial kit for humans to be inaccurate, but the fT_4-RIA was highly accurate and readily discriminated hypothyroid dogs. Larsson (1988) found that the fT_4 and the serum cholesterol were the best combination of initial screening tests to detect hypothyroid dogs. On the other hand, in the hyperthyroid cat, Hays *et al.* (1988) found no differences in dialyzable T_4 from the normal. They infer that the total T_4 is sufficient for diagnosis and that the free hormone is not needed in the cat. In the horse, Messer *et al.* (1995) report a mean fT_4-RIA of 14.0 ± 1.16 pmol/liter.

The fT_3-RIA parallels fT_4-RIA in its binding characteristics. Since fT_3 is the physiologically active form of the hormone, it is potentially the single most reliable

test of thyroid function. In the horse, Messer *et al.* (1995) report a mean fT_3-RIA of 0.89 ± 0.53 pmol/liter.

4. *Triiodothyronine Uptake*

The uptake of radiolabeled triiodothyronine by red cells (T_3 uptake) *in vitro* as a test of thyroid function was reported by Hamolsky *et al.* (1959). This test measured the partitioning of radioiodine-labeled T_3 between TBG and a secondary binding agent, in this case, RBC. Serum TBG is the primary binding agent, and it binds T_4 more firmly than it does T_3 (Section VI). Therefore when ^{131}I-T_3 is added to the serum, it will bind first to any unbound receptor sites on the TBG. When RBC or another secondary binding agent such as resin or charcoal is added, excess unbound labeled T_3 will bind to the secondary agent. The radioactivity of the RBC (or resin) will thus be inversely proportional to the amount of unbound TBG. The T_3-uptake test is therefore an indirect measure of the amount of unbound TBG. The uptake is low in hypothyroidism where the low T_4 leaves excess unbound binding sites on the TBG and high in hyperthyroidism where there are few binding sites on the TBG. The T_3 uptake should not be confused with the T_3-RIA.

There are many modifications to the test, basically in the choice of secondary binding agents. Pain and Oldfield (1969) surveyed six T3-uptake methods including the red-cell uptake, resin uptake, resin-sponge uptake, Sephadex, charcoal–hemoglobin, and the thyroid binding index. They concluded that the original RBC T_3 uptake gave overall satisfactory results, but only two of the newer methods, Sephadex and charcoal, gave satisfactory results for both hyper- and hypothyroidism. On the basis of ease of performance, the T_3 uptake by charcoal–hemoglobin (Irvine and Standeven, 1968) is the test of choice.

The T_3-uptake test is widely used in humans for the indirect assay of unbound TBG, from which the free thyroxine index (FTI) is calculated. In animals, however, the results are so poorly correlated with thyroid activity as to be virtually useless. Wide variations in the hormone binding proteins and their degree of binding account for these inaccuracies (Table 21.1).

5. *Thyroxine Uptake*

This assay is a modification of the β-galactosidase EIA described in Section VIII.B. (Horn *et al.*, 1991). In this case, no antibodies are added to the system, and the thyroxine enzyme donor fragment is free to bind with TBG in the serum. The remaining thyroxine enzyme donor fragment binds to the thyroxine acceptor fragment to generate the active enzyme. Thus, the activity of β-galactosidase is inversely proportional to the amount of TBG in the serum.

6. *Free Thyroxine Index*

The total T_4 represents the thyroxine bound to TBG (T_4–TBG) and is readily measured as the T_4-RIA. The T_3 uptake or the T_4 uptake as described earlier represents the unbound TBG and, as indicated previously, is also easily measured. Referring to the equilibrium equation (21.2), it can be readily seen that

$$fT_4 = k\frac{T_4\text{–TBG}}{\text{TBG}} = T_4 \times T_3 \text{ uptake (or } T_4 \text{ uptake)} = \text{FTI.}$$

The product, $T_4 \times T_3$ uptake, is the free thyroxine index (FTI) and is the calculated index of the amount of fTT_4. The FTI is still widely used in humans, where it correlates well with thyroid disease (Wilke and Eastment, 1986), but is invalid for use in animals. The free hormones should be determined in animals using direct fT_3 and fT_4 immunoassays.

7. *Thyroid-Binding Globulin, Thyroglobulin, and Thyroid Autoantibodies*

Thyroid-binding globulin (TBG) and thyroglobulin (Tg) or colloid are measured by RIA. The standard technique for thyroglobulin antibodies (TgAb) is hemagglutination, but it is being supplanted by the ELISA (Voller *et al.*, 1980) as a superior method (Roman *et al.*, 1984). Haines *et al.* (1984), using ELISA, detected TgAb in a high percentage of dogs with hypothyroidism, dogs with other endocrine diseases, and dogs that were closely related to the TgAb-positive dogs, but found a low percentage in healthy unrelated dogs. They conclude that thyroid autoimmunity is strongly genetically influenced in the dog.

8. *Thyroid-Stimulating Hormone*

Serum TSH is measured by radioimmunoassay (TSH-RIA) or by the two-site immunoradiometric assay (IRMA) in humans. The cross reactivity of the anti-human-TSH antibody for dog TSH is insufficient for it to be used as an accurate diagnostic test in the dog. Using the human TSH-RIA assay method for the dog, the normal values were 5.9 ± 4.1 μU/ml (Kaneko *et al.*, 1975), and 3.50 ± 1.67 μU/ml (Larsson, 1981). The human assay method used in monkeys (*M. mulatta*) gave 0.2–2.6 μU/ml (1.53 μU/ml) (Belchetz *et al.*, 1978). A TSH-RIA using an anti-canine TSH has become commercially available specifically for use in dogs.

9. Thyrotrophin-Releasing Factor

As with TSH, no reliable thyrotrophin-releasing factor (TRF) assay has been developed for use in domestic animals. Purified TRH, however, is available and is used in the TRF response test.

C. Radionuclide Uptake Tests of Thyroid Function

1. Radioiodine Uptake

Radioiodine is taken up by the thyroid gland in exactly the same manner as the nonradioactive isotope, and its uptake remains as one of the most definitive tests for thyroid function. With the development of direct hormone assays, radioiodine uptake tests are now largely used in nuclear medicine for imaging and localizing of active thyroid nodules and "hot spots" and for estimating therapeutic doses of radioiodine. Radioactive ^{99m}Tc-pertechnetate is also taken up and is now widely used for imaging.

The normal uptake at 72 hours is 10–40% in the dog (Kaneko *et al.*, 1959), compared to a range of 7–37% reported by Lombardi *et al.* (1962). The normal uptake at 24 hours is 7–35% and at 48 hours is 8–38%. The correlation of the 72-hour uptake with thyroid function has made it a reliable diagnostic test of thyroid disease in dogs. The normal uptake in cats at 24 hours is 9.2% (Peterson *et al.*, 1983) whereas the maximal uptake is about 33% at 3–5 days postinjection (Broome *et al.*, 1988). Iodine-containing compounds, including exogenous thyroid hormone, also interfere with thyroid uptake (Table 21.4), so the uptake test should be deferred for at least 2 weeks if iodine compounds have been administered.

2. The Conversion Ratio

The conversion ratio (CR) gives the fraction of the injected radioiodine that has been converted to thyroxine during the radioiodine uptake test. The serum proteins with their bound radioactive hormones are separated from non-protein-bound serum iodides using a resin and then counted for radioactivity (Scott and Reilly, 1954; Zieve *et al.*, 1956). The result, when expressed as the ratio of protein-bound radioactivity to total plasma radioactivity, is the conversion ratio. Therefore, it reflects the amount of labeled thyroid hormone that was formed by the gland from the injected radioiodine. A CR of 2–6% has been reported (Lombardi *et al.*, 1962) for normal dogs. This test is useful in the diagnosis of hyperthyroidism in humans, but its value in animals is unknown.

3. Thyroxine Secretion Rate

The output of thyroxine by the thyroid gland is also a direct indicator of thyroid function and can be determined by several methods. Most data on thyroxine secretion rate (TSR) in domestic animals have been obtained by a technique based on the amount of exogenous L-thyroxine necessary to inhibit the release of radioactivity by the thyroid, that is, by thyroxine suppression. Another method has been to calculate the TSR from the fractional turnover rate of injected radiothyroxine and the T_4 or PBI. The TSR has been determined in many domestic animals, including the cow (Pipes *et al.*, 1963), sheep (Henneman *et al.*, 1955), goat (Flamboe and Reineke, 1959), pig (Sorenson, 1962), horse (Irvine, 1967), and dog (Kallfelz, 1973). A wide variation in the reported values is probably the result of differences in technique and conditions of study. The TSR is also affected by age, lactation, diet, season, and training in the case of horses. In animals, the TSR appears to vary from a low of about 0.108 mg (0.139 μmol)/100 kg/day in the horse to a high of about 0.46 mg (0.59 μmol)/kg/day in the cow or 0.49 mg (0.63 μmol)/kg/day for the dog.

D. Trophic Hormone Response Tests

1. Thyroid-Stimulating Hormone Response

The response of the thyroid to TSH injection is a means of evaluating thyroid activity, as well as of differentiating a primary hypothyroidism due to a thyroid lesion from a hypothyroidism secondary to a pituitary lesion. The responsiveness of the thyroid to the TSH injection is evaluated by an increase (or failure to increase) as evidence of thyroid activity (or lack of activity). A variety of dosages of TSH have been used, as well as a variety of procedures, to detect this increase in activity, among them the radioiodine uptake test (Kaneko *et al.*, 1959), the radioiodine uptake curve (Siegel and Belshaw, 1968), the PBI (Siegel and Belshaw, 1968), the T_4-CPB (Hoge *et al.*, 1974), the T_4-RIA (Kaneko *et al.*, 1978), and, more recently, imaging. In the general procedure, thyroidal activity (or lack of activity) is first established by the measurement of serum hormones, and this is followed by the TSH response test. In a primary hypothyroidism where the lesion is localized in the thyroid, there is no response to the exogenous TSH. If the hypothyroidism is due to a pituitary hypofunction with a deficiency of TSH, or a hypothalamic lesion with a lack of TRH, the thyroid will respond to the exogenous TSH, as shown by a significant increase in serum hormone concentrations. Glucocorticoids and phenylbutazone are also well known to depress thyroid activity, so the TSH response

test is useful in detecting low hormone concentrations due to drugs or in Cushing's disease.

A useful procedure for the TSH response test is first to obtain a serum sample for baseline T_4 or T_3, then to inject 10 IU of bovine TSH intravenously. Oliver and Waldrop (1983) and Held and Oliver (1984) recommend a minimum of 5 IU for the dog and horse, respectively. After 4 hours, a second serum sample is taken and hormone again measured. The normal response in dogs is a doubling or more of the hormone above baseline level. In the primary hypothyroid individual, there a virtual absence of a response. In the drug-induced or Cushing's patient with low hormone there will be a response to well within the normal hormone concentrations. The secondary (TSH) or tertiary (TRH) hypothyroid patient will have a response similar to the drug-induced or Cushing's patient. In cats, Peterson *et al.* (1983) found T_4 to increase almost threefold above the baseline at 4 hours post-TSH. In the baboon, the TSH response test had peaks of more than double the baseline at 8 and 12 hours for T_3 and T_4, respectively (Maul *et al.*, 1982). In horses, Messer *et al.* (1995), at 6 hours after TSH administration, found significant increases in T_4 , T_3, and fT_4, but not significantly in fT_3. They suggest that the TSH response test may not be as valuable for thyroid disease diagnostics in the horse as it is in the dog and cat.

2. *Thyrotrophin-Releasing Factor Response*

The response to thyrotrophin-releasing factor (TRF) as developed for humans has been used in dogs and cats. In the dog, there was no T_4-RIA, T_3-RIA, or T_3 uptake response to exogenous human TRF (Kraft and Gerbig, 1977). TSH could not be measured, but presumably the human TRF did not stimulate TSH release by the pituitary. Larsson (1981) measured TSH after giving TRH, and, although a significant difference was found, the overlap was too great to be of diagnostic value. Lothrop *et al.* (1984), however, found a doubling of T_4-RIA at 6 hours postinjection in dogs and cats. Therefore, the TRF response test must be further evaluated in animals. Some (Jones, 1993) recommend the TRH response test in cats in preference to the TSH test, particularly in hyperthyroid cats. At 4 hours after the IV administration of TRH, normal cats have a greater than 50% increase in their serum T_4, whereas hyperthyroid cats have a minimal or no increase.

3. *Triiodothyronine Suppression Test*

In cats, T_3 has an inhibitory effect on the secretion of TSH and injection of T_3 is followed by a fall in serum T_4 levels. In hyperthyroid cats, because of their autonomous production of T_4, administered T_3 will have no suppressing effect on their high levels of serum T_4. For the test, after a pretest serum sample is taken, 25 μg T_3 is given t.i.d. for 2 days. Four hours after the last dose, a serum sample for T_4 is taken. In hyperthyroid cats, there is little or no fall in serum T_4, in contrast to a greater than 50% suppression in normal cats (Jones, 1993).

XI. DISEASES OF THE THYROID

Thyroid disease has been most extensively studied and reviewed in the dog (Belshaw, 1983). In the cat, the incidence of hyperthyroidism has increased greatly in the last decade and is the most frequently encountered endocrinopathy in this species (Peterson *et al.*, 1994). In the horse, Lowe *et al.* (1974) described the clinical effects of experimental thyroidectomy in mares and stallions, and hypothyroidism remains as a frequent consideration in breeding problems. In ruminants, a congenital goiter has been described in Merino sheep and in Afrikander cattle. Local enlargements or nodules are also seen in all animals; these are usually benign tumors.

A. Goiter

Goiter may be defined as an enlargement of the thyroid gland that is not due to inflammation or malignancy. There are two general types of goiters: (1) nontoxic goiters, which produce either normal amounts of hormone (simple goiter) or below-normal amounts of hormone (hypothyroid), and (2) toxic goiters, which produce excess amounts of hormone (hypertrophy). Furthermore, a defect or deficiency at any trophic step can also result in thyroid disease. Iodine deficiency (endemic goiter) is well known in iodine-deficient areas of the world. Goitrogenic materials, either natural substances or drugs, induce goiters by their blocking effects on steps in the hormonogenic pathways. There are also rare types of familial goiters associated with defects in hormone synthesis (dyshormonogenesis) in humans (Stanbury and Dumont, 1983) and that find their counterparts in Merino sheep (Rac *et al.*, 1968) and in Afrikander cattle (Van Zyl *et al.*, 1965). Falconer (1987) reviewed the congenital goiter in the Merino sheep in which the fundamental defect is a failure of thyroglobulin synthesis. The goiter is inherited as an autosomal recessive and is frequently seen in Australia. The similar congenital goiter in the Afrikander cattle (Ricketts *et al.*, 1985) is also inherited as an autosomal recessive. These cattle have a thyroglobulin synthesis defect involving defective gene splicing of the thyroglobulin gene transcript. In Bongo antelopes, goiter

seen in a group of adults was associated with synthesis of an abnormal 19S thyroglobulin (Schiller *et al.*, 1995). The goitrous antelopes were hormonally euthyroid, but had other manifestations of hypothyroidism such as reproductive difficulties. Iodine-deficiency goiter observed in seven thoroughbred foals in the northern island of Hokkaido, Japan (Osame and Ichijo, 1994), was attributed to iodine deficiency in the soil of the region. All foals had readily detectable thyroid enlargements, and four of the seven had clinical signs of thyroid deficiency as well. The goiters receded after iodine supplementation of the feed.

Simple goiter is a compensatory increase in thyroid glandular mass (hyperplasia and hypertrophy) so that the gland maximizes iodine uptake and is able to synthesize and release a normal amount of T_4. At this time, the patient is physiologically normal, but the gland can become quite large. Ultimately, in iodine deficiency, the goitrous gland fails to synthesize sufficient T_4 and hypothyroidism occurs.

B. Hypothyroidism

Hypothyroidism may be the result of a variety of causative factors. Thyroiditis, with similarities to Hashimoto's thyroiditis in humans, has been reported in about 12% of beagle dogs (Beierwaltes and Nishiyama, 1968). Antithyroglobulin antibodies were found in these dogs. In the adult dog, follicular atrophy is probably the most common cause of hypothyroidism (Clark and Meier, 1958). Finally, hypothyroidism may be secondary to a pituitary insufficiency.

The hypothyroid dog is typically obese, lethargic, has myxedema, a dry skin, and a sparse hair coat. Hypothyroidism is therefore an important differential in the diagnoses of dermatoses. The requirement of T_4 for normal reproduction, growth, and development is well known, so hypothyroidism is an important differential in reproductive failures. Experimentally thyroidectomized mares and stallions failed to grow, were lethargic, had coarse, dull hair coats and increased serum cholesterol (Lowe *et al.*, 1974). Hypothyroid horses tend toward obesity and crestiness.

In the initial screen, an increased cholesterol is often the first clue to hypothyroidism. Larsson (1988) concluded that fT_4 and cholesterol are the best indicators of canine hypothyroidism. Definitive laboratory findings in hypothyroidism of animals are a low T_4 and/or T_3 with little or no response to the TSH response test. Therefore, the recommended algorithm is to first obtain the total T_4 and T_3 (and the fT_4 and fT_3 if available). If the results are equivocal, this is followed by the TSH response test. Other definitive studies such as the ^{131}I uptake and the ^{99m}Tc-pertechnetate scans can be used in specialized hospital settings for the identification of isolated thyroid nodules.

In human thyroid disease diagnostics, TSH is now considered to be the single best test of thyroid status (Beckett, 1994) and to be more cost-effective than T_4. TSH can now be readily assayed with a functional sensitivity of 0.01–0.02 mU/liter. Because of this sensitivity, human thyroidologists now recommend that TSH be used as the initial test and that T_4 or preferably fT_4 be used only on a selected basis. In the event that similar degrees of accuracy and sensitivity evolve for dog TSH, this may well become the definitive test for hypothyroidism in the dog.

C. Hyperthyroidism

Hyperthyroidism or toxic goiter is characterized by weight loss, hyperactivity, a voracious appetite, and increased thyroid hormones. Hyperthyroidism is rarely seen in dogs (Meier and Clark, 1958), but in the cat, in the past decade, the high incidence of hyperthyroidism has been recognized as a common endocrinopathy (Holzworth *et al.*, 1980; Peterson *et al.*, 1983). The most common form of hyperthyroidism in the cat is a functional thyroid adenoma.

Increases in T_4 and/or T_3 are virtually pathognomonic signs of hyperthyroidism in the cat. In 131 cases, T_4 was increased to between 4.0–54.1 μg/dl (51.5–696.3 nmol/liter) in all cats, and T_3 was between 54–1000 ng/dl (0.83–15.36 nmol/liter) in 97% of the cats (Peterson *et al.*, 1983). Hays *et al.* (1988) suggest that T_4 and T_3 are sufficient for diagnosis and that the free hormones are not needed for the diagnosis. In the 131 cases, the mean 24-hour ^{131}I uptake was 39.1%, compared to 9.2% in normal cats. There was no increment of response above the baseline value to the TSH response test in these cats, as would be expected for a tumor. ^{99m}Tc-pertechnetate scans demonstrated increased uptake and size in one or both lobes of the thyroid.

The TRH response test is equivocal for use in the hyperthyroid cat, but Jones (1993) found little or no increase in serum T_4 in these cases. The T_3-suppression test similarly had no decrease in serum T_4 in hyperthyroid cats and is currently considered to be the most useful of the function tests in hyperthyroid cats.

D. Tumors of the Thyroid Gland

Except for the dog and cat, tumors of the thyroid are rare in animals (Lucke, 1964). In the dog, Brodey and Kelly (1968) found no evidence of clinical thyroid disease associated with thyroid tumors. Loar (1986), however, found that about 20% of thyroid tumors were

functional. Belshaw (1983), using scintigraphic imaging in dogs, identified functional thyroid tumors and their metastases. Interestingly, a majority of thyroid carcinomas in dogs were associated with high serum thyroglobulin (Tg), but there was no direct correlation with T_4 (Verschueren and Gosling, 1992).

In feline hyperthyroidism, a functional thyroid adenoma is the most common finding.

CHAPTER

22

Clinical Reproductive Endocrinology

LARS-ERIK EDQVIST AND MATS FORSBERG

I. INTRODUCTION

Clinical reproductive endocrinology includes the study of diseases of the endocrine glands involved in reproduction and their secretory products, the reproductive hormones. To obtain a satisfactory understanding of the complex endocrinological events that occur during normal and abnormal reproductive function, quantification of specific hormones is necessary. Initially, biological assay systems that measured the effect of a hormone on its target tissue were used; weight-gain change was mainly used as the measure of hormone concentration. These assays were relatively imprecise, time consuming, and expensive. Later they were replaced by chemical determinations for steroid hormones. These assay systems usually required large volumes (often 1 liter) of plasma or serum, which made serial blood sampling of individual animals impossible. Some steroid hormone patterns were studied via urine analysis in 24-hour urine aliquot. Collection of such urine aliquots from domestic species was difficult and not practical under field conditions.

Major progress in hormone analytical techniques occurred as the result of the development of immunoassay and related systems. The first of the assays, radioimmunoassay, was developed in 1959 (Berson and Yalow, 1959) with the competitive protein binding assay following a few years later (Murphy, 1964). Nonradiometric assays, such as enzyme immunoassay, were developed in the 1970s (Engvall and Perlmann, 1971; van Weemen and Schuurs, 1971). These assay systems are sensitive, specific, and relatively inexpensive, and they require small amounts of assay material. They have been of special value for studying endocrinological reproductive function in domestic animals, in that they have made possible the study of dynamic endocrine changes through the assay of serial blood samples from the same animal. The immunoassay systems have also been useful as diagnostic aids for the identification

and elucidation of clinical reproductive problems. In clinical practice, these methods are important from both a diagnostic and a therapy-monitoring point of view.

Because this book deals with clinical biochemistry in domestic animals, the main emphasis of the chapter is on the determination of hormones and the use of the data as diagnostic aids. General reproductive endocrinology in domestic species is broadly covered. Readers specifically interested in this subject are referred to specialized books dealing with this matter.

A. Definition of Hormones

The best-understood humoral control system in the body is the endocrine system. This system uses specific messengers, termed hormones, to regulate important body functions. By the classical definition, hormones are chemical substances that are synthesized and secreted by ductless endocrine glands in minute quantities directly into the blood vascular system and are transported to a remote target organ where they regulate the rates of specific biochemical processes. The classic endocrine glands include the pituitary, thyroid, parathyroid, adrenal, pancreas, ovary, testis, placenta, and pineal glands.

In the case of reproduction, the pituitary and pineal glands, gonads, and placenta play a primary role in controlling the system. Other endocrine glands such as the adrenal and thyroid glands also have some influence on reproductive function. Other organs such as the uterus and the hypothalamus, although they may not fulfill the strict definition of endocrine glands, can synthesize and secrete hormones that have a profound influence on reproductive function.

B. Chemical Classes of Reproductive Hormones

1. Peptide and Protein Hormones

a. Releasing Hormones

Several types of hormones are involved in the regulation of reproduction. Releasing hormones are peptide hormones that are produced within the hypothalamus and transferred via the hypothalamo–hypophyseal portal veins to the adenohypophysis, where they regulate the synthesis and/or release of adenohypophyseal hormones. Gonadotropin-releasing hormone (GnRH), a decapeptide with the sequence pGlu–His–Trp–Ser–Tyr–Gly–Leu–Arg–Pro–Gly–NH_2, regulates the release of two important reproductive hormones, namely luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Thyrotropin-releasing hormone, a tripeptide (pGlu–His–Pro–NH_2) that regulates the synthesis and release of thyroid-stimulating hormone (TSH), also causes the release of prolactin in several species.

b. Hypophyseal Hormones

Luteinizing hormone and FSH are glycoproteins containing 13–25% carbohydrate. The molecular weight of LH in domestic animals (bovine, ovine, porcine, equine) is about 30,000. Ovine and equine FSH have molecular weights of about 32,000. Prolactin is a protein with a molecular weight of approximately 23,000 (bovine, ovine, porcine).

The cells of the adenohypophysis can be divided into basophils (affinity for basic stains) and acidophils (affinity for acid stains). Luteinizing hormone and FSH are produced within basophilic cells; it has been demonstrated that LH and FSH can be present within the same cell. Prolactin, on the other hand, has been localized in acidophilic cells. As pointed out previously, the releasing hormones are important regulators of the synthesis and/or release of these hormones from the adenohypophysis.

c. Neurohypophyseal Hormones

The posterior pituitary is responsible for storage and release of oxytocin, an important reproductive hormone, and antidiuretic hormone (vasopressin). These two hormones are synthesized primarily in the regions of the paraventricular and supraoptic nuclei of the hypothalamus. The hormones are transported to the posterior pituitary by axoplasmic fluid. Release of these hormones occurs as a result of stimulation of the nerve cell bodies in the nuclei. Oxytocin is an octapeptide with a molecular weight of 1000.

d. Placental Gonadotropins

A gonadotropin called pregnant mare serum gonadotropin (PMSG) is produced by mares during early pregnancy (days 40–140) by fetal trophoblastic cells of the chorionic girdle, which attach to, invade, and phagocytose the maternal epithelium and become embedded within the uterus as specialized endometrial cups. This process begins on day 36 of pregnancy. The hormone has recently been renamed equine chorionic gonadotropin (eCG) due to its close relationship with human chorionic gonadotropin (hCG) (Farmer and Papkoff, 1979). No specific placental gonadotropins have been demonstrated in other domestic species.

e. Subunits

Luteinizing hormone and FSH, as well as TSH, consist of two nonidentical subunits designated α and β. Chemical and biological studies have indicated that the

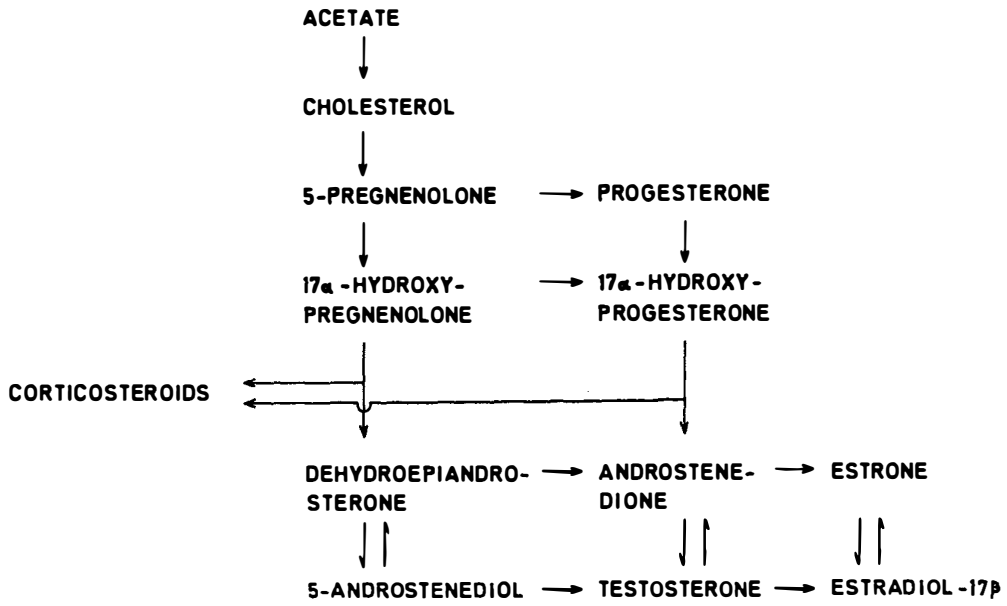

FIGURE 22.1 Pathway for the synthesis of biologically active steroids from acetate. The steroids secreted from the gonads and the adrenal are formed from acetate and cholesterol.

α-subunit is identical for these glycoprotein hormones within a species, whereas the β-subunit, unique for each hormone within a species, determines the biological activity. Subunits, by themselves, possess little or no biological activity. Individual subunits are probably not released into the circulatory system under normal physiological conditions.

2. *Steroid Hormones*

Steroid hormones are derived from a common precursor molecule, cholesterol, via the metabolic pathway schematically outlined in Fig. 22.1. More than 1,500 biologically active steroids have been isolated from biological material or have been produced synthetically. The molecular weight of steroid hormones is low, usually below 500 (Table 22.1). Examples of steroids that play an important role in reproductive processes are estrogens, androgens, and progestogens, with the main source being the gonads. The structures of the most important sex steroids are given in Fig. 22.2. The most common steroid hormones are usually designated by a trivial name, such as estradiol, testosterone, or progesterone. The International Union of Pure and Applied Chemistry (IUPAC) has recommended systematic names for steroid hormones. These

TABLE 22.1 Nomenclature[a] and Molecular Weights of Some Biologically Important Steroids and Prostaglandins

Trivial name	Systematic name	Molecular weight
Androstenedione	4-Androstene-3,17-dione	286
Cortisol	11β,17α,21-Trihydroxy-4-pregnene-3,20-dione	363
17β-Estradiol	1,3,5(10)-Estratriene-3,17β-diol	272
Estrone	3-Hydroxy-1,3,5(10)-estratrien-17-one	270
17α-Hydroxyprogesterone	17α-Hydroxy-4-pregnene-3,20-dione	331
Pregnenolone	3β-Hydroxy-5-pregnen-20-one	317
Progesterone	4-Pregnene-3,20-dione	315
Testosterone	17β-Hydroxy-4-androsten-3-one	288
$PGF_{2\alpha}$	9α,11α,15-Trihydroxyprosta-5,13-dienoic acid	354
15-Keto-13,14-dihydro-$PGF_{2\alpha}$	9α,11α-Dihydroxy-15-ketoprost-5-enoic acid	354

[a] Revised Tentative Rules for Nomenclature of Steroids (1968). *Biochim. Biophys. Acta* **164,** 453.

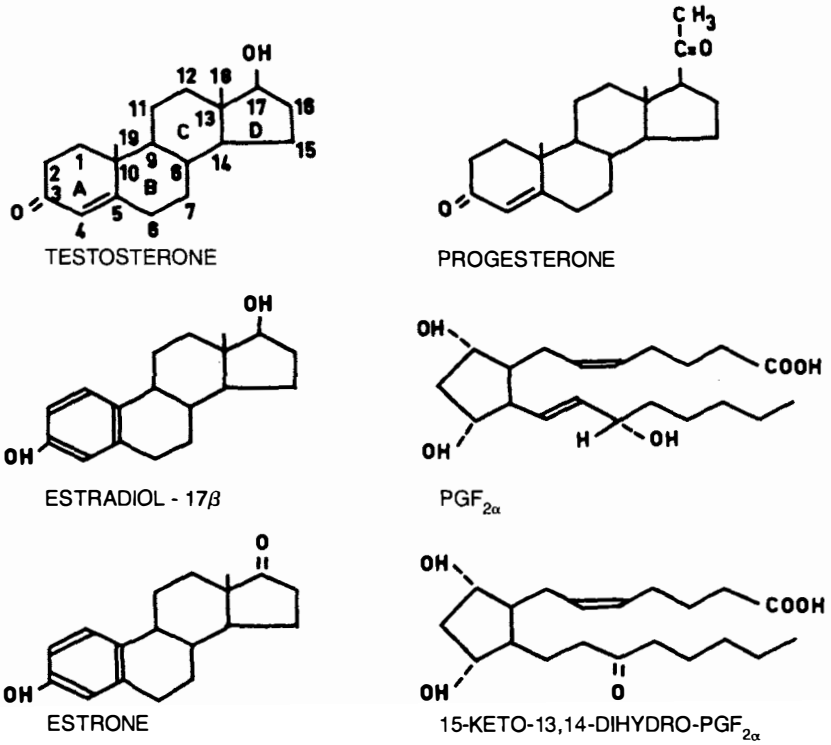

FIGURE 22.2 The number sequence for the carbon atoms of the steroid skeleton and lettering sequence for the four rings are shown for testosterone. The structures of three other important sex steroid hormones, estrone, estradiol-17β, and progesterone, as well as the structures of prostaglandin $F_{2\alpha}$ and its blood plasma metabolite 15-keto-13,14-dihydroprostaglandin $F_{2\alpha}$, are also depicted.

systematic names describe the chemical and steroisometric characteristics of the particular steroid hormone (Table 22.1).

3. *Prostaglandins*

Prostaglandins constitute a group of 20-carbon unsaturated fatty acids with molecular weights usually between 300 and 400 (Table 22.1). Prostaglandins are not hormones in the strictest sense, and the expressions "parahormones" or "local hormones" have been used to describe these substances. This is because prostaglandins are not secreted from any particular gland, and the biological half-life of prostaglandins is usually extremely short, allowing, in most cases, only a local action. Several different prostaglandins are found in a number of types of mammalian tissues. One prostaglandin released from the uterus, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), plays an important role in regulating reproductive cycles in domestic species through the control of luteal activity in nonpregnant animals and the initiation of delivery in pregnant animals. The structures of prostaglandin $F_{2\alpha}$ and its main metabolite, 15-keto-13,14-dihydroprostaglandin $F_{2\alpha}$, are given in Fig. 22.2.

C. Hormone Receptors

Steroid hormones are fat soluble, so they are able to enter all cells of the body because the lipid cellular boundaries present no barrier to the steroid. The question thus arises as to how specific actions occur in this physiological situation. Steroid hormone concentrations in plasma are very low compared to those of many compounds, including their important precursor, cholesterol. For example, plasma estrogens in nonpregnant domestic animals range from as low as 10 pmol/liter to as high as 150 pmol/liter. In this situation, most cells within the body have very low concentrations of estrogen. The specificity of tissue response occurs because cells of tissues that have need of estrogen stimulation should have receptors that enable those particular cells to concentrate the hormone within the cell and, more importantly, to elicit particular cellular responses. Hence the important generalization that specific tissue responses require specific receptors to be present within the cell, in this case, for a particular steroid hormone.

Binding of a hormone to a receptor in a target cell can be considered to be the primary event in the action of that hormone. Such a hormone–receptor interaction

will cause a measurable and distinct biological response for each hormone. Receptors are defined by the criteria of having a limited binding capacity (receptors are saturable, which limits the number of hormone molecules that can enter a target cell), of binding specific hormones (e.g., estrogen receptors are specific for estrogenic compounds), and of creating a biological response upon binding.

Steroid hormones enter cells by passive diffusion and bind to receptors inside the cell. It is assumed that only non-protein-bound or free hormone can enter target cells. The protein-bound steroid is thus virtually biologically inactive, and only the minute quantity of free (non-protein-bound) steroid can enter the cell. The protein binding is, however, reversible, and as free hormone leaves the vascular system into target cells, protein-bound hormone will be released to replace the deficit. On entry, the steroid interacts with its receptor in the target cell. When the steroid interacts with its receptor, a steroid–receptor complex is formed. The hormone–receptor complex is then "activated" and alters gene expression. The target cell responds by increased RNA synthesis with the transcription of specific mRNA that enters cytoplasm and stimulates protein synthesis. The specific effect of steroid hormones on target cells is altered cell function related to a change in the pattern of protein synthesis.

Protein hormones such as LH and FSH do not enter the target cell to exert their effects, but interact with their receptors, which are located on the plasma membranes of the cell. The binding of the hormone to the cell surface receptor activates one or more second messengers, such as cyclic AMP (3′,5′-AMP). The second messenger is the intracellular mediator of many actions of LH and FSH in the ovary and the testis. Second messenger is thought to activate another intracellular enzyme, protein kinase, which will influence the transport of cholesterol into the mitochondrion and the conversion of cholesterol to pregnenolone, which is the rate-limiting step in the biosynthetic pathway for the steroids that play a significant role in reproductive processes.

D. Interconversion of Steroids in Target Tissues

The effects of steroid hormones on cells can be accentuated or modulated by the conversion of the entering hormone to another form. For example, many of the tissues that are particularly responsive to androgens have the enzyme 5α-reductase, which converts testosterone to 5α-dihydrotestosterone (5α-DHT). 5α-DHT has a much higher affinity for the androgen receptor within the target cell, which makes 5α-DHT more biologically active than testosterone in terms of its androgenic effects. The androgenic potency of 5α-DHT is twice that of testosterone.

Another important interconversion of steroid hormones is the one resulting from the increase in circulating cortisol concentrations that occurs in the fetal lamb prior to parturition. The elevated fetal cortisol concentrations stimulates 17α-hydroxylase, C17–C20 lyase activity, and probably aromatase activity in the placenta. These enzymes make it possible for progesterone to be converted to estrogens in the placenta. Estrogens then affect the synthesis of prostaglandin $F_{2\alpha}$, which precipitates delivery. The interconversion of progesterone to estrogen is well documented in the sheep and probably occurs in a similar way in the goat and the cow.

E. Synthesis and Clearance of Hormones

The determination of concentrations of hormones in biological fluids, including plasma, urine, saliva, and feces, has been useful in determining the reproductive status of animals. Although there are a number of factors that can influence hormone concentrations, the overriding factors are synthesis and clearance. Of greatest interest is the rate of synthesis of a hormone from a particular endocrine gland, because factors that govern clearance are usually stable; therefore, the concentration of a hormone usually reflects its rate of synthesis or secretion.

The synthesis of steroid hormones of the reproductive system is under the control of gonadotropins that are released in pulsatile fashion. This mechanism has a profound influence on the secretion of testosterone in the male, in that changes in pulsatile rate can occur a number of times a day with increases in pulse rate resulting in greatly increased concentrations of testosterone. For example, in males of many domestic species, testosterone values can vary from 3.5 to 20 nmol/liter within a period of a few hours, with the extremes still representing normal production of testosterone by the testes. The usual judgement as to normalcy is based on an animal having at least the minimal or basal concentration. In the female, estrogen and progesterone synthesis by the ovary is also under the control of a pulsatile mode of gonadotropin secretion. The pulse rate usually remains relatively stable over limited periods of time so that fluctuations in concentration of these hormones are not as acute as for androgens. Thus, gonadotropin pulsatility is not a consideration in interpreting the significance of progesterone and estrogen concentrations in biological fluids.

In the female, synthesis rates for ovarian steroid hormones are obviously related to ovarian function.

Progesterone concentrations, relatively stable during the luteal phase of the estrous cycle, decline rapidly over a 24- to 36-hour period during luteolysis. Estrogen values continually increase during the follicular phase of the cycle, declining with the onset of the gonadotropin preovulatory surge as the granulosa is converted from estrogen to progesterone production. Even though secretion rates can change for both progesterone and estrogen, analysis of these hormones usually provides useful information as to luteal or follicular activity, respectively. If one wishes to use hormone values (in blood, for example) as an indication for secretory activity of an endocrine organ, one other factor must be considered: the conversion of steroid hormones by peripheral tissues. For example, in primates, estrone concentrations are derived mainly from the conversion of ovarian estradiol-17β and adrenal androstenedione by tissues such as the liver.

Steroids are eliminated via conjugation with glucuronic acid and/or sulfates to form inactive mono- or diglucuronides or sulfates. These conjugates are all water soluble, with excretion occurring via urine or bile (feces). Conjugation occurs mainly in the liver, and the conjugates lack steroidal activity. Steroids are also rendered inactive by their metabolism to compounds that have greatly reduced biological activity. In this way, steroids are rapidly cleared from the bloodstream. Clearance is defined as the volume of blood that would be totally cleared of a particular steroid per unit time. Clearance can thus be expressed as liters/minute, and the clearance for most steroid hormones is around 1 liter/minute. In most situations, the clearance rate of steroids is relatively constant, so that blood concentrations are a relatively good measure of fluctuations in production rates.

Placental gonadotropic hormones such as hCG and eCG are produced in high concentrations and have much longer half-lives than the pituitary gonadotropins and prolactin. The latter have half-lives around 10–30 minutes, whereas the corresponding figures for the placental hormones are from 1.5 days for hCG to 6 days for eCG. One exception is equine LH, which has structural similarities to eCG and also has a much longer half-life (days) than LH from other species. The half-lives are increased because the molecules contain a larger carbohydrate moiety than do FSH and LH of most other species.

In the blood, prostaglandins are rapidly metabolized to their respective 15-keto-13,14-dihydro compounds (Fig. 22.2). Primary prostaglandins such as $PGF_{2\alpha}$ have a half-life in the peripheral circulation that is less than 20 seconds, whereas 15-keto-13,14-dihydro-$PGF_{2\alpha}$ has a somewhat longer half-life of about 8 minutes. Ninety percent or more of $PGF_{2\alpha}$ is metabolized during one passage through the lungs. The 15-keto metabolites are biologically inactive and are degraded into short dicarboxylic acids before being excreted into urine. An example of the rapid metabolism of prostaglandins is the fact that more than 90% of a 25-mg intramuscular injection of $PGF_{2\alpha}$ in the cow is excreted in the urine and feces (2:1 ratio) over a 48-hour period (Neff *et al.*, 1981).

II. ASSAY METHODS

The radioimmunoassay technique was originally introduced for the measurement of plasma insulin (Berson and Yalow, 1959), and the enzyme immunoassay techniques for the quantitative determination of immunoglobulin G (Engvall and Perlmann, 1971). The techniques are competitive and utilize the same basic principle, which is based on the ability of nonlabeled hormone to compete with a fixed amount of isotopically or enzymatically labeled hormone for the binding sites on a fixed amount of protein. The nonlabeled hormone reduces the number of free binding sites on the protein, thus decreasing the availability of the binding sites to the labeled hormone. At equilibrium, the free hormone is separated from the protein-bound hormone, and the reaction is quantified by the determination of the amount of labeled hormone that is antibody-bound or free (Fig. 22.3). The degree of inhibition of binding of the labeled hormone to the binding protein is a function of the concentration of nonlabeled hormone present in the solution. As a basis for the quantification, a standard curve is developed with fixed amounts of labeled hormone and binding protein incubated together in the presence of a known and graded concentration of unlabeled hormone (Fig. 22.3).

Certain disadvantages exist to the use of radioisotopes as labels in immunoassays, including the limited shelf life and stability of radiolabeled compounds, the need for relatively expensive counting equipment (especially for tritium-labeled compounds), the need for well-trained personnel and specialized laboratory equipment, and problems in disposal of radioactive waste. Consequently, attempts have been made to develop assays that use nonisotopic labels such as enzymes, fluorogens, and chemiluminescent precursors. Enzyme immunoassays can be as sensitive, accurate, and precise as radioimmunoassays, and specificity depends on the quality of the antibody, as is true for radioimmunoassay systems (Munro and Stabenfeldt, 1984). Of particular interest in domestic animals has been the use of these techniques in the determination of progesterone in blood (Munro and Stabenfeldt, 1984; Meyers *et al.*, 1988; Lopate and Threlfall, 1991) and in milk (Arnstadt and Cleere, 1981; Sauer *et al.*, 1981; Allen and Foote, 1988; Etherington *et al.*, 1991). Enzyme

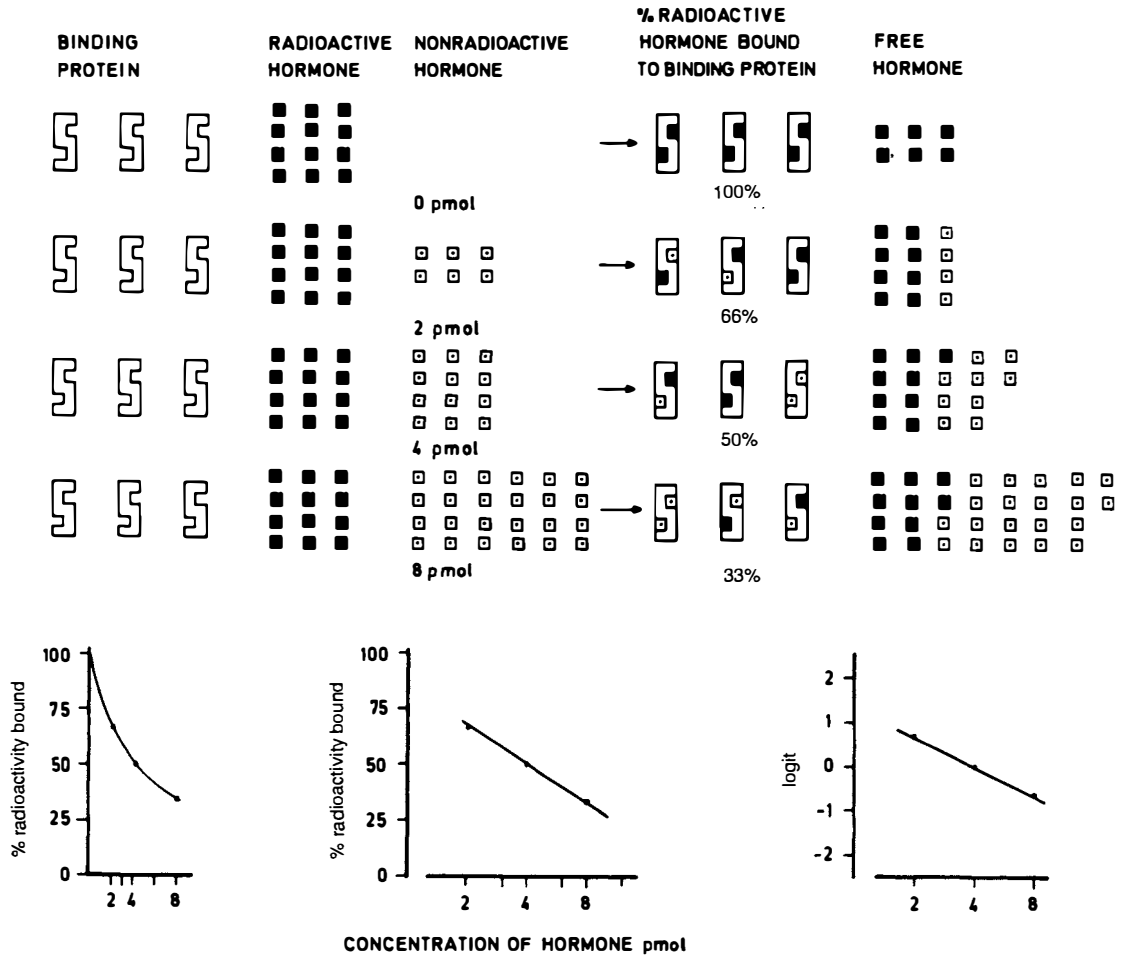

FIGURE 22.3 The principle of an immunoassay technique is based upon the ability of the binding protein to bind the labeled hormone. Excess labeled hormone is added to ensure saturation of the hormone-binding sites on the binding protein. The addition of increasing amounts of nonlabeled hormone (2, 4, and 8 pmol) results in a proportional decrease in the quantity of labeled hormone bound to the binding protein. Separation of labeled hormone bound to the binding protein from free hormone must be achieved before quantification can be done. In the lower part of the figure, this reaction is depicted in three different ways. In the panel to the left and in the middle, percent labeled hormone bound to the binding protein is on the ordinate, and the amount of hormone on a linear scale (left) and log scale (middle) is on the abscissa. In the panel to the right, the logit of the response variable is on the ordinate, and the amount of hormone is plotted on a log scale. The method depicted in the middle and to the right can be used for determination of parallelism. The logit/log transformation (right) is frequently used when immunoassay data are analyzed by computer.

immunoassay in the laboratory setting is very efficient, particularly in the time required for the assay reaction (2 hours or less), in ease of separation of bound from free hormone when using the microtiter plate system (30 seconds to wash 96 wells on a microtiter plate), and in speed of end-point analysis (optical densities can be determined in 1 minute for a 96-well microtiter plate).

Among the various approaches to enzyme immunoassay, the double antibody sandwich method for determination of hormones is frequently used. In this assay system, the plastic wells are coated with antibody. The sample to be processed is then added, and its hormone binds to the antibody-coated plastic well. A second enzyme-labeled antibody directed against another epitope of the hormone is then added. The amount of enzyme-labeled antibody bound is directly proportional to the amount of hormone in the sample. There are two advantages with this methodology: (1) the hormone does not need to be isolated for labeling, and (2) the same general technique can be used to label different antibodies. The method can only be used to assay hormones with at least two binding sites; thus, it is unsuitable for measurement of low-molecular-weight hormones such as steroid hormones.

The analytical equipment used for enzyme immunoassay can be used for a variety of determinations, including those involved in disease surveillance and

drug analysis. This flexibility allows for the sharing of one specialized spectrophotometer among several disciplines at a great reduction in cost. Another benefit is that the analytical equipment needs little maintenance. The elimination of the problems engendered by use of radioisotopes is a major advantage for enzyme immunoassay. This advantage and the fact that color change is fundamental to enzyme immunoassay means that the assay can be used visually to determine the presence or absence of a corpus luteum (CL) in domestic and other species. Today, it is possible to use enzyme-immunoassay analytical systems for progesterone in blood or milk on the farm beside the animal to get a direct assessment of the functional ovarian status of an animal (Nebel *et al.*, 1989; Herrier *et al.*, 1990; Matsas *et al.*, 1992; Romagnolo and Nebel, 1993).

Chemiluminescent-labeled immunoassays are commercially available. All cases of chemiluminescence assay systems are based on a reaction producing light in the visible spectrum. Such an analytical system is used in the authors' laboratory for the determination of several different hormones in domestic species (Forsberg *et al.*, 1993a). A microtiter plate with 96 wells can be read and processed in less than 2 minutes.

It is interesting to note from a historical basis that radioimmunoassay originally developed by endocrinologists was later utilized by immunologists. Conversely, enzyme immunoassay developed by immunologists for studying mechanisms of disease was later adopted by endocrinologists (Dray *et al.*, 1975). For the foreseeable future, immunoassay techniques, especially enzyme immunoassays, will be the laboratory methods of choice in reproductive diagnostic endocrinology of domestic species.

A. Immunoassay

1. Production of Antibodies

Immunoassay techniques utilize antibodies as binding protein. Hormones such as LH and FSH, which are glycoproteins with molecular weights of around 30,000, are antigenic because of their size and chemical composition. In general, a lower level of purity is required of the polypeptide hormones for antibody production as compared to the hormone used in the labeling procedure.

If an assay for bovine LH utilizes an antibody to bovine LH or radio- or enzyme-labeled bovine LH as tracer, and bovine LH as the standard, the assay system is completely species specific and is said to be of the homologous type. Such a system represents the ideal immunoassay system for measuring a polypeptide hormone. Because of limited availability and/or lack of suitable purity of polypeptide hormone preparations, heterologous assay systems have been developed. In these cases, an antiserum to a polypeptide hormone of one species has been used for the determination of the same polypeptide hormone in another species. The standard hormone used for quantification of the assay should, however, originate from the same species for which the measurements are performed.

There are polypeptide hormone antisera available that show a high degree of cross reactivity. One such antiserum of special interest in the field of reproductive hormones in domestic species is a polyclonal LH antiserum raised against ovine LH (Niswender *et al.*, 1969). This antiserum reacts specifically with LH from other species and has been used for the determination of LH in approximately 45 species including the cow, sheep, pig, cat, and dog (Millar and Aehnelt, 1977; Madej and Linde-Forsberg, 1991). A monoclonal antibody generated against bovine LH has been reported to have high cross reactivity among species (Matteri *et al.*, 1987; Bravo *et al.*, 1992; Forsberg *et al.*, 1993b).

Steroid hormones and prostaglandins have considerably lower molecular weights and thus are not immunogenic per se. However, these structures can be rendered immunogenic if covalently linked to large carrier molecules such as bovine serum albumin, and specific antibodies can be elicited in this fashion (Landsteiner and Van der Scherr, 1936). In order for such a hormone–protein conjugate to be immunogenic, approximately 10–20 hormone molecules should be present per molecule of protein. In the case of bovine serum albumin, about 30% of the sites available for conjugation should be occupied.

Most naturally occurring steroid hormones and prostaglandins contain hydroxyl or ketone groups that are used to prepare derivatives containing active groups such as carboxyl or amino groups. These groups are then activated so that they react with amino or carboxyl groups of the protein molecule. The specificity of the antisera obtained by immunization with a steroid–protein conjugate is dependent on the site used for conjugating the steroid to the protein. More specific antisera are obtained if the hapten (steroid) is attached to the protein at a site remote from the characteristic functional groups of the hormone (Lindner *et al.*, 1970).

The most frequent species used for production of polyclonal antibodies are sheep and rabbits. One of the most popular and efficient schedules for immunization involves multiple injections in the back and neck of the animal of the antigen emulsified in complete Freund's adjuvant (Vaitakaitus *et al.*, 1971). During immunization, the developing antibody titer is monitored, and a relative large number of milliliters of serum can be obtained when a suitable titer has been achieved. A

few milliliters of a high-titer antiserum are usually sufficient for millions of immunoassay determinations. Antisera seem to be quite stable when stored at −20° C, although the usual preferred temperature is −70° C.

A new development in the technology of antibody production was the discovery that hybridomas could be used to produce an endless supply of antibodies with certain specificity (Köhler and Milstein, 1975). The procedure involves the fusion of two cell lines: B lymphocytes selected for the production of a specific antibody and myeloma cells that have the capacity for permanent growth. Antibody production occurs by injection of the cell lines into mice; permanency is assured by maintaining a supply of cells in the frozen state. Monoclonal antibodies can be used for the quantitative immunoassay of hormones. They have the advantages of specificity, unlimited supply over time, and the possibility of standardizing assay methods between laboratories. Disadvantages are that they have lower affinities than do polyclonal antibodies, and they do not always form precipitates with antigens. Mixing of monoclonal antibodies may result in an increase of affinity (Ehrlich *et al.*, 1982).

2. *Labeled Hormone*

In radioimmunoassay techniques for polypeptide hormones, the antigen (hormone) is most commonly used for preparing the radioactive tracer. Usually, radioactive iodine, ^{125}I, is used for radioiodination of the antigen. The two most frequently used techniques for iodination are free or immobilized chloramine-T (Iodobeads) (Hunter and Greenwood, 1962; Markwell, 1982) and the lactoperoxidase procedure (Thorell and Johansson, 1971). Peptide hormones containing tyrosyl or histidyl residues can also be iodinated with these techniques.

Many RIA systems for steroid hormones and prostaglandins utilize tritiated forms of these molecules that are available commercially. Because tritium has a considerably longer half-life than iodine, tritium tracers can be used in many cases over several years, whereas the iodinated tracers often have to be prepared monthly. There are, however, certain advantages in using iodinated tracers for steroid hormones and prostaglandins: Simpler and cheaper counting systems can be used, that is, gamma counting as opposed to liquid scintillation counting. Another advantage of radioiodine over tritium is its higher specific activity, which increases the sensitivity of the assay. Direct incorporation of iodine in the skeleton of steroid hormones results in a loss of the immunoreactivity. Thus, the approach taken for radioiodination of steroid hormones has been to link a tyrosyl or histidyl molecule to the steroid molecule, making direct radioiodination possible (Niswender, 1973), or to iodinate a compound such as tyramine and conjugate the iodinated compound to the steroid molecule (Lindberg and Edqvist, 1974).

Most EIA systems for steroid hormones use horseradish peroxidase, alkaline phosphatase, or β-galactosidase as labels. The enzyme-labeled steroid is produced the same way as has been described for the synthesis of steroid–protein conjugates for the production of antibodies.

3. *Separation of Antibody-Bound and Free Hormone*

An essential part of any immunoassay system is an efficient procedure for the separation of antibody-bound and free hormone. Several different approaches have been taken to achieve a rapid and efficient separation. Currently, the most frequent separation procedures in use are based on (1) antibodies coupled to an insoluble polymer, (2) precipitation of antibody-bound hormone, or (3) adsorption of free hormone.

Antibodies coupled to an insoluble polymer have been used for separating antibody-bound and free hormone in RIA procedures for both protein hormones (Wide and Porath, 1966) and steroid hormones (Abraham, 1969). One procedure involves decanting from polystyrene tubes in which antibodies have been adsorbed to the surface of the tube, which is followed by determination of radioactivity in the antibody-bound (contained in the tube) or free (contained in the eluent) form. In most EIA systems designed for low-molecular-weight hormones, antibody-bound hormone is measured after free hormone has been removed by washing the wells of the microtiter plate that have been previously coated with antibody.

Another common procedure for RIA utilizes antibodies covalently coupled to an insoluble polymer granule (Wide and Porath, 1966). In this case, free and antibody-bound hormone are separated through centrifugation. After removal of the supernatant containing the free hormone, the antibody-bound radioactivity can be determined. Antibody-coated glass beads have been used in both RIA and EIA (Schmidt *et al.*, 1993). Separation is achieved by washing the bead, and then the radioactivity or enzyme activity is determined.

Precipitation of antibody-bound hormone has been achieved through the addition of ammonium sulfate (Mayes and Nugent, 1970) or polyethylene glycol (Desbuquois and Aurbach, 1971), leaving the free hormone in the solution. The latter precipitation procedure has been found advantageous for the precipitation of prostaglandin–antibody complexes (Van Orden and Farley, 1973). Precipitation of the antibody-bound hor-

mone complexes can also be achieved through the addition of a second antibody prepared against the first antibody. Thus, in an RIA technique for bovine LH that utilizes an antiserum to bovine LH raised in a rabbit (first antibody), the second antibody will be an antibody prepared against rabbit gamma globulin. The addition of the second antibody will result in a precipitate containing the antibody-bound LH, which can be separated from the supernatant by centrifugation. The time required for the separation can be decreased by the addition of polyethylene glycol (Eisenman and Chew, 1983). Systems using a second antibody coupled to insoluble particles are efficient and commonly used (Dericks-Tan and Taubert, 1975; Forsberg *et al.*, 1993b).

For steroid hormones, a traditional separation procedure is the adsorption of free hormone to dextran-coated charcoal. After the addition of the charcoal, the separation of free and antibody-bound steroid is achieved through centrifugation. This method is rapid and efficient in separating free and bound steroid hormones. However, the charcoal can also adsorb some of the antibody-bound steroid, which is called "stripping." To control this, timing of the reaction is important. Carrying out the reaction at 4°C has been found to limit this dissociation (Abraham, 1974).

4. *Reliability Criteria*

The reliability of immunoassay analyses depends on specificity, sensitivity, accuracy, and precision.

a. Specificity

The specificity of an immunoassay, or its freedom from interference by substances other than the one to be measured, is dependent on several different factors, the most important being the specificity of the antiserum used. Demonstration of specificity for the immunoassay of large protein hormones such as LH and FSH is relatively difficult and relies upon indirect criteria. Because it is not possible to synthesize these hormones, they must be isolated and purified from biological material. The purity of such preparations is variable, and the most common cause of nonspecificity for these hormones is impurity of the immunizing material.

A relatively common finding is the cross reaction of TSH with antibodies to LH, and vice versa. Antibody specificity is usually demonstrated by testing the binding of hormones other than the one intended to be measured to the antibody. If, for example, bovine TSH significantly inhibits the binding of bovine LH to an antibody to bovine LH, this indicates that the antiserum used is nonspecific or that the TSH preparation contains LH. If the inhibition curves are parallel, the latter explanation is likely because the parallelism indicates the same binding kinetics. It should be noted that parallelism, in itself, is not adequate proof of specificity. As indicated previously, both LH and TSH are composed of two subunits, an α-subunit that is identical for the two hormones and a β-subunit that is unique for each hormone. It is possible that an antiserum could contain binding sites that will react only with the α-subunit. In such a case, the dose–response curve of LH and TSH utilizing such an antisera will be parallel, the assay system will not be hormone specific, and thus the system will be invalid for the measurement of LH (Niswender and Nett, 1977). Double antibody sandwich methods utilizing monoclonal and/or polyclonal antisera can partly reduce the problem.

In the case of immunoassay techniques for steroid hormones and prostaglandins, the same proof of specificity has to be undertaken. Here the situation is simpler, because lower-molecular-weight hormones can easily be purified and, in most cases, produced synthetically. Furthermore, comparison of immunoassay results with results obtained by mass fragmentography gives very valuable information, because the latter technique can be considered as an absolute proof of structure and thus specificity.

Some idea as to the specificity of an antiserum to a steroid hormone can be gained from the position of the steroid molecule that is used as the anchoring point to the protein (Fig. 22.2). If an antiserum to estradiol-17β is produced through the use of an antigen conjugated via the hydroxyl group at carbon 17 of the steroid, the resulting antiserum will react almost equally well with estrone and thus will have relatively poor specificity. This is because the only structural difference between the estradiol-17β and estrone molecules is the configuration at position 17 (Fig. 22.2). In general, steroid antibodies are more specific for the portion of the steroid molecule that protrudes from the carrier protein and less specific for the portion of the steroid used for linkage to the protein. Thus, in the case of estradiol-17β, highly specific antibodies have been developed after immunization with conjugates when carbon 6 of the B ring has been used as the site of attachment to the protein (Exley *et al.*, 1971). By use of the same fundamental principle concerning the selection of appropriate sites for conjugation, specific antibodies have been produced against progesterone conjugated to the protein through carbon 11 and to testosterone through carbons 1 and 3 (Niswender and Midgley, 1970).

Protein hormone determination by immunoassay is often performed on blood serum or plasma. The influence of serum or plasma on the binding of the tracer to the antibody must be investigated. The assay of different amounts of serum or plasma should result

in curves parallel to those obtained with protein hormone standard. In some steroid hormone immunoassays, the hormone is extracted by an organic solvent from a plasma sample. Organic solvents can also be used as a means to selectively remove steroids from biological fluids. For example, most immunoassay procedures designed to measure progesterone utilize antisera developed against a progesterone-11-protein conjugate, which results in a minor cross reaction with corticosteroids (Thorneycroft and Stone, 1972). If a nonpolar solvent such as petroleum ether is used for the extraction of progesterone from serum or plasma samples, about 80–90% of progesterone is extracted, leaving the more polar corticosteroids in the plasma (Johansson, 1969). The use of such a selective extraction system increases the overall assay specificity. Direct analytical systems for steroid hormones omitting the extraction step are also employed. Because steroid hormones in a blood sample to be analyzed are bound to carrier proteins, direct assay systems have to secure that all steroid molecules, both free and protein-bound, in the sample are given equal opportunities to interact with the antibody used in the assay. The synthetic steroid danazol (17α,2,4-pregnanedien-20-yno(2,3-d)isoxazol-17-ol) can be used to displace progesterone from the binding proteins (Carrière and Lee, 1994). Likewise, 8-ANS (8-anilino-1-naphthalenesulfonic acid) and levonorgestrel (D(−)-norgestrel) can be used to enhance the displacement of testosterone from its binding proteins (Hoyle and Ebert, 1990). Certain immunoassay systems may require purification of the plasma extract to achieve an acceptable specificity.

The main problem in the immunoassay of primary prostaglandins is that they can continue to be formed in large amounts by platelets after the blood sample has been obtained (Samuelsson *et al.*, 1975). Therefore, the concentrations of $PGF_{2\alpha}$ reported in blood serum or plasma appear, in most cases, to be 100–1000 times higher than the actual values (Granström and Kindahl, 1976). The primary prostaglandins have a very short half-life in the circulation (Hamberg and Samuelsson, 1971) and are rapidly converted to their corresponding 15-keto-13,14-dihydro derivatives. The latter have considerably longer half-lives and occur in higher concentrations than the parent compounds (Beguin *et al.*, 1972). Analysis of metabolites of prostaglandin $F_{2\alpha}$ avoids the problem of the overestimation observed for the parent compound in that the metabolites are formed only within the body and values thus remain stable once a blood sample has been obtained. Radioimmunoassay systems utilizing antibodies to 9α,11α-dihydroxy-15-ketoprost-5-enoic acid and 5α,7α-dihydroxy-11-ketotetranorprosta-1,16-dioic acid have been developed (Granström and Samuelsson, 1972). Most problems involved in the determination of the primary prostaglandins are avoided if their main metabolites, the 15-keto-13,14-dihydro compounds, are measured.

b. Sensitivity

The sensitivity of an immunoassay is defined as the smallest quantity of hormone that the assay can detect reliably. Usually, two kinds of sensitivity are evaluated. The sensitivity of the standard curve is defined as the smallest amount of hormone that is significantly different from zero at the 95% confidence limit. However, the most meaningful sensitivity to establish is the smallest amount of hormone that can be measured per unit of biological fluid, for example, per milliliter of plasma.

c. Accuracy

The accuracy of an assay is defined as the extent to which the measurement of a hormone agrees with the exact amount of the hormone. Accuracy is often determined by comparing immunoassay data with values determined by other procedures such as gravimetry, gas–liquid chromatography, and mass spectrometry. For steroid hormones and prostaglandins, accuracy is also often determined by recovery experiments in which different amounts of hormones are added to a biological fluid, such as plasma, that contains low concentrations of the hormone. The amount of hormone measured in the assay is then compared with the amount of hormone added.

d. Precision

Two types of precision are usually evaluated. The within-assay precision is determined from duplicate measurements of the same sample within the same assay. The between-assay precision is determined from replicate analyses of the same sample in different assays. Usually the between-assay variance is greater than the within-assay variance. Assay variance should be checked continuously with each assay of a certain hormone by use of plasma pools containing set amounts of the hormone. Usually three different plasma sets containing low, medium, and high hormone concentrations are used. Within- and between-assay variations in immunoassay procedures are usually greater than for most other routine procedures used in clinical chemistry.

B. Summary

The use of immunoassay techniques has dramatically increased our knowledge and understanding of reproductive endocrinology in domestic species. These

procedures are relatively simple to perform, inexpensive, sensitive, and specific. Data gained from these techniques have resulted in characterization of endocrine changes throughout the estrous cycle and pregnancy in domestic animals.

III. PHYSIOLOGY OF REPRODUCTIVE HORMONES IN THE FEMALE

This section is relatively brief in its coverage of endocrinological events during the reproductive cycle. Readers interested in a more complete presentation of hormonal events involved in reproduction are referred to texts dealing specifically with the subject. Also, some hormones with some influence on reproductive processes, such as those of the thyroid and adrenal glands, are not covered in this section.

A. Estrous Cycle

The major endocrine events that precede ovulation have been well documented in the cow (Chenault *et al.*, 1975), ewe (Nett *et al.*, 1974), sow (Shearer *et al.*, 1972), mare (Evans and Irvine, 1975; Palmer and Jousset, 1975; Stabenfeldt *et al.*, 1975), dog (Concannon *et al.*, 1975), and cat (Shille *et al.*, 1979b). In large domestic animals (cattle, horse, pig, sheep, and goat), follicle growth occurs during the luteal phase in spite of the inhibitory nature of progesterone, the main secretory product of the CL. Although follicles are usually not ovulated during the luteal phase in most species, the mare occasionally ovulates during the luteal phase (Hughes *et al.*, 1973).

With regression of the CL, follicles grow rapidly prior to ovulation because of gonadotropin stimulation. The follicles secrete increasing amounts of estrogen during development, which is important for onset of sexual receptivity as well as for the initiation of the surge release of gonadotropins that is essential for the ovulatory process (Fig. 22.4). Estrogens initiate the release of LH and FSH through the release of GnRH (Moenter *et al.*, 1990). In most species, the preovulatory surge of gonadotropins begins approximately 24 hours before ovulation and is usually of short duration, for example, 8–10 hours in the cow. The mare is an exception in that large amounts of LH are released during an 8- to 9-day period with ovulation occurring on the third day (Geschwind *et al.*, 1975). Another important function of GnRH is to elicit sexual receptivity. Thus, the onset of the preovulatory LH surge and sexual receptivity are coordinated via GnRH synthesis and release.

Following ovulation, a CL is formed under the influence of pituitary gonadotropins. In most species, LH is the major luteotropin; prolactin is thought to play a role in sheep and in rodents and may be the predominant luteotropin in these species. If pregnancy does not ensue, the CL regresses, which permits the estrous cycle to be repeated. This well-timed sequence occurs repetitively at set intervals if not interrupted by pregnancy.

A summary of estrous-cycle activity in common domestic animal species is given in Fig. 22.5. Seasonal breeders, such as the mare, ewe, doe, and queen, undergo cyclic ovarian activity only during the breeding season, whereas the cow, sow, and bitch are affected little, if any, by photoperiod and can have cyclic ovarian activity throughout the year. Estrous-cycle length is approximately 21 days in the cow, doe, mare, and sow and 17 days in the ewe. The bitch has a much longer estrous cycle, the luteal phase often being between 50 and 80 days in duration. The interval between cyclic ovarian activity in the bitch is extended even

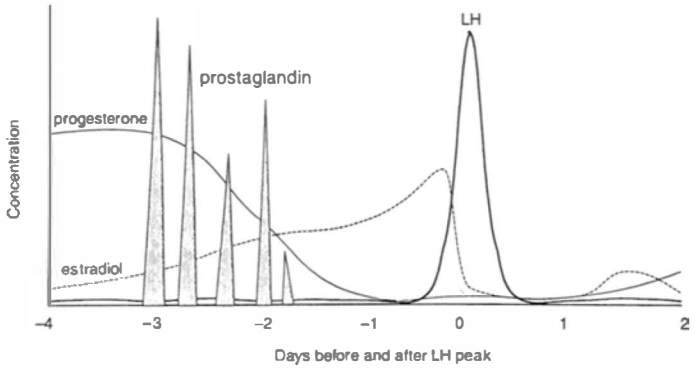

FIGURE 22.4 Schematic presentation of the preovulatory events in general applicable to the cow, doe, ewe, and sow. These endocrine events also occurs in the mare, but in this species, the release of LH occurs over a considerably longer time period.

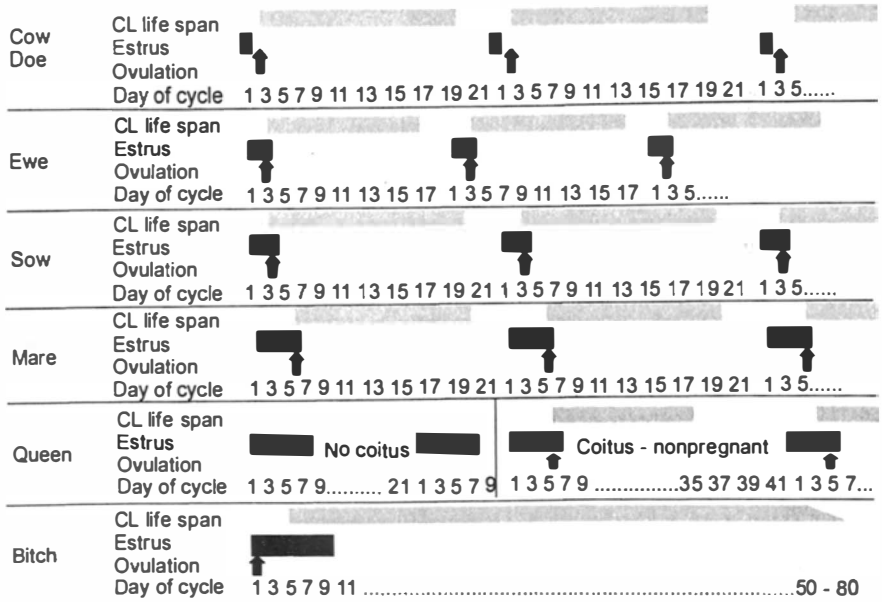

FIGURE 22.5 Comparative data on the duration of estrus, time of ovulation, and duration of CL function in the cow, ewe, sow, mare, queen, and bitch. (Modified from Stabenfeldt, 1974; Edqvist and Stabenfeldt, 1989.)

further by the occurrence of a 4 to 5-month anestrum period following regression of the CL. The cat is an induced ovulator, requiring coital stimulation for ovulation and thus for CL formation. In the absence of coitus, follicles develop every 15–20 days, with follicular growth and regression occupying 5–7 days of each period. An ovulatory, nonfertile mating results in the formation of CL that persist for approximately 35 days and a syndrome termed pseudopregnancy in the cat.

B. Control of the Corpus Luteum

The regression of the CL (luteolysis) is a key event that is responsible for the well-timed estrous cyclicity seen in most domestic species. The importance of the uterus in the control of the lifespan of the CL has been documented through hysterectomy in the cow, ewe, sow, and mare (du Mesnil du Buisson and Dauzier, 1959; Wiltbank and Casida, 1956; Stabenfeldt *et al.*, 1974a). Removal of the uterus from these species during the luteal phase results in prolongation of luteal activity. It is now well established that the uterus in these species synthesizes and releases $PGF_{2\alpha}$, which causes the CL to regress (McCracken *et al.*, 1972).

The temporal release patterns of $PGF_{2\alpha}$ (Fig. 22.4), usually in a pulsatile mode lasting a few hours, have been described in the ewe (Harrison *et al.*, 1972; Barcikowski *et al.*, 1974), sow (Gleeson *et al.*, 1974), doe (Fredriksson *et al.*, 1984), and cow (Nancarrow *et al.*, 1973). Some of the problems involved in determining $PGF_{2\alpha}$, such as its short half-life and formation by platelets at collection, can be avoided if the main plasma metabolite, 15-keto-13,14-dihydro-$PGF_{2\alpha}$, is determined. Data are available on the patterns of the metabolite during luteolysis in the cow (Kindahl *et al.*, 1976a,b), ewe (Peterson *et al.*, 1976), mare (Neely *et al.*, 1979), doe (Fredriksson *et al.*, 1984), and sow (Shille *et al.*, 1979a).

Regression of CL is usually accomplished within 48 hours following the onset of the prostaglandin release. It is likely that estrogens, presumably of ovarian follicle origin, initiate $PGF_{2\alpha}$ release. Estrogen also initiates the formation of endometrial oxytocin receptors (McCracken *et al.*, 1984), which in sheep are important for pulsatile synthesis and release of $PGF_{2\alpha}$ in that oxytocin can initiate the release of $PGF_{2\alpha}$ (Sharma and Fitzpatrick, 1974). In ruminants, oxytocin is synthesized and released from the CL in response to $PGF_{2\alpha}$, which in turn initiates the synthesis and release of $PGF_{2\alpha}$ by the uterus. This mechanism is the basis for the pulsatile secretion of $PGF_{2\alpha}$ (for reviews, see Flint *et al.*, 1992; Whates and Denning-Kendall, 1992). In the dog and cat, $PGF_{2\alpha}$ does not appear to be involved in luteolysis, although its precise role is still uncertain.

C. Early Pregnancy

Modification of $PGF_{2\alpha}$ release is essential for the establishment of pregnancy in the species (cow, ewe, mare, and sow) in which this compound serves as the luteolysin (Kindahl *et al.*, 1976a; Nett *et al.*, 1976; Shille *et al.*, 1979a). The rapid elongation of fetal membranes,

which precedes the critical time of the initiation of luteal regression by about 3 days in the nonpregnant animal, appears to be important for the modification of prostaglandin release. Fredriksson *et al.* (1984) for goats and Zarco *et al.* (1988) for sheep have shown that the main change in $PGF_{2\alpha}$ synthesis and release in nonpregnant vs pregnant animals involves a continuous, not pulsatile, mode of secretion. In fact, $PGF_{2\alpha}$ concentrations increase at the onset of pregnancy, but the release is continuous, which allows for the prolongation of luteal activity.

Maternal recognition of pregnancy in the cow, ewe, doe, and sow involves mechanisms that alter the prostaglandin release to protect the CL from luteolysis. In the cow, ewe, and doe, conceptuses secrete trophoblast proteins between days 10 and 21–24 of pregnancy. These substances are produced before the blastocyst attaches to the endometrium, are secreted into the uterine lumen, and bind to uterine oxytocin receptors, blocking the episodic uterine $PGF_{2\alpha}$ secretion (for a review, see Flint *et al.*, 1992). In the sow, in which the maternal recognition of pregnancy is controlled by conceptus-derived estrogens (Perry *et al.*, 1976; Fig. 22.6), similar trophoblast proteins have been isolated from preimplantation blastocysts (La Bonnardière, 1993).

Significant increases in intraluminal $PGF_{2\alpha}$ have been observed in pigs (Frank *et al.*, 1978) and cattle (Thatcher *et al.*, 1979), but not in horses (Zavy, 1979), beginning about two weeks postconception. Possible uterine antiluteolytic factors include PGE (Hoyer *et al.*, 1978), and PGE_2 (Magness *et al.*, 1978), with increased production of PGE_2 by endometrial tissue having been demonstrated in ewes during early pregnancy (Ellinwood *et al.*, 1979).

Modification of the release pattern of $PGF_{2\alpha}$ (pulsatile to continuous) by the luteotropic products from the conceptus and uterus is probably the most important factor that allows luteal activity to continue. The net result is that luteal activity is extended in the cow, ewe, mare, and sow beginning at about 14 days following ovulation. Modification of $PGF_{2\alpha}$ release does not appear to be important for the establishment of pregnancy in the dog and cat.

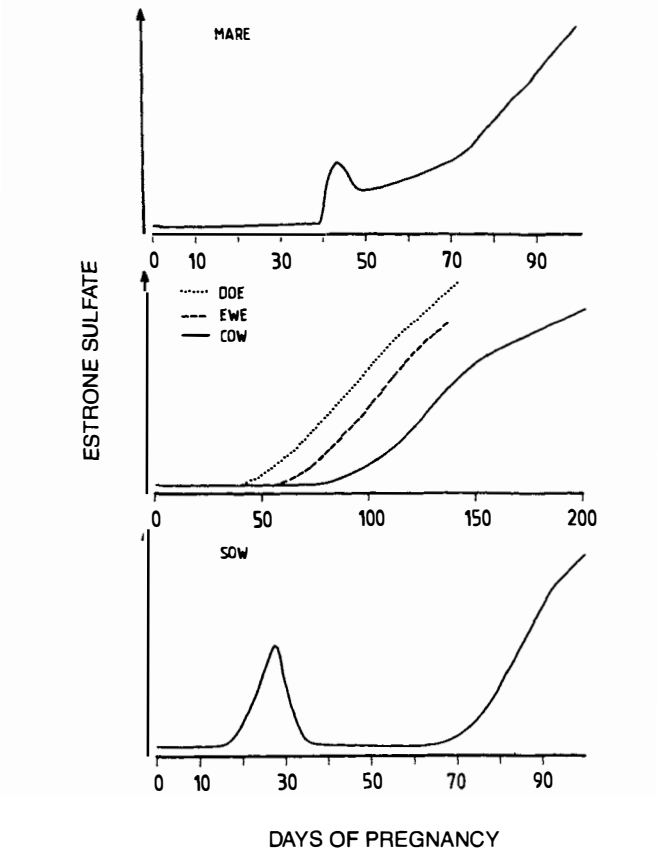

FIGURE 22.6 Blood levels of conjugated estrogens (mainly estrone sulfate) during early pregnancy in the mare, doe, ewe, cow and sow. Data derived from Kindahl *et al.*, 1982 (mare); Chaplin and Holdsworth (1982) (doe); Tsang (1978) (ewe); Gaiani *et al.*, (1982) (cow); and Robertson and King (1974) (sow).

D. Pregnancy and Parturition

The presence of a CL is necessary for the maintenance of pregnancy in the vast majority of cows (Estergreen *et al.*, 1967). The pig also requires luteal support throughout gestation (du Mesnil du Bussion and Dauzier, 1957). In the ewe, the presence of a CL is required for the first 50–60 days of gestation (Linzell and Heap, 1968). After this time period, the fetoplacental unit secretes significant amounts of progesterone. The dog requires the presence of a CL for all of gestation. Sokolowski (1971) found that ovariectomy even as late as day 56 postbreeding resulted in premature delivery.

The necessity for secondary CL, formed in the mare between days 40 and 60 of gestation, has been discussed over the years. The secondary CL are the result of eCG secretion by the endometrial cups, which are formed from a circular band of cells of placental origin (chorionic girdle cells) that invade the endometrium and form isolated endocrine organs of temporary function (Allen, 1969). Although secondary CL are not essential for the maintenance of pregnancy in the mare in that the primary CL continues to function for up to 150 days, they do add extra progestational support for the pregnancy during the time placental production of progesterone is being established. Progesterone support of pregnancy in the mare begins to be assumed by the placenta as early as day 50 of gestation but is not complete for all mares until approximately 100 days or later, a time that coincides with the beginning

demise of both primary and secondary CL (Holtan *et al.*, 1979).

It has been demonstrated that eCG has a close immunological relationship with equine LH (Farmer and Papkoff, 1979); further, a luteotropic effect of eCG has been shown by incubation studies of CL (Squires *et al.*, 1979). If fetal loss occurs after the formation of endometrial cups, continuing eCG production supports luteal activity, even to the point of making lysis of these CL difficult in conjunction with the pharmacological administration of prostaglandin $F_{2\alpha}$.

The endocrine activity of the fetoplacental unit can be monitored through the measurement of conjugated estrogens, especially estrone sulfate, in peripheral plasma or urine (Fig. 22.6). In the pregnant sow, concentrations of estrone sulfate become detectable at day 17 of pregnancy, increase until about day 28, then decline to low or undetectable values, and then increase again beginning around days 75–80 of pregnancy, remaining high until parturition (Robertson and King, 1974). In the mare, estrone sulfate values begin to increase around days 35–40 of pregnancy with accentuated production at 80–90 days and with the highest values obtained from day 150 to parturition (Terqui and Palmer, 1979; Kindahl *et al.*, 1982). In the cow (Gaiani *et al.*, 1982) and ewe (Tsang, 1978), estrone sulfate levels can be detected from around day 70–80 after conception, and in the goat, concentrations start to increase around day 50 of pregnancy (Chaplin and Holdsworth, 1982). In the pregnant cow, estrone sulphate concentrations in milk start to increase between days 100 and 120 (Hatzidakis *et al.*, 1993; Henderson *et al.*, 1994). In all species, high values of estrone sulfate in the peripheral blood, milk, or urine are strong evidence for the presence of a viable fetus.

The mare produces two estrogens during pregnancy that are unique to equids, equilin and equilenin, both of which have unsaturated B rings (Girard *et al.*, 1932). By fetal gonadectomy in the horse, Pashen and Allen (1979) have shown the importance of fetal gonads in the production of estrogen in cooperation with the placenta. Little evidence of estrogen production during pregnancy has been reported for the dog (Hadley, 1975). Estrogen production by the fetoplacental unit in the cat also appears to be minimal during gestation (Verhage *et al.*, 1976).

An important endocrine change that occurs prior to parturition in the cow, ewe, and sow involves an increase in the synthesis and release of unconjugated estrogens by the fetoplacental unit. This increased estrogen synthesis is reflected in elevated plasma estrone concentrations in the pregnant cow beginning 20–30 days prepartum (Edqvist *et al.*, 1973), in the ewe about 2 days before parturition (Challis *et al.*, 1971), and in the pig about 1 week before delivery (Robertson and King, 1974). In the cow (Stabenfeldt *et al.*, 1970; Edqvist *et al.*, 1973) and bitch (Smith and McDonald, 1974), parturition is preceded by an abrupt fall in progesterone concentrations 24–48 hours prior to delivery. In the ewe (Stabenfeldt *et al.*, 1972), mare (Noden *et al.*, 1978), and sow (Baldwin and Stabenfeldt, 1975), partial withdrawal of progesterone occurs prior to delivery. In the cow (Fairclough *et al.*, 1975; Edqvist *et al.*, 1976, 1978), ewe (Liggins *et al.*, 1972), and bitch (Concannon *et al.*, 1988), it has been demonstrated that prostaglandin release initiates regression of the CL and thus is responsible for the withdrawal of progesterone.

High estrogen and prostaglandin concentrations combined with low progesterone concentrations increase the contractile state of the uterus. Prostaglandins may also initiate cellular changes within the cervix, in addition to the effect of relaxin, which result in cervical softening and dilation. Cervical stimulation, the result of the initial entry of the fetus into the pelvic canal, causes the reflex release of oxytocin from the posterior pituitary. This increases the intensity of uterine contractions and thus aids the final delivery process.

IV. CLINICAL ASPECTS OF REPRODUCTIVE ENDOCRINOLOGY

The development of immunoassay techniques for hormone determinations in domestic species has created laboratory procedures that are useful as diagnostic aids in clinical work. For some reproductive hormones, relatively well defined indications for their clinical use are known at present and more are likely to be identified in the future. Important differences exist between humans and animals with respect to endocrine analysis. For example, steroid hormone concentrations are much lower (10-fold less in the case of estrogens) in animals, which produces a requirement for more rigorous assay systems. In animals, the most useful information comes from assessing gonadal or fetoplacental activity (vs pituitary activity), and thus, the determination of steroid hormones is emphasized. Besides the fact that gonadotropin values are less useful for the assessment of clinical situations, variations in amino acid composition of specific hormones among species mean that multiple systems have to be developed to determine the content of one protein hormone across species lines. Antibodies such as the one developed for LH by Niswender *et al.* (1969), which is able to detect LH in many species, are the exception.

For hormone analyses to be useful as a diagnostic tool, certain criterion have to be fulfilled. The concentration of the hormone at the sampling site (usually

a peripheral vein) should closely correlate with the amount of the hormone being released from the endocrine gland. It is preferable that the release pattern of the hormone be steady, which allows valid information to be obtained on the secretory status of the endocrine gland from one sample. Several reproductive hormones do not fulfill the latter criterion, and thus their determination is not useful from a routine diagnostic view. For example, the duration of the LH surge observed in conjunction with ovulation is short in most domestic species except the horse. In the cow, the preovulatory LH peak has a duration of 8–10 hours, requiring samples to be obtained every 4 hours to detect the peak (Karg *et al.*, 1976). In the mare, the duration of the peak is considerably longer, 8–9 days, which allows a less frequent sampling interval (Geschwind *et al.*, 1975). However, the long duration of LH peak in the mare prevents the determination from being useful in predicting ovulation.

One reproductive hormone, progesterone, has been found to be of significant clinical value in females of most domestic species, and overall, its analysis gives the most useful information on the reproductive status of animals. Other hormones with established or potential clinical use will be discussed further for each species. As a percentage of total number of clinical assays, the highest number have been utilized as pregnancy tests. It is worth keeping in mind that the analysis of hormones as a diagnostic aid in solving clinical problems supplements, but does not replace, the information that should be gained by a careful clinical examination.

Although blood has been the usual medium for hormone analysis, milk, urine, saliva, and even feces are also sources for gaining useful endocrine information. The latter substances have the advantage in certain situations of being easier to collect and, at the very least, they avoid the use of venipuncture. It has been shown that the determination of estrogen conjugates in urine is much more effective in revealing ovarian follicle production of estrogens than the analysis of either free or conjugated estrogen in plasma.

A. Cattle

1. Progesterone

Several reports are available on progesterone concentrations in blood during early pregnancy in cattle (Pope *et al.*, 1969). A finding of importance is that progesterone can be measured in the milk of lactating cows and, further, that its concentration accurately reflects the concurrent plasma concentration of progesterone (Laing and Heap, 1971).

The difference that exists in both plasma and milk progesterone concentrations 19–24 days after a fertile breeding as compared to a nonfertile breeding has been used as an early pregnancy test (Shemesh *et al.*, 1968; Robertson and Sarda, 1971; Fig. 22.7). The plasma progesterone concentration in blood of pregnant cows at 21 days postbreeding is almost always at least 2 ng/ml (6 nmol/liter) and usually 4–8 ng/ml (13-26 nmol/liter), as compared to less than 0.5 ng/ml (1.6 nmol/liter) in the nonpregnant animal at the same time. Elevated progesterone concentrations, however, only reflect the presence of luteal tissue and are not directly indicative of the presence of a fetus *in utero*. Furthermore, a slight prolongation of luteal activity in a nonpregnant animal can occur that results in elevated progesterone concentrations at day 21, a situation in which the analytical progesterone result would be positive and the animal would be falsely considered pregnant. The accuracy of the forecast for pregnancy (positive forecast) thus is often lower than desirable, in most cases ranging between 75 and 90%. The negative forecast, however, is more accurate; cows having low progesterone concentrations in milk or blood 21 days postbreeding will almost always not be pregnant. The accuracy of the positive forecast can be increased if progesterone analyses are also carried out on samples obtained at the time of insemination to eliminate animals inseminated during the luteal phase of the estrous cycle. Cows inseminated during the luteal phase will be in the luteal phase 21 days later and the animal will be falsely considered pregnant.

It should be recognized that the main focus of early pregnancy diagnosis is for more efficient management of breeding. In most cases involving early pregnancy diagnosis, pregnancy status needs to be verified again at about 40 days postbreeding. In spite of its limitations, progesterone analysis for pregnancy diagnosis is the most common clinical use of any of the reproductive hormones. Progesterone analysis can also be used for the retrospective confirmation of the absence (or presence) of a CL at the time of insemination in cattle. Since inadequate detection of estrus is the most common cause of low fertility in herds utilizing artificial insemination, the determination of progesterone concentrations at the time of insemination can be a useful tool when herds with fertility problems are encountered. Karg *et al.* (1976) indicated that improper timing of insemination, as judged from milk progesterone determinations, occurred in 15% of the cases in a controlled field test; the figure rose to 26% under practical field conditions. Lower figures have been reported by others, namely 0 to 3% in the Netherlands (Van de Wiel *et al.*, 1978), and 4% in Sweden (Oltner and Edqvist, 1981). The use of progesterone determinations in milk obtained at the time of insemination in

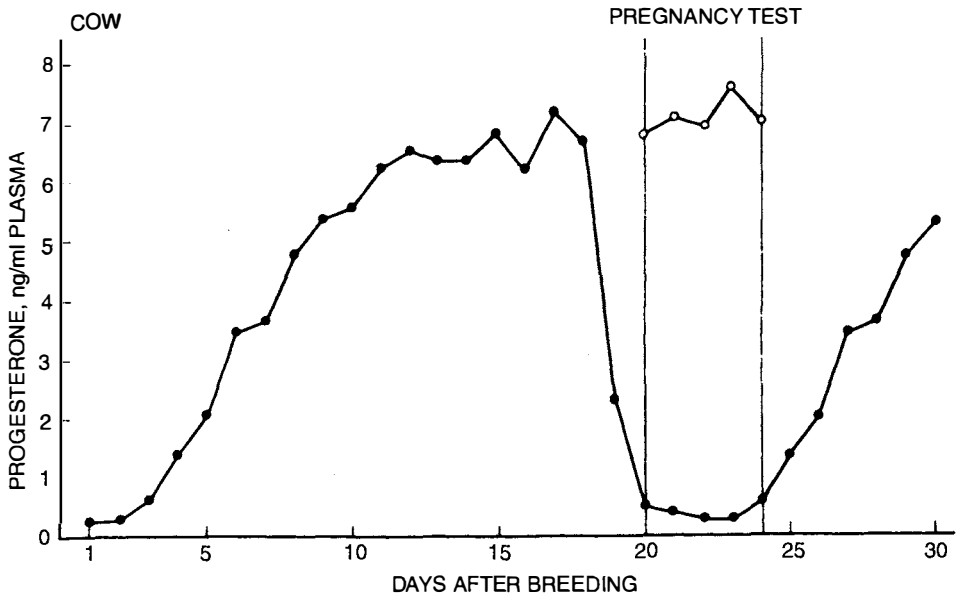

FIGURE 22.7 Time after breeding for utilizing progesterone analysis as a means of pregnancy diagnosis. Progesterone content in nonpregnant (●) cows compared with progesterone content of pregnant animals (○) (Stabenfeldt *et al.*, 1969b).

cows with questionable heat signs and inconclusive genital-tract findings can serve as a valuable tool for educating the staff responsible for insemination (Garcia and Edqvist, 1990).

A potential important area for the diagnostic use of progesterone analysis is the elucidation of clinical syndromes in the postpartum period, in which cows fail to show sexual receptivity for extended periods of time. Animals that have reestablished ovarian activity can often be distinguished from those that have not. Elevated progesterone values indicate that significant ovarian activity is present. Cows that have luteal activity can be manipulated through $PGF_{2\alpha}$ treatment with a reasonable expectation of initiation of a new cycle. Progesterone determinations can also be used to verify the presence of luteal tissue in conjunction with endometritis/pyometra (Pepper and Dobson, 1987) and ovarian cysts (Booth, 1988; Sprecher *et al.*, 1990). Both conditions should respond to prostaglandin therapy. Differentiation of luteal vs follicular ovarian cysts in cattle is not usually done because it is technically difficult by palpation *per rectum* and because the same gonadotropin treatment can be used in both situations. Luteinization of the structure with a luteotropin is followed in 10–14 days with prostaglandin treatment. In both cases though, the use of progesterone analysis is useful in establishing the therapeutic response.

2. *Estrone Sulfate*

High concentrations of estrone sulfate are found in blood beginning at about day 80 of pregnancy and in milk from about day 100 (Fig. 22.6). In studies using estrone sulfate concentrations in milk samples collected at 120 days or more of gestation as an indicator for pregnancy status, an overall accuracy rate of 96% was found (Power *et al.*, 1985). A similar figure has also been reported by McCaughey *et al.* (1982). These authors suggested that estrus and mastitis may influence the accuracy of the test. When comparing peripheral blood concentrations of estrone sulfate among three breeds of cattle, it was found that the breed giving birth to the lightest calves had lower estrone sulfate concentrations in the interval 101–200 days of gestation (Abdo *et al.*, 1991).

3. *Other Substances*

A protein of placental origin (bovine pregnancy-specific protein B; bPSBP) has been observed in the blood of pregnant cows beginning between days 16 and 21 of gestation (Sasser *et al.*, 1983; Sasser and Ruder, 1987). This discovery of a protein that is observed only if an embryo is present opens the way for an early and definitive pregnancy diagnosis in cattle by blood analysis. Humblot *et al.* (1988) compared diagnosis of pregnancy in Friesian cattle by determination of progesterone and bPSBP in blood. The study revealed the accuracy (ratio of cows positive and pregnant to total cows with positive) of the positive forecast to be 67.2% (82/122) for progesterone on day 24 after insemination. The accuracy of the negative forecast for progesterone was 98% (52/53). The accuracy of the positive forecast for bPSPB increased with gestation age from 86.2% (50/58) on day 24 to 98.8% (83/84) on

day 70. The accuracy of the negative diagnoses by bPSPB increased from 71.8% (84/117) on day 24 to 100% (83/83) on days 30 to 35. The authors concluded measurement of bPSPB 30 days after insemination is an efficient test both for positive and negative pregnancy diagnoses. A cardinal principle of pregnancy detection is that the test should be effective by the time the estrous cycle would end if the animal was not pregnant. This reemphasizes the main point of early pregnancy detection: It is done so the animal can be rebred if not pregnant. The test fulfilling this criterion has yet to be found.

B. Sheep

1. *Progesterone*

Progesterone analysis as an early test for pregnancy has been used in sheep (Robertson and Sarda, 1971). In the ewe, the progesterone analysis has to be carried out on blood samples, because most breeds of sheep are not lactating at the time of breeding. Maximal luteal phase progesterone concentrations in the ewe are approximately 2–4 ng/ml (6–13 nmol/liter), whereas the concentrations at estrus range from 0.15 to 0.25 ng/ml (0.5–0.8 nmol/liter) (Stabenfeldt *et al.*, 1969c; Dickie and Holzmann, 1992). Using an amplified enzyme immunoassay technique for plasma progesterone, an accuracy of 100% was reported for the diagnosis of pregnancy using samples taken between days 15 and 16 from a flock of 130 ewes (106 diagnosed pregnant and 24 diagnosed nonpregnant) (McPhee and Tiberghien, 1987).

A relatively marked increase in progesterone values from 2–4 ng/ml (6–13 nmol/liter) to 12–20 ng/ml (38–64 nmol/liter) occurs between days 60 and 125 of pregnancy (Stabenfeldt *et al.*, 1972). This increase is due to increased progesterone production from the fetoplacental unit. The contribution of the CL to progesterone concentrations remains constant throughout pregnancy. Thus, the relatively large difference in progesterone concentrations between nonpregnant ewes with a CL present and ewes with fetus(es) present could be used to minimize the relatively high false-positive forecasts observed for sheep at 17 days postbreeding. In a trial that determined plasma progesterone concentrations in 46 ewes on days 18 and 70 after mating, correct pregnancy diagnoses were made for 80% and 93% of ewes, respectively (Weigl *et al.*, 1975). This approach might be useful for intensive sheep operations for the identification of nonpregnant animals for early culling. The limitations of progesterone analysis as a pregnancy test discussed for cattle apply to sheep as well.

2. *Estrone Sulfate*

In the pregnant ewe, estrone sulfate produced from the fetoplacental unit is detected in elevated concentrations beginning at around day 70 after conception (Tsang, 1978; Fig. 22.6). Worsfold *et al.* (1986) determined estrone sulfate concentrations in blood from ewes bred 85 days previously and found the accuracy of the nonpregnant vs pregnant interpretations was 44% and 88%, respectively. A considerable overlap in estrone sulfate values between ewes with single and multiple fetuses was found, and even at day 116 of pregnancy, estrone sulfate concentrations overlapped between groups of ewes with single and multiple fetuses. Because of this finding, the authors concluded that estrone sulfate concentrations could not be used as a predictive tool for litter size (Fletcher and Worsfold, 1988).

3. *Other Substances*

Circulating pregnancy-associated proteins have been reported in sheep. A heat-labile protein with a molecular weight of around 8000 was found in sera of sheep as early as day 6 of gestation (Cerini *et al.*, 1976). It has been demonstrated that the bovine pregnancy-specific protein B also can be used for early detection of pregnancy in the ewe because pregnant ewes have a blood antigen that cross reacts with antibodies to bPSPB (Ruder *et al.*, 1988). In a study comparing the accuracy of detecting pregnancy with an ultrasonic device, a real-time scanning instrument, and RIA for bPSPB in ewes, it was concluded that the RIA for bPSPB detected pregnancy earlier and more accurately than the ultrasonic device and was as accurate as the real-time scanning instrument (Ruder *et al.*, 1988).

Ovine placental lactogen (oPL) has been demonstrated in the peripheral blood of pregnant ewes (Kelly *et al.*, 1974). Increased maternal oPL concentrations occur between 40 and 50 days of pregnancy, reach maximum concentrations between days 120 and 140, and decline as parturition approaches (Chan *et al.*, 1978). The determination of oPL concentrations might be used as a basis for a specific pregnancy test in the ewe.

C. Pig

1. *Progesterone*

Luteal-phase progesterone concentrations in the pig are considerably higher than in cattle and sheep, namely, 20–50 ng/ml (64–159 nmol/liter), whereas

concentrations at estrus are below 0.5 ng/ml (1.6 nmol/liter) (Stabenfeldt *et al.*, 1969a). The difference in progesterone values between nonpregnant and pregnant animals 19–24 days after service has been used as an early pregnancy test (Robertson and Sarda, 1971; Edqvist *et al.*, 1972; Saiz *et al.*, 1988). In the pig, progesterone determination is usually performed on blood. Because of the sensitivity of the assay systems and the concentration of progesterone in blood in pigs during the luteal phase, analyses can be performed on a small volume of blood (about 10 drops), allowing the sample to be obtained through a small incision in an ear vein. The limitations associated with using progesterone determinations as a pregnancy test in the pig are similar to those previously discussed for cattle. Progesterone analyses have also been used to determine ovarian activity in clinically anestrous gilts, as well as to establish the stage of the estrous cycle in gilts and subsequent response to treatment (King *et al.*, 1985). It is also possible to monitor luteal-phase activity in the sow through measurement of fecal gestagens (Hultén *et al.*, 1994).

2. *Estrone Sulfate*

Previous studies of estrogen concentrations in urine revealed a marked increase in estrogen between day 20 and 30 of pregnancy in pigs (Velle, 1958). Studies of blood concentrations of estrone sulfate in pigs during pregnancy showed patterns similar to those determined in urine (Robertson and King, 1974; Fig. 22.6). In early pregnancy in the pig, it has been hypothesized that estrogen synthesized by the early preimplantation embryo may be the messenger for the maternal recognition of pregnancy (Perry *et al.*, 1976) and that the elevated estrone sulfate concentrations in the maternal circulation during early pregnancy reflect fetal synthesis. The determination of estrone sulfate in early pregnancy in the pig is thus a specific pregnancy test (Edqvist *et al.*, 1980, Cunningham *et al.*, 1983). The index of discrimination between estrone sulfate concentrations in blood of pregnant vs nonpregnant pigs around 25 days after breeding is very high. As a pregnancy test, Sugiyama *et al.* (1985) reported an accuracy rate of 98% in pigs between days 20 and 26 of pregnancy. Horne *et al.* (1983) found litter size on days 20–26 of pregnancy to be positively correlated with estrone sulfate values, but such a relationship was not found later in pregnancy. During the latter part of pregnancy, the maternal blood concentrations of estrogens (estrone sulfate, estrone, and estradiol-17β) are very high and can thus be used to confirm pregnancy at this stage of gestation (Fig. 22.6).

In the pregnant sow, the concentration of estrogen in urine and feces follows the same pattern as in blood (Choi *et al.*, 1987). Szenci *et al.* (1993) compared ultrasonography and the determination of unconjugated estrogen in feces at 25 to 30 days after insemination for the diagnosis of pregnancy in pigs. Based on farrowing data, the positive and negative predictive values for the ultrasound were 93.2 and 100%, respectively. For the determination of unconjugated estrogens, the corresponding predictive values were 93.8 and 55.1%, respectively.

D. Horse

1. *eCG (PMSG)*

Although pregnancy diagnosis has been done in mares through the measurement of equine chorionic gonadotropin (eCG), formerly named pregnant mare serum gonadotropin (PMSG), the main drawback to its use is that the presence of eCG does not guarantee the presence of a fetus, but indicates that a viable fetus was present at the time of endometrial cup formation. This situation exists because endometrial cups have autonomy of function and continue to secrete PMSG for a period of time in spite of loss of the fetus (Allen, 1969). This means that both mares with normal pregnancies and mares that experience embryonic mortality after day 40 of gestation will have elevated eCG concentrations in blood. The use of eCG determinations as a positive pregnancy diagnosis test will cause some mares to be diagnosed as pregnant that will not deliver a foal (Mitchell, 1971; Jeffcott *et al.*, 1987; Fig. 22.8).

2. *Progesterone*

Progesterone analysis is useful for establishing the presence or absence of ovarian activity in animals with puzzling behavioral patterns. Agitated or aggressive behavior, often interpreted as sexual in orientation, occurs without regard to luteal status. Progesterone analysis can be helpful because elevated values directly indicate the presence of a CL and, additionally, are evidence that folliculogenesis and ovulation are normal. Relatively low luteal-phase values for progesterone (1–3 ng/ml; 3–10 nmol/liter) vs normal luteal-phase values (>3 ng/ml; >10 nmol/liter) are often associated with the presence of a persistent CL (Stabenfeldt *et al.*, 1974b). Progesterone values of mares with persistent luteal activity are low because some $PGF_{2\alpha}$ synthesis and release often occurs about 14 days post-ovulation, albeit insufficient to cause complete luteolysis (Neely *et al.*, 1979).

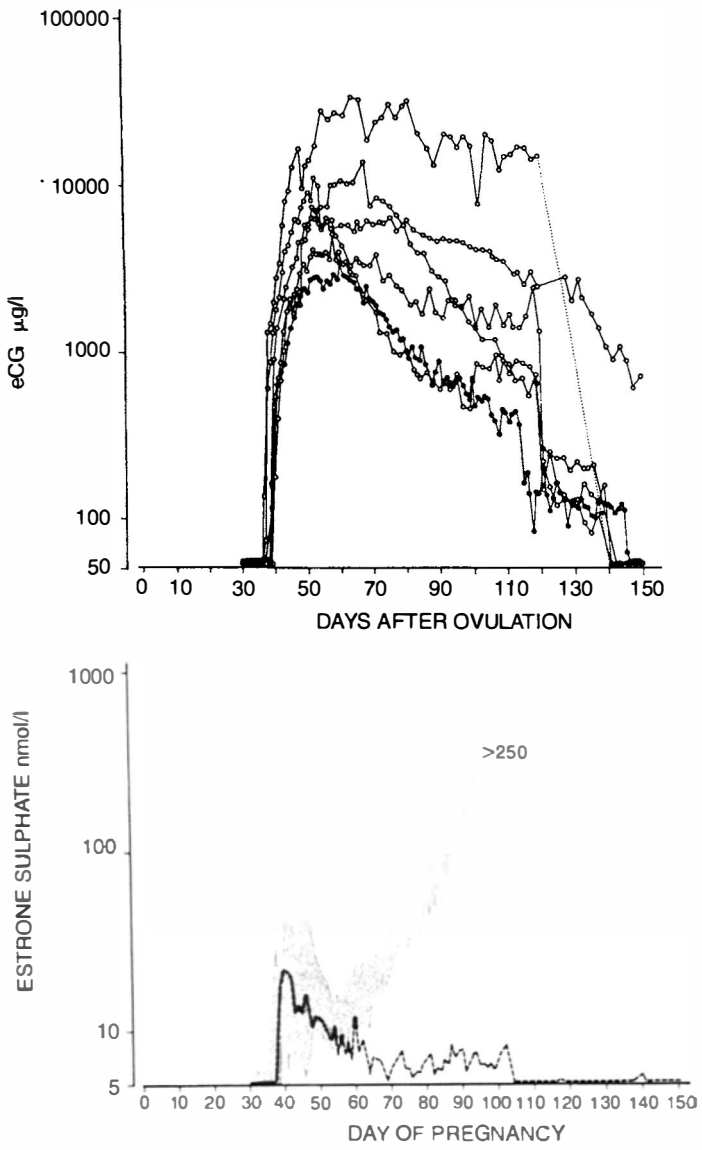

FIGURE 22.8 (Upper) Blood plasma concentrations of eCG in five normal pregnant mares (○) and in one mare in which the fetus died around day 50 of pregnancy (●). (Lower) Geometric means of blood plasma concentrations of estrone sulfate in the five normal mares (shaded area) and the estrone sulfate concentration in the mare in which the fetus died around day 50 and was aborted on day 113 of pregnancy (Darenius *et al.*, 1988).

Progesterone analyses can also be useful in mares that fail to manifest sexual receptivity, yet have cyclic ovarian activity (Hughes *et al.*, 1973). Progesterone analysis at 5-day intervals over 20 days (approximately one estrous cycle length) can verify the presence or absence of cyclic ovarian activity. The time of ovulation can also be predicted within a 2- to 3-day interval, a prediction that can be helpful to the veterinary practitioner anticipating the next time of ovulation. Breeding may have to occur by artificial means in these situations. Hinrichs *et al.* (1988) compared the accuracy of determining day of ovulation ±1 day using three different methods: (1) an immediate, qualitative ELISA for progesterone in blood, (2) a quantitative ELISA for progesterone in blood, and (3) daily teasing to detect estrus. Ovulation was detected by ultrasound examination per rectum. The accuracy in determining day of ovulation ±1 day using the three methods was 72% for the qualitative progesterone assay, 88% for the quantitative progesterone assay, and 86% for teasing.

3. *Conjugated Estrogens*

Estrone in its unconjugated form (free estrogen) reflects important physiological events in the mare beginning at about day 75 of gestation when the fetoplacental unit begins to produce estrone in rapidly increasing amounts (Nett *et al.*, 1975). More importantly, it has been shown that estrone is rapidly conjugated after secretion to water-soluble estrogen conjugates and the ratio between free and conjugated forms is 1 : 100 (Terqui and Palmer, 1979). Terqui and Palmer (1979) and Kindahl *et al.* (1982) have shown that significant increases in estrone conjugate concentrations occur between days 35 and 40 of gestation (Fig. 22.8). Kindahl *et al.* (1982) showed the increase to be 10- to 20-fold between days 35 and 40. Concentrations then decline slightly, with a further increase noted at the same time that free estrone concentrations begin to increase. The initial source of increased estrone production during gestation days 20 and 70 is the ovaries (Daels *et al.*, 1990). Later on, its occurrence is likely driven by the attachment of the embryo and the production of eCG (PMSG). Sist *et al.* (1987) found a majority of pregnant mares to have significantly higher serum estrone sulfate concentrations by day 60 after breeding. They also determined estrone sulfate in milk from pregnant mares and reported concentrations to be lower than in serum but following the same pattern. In the authors' experience, mares should be pregnant for more than 90 days before analyses of estrone sulfate in plasma can serve as a reliable indicator of pregnancy (Fig. 22.8).

Estrone conjugate concentrations in urine can be used to document pregnancy in the mare and, in fact, may be more accurate than plasma analysis because of the concentrating aspects associated with urine formation (Daels *et al.*, 1991). Increased amounts of fecal estrogens and gestagens have also been reported in the pregnant mare (Schwarzenberger *et al.*, 1991).

In addition to being a means of confirmation of pregnancy, estrone conjugate analysis also allows the soundness of the pregnancy to be assessed because estrogen concentrations reflect the dynamics of a growing fetus. Thus, it is possible not only to indicate that pregnancy is in progress by estrone conjugate analysis, but also to indicate whether the pregnancy is proceeding well or is in some state of compromise. Analysis of estrone conjugates is an important aid for the verification of pregnancy in the mare and does not suffer the drawback of false positive diagnosis as is the case for eCG (Fig. 22.8). Estrone conjugate analysis also has been used to assess follicle growth patterns in nonpregnant mares, a test that was difficult to do by determining free estradiol-17β (Makawiti *et al.*, 1983; Daels *et al.*, 1991).

4. *Testosterone*

Testosterone values vary in the mare according to the reproductive state. Values, usually less than 15 pg/ml (52 pmol/liter) during anestrum, range between 20 and 40 pg/ml (69–139 pmol/liter) during cyclic ovarian activity, with the higher values being observed during the follicular phase of the cycle immediately before ovulation. Testosterone determinations have been used to aid the diagnosis of granulosa-theca cell tumors in the mare (Stabenfeldt *et al.*, 1979) and to differentiate granulosa-theca cell tumors from ovarian teratoma (Panciera *et al.*, 1991). Leydig-like cells in the theca appear to be the source of testosterone. In cases of granulosa-theca cell tumors, testosterone values vary with values ranging from 40 pg to over 100 pg/ml (139–347 pmol/liter). These tumors generally develop slowly, and it is not known whether this slow development also reflects a slowly developing capacity for testosterone production or whether there is variability in the number of testosterone-secreting cells among tumors. Aggressive stallion-like behavior is associated with values less than 150 pg/ml (520 pmol/liter) (Meinecke and Gips, 1987). In the authors' experience, this is the only clinical situation involving abnormal behavior in the mare in which a direct relationship to gonadal steroids has been established.

Testosterone determinations in the male horse have been used as an aid in the diagnosis of cryptorchidism. Cox (1975) reported that horses with less than 40 pg/ml (139 pmol/liter) plasma should be considered castrated, whereas animals with concentrations less than 100 pg/ml (347 pmol/liter) should be considered as having testicular tissue present. Although some cryptorchid animals have testosterone concentrations less than 100 pg/ml (347 pmol/liter), most have values range from 200 to 1000 pg/ml (693–3467 pmol/liter) (Cox, 1975). Testosterone concentrations in intact males usually range from 1000 to 2000 pg/ml (3467–6934 pmol/liter) (Cox *et al.*, 1973; Berndtson *et al.*, 1974). hCG administration for the purpose of stimulating testosterone production by the testes has been suggested as a means of resolving cases in which values are between 40 and 100 pg/ml (139–347 pmol/liter). The dosage of injected hCG has been 6000–12,000 I.U. (Cox *et al.*, 1986; Arighi and Bosu, 1989; Silberzahn *et al.*, 1989), and the second sample for analysis of testosterone was obtained after 30–120 minutes (Cox *et al.*, 1986), after 24 hours (Arighi and Bosu, 1989), or after 3 days (Silberzahn *et al.*, 1989). For routine diagnosis, the authors do not recommend the use of hCG because most single baseline determinations are adequate for diagnosis. The main value of a second determination is for substantiation of the first values, and thus the

time and expense required for the second sample is not commensurate with the information to be gained (Stabenfeldt and Hughes, 1980).

Analysis for estrone sulfate conjugates for the diagnosis of cryptorchidism may be preferred over that for testosterone because it requires only one analysis and the accuracy is slightly improved (Cox *et al.*, 1986). Arighi and Bosu (1989) recommended both resting testosterone and estrone sulfate to diagnose accurately the presence of testicular tissue. It should be noted, however, that estrone sulfate analysis for cryptorchidism cannot be used in horses less than 3 years of age or in donkeys because little estrone sulfate is produced in either of these situations.

It is the authors' experience that the presence of sexual behavior in suspected cases of equine cryptorchidism is not necessarily dependent upon elevated testosterone concentrations in that many patients (about one-third) referred because of behavioral problems are, in fact, castrated. In essence, some animals can maintain normal libido with low circulating concentrations of testosterone. In this situation, testosterone analysis is very helpful either to eliminate unnecessary surgery or to indicate to the surgeon that testicular tissue is present and should be found on surgical entry.

E. Dog

1. Progesterone

In the bitch, there is little difference between the progesterone patterns of the pregnant and nonpregnant luteal phase. Plasma concentrations of progesterone are elevated throughout the luteal phase. However, although mean concentrations of progesterone are higher during the latter part of the pregnant luteal phase than during the nonpregnant luteal phase, these differences are not significant enough to allow progesterone determinations to be used as a pregnancy diagnosis test.

Bitches usually ovulate at the onset of sexual receptivity, remain sexually receptive for about the first week of luteal activity, and, in fact, are fertile during this period of time (Holst and Phemister, 1974). Progesterone analysis can be used to confirm the occurrence of ovulation. Concentrations usually increase slightly above baseline in the periovulatory period, reaching about 15 nmol/liter at ovulation, followed by a sustained increase beginning 24 hours following ovulation (Concannon *et al.*, 1975; Fig. 22.9). This approach may be used in a retrospective analysis of a breeding cycle in an attempt to correlate the time of ovulation with other criteria such as vaginal cytological changes. The determination of progesterone in daily samples of blood obtained during the periovulatory period gives a more precise timing of ovulation than can be obtained by vaginal cytology (Linde and Karlsson, 1984).

In situations wherein a particular pairing of animals does not result in a mutual sexual attraction and where artificial insemination must be used, progesterone analysis is a useful tool to verify ovulation. Artificial insemination with frozen–thawed semen usually results in lower pregnancy rates than artificial insemination using fresh semen. Using progesterone determinations to pinpoint ovulation, it was found that the pregnancy rate following insemination with frozen–thawed semen could be improved when the insemination was performed at progesterone concentrations less than 30 nmol/liter (Linde-Forsberg and Forsberg, 1989, 1993; Fig. 22.9).

Progesterone analysis can also be useful in cases of short estrous-cycle intervals to determine if ovulatory failure has occurred, a situation in which progesterone concentrations are low following the termination of estrus. Progesterone analysis is also useful in cases when there is some question as to the completeness of removal of ovarian tissue during an ovariohysterectomy. An important distinction concerning the dog is that, unlike other domestic species, the bitch is keyed into sexual receptivity at the end of the follicular phase by progesterone. Thus, dogs may be sexually attractive because of odors arising from the vagina that are due to factors such as infection. However, bitches will only accept males in the presence of increased progesterone concentrations, a situation which is almost always associated with luteal tissue as part of a remaining ovarian remnant.

2. Testosterone

The most common endocrine test in male dogs is testosterone for the purpose of checking the secretory status of the Leydig cells. Testosterone values in normal dogs range from about 1 ng/ml (3.5 nmol/liter) to about 10 ng/ml (35 nmol/liter) because of the pulsatile release pattern of testosterone. Testosterone concentrations in castrated dogs are less than 0.5 nmol/liter.

Assay of basal testosterone concentration may allow the diagnosis of the absence of testicular tissue in the same manner as described previously for the male horse. Sometimes the positive confirmation of presence of testicular tissue may require the use of hCG or GnRH to stimulate testosterone production. In this situation, a resting plasma sample is collected immediately before the administration of the stimulating hormone, and a second blood sample is collected 1 hour later. A significant increase in plasma testosterone concentration is diagnostic of the presence of testicular tissue.

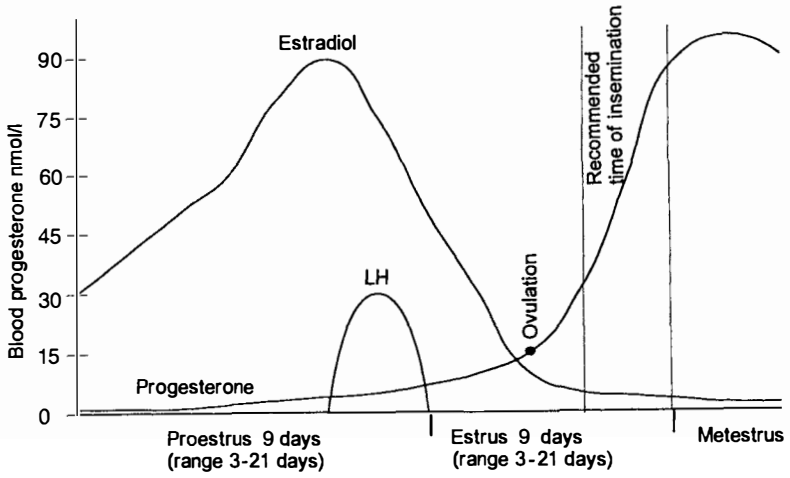

FIGURE 22.9 Schematic representation of the temporal relationships among estradiol, progesterone, peak of luteinzing hormone (LH), and ovulation in the bitch. The recommended time of mating or artificial insemination is based on the progesterone concentration.

Testosterone analysis is done in conjunction with fertility examinations, often in stud animals that are presented as infertility cases following a prolonged show tour. Most of these animals have testosterone concentrations that are compatible with normal spermatogenesis, although sperm counts are often very low. The management of this syndrome is still uncertain.

The authors have observed feminizing syndromes in intact dogs in which concentrations of testosterone are greatly decreased below normal (to 100 pg/ml or less; ≤350 pmol/liter), and estradiol values are 2–3 times normal (30–45 pg/ml vs the normal 15 pg/ml; 110–165 pmol/liter and 55 pmol/liter). It is thought that a majority of these cases involve Sertoli cell tumors. Dogs with confirmed Sertoli cell tumors have high peripheral plasma levels of inhibin and suppressed levels of LH and testosterone (Grootenhuis *et al.*, 1990). These authors were, however, unable to detect differences in blood concentrations of estradiol between dogs with Sertoli cell tumors and control dogs.

3. *Relaxin*

Relaxin is produced in the pregnant dog beginning between days 20 and 25 of gestation but is undetectable during anestrus, throughout nonpregnant ovarian cycles, and in male dogs (Steinetz *et al.*, 1987). Maximal concentrations are attained by days 40–50 of pregnancy and are followed by slight declines before parturition. Relaxin is produced predominantly by the placenta, and it is thus possible to use relaxin analysis to confirm pregnancy in the dog.

F. Cat

1. *Progesterone*

Progesterone analysis can be used to verify the occurrence of ovulation in the cat following coitus. Ovulation usually occurs 24–36 hours after coital contact with a male at the appropriate time of the follicular phase of the estrous cycle (Shille *et al.*, 1983). If the breeding schedule is very limited in time, it is possible for a cat to be bred too early in the follicular phase with coitus failing to elicit LH release. More rarely, females may allow copulation at times other than the follicular phase. In both these situations, ovulatory failure would be documented by the finding of low progesterone values 10 days postbreeding. In one study, progesterone concentrations greater than 1.87 ng/ml (6 nmol/liter) were consistently associated with luteal-phase ovaries, and values less than 0.15 ng/ml (0.5 nmol/liter) were associated with follicular-phase ovaries (Lawler *et al.*, 1991).

2. *Estrogen*

As the cat is an induced ovulator (requires coitus), estradiol analysis can be used to assess the presence of ovarian follicle activity with values ranging from 10 pg/ml (37 pmol/liter) in the interfollicular phase to 60 pg/ml (220 pmol/liter) during folliculogenesis. As indicated previously, queens have ovarian follicle growth patterns that last 5–7 days, followed by a slightly longer interval prior to the next growth phase (Shille *et al.*, 1979b). Estrogen analysis could document the presence or absence of ovarian follicular activity in animals that fail to manifest sexual activity. It also

could be used to assess the completeness of an ovariohysterectomy in cats that are spayed, but that present signs suggestive of sexual receptivity. The usual finding is that of low estrogen concentrations, which indicates that the behavior is not sexual in orientation. In the domestic cat, estrogen metabolites are primarily excreted in the feces (Shille *et al.*, 1990; Möstl *et al.*, 1993). Analyses of fecal steroids is a useful noninvasive approach for monitoring ovarian function in exotic felines (Graham *et al.*, 1993).

3. *Testosterone*

Testosterone analyses can be used to evaluate Leydig cell function in the testis of the male cat. The range of values is usually between 1 and 10 ng/ml (3.5–35 nmol/liter).

4. *Relaxin*

Relaxin is produced by the fetoplacental unit beginning about day 20 of gestation. Maximal concentrations are achieved by day 30–35 (Addiego *et al.*, 1987). Relaxin concentrations thus can be used to assess pregnancy status in the cat and even to assess its normalcy, based on the fact that fetoplacental units in jeopardy produce less relaxin.

V. GENERAL COMMENTS

A. Hormone Concentrations

In the foregoing presentation, concentrations of hormones have not been emphasized. This is because there is still some variability in the values reported by various laboratories. It is important that clinical endocrinology laboratories understand and have experience with their assay systems in relation to particular clinical syndromes. For example, the actual concentration of progesterone during the follicular phase of the estrous cycle of domestic animals is approximately 100 pg/ml (318 pmol/liter), certainly no greater than 200 pg/ml (636 pmol/liter) plasma. Some laboratories, however, report basal values of 1–2 ng/ml (3.2–6.4 nmol/liter) for progesterone. The authors have used 1 ng/ml (3.2 nmol/liter) as the lowest concentration of progesterone that is compatible with an actively secreting CL, especially for the cow, ewe, mare, and sow, and pay particular attention to the accuracy of values in this range. Actually, even values between 0.5 and 1.0 ng/ml (1.6–3.2 nmol/liter) are viewed as indicating luteal activity. It is possible to produce useful information with higher basal concentrations; however, the line that divides the presence and absence of

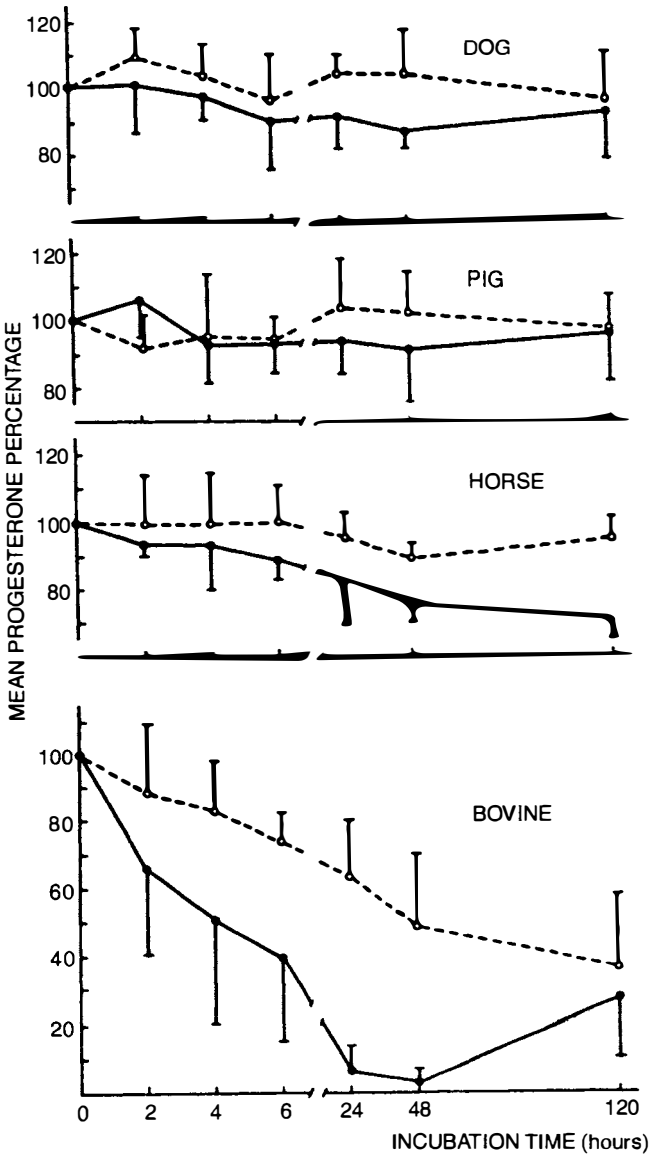

FIGURE 22.10 Mean (and SD) plasma progesterone percentage after storage of heparinized whole blood from 4 dogs, 4 pigs, 4, horses, and 8 cows at 20°C (●) and at 4°C (○). The intial progesterone value at time 0 has arbitrarily been set at 100% (Oltner and Edqvist, 1982).

CL activity must be precisely known. The reference values developed by laboratories are dependent upon the type of assay used.

It is possible to have a wide range of values for a particular hormone and still have normal physiological conditions. Luteal-phase progesterone concentrations in the cow, for example, range between 2 and 12 ng/ml (6–38 nmol/liter) because of pulsatile gonadotropin secretion (Walters *et al.*, 1984) with no adverse effect on the preparation of the animal for the nurture of a potential embryo. Hormone values can also depend

upon the type of material used in the assay. Luteal-phase progesterone values are approximately 4 ng/ml (13 nmol/liter) in fat-free milk, between 5 and 35 ng/ml (16–111 nmol/liter) in whole milk, and approximately 250 ng/ml (795 nmol/liter) in milk fat.

B. Material for Analysis and Storage Effects

1. Blood

The treatment and storage of samples prior to analysis can influence the hormone value obtained for a blood sample. Red blood cells from cows have the capacity to metabolize progesterone to other steroids (Short, 1958; Fig. 22.10). The rapid decrease, about 10–20% reduction per hour, in the progesterone content in heparinized bovine blood samples appears to be due to the conversion of progesterone to 20β-hydroxylated gestagens. Also, other 20-keto-gestagens such as pregnenolone and 17α-hydroxyprogesterone undergo a similar conversion to 20β-hydroxylated gestagens, and their blood concentrations are reduced during storage (Choi *et al.*, 1989). The drop in progesterone concentration in heparinized whole blood follows glycolysis, and when glucose concentrations are low, the enzymatic degradation of progesterone in heparinized cow blood is to some degree inhibited (Oltner and Edqvist, 1982; Fig. 22.10). The use of anticoagulants, such as sodium fluoride, that block glycolysis greatly reduces the rate of decline in whole-blood progesterone concentrations (Vahdat *et al.*, 1979; Pulido *et al.*, 1991). Temperature also plays a significant role in regulating the rate of decline in progesterone; the lower the temperature of storage, the slower the rate of progesterone decline (Fig. 22.10).

The enzymes responsible for progesterone conversion are present in the red blood cells, and harvesting serum or plasma as soon as possible after collection of the sample prevents the metabolism of progesterone (Vahdat *et al.*, 1979). If serum or plasma cannot be separated within 30 minutes, the sample should be put on ice to retard enzymatic processes.

A decline in progesterone concentration also occurs in stored whole blood from the ewe (Van der Molen and Groen, 1968; Wiseman *et al.*, 1982/83), although the decline is not as rapid and pronounced as in the cow. On the other hand, no significant decrease in progesterone of whole blood of female goats was found during storage at room temperature for 24 hours (Navarro *et al.*, 1990). Some decline in progesterone also seems to occur during storage of equine whole blood (Fig. 22.10). For other domestic animals discussed in this chapter, no major effects of storage on progesterone concentrations have been reported.

Storage of bovine whole blood also results in significant decreases of 17-keto-androgens (e.g., androstenedione, dehydroepiandrosterone) and 17-keto-estrogens (e.g., estrone) because 17α-hydroxysteroid dehydrogenase present in red blood cells converts the steroids to epitestosterone and estradiol-17α, respectively (Choi *et al.*, 1989). Concentrations of testosterone and estradiol-17β are not influenced when whole bovine blood is stored for 24 hours at 20°C (Choi *et al.*, 1989).

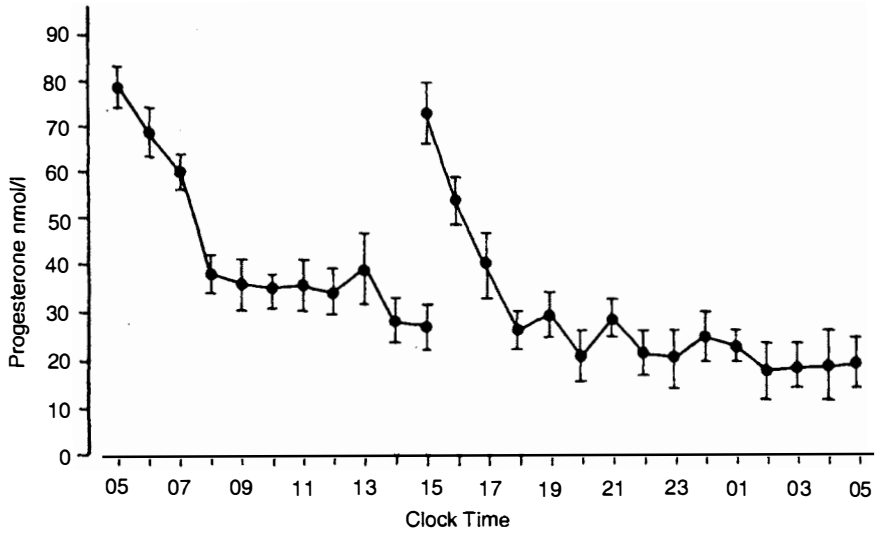

FIGURE 22.11 Hourly changes during 24 hours in whole-milk concentrations of progesterone, mean and SE of 12 cows (Garcia and Edqvist, 1990).

Plasma or serum samples can be stored frozen for long periods of time without significant loss in reproductive hormone concentration. Sample-handling procedures from blood collection to the freezing of serum or plasma should be standardized for each species and hormone determined.

2. *Milk*

Milk samples for progesterone analysis can be preserved with sodium azide, potassium dichromate, or thimerosal for storage at room temperature for about 3 weeks and for several months if the milk is stored at 4–5°C (Nachreiner *et al.*, 1986, 1992). There is a difference in progesterone content among colostrum, composite milk, and strippings because of variation in milk-fat content (Garcia and Edqvist, 1990; Fig. 22.11). This difference is less obvious when skim milk is used for the immunoassay of progesterone, but the temperature must be controlled at centrifugation since warm butterfat will absorb progesterone more readily than cold butterfat (Nachreiner *et al.*, 1986, 1992). A common recommendation for sampling of milk for analyses of progesterone is to obtain strippings after milking.

Calcium-Regulating Hormones and Diseases of Abnormal Mineral (Calcium, Phosphorus, Magnesium) Metabolism

THOMAS J. ROSOL AND CHARLES C. CAPEN

I. CALCIUM METABOLISM

A. Introduction

Calcium (Ca) is a mineral that plays a central role in maintaining the homeostasis of vertebrate animals, including muscle contraction, blood coagulation, enzyme activity, neural excitability, hormone secretion, and cell adhesion, in addition to being an essential structural component of the skeleton (Capen and Rosol, 1993b). The precise control of calcium ion in extracellular fluids is vital, therefore, to the health of

man and animals. To maintain a constant concentration of calcium, despite variations in intake and excretion, endocrine control mechanisms have evolved that primarily consist of the interactions of three major hormones. Although the direct roles of parathyroid hormone (PTH), calcitonin (CT), and vitamin D frequently are emphasized in the control of blood calcium, other hormones, such as adrenal corticosteroids, estrogens, thyroxine, somatotropin, glucagon, and parathyroid hormone-related protein, may contribute to the maintenance of calcium homeostasis under certain conditions (Capen, 1989; Capen and Rosol, 1993b). Calcium is also involved in the pathogenesis of metabolic diseases that disrupt the normal regulation of Ca balance and may result in hypercalcemia or hypocalcemia (Chew *et al.*, 1992).

B. Calcium in the Body

The majority of the Ca of the body (99%) is present in the inorganic matrix of bone as hydroxyapatite (Fig. 23.1). Most of the remaining Ca (0.9%) is sequestered in the plasma membrane and endoplasmic reticulum of cells. Extracellular fluid contains 0.1% of the body's Ca mass, with a total Ca concentration of about 2.5 mmol/liter (Brown, 1994). Approximately 50% of the extracellular Ca (1.2 mmol/liter) is in the ionized form (Ca^{2+}), which is the biologically active form of Ca. Neonatal animals have slightly greater extracellular Ca concentrations compared to those of adults (Hazewinkel, 1991; Chew *et al.*, 1992; Szenci *et al.*, 1994b). There is very little Ca in the cytosol of cells (approximately 100 n*M*), which is predominantly in the ionized form.

Vertebrate animals, such as the marine fishes, originally evolved in an environment with a high concentration of Ca^{2+} (Copp, 1969b). Seawater contains approximately 10 mmol/liter Ca^{2+}, but the extracellular fluids of marine fishes contain less than 2 mmol/liter Ca^{2+}. Therefore, fishes have to limit and regulate Ca^{2+} absorption from the intestinal tract, skin, or gills and to develop mechanisms to excrete Ca^{2+} efficiently. This resulted in the development of hormones that reduce serum Ca^{2+} concentration and include calcitonin and stanniocalcin. Fishes lack parathyroid glands, which have the primary role of reducing the loss of body Ca^{2+} and maintaining serum Ca^{2+}. Parathyroid glands first appear phylogenetically in amphibians that spend all or part of their life cycle on land, an environment low in Ca^{2+}. In terrestrial vertebrates, both the parathyroid glands and the kidneys are important in preserving total body Ca. Because there is less need for promoting the excretion of Ca or lowering serum Ca^{2+} in land animals, hormones such as calcitonin are less critical in maintaining Ca homeostasis.

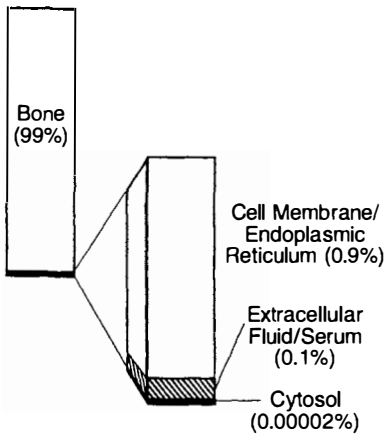

FIGURE 23.1 Distribution of calcium (Ca) in the body. (Rosol *et al.*, 1995a.)

C. Function of Calcium

Calcium serves two primary functions in the body: (1) to maintain the structural integrity of bones and teeth, and (2) as a messenger or regulatory ion (Ebashi, 1985). The 10,000-fold concentration gradient of Ca^{2+} between the extracellular fluid (1.2 mmol/liter) and the cytoplasm (100 n*M*) permits Ca^{2+} to function as a signaling ion to activate intracellular processes. The lipid bilayer of the cell membrane has a low permeability to Ca^{2+}; therefore, influx of Ca^{2+} into the cytoplasm is controlled by a heterogeneous group of Ca channels regulated by membrane potential, cell membrane receptors, or intracellular secondary messengers (Miller, 1992; Brown, 1994). Influx of Ca^{2+} into cells can: (1) regulate cellular function by interactions with Ca-binding proteins (e.g., calmodulin) and Ca-sensitive protein kinases, and (2) stimulate biologic responses such as neurotransmitter release, contraction, and secretion. Ionized calcium also plays an important role in cell adhesion and blood coagulation. In addition, Ca^{2+} may regulate cellular function by binding to a G-protein-linked Ca^{2+}-sensing receptor in the cell membrane, such as in parathyroid chief cells or renal epithelial cells (Brown *et al.*, 1995).

It is critical for cells to maintain the normal low level of intracellular Ca^{2+}. If cellular Ca homeostasis fails as a result of anoxia, an energy-deprived state, or perturbed membrane integrity, cell viability is threatened due to uncontrolled entry of Ca^{2+} through the plasma membrane or from intracellular stores (Siesjö, 1989).

D. Forms of Calcium

Extracellular and serum Ca exists in three forms: (1) ionized Ca^{2+}; (2) complexed Ca^{2+} (5% of total Ca) to anions such as citrate, bicarbonate, phosphate, or

lactate; and (3) protein-bound Ca^{2+} (45% of total Ca) (Fig. 23.2) (Chew *et al.*, 1992; Capen and Rosol, 1993b). The protein-bound fraction of Ca^{2+} is principally bound to negatively charged sites on albumin, with smaller amounts bound to globulins. The protein-bound form of Ca^{2+} is dependent on serum pH, and alterations in serum pH will change the $[Ca^{2+}]$. As the pH of serum becomes more acidic, the $[Ca^{2+}]$ will increase because of competition of H^+ for binding to the negatively charged sites on serum proteins. The ionized and complexed Ca^{2+} compose the ultrafilterable fraction of Ca^{2+} and represent the fraction that is present in the glomerular filtrate. The concentration of ionized Ca^{2+} in the serum is approximately 1.25–1.6 mmol/liter (5.0–6.4 mg/dl) in most domestic animals.

E. Measurement of Calcium

Total serum Ca concentration in serum, heparinized plasma, or urine can be measured directly using atomic absorption spectrophotometry or a colorimetric assay using *o*-cresolphthalein complexone (Table 23.1) (Fraser *et al.*, 1987). Total serum Ca concentration in dogs is partially dependent on serum albumin or total protein content, but can be standardized using the following formulas: (1) Adjusted Ca (mg/dl) = Ca (mg/dl) − albumin (g/dl) + 3.5, or (2) Adjusted Ca (mg/dl) = Ca (mg/dl) − 0.4[total serum protein (g/dl)] + 3.3 (Meuten *et al.*, 1982). This correction procedure has not been validated with ionized Ca to determine whether it has true biological significance. In cats, horses, and cattle, there is a significant linear relationship between serum Ca and albumin concentrations (Bienzle *et al.*, 1993). Variability in the serum concentrations of Ca and albumin precluded determination of a dependable correction formula in cats (Flanders *et al.*, 1989). Serum or urine, but not plasma, can be stored at 4°C for weeks or months. Urine should be acidified with 6 *M* HCl to a pH of 3–4 during or immediately after collection to prevent Ca precipitation with anions or proteins. Urine Ca concentration may be low (<4 mg/dl, 1.6 mmol/liter) in normal animals of most species and below the sensitivity of colorimetric assays for Ca. Therefore, atomic absorption spectrophotometry often is necessary for measurement of Ca in urine. Calcium content of feces, tissue, or food that has been ashed also can be measured by atomic absorption spectrophotometry.

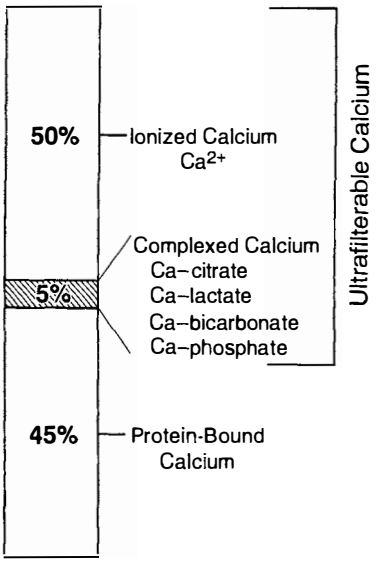

FIGURE 23.2 Fractions of extracellular calcium (Ca). (Rosol *et al.*, 1995a.)

Ionized blood or plasma $[Ca^{2+}]$ can be measured using an instrument equipped with a Ca^{2+} ion-selective electrode (Table 23.1) (Fraser *et al.*, 1987). It is most informative to measure the biologically active form of Ca^{2+} (ionized Ca^{2+}), but this is not always practical because it requires special instrumentation and proper sample handling. In most cases, changes in serum total Ca parallel changes in serum Ca^{2+} (Lincoln and Lane, 1990; Chew *et al.*, 1992). Ionized $[Ca^{2+}]$ can be measured in heparinized whole blood, plasma, or serum. Heparin can bind Ca^{2+} and variably lower the serum Ca^{2+} concentration artifactually; therefore, the amount of heparin should be standardized for all samples (Forman and Lorenzo, 1991). Serum or plasma can be stored 48 hour or longer at 4°C (Szenci *et al.*, 1991, 1994a; Schenck *et al.*, 1995). Anaerobic collection is critical to prevent changes in the pH of the sample. It is important to measure $[Ca^{2+}]$ at the same pH as the blood at time of collection for the most biologically relevant value, because correction formulas to adjust Ca^{2+} to pH 7.4 have not been validated in animals (Kohn and Brooks, 1990).

F. Daily Calcium Balance and Movement

Calcium is absorbed from food in the gastrointestinal tract, with the greatest absorption occurring in the duodenum (McDowell, 1992a). In normal animals an equivalent amount of Ca is excreted primarily in the urine, with small losses in sweat and intestinal secretions. The Ca released from bone by osteoclastic bone resorption and deposited in bone by bone formation are balanced in normal adult animals. Therefore, intestinal Ca absorption is the major determinant of the amount of Ca excreted in the urine in adult animals.

Calcium can move across epithelial barriers by two routes: (1) transport between cells, and (2) transport through cells (Yanagawa and Lee, 1992; Brown, 1994). Transport of Ca between cells occurs by two mecha-

TABLE 23.1 Measurement of Calcium in Blood and Urine

	Test	Sample requirements/ handling	Methods	Comments	Reference ranges (OSU values)[a]
Blood calcium	Total calcium	Blood, serum, plasma	Atomic absorption, colorimetry		9.4–12.0 mg/dl (dog)[b] 8.4–11.0 mg/dl (cat) 11.7–13.6 mg/dl (horse) 8.7–11.4 mg/dl (cow)
	Ionized calcium	Anaerobic collection of blood, serum, or plasma	Calcium ion-specific electrode	Obtain blood pH.	5.2–6.0 mg/dl (dog) 4.3–5.9 mg/dl (cat) 6.0–7.2 mg/dl (horse)
Urine calcium handling	Total calcium	Acidify urine to prevent calcium precipitation	Atomic absorption, colorimetry	Colorimetry may be too insensitive in some species. Total Ca value is of no use.	NA[c]
	Ca/Cr ratio			Good measure of Ca excretion at one time point. Collection from fasting animals is an indirect measure of bone resorption.	$0.5–2.3 \times 10^{-2}$ (fasted dogs)
	Fractional calcium excretion	Collect urine from fasted animal		Measure of renal calcium reabsorption; decreased by parathyroid hormone.	$0.05–0.14 \times 10^{-2}$ (fasted dogs)
	24-hour calcium excretion			Good measure of daily calcium loss in urine.	0.17–0.70 mg/kg/d (fasted dogs)

[b] To convert mg/dl to mmol/liter, divide by 4.
[c] NA = not appropriate.

nisms, convection and diffusion. Convection (solvent drag) is the movement of Ca with the flow of water. A change in Ca concentration on either side of the epithelium is not necessary for Ca movement between the cells. Convection of Ca occurs in the process of glomerular filtration and with water reabsorption in the proximal convoluted tubules. Diffusion is the passive movement of Ca down an electrical or chemical gradient. For example, Ca diffuses from the lumen of the proximal convoluted tubules to the renal interstitium because there is a higher [Ca^{2+}] in the lumen.

In order for Ca to move through cells, mechanisms have evolved for the regulation of Ca transport into the cytosol, buffering in the cytoplasm, and release from the cell (Yanagawa and Lee, 1992; Brown, 1994). Large concentration and electrical gradients are present for Ca^{2+} to enter cells. There is a 10,000-fold concentration gradient from extracellular to intracellular fluids and the interiors of cells are negatively charged (−50 to −100 mV). The regulation of Ca absorption by cells is accomplished by Ca channels in the cell membrane (Miller, 1992; Brown, 1994). After the Ca^{2+} channels are opened, there is rapid diffusion of Ca^{2+} into the cell. The rise in intracellular Ca^{2+} can stimulate biological processes by interaction with Ca^{2+}-binding enzymes and regulatory proteins (Rasmussen, 1986a, 1986b). It is also possible for an increase in the transcellular flux of Ca^{2+} to stimulate biological processes without a net increase in intracellular [Ca^{2+}]. In some cells or tissues, the intracellular Ca^{2+} signal oscillates (e.g., hepatocytes responding to norepinephrine) (Berridge, 1990) or can be transmitted intercellularly by gap junctions (Sanderson *et al.*, 1994). The Ca^{2+} that enters the cytosol is rapidly buffered by Ca-binding proteins (e.g., calbindin and calmodulin) and by transport into mitochondria and endoplasmic reticulum. It is important to buffer intracellular Ca^{2+}, because high concentrations of intracellular Ca^{2+} can be toxic to cells.

Calcium can be transported from the cytoplasm to intracellular vesicles (e.g., endoplasmic reticulum) or the extracellular space by membrane-associated Ca^{2+}-ATPases (Grover and Khan, 1992; Raeymaekers and Wuytack, 1996) and a cell membrane Na^+/Ca^{2+} exchanger (Dominguez and Juhaszova, 1992). The Na^+/Ca^{2+} exchanger permits the transport of one Ca^{2+} ion outside of the cell with the entry of three Na^+ ions. The Na^+ enters the cell down a chemical and electrical gradient. The Ca^{2+}-ATPases are dependent on intracel-

lular [ATP] and the Na^+/Ca^{2+} exchanger is indirectly dependent on [ATP], because ATP is necessary for the cell membrane Na^+/K^+ ATPase to maintain a steep gradient of Na^+ across the cell membrane.

A final mechanism by which Ca^{2+} is transported through cells is vesicular transport (Yanagawa and Lee, 1992). In this form of Ca^{2+} movement, Ca^{2+} is absorbed as a constituent of a vesicle (e.g., pinocytosis) and is transported across the cell in the vesicle. There is no need for Ca^{2+} buffering, because it does not directly enter the cytoplasm. This form of Ca^{2+} transport currently is not well understood; however, the mammary gland secretes most of its Ca by secretory vesicles. Intracellular Ca is pumped by a Ca^{2+} ATPase into the Golgi apparatus of mammary epithelial cells, the Ca^{2+} binds to citrate and casein, and the complexed Ca^{2+} is secreted in the form of secretory vesicules (Atkinson *et al.*, 1995).

G. Renal Handling of Calcium

The kidney normally reabsorbs 98% or more of the filtered Ca. This high degree of reabsorption is important to maintain balance of Ca in the body, but permits the kidneys, if necessary, to excrete large amounts of Ca in the urine (Bronner, 1989; Rouse and Suki, 1990; Bindels, 1993). Most filterable Ca (ionized and complexed Ca) enters the glomerular filtrate by convection and is reabsorbed by the renal tubules. The kidneys reabsorb approximately 40-fold more Ca than is absorbed by the intestinal tract because of the high degree of blood flow and ultrafiltration in the glomerulus. Reduction of glomerular filtration impairs the ability of the kidneys to excrete Ca.

Most filtered Ca (70%) is reabsorbed in an unregulated manner in the proximal convoluted tubules by diffusion and convection with water uptake between the epithelial cells (Fig. 23.3). The thick ascending loop of Henle absorbs about 20% of the filtered Ca, but the precise mechanism is unclear. Much of the Ca reabsorption appears to be passive, but an active component may also be present (Rouse and Suki, 1990). The site of active regulation of Ca reabsorption is the distal convoluted tubule that reabsorbs approximately 10% of the filtered Ca. The principal stimulator of Ca reabsorption in the distal convoluted tubule is parathyroid hormone (Bindels, 1993). Ca reabsorption in the distal convoluted tubule is an active transcellular process that requires the presence of Ca channels in the luminal cell membrane (Miller, 1992), intracellular Ca-binding proteins (calbindins) (Bouhtiauy *et al.*, 1994a, 1994b), and a Ca^{2+}-ATPase (Grover and Khan, 1992) and Na^+/Ca^{2+} exchanger (Dominguez and Juhaszova, 1992) in the basolateral cell membranes (Bronner, 1989; Rouse and Suki, 1990). Factors associated with increased or decreased Ca excretion are presented in Table 23.2 (Canzanello *et al.*, 1990; Chew *et al.*, 1992; Bindels, 1993). Renal epithelial cells express the Ca^{2+}-sensing receptor on their cell membranes, and the distribution of the receptor overlaps with the localization of PTH receptors, so the kidneys may partially autoregulate the renal reabsorption of calcium based on the blood Ca^{2+} concentration (Brown and Hebert, 1996).

Measurements of Ca excretion in animals include urine [Ca], Ca/Cr ratio in the urine, fractional Ca excretion, and 24-hour Ca excretion (Table 23.1) (Nordin *et al.*, 1967; DiBartola *et al.*, 1980; Morris *et al.*, 1984; Fleming *et al.*, 1991; Lulich *et al.*, 1991; Chew *et al.*, 1992;

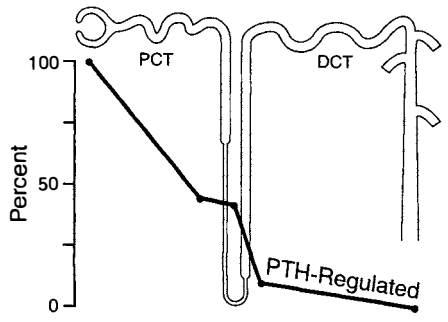

FIGURE 23.3 Sites of calcium (Ca) reabsorption in the nephron. The greatest amount of filtered Ca is reabsorbed passively in the proximal convoluted tubule (PCT). The site of active regulation of Ca reabsorption by parathyroid hormone (PTH) is in the distal convoluted tubule (DCT) (Rosol *et al.*, 1995a.)

TABLE 23.2 Factors Affecting Urinary Calcium Excretion

Factors that increase urinary Ca excretion
Saline infusion or high dietary Na^+ content
High dietary protein
Hypercalcemia (due to increased filtered Ca)
Vitamin D deficiency or excess
Acidosis
Mineralocorticoid/glucocorticoid excess
Osmotic diuretics
Loop diuretics (e.g., furosemide)
Factors that decrease urinary Ca excretion
Parathyroid hormone
Calcitonin
Dehydration
Alkalosis
Hypercalcemia (due to reduction of GFR)
Thiazide diuretics

Fleming *et al.*, 1992). Urinary Ca excretion correlates with dietary absorbance in normal adult animals. The concentration of Ca in the urine is of little value because of large fluctuations in normal urine and is usually <4 mg/dl (1.6 mmol/liter). Horses excrete larger amounts of Ca in the urine, and urine [Ca] is typically much higher than 4 mg/dl (1.6 mmol/liter). The Ca/Cr ratio of the urine is a better indicator of Ca excretion because it corrects for errors in timing of urine collections, urine concentration or dilution, and differences in lean body mass (Weaver, 1990). Calculation of fractional Ca excretion requires measurement of urine and serum Ca and Cr concentrations and is an indication of renal calcium reabsorption at the time of analysis as well as the degree of excretory renal function (DiBartola *et al.*, 1980). Fractional Ca excretion is best measured in a fasting animal to eliminate the effect of dietary Ca on renal Ca excretion. Measurement of Ca excretion in a fasting animal is an indirect measurement of bone resorption, because Ca released from bone and the obligate renal Ca loss are the major sources of urinary Ca when there is little gastrointestinal Ca absorption. The 24-hour Ca excretion is a good measurement of daily Ca loss and may be used to investigate daily Ca balance.

H. Intestinal Calcium Absorption

There are two components of Ca absorption from the intestinal tract, namely, saturable or transcellular transport and nonsaturable or intercellular (paracellular) transport (Favus, 1992). Percent intestinal absorption is proportional to dietary intake (Hazewinkel, 1991). Low-Ca diets are associated with high absorption rates (up to 95%) and high-Ca diets have low absorption rates (about 40%). Although high-Ca diets have low absorption rates, they can increase serum Ca concentrations because of the presence of nonsaturable intestinal absorption. In contrast, diets deficient in Ca are associated with normal serum Ca concentrations because of compensation by parathyroid hormone-stimulated bone resorption, renal Ca reabsorption, and increased 1,25-dihydroxyvitamin D synthesis.

Saturable transport is a carrier-mediated, vitamin D–dependent process and occurs predominantly in the duodenal segment of the small intestine, but also occurs in the cecum and colon (Favus, 1992; McDowell, 1992a; Karbach and Feldmeier, 1993). Saturable transport requires influx of Ca into intestinal epithelial cells via Ca^{2+} channels, movement and buffering in the cytoplasm, and basolateral exit by a Ca^{2+}-ATPase. The active form of vitamin D (1,25-dihydroxyvitamin D) stimulates transcellular transport of Ca^{2+}. One function of 1,25-dihydroxyvitamin D in the intestinal epithelial cell is to increase the expression of calbindin, an intracellular Ca-binding protein. In contrast, nonsaturable Ca transport occurs throughout the small intestine and is the main mechanism of Ca absorption in animals with vitamin D deficiency. Nonsaturable Ca^{2+} transport is dependent on the luminal [Ca^{2+}]. As dietary intake of Ca increases, much of the Ca in the intestinal lumen is unavailable for nonsaturable absorption because of precipitation of Ca salts or complexes formed with anions (McDowell, 1992a).

Fractional intestinal Ca absorption is approximately 20–40% in adult animals and can exceed 60% during increased demand for Ca (Hazewinkel, 1991). Fractional absorption is increased during pregnancy, lactation, and growth, and when animals are fed low-Ca diets (Favus, 1992). The primary adaptive influence on Ca absorption is the circulating 1,25-dihydroxyvitamin D concentration. Factors that increase intestinal Ca absorption directly or indirectly by stimulation of 1,25-dihydroxyvitamin D synthesis include parathyroid hormone, growth hormone, testosterone, estrogen, and furosemide (Favus, 1992). Factors that reduce intestinal absorption of Ca include glucocorticoids, thyroid hormones, chronic acidosis, and lumenal conditions that induce complexation of Ca^{2+} (high concentrations of phosphate, phytates, oxalate, fatty acids, pH > 6.1, and other anions) (Favus, 1992).

I. Bone and Calcium Balance

There are two sources of Ca^{2+} in bone that can enter the circulation: (1) readily mobilizeable Ca salts in the extracellular fluid, and (2) hydroxyapatite crystals that require digestion by osteoclasts before Ca^{2+} can be released from bone. The nature and regulation of the readily mobilizable Ca in bone is poorly understood; however, it is present in small amounts and is likely to play a role in the fine regulation of serum Ca concentration (Parfitt, 1987). If there is a significant need for Ca from bone it must come from osteoclastic resorption of hydroxyapatite crystals. In adult animals there is a stable balance between Ca deposition associated with bone formation and Ca release associated with osteoclastic bone resorption. In young animals, bone has a positive Ca balance because of the relative excess of bone formation. Conditions that result in excessive bone resorption (e.g., humoral hypercalcemia of malignancy, osteolytic bone metastases, or primary hyperparathyroidism) can release large amounts of Ca from bone and contribute to the development of hypercalcemia (Rosol and Capen, 1992).

J. Cell Membrane Calcium Ion–Sensing Receptor

The concentration of ionized calcium in serum and extracellular fluid can regulate cellular function by interacting with a recently identified Ca^{2+}-sensing recep-

tor in the plasma membrane of various cells (Brown *et al.*, 1993; Chattopadhyay *et al.*, 1996). The cell membrane Ca^{2+} receptor belongs to the family of 7-transmembrane domain G-protein-linked receptors and is unique because its ligand is an ion. The Ca^{2+} receptor plays an important role in the regulation of extracellular Ca^{2+} homeostasis and is present on parathyroid chief cells, thyroid C-cells, renal epithelial cells, brain, and placenta, among other tissues. The Ca^{2+} receptor is responsible for sensing serum Ca^{2+} concentration and modifying parathyroid hormone secretion, calcitonin secretion, and calcium transport by renal epithelial cells (Pollak *et al.*, 1993; Brown and Hebert, 1996; Chattopadhyay *et al.*, 1996). Mutations in one or both of the Ca^{2+}-sensing receptor genes in humans result in familial hypocalciuric hypercalcemia or neonatal severe hypercalcemia, respectively, because of an inadequate ability to sense the extracellular Ca^{2+} concentration and coordinate the appropriate cellular response (Pollak *et al.*, 1993). Familial hypocalciuric hypercalcemia is a benign condition characterized by mild hypercalcemia, decreased urinary excretion of Ca, and inappropriately normal parathyroid hormone (PTH) levels. In contrast, neonatal severe hypercalcemia is a lethal condition unless total parathyroidectomy is performed early in life to reduce markedly elevated PTH levels.

II. CALCIUM-REGULATING HORMONES

A. Parathyroid Hormone

1. Development and Anatomy of the Parathyroid Gland

Parathyroid glands are present in all air-breathing vertebrates. Phylogenetically, parathyroids first appear in amphibians coincidentally with the transition from an aquatic to a terrestrial life. Parathyroid glands in tetrapods have arisen from the need to protect against the development of hypocalcemia and the necessity to conserve calcium to maintain skeletal integrity in terrestrial animals, which often are in a relatively low calcium–high phosphorus environment (Copp *et al.*, 1962; Coleman, 1969).

Embryologically, parathyroids are of entodermal origin, being derived from the III and IV pharyngeal pouches in close association with primordia of the thymus. The entodermal bud that forms the thyroid gland arises on the midline at the level of the first pharyngeal pouch. Calcitonin-secreting C cells of neural crest origin reach the postnatal thyroid gland by migrating into the ultimobranchial body. This lateral pharyngeal pouch moves caudally in mammals to fuse with the primordia of the thyroid gland and distributes C cells into each thyroid lobe.

In the dog and cat both the external and internal parathyroids are close to the thyroid gland. The external parathyroid (III) in the dog is from 2 to 5 mm in length and is found in the loose connective tissue cranial and slightly lateral to the anterior pole of the thyroid. The internal parathyroid (IV) is smaller, flatter, and situated on the medial surface of the thyroid beneath the fibrous capsule. The blood supply of the two glands in the dog is separate, with the external parathyroid being supplied by a branch from the cranial thyroid artery and the internal parathyroid by minute ramifications of the arterial supply to the thyroid (Smithcors, 1964).

In other species such as cattle and sheep the larger external parathyroid gland is located a considerable distance cranial to the thyroid in the loose connective tissue along the common carotid artery. The smaller internal parathyroid is situated on the dorsal and medial surface of the thyroid gland. The larger lower parathyroid gland in horses is located a considerable distance from the thyroid in the caudal cervical region near the bifurcation of the bicarotid trunk at the level of the first rib. Pigs have only a single pair of parathyroids found cranial to the thyroid, embedded either in thymus (young animals) or in adipose connective tissue (adult pigs). Rats also have a single pair of parathyroid glands that are located close to the thyroid.

2. Functional Cytology

The parathyroid glands contain a single basic type of secretory cell whose principal function is secretion of parathyroid hormone (Capen and Roth, 1973). The parathyroids of man and animals are composed of chief cells in different stages of secretory activity (Capen, 1975). Experimental and pathological evidence has accumulated to suggest that certain fine structural characteristics of chief cells are associated with different stages of synthetic and secretory activity (Munger and Roth, 1963; Capen, 1971).

Chief cells in an inactive or resting stage predominate in the parathyroid glands of man and most animal species. Inactive chief cells are cuboidal, have uncomplicated interdigitations between contiguous cells, and contain poorly developed organelles and infrequent secretory granules. The cytoplasm has either numerous lipid bodies and lipofuscin droplets (e.g., bovine glands) or aggregations of glycogen granules (e.g., human and feline glands). The Golgi apparatus is small, composed of straight or curved stacks of agranular membranes, and associated with few prosecretory granules and vesicles in the process of formation. In-

dividual profiles of granular endoplasmic reticulum, ribosomes, and small mitochondria are dispersed throughout the cytoplasm. Chief cells in the active stage of secretion occur less frequently in the parathyroid glands of most species. The cytoplasm of active chief cells has an increased density of organelles, secretory granules, and loss of glycogen particles and lipid bodies (Roth and Capen, 1974).

3. *Biosynthesis*

A larger biosynthetic precursor (preproparathyroid hormone, preproPTH) is the initial translation product synthesized on ribosomes of the rough endoplasmic reticulum in chief cells (Arnaud *et al.*, 1971; Cohn and MacGregor, 1981). It is composed of 115 amino acids and contains a hydrophobic signal or leader sequence of 25 amino acid residues that facilitates the penetration and subsequent vectorial discharge of the nascent peptide into the cisternal space of the rough endoplasmic reticulum (Fig. 23.4) (Habener and Potts, 1978). PreproPTH is rapidly converted within 1 minute or less of its synthesis to proparathyroid hormone (proPTH) by the proteolytic cleavage of the N-terminal sequence of 25 amino acids (Fig. 23.4) (Habener, 1981).

The intermediate precursor, proPTH, is composed of 90 amino acids and moves within membranous channels of the endoplasmic reticulum to the Golgi apparatus (Fig. 23.4). Enzymes with trypsin-like and carboxypeptidase-B-like activity within membranes of the Golgi apparatus cleave a hexapeptide from the N-terminal (biologically active) end of the molecule forming active parathyroid hormone (PTH) (Habener *et al.*, 1977; MacGregor *et al.*, 1978). Active PTH is packaged into membrane-limited, macromolecular aggregates in the Golgi apparatus for subsequent storage in chief cells (Fig. 23.5). Under conditions of increased demand, PTH may be released directly from chief cells without being packaged into secretion granules. Biologically active PTH secreted by chief cells is a straight chain polypeptide consisting of 84 amino acid residues with a molecular weight of approximately 9500 (Rosol *et al.*, 1996).

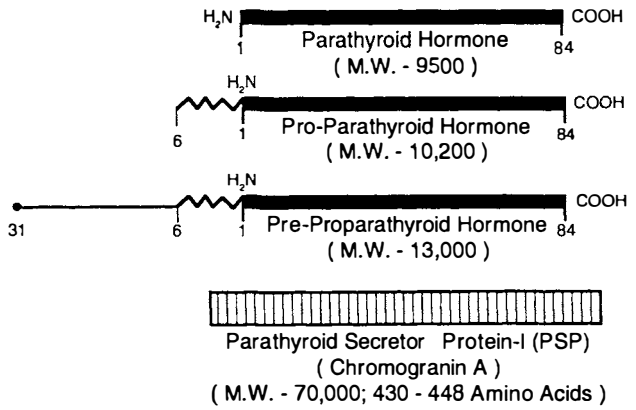

FIGURE 23.4 Chemistry of parathyroid hormone and related peptides synthesized by chief cells. Active parathyroid hormone is first synthesized as part of a large biosynthetic precursor molecule. Pre-proparathyroid hormone (115 amino acids) is the initial translational product from ribosomes and is rapidly converted to proparathyroid hormone in the rough endoplasmic reticulum. Proparathyroid hormone (90 amino acids) is converted enzymatically to active parathyroid hormone (84 amino acids) in the Golgi apparatus as the hormone is packaged into secretory (storage) granules. Parathyroid secretory protein (chromogranin A) is a high-molecular-weight molecule synthesized by chief cells, incorporated into storage granules with active parathyroid hormone, and secreted in parallel with active hormone in response to changes in blood calcium. It is necessary for normal secretory granule function and maturation. (Capen, 1989.)

In the early phases of secretory activity the endoplasmic reticulum of chief cells aggregates into large lamellar arrays, and free ribosomes group into clusters (Roth and Raisz, 1966) . It is at this stage that preproPTH is synthesized by the chief cells (Fig. 23.5). This is followed by packaging of the PTH, in which the Golgi apparatus enlarges and often appears as multiple complexes in several parts of the chief cell associated with many prosecretory granules. As this occurs, the granular endoplasmic reticulum involutes and disperses.

4. *Storage and Secretion*

a. Secretory Granules

The secretory granules develop by sequential accumulation and condensation of finely granular material within cisternae of the Golgi apparatus. Prosecretory granules are concentrated in the vicinity of the Golgi apparatus and occasionally are observed in the process of becoming detached from the membranes of the Golgi complex. Secretory ("storage") granules have been demonstrated readily at the level of ultrastructure within chief cells of the parathyroid glands in man and all animal species examined (Capen and Roth, 1973; Roth and Capen, 1974). The paucity of secretory granules in certain species (e.g., rat) initially led some investigators to erroneously suggest that chief cells do not have a mechanism for the storage of preformed hormone.

The secretory granules in chief cells usually are small, ranging from 100 to 300 nm in their greatest diameter, and are composed of fine, dense particles. They are electron dense, are surrounded by a delicate, closely applied limiting membrane, and are round to oval. The number of granules within chief cells varies considerably between species, with bovine parathyroids having consistently more secretory granules than man and other animals (Capen *et al.*, 1968). Chief cells

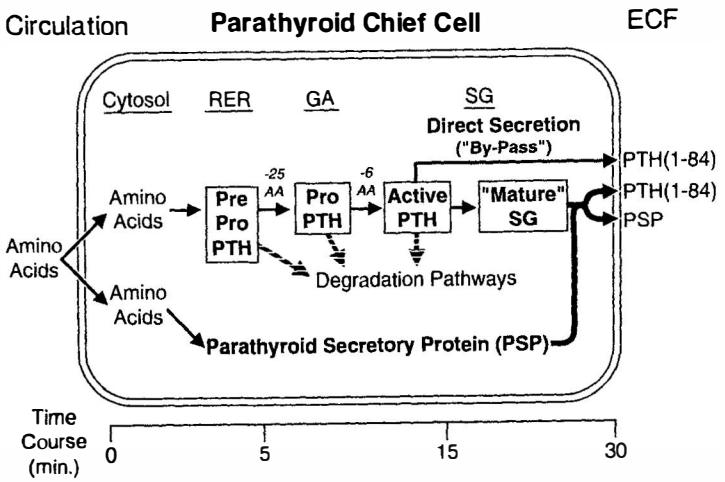

FIGURE 23.5 Subcellular compartmentalization, transport, and cleavage of precursors of parathyroid hormone (PTH). Pre-proparathyroid hormone (pre-pro-PTH) is the initial translation product from ribosomes of the rough endoplasmic reticulum (RER), which is rapidly converted to proparathyroid hormone (pro-PTH). The hydrophobic sequence at the amino-terminal end of prepro-PTH molecule facilitates penetration of the leading portion of the nascent peptide into the lumen of the endoplasmic reticulum. Pro-PTH is transported to the Golgi apparatus (GA), where it is converted enzymatically by a carboxypeptidase to biologically active PTH. A major portion of the biosynthetic precursors and active PTH is degraded by lysosomal enzymes and is not secreted by chief cells under normal conditions.

have fewer storage granules than many other endocrine cells concerned with the biosynthesis of polypeptide hormones, e.g., adenohypophysis and calcitonin-secreting C cells of the thyroid (Fig. 23.6) (Capen and Young, 1967).

The secretory granules migrate peripherally in chief cells, and their limiting membrane fuses with the plasma membrane of the cell. An internal cytoskeleton composed of microtubules and contractile filaments is important in the control of peripheral movement of

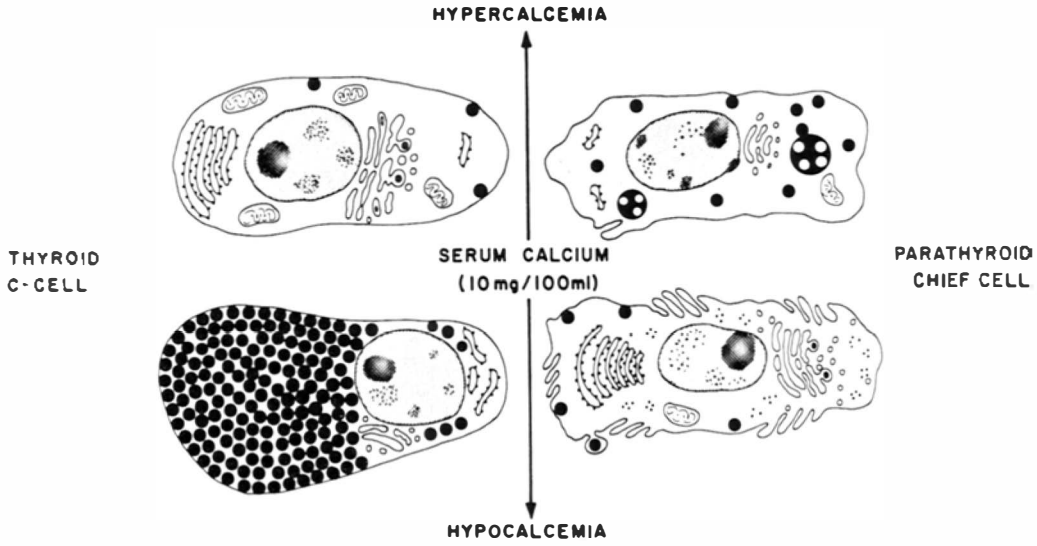

FIGURE 23.6 Response of parathyroid chief cells and thyroid C cells to hypercalcemia and hypocalcemia. C cells accumulate secretory granules in response to hypocalcemia, whereas chief cells are nearly degranulated but have an increased development of synthetic and secretory organelles. In response to hypercalcemia, C cells are degranulated and chief cells are predominantly inactive with small numbers of secretory granules. (Capen, 1989.)

secretory granules and liberation of secretory products from chief cells (Youshak and Capen, 1970). Secretory granules are extruded from chief cells by exocytosis (emiocytosis) into perivascular spaces (Fetter and Capen, 1970; Capen, 1971).

b. Chromogranin A

In addition to parathyroid hormone, secretory granules in chief cells (Fig. 23.5) also contain chromogranin A (parathyroid secretory protein-I). Chromogranin A (CGA) was first isolated from secretory granules of the bovine adrenal medulla (Winkler and Fischer-Colbrie, 1992). Chromogranin A, a 49-kDa peptide, is a major constituent of secretory granules of the adrenal medulla, pituitary, parathyroid, thyroid C cells, pancreatic islets, endocrine cells of the gastrointestinal tract, and sympathetic nerves and composes up to 50% of the total protein secreted by the parathyroid. Chromogranin A shares considerable homology between species. Immunologic cross reactivity to mammalian proteins has been observed in reptiles, amphibians, fish, and *Drosophila* tissues. Chromogranin A is synthesized as a pre-protein and is directed to the internal cavity of the rough endoplasmic reticulum (rER) by the N-terminal pre-region of the peptide. Once inside the rER, the pre-region is cleaved by a signal peptidase.

Although the functions of CGA are still under investigation, several roles have been postulated. Chromogranin A is suspected to play an important role in the maturation of secretory granules. Inside the Golgi apparatus, CGA is involved in the packaging of contents into newly formed vesicles. Chromogranin A precipitates as it diffuses into the trans-Golgi network. Other secretory products such as parathyroid hormone become entrapped in the growing CGA conglomerate and subsequently are packaged into a secretory granule (Cohn *et al.*, 1994). Chromogranin A has a large calcium-binding capacity that may enhance vesicle stability. As granules mature, they accumulate large amounts of calcium (up to 40 m*M*), which also may serve as a route of Ca^{2+} secretion. However, free (ionized) calcium concentrations remain in the micromolar range because most Ca^{2+} is bound to CGA. Chromogranin A–calcium complexes are important in maintaining the integrity of the secretory granule, because the absence of calcium will cause dissociation of protein complexes and result in osmotic lysis of the vesicle. Therefore, the intragranular functions of CGA include hormone packaging, stabilization of the granule against osmotic gradients, and excretion of intracellular calcium.

During the process of secretion the contents of secretory granules are extruded into the pericapillary spaces. The pH and calcium concentration of the extracellular fluid promote dissociation of CGA complexes and solubilization of its bound calcium and other contents of the granule. Once solubilized, extracellular peptidases cleave CGA into biologically active peptides that act as paracrine or autocrine regulators of secretion (Deftos, 1991). Most of the CGA-derived peptides have been reported to decrease hormone secretion.

5. *Control of Secretion*

Secretory cells in the parathyroid gland store small amounts of preformed hormone, but are capable of responding to minor fluctuations in calcium concentration by rapidly altering the rate of hormonal secretion and more slowly by altering the rate of hormonal synthesis. The parathyroids have a unique feedback control by the concentration of calcium (and to a lesser extent magnesium) ion in serum.

Interaction of serum ionized calcium with the Ca^{2+}-sensing receptor on chief cells results in the formation of an inverse sigmoidal relationship between serum Ca^{2+} and PTH concentrations (Fig. 23.7) (Silver, 1992; Cloutier *et al.*, 1993; Brown, 1994). The serum $[Ca^{2+}]$ that results in half-maximal PTH secretion is defined as the serum calcium "set point" and is stable for an individual animal. The sigmoidal relationship between serum $[Ca^{2+}]$ and PTH secretion permits the chief cells to respond rapidly to a reduction in serum Ca^{2+}. Binding of Ca^{2+} to the Ca^{2+}-sensing receptor results in an increase in the intracellular Ca^{2+}concentration of chief cells and a reduction in PTH secretion. This makes the parathyroid chief cells unique, because increased intracellular Ca^{2+} concentrations are a stimulus for secretion in most cell types. The major inhibitors of PTH synthesis and secretion are increased serum $[Ca^{2+}]$ and

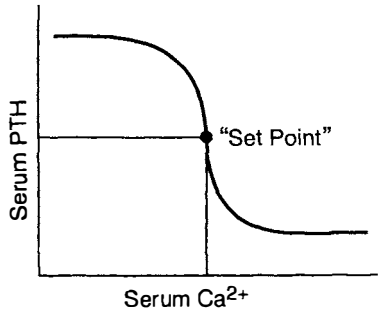

FIGURE 23.7 The serum Ca "set point" is defined as the concentration of serum Ca at which the concentration of serum parathyroic hormone (PTH) is half-maximal. The sigmoidal relationship betweer serum Ca and PTH enables the parathyroid glands to rapidly respond to minor reductions in serum Ca and increase PTH secretior and serum PTH concentration to return serum Ca to normal levels The concentration of serum Ca in most normal animals is maintainec at a level less than the "set-point" concentration. (Rosol *et al.*, 1995a.)

1,25-dihydroxyvitamin D. Inhibition of PTH synthesis by 1,25-dihydroxyvitamin D completes an important endocrine feedback loop between the parathyroid chief cells and the renal epithelial cells, because PTH stimulates renal production of 1,25-dihydroxyvitamin D (Fig. 23.8).

If the blood calcium is elevated by the intravenous infusion of calcium, there is a rapid and pronounced reduction in circulating levels of immunoreactive parathyroid hormone (iPTH); however, a small percentage of PTH secretion is nonsuppressible (Fig. 23.9). Therefore, there are always low concentrations of circulating PTH in the blood even under conditions of hypercalcemia. Conversely, if the blood calcium is lowered by infusion by EDTA (ethylenediaminetetraacetic acid), there is a brisk and substantial increase in iPTH levels (Fig. 23.9). The concentration of blood phosphate has no direct regulatory influence on the synthesis and secretion of PTH; however, certain disease conditions with hyperphosphatemia in both animals and man are associated clinically with hyperparathyroidism. An elevated blood phosphorus level may lead indirectly to parathyroid stimulation by virtue of its ability to lower blood calcium (Krook and Lowe, 1964). If the blood phosphorus is elevated significantly by an infusion of phosphate and calcium administered simultaneously in amounts to prevent the accompanying reduction of blood calcium, plasma iPTH levels remain within the normal range (Fig. 23.9).

Magnesium ion has an effect on parathyroid secretory rate similar to that of calcium, but its effect is not equipotent to that of calcium (Mayer and Hurst, 1978). The reduced potency of Mg^{2+} compared to that of Ca^{2+} may be due to reducing binding affinity of Mg^{2+} for the Ca^{2+}-sensing membrane receptor on chief cells. The more potent effects of Ca^{2+} in the control of PTH secretion, together with its preponderance over Mg^{2+} in the extracellular fluid, suggest a secondary role for magnesium in parathyroid control.

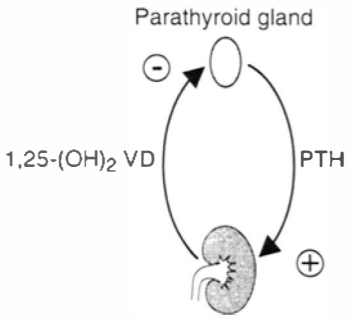

FIGURE 23.8 Endocrine negative-feedback loop between the parathyroid gland and the kidney involving serum concentrations of parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D (1,25-$(OH)_2$VD). (Rosol *et al.*, 1995a.)

Calcium ion not only controls the rate of biosynthesis and secretion of parathyroid hormone, but also other metabolic and intracellular degradative processes within chief cells (Chu *et al.*, 1973). An increase of calcium ions in extracellular fluids rapidly inhibits the uptake of amino acids by chief cells, synthesis of proPTH, and conversion to PTH, and secretion of stored PTH and increases the intracellular degradation of PTH (Cohn *et al.*, 1974). The shifting of the percentage of flow of proparathyroid hormone from the degradative pathways to the secretory route represents a key adaptive response of the parathyroid gland to a low-calcium diet. During periods of long-term calcium restriction the enhanced synthesis and secretion of PTH would be accomplished by an increased capacity of the entire pathway in individual hypertrophied chief cells and through hyperplasia of active chief cells.

Recently synthesized and processed PTH may be released directly in response to increased demand and bypass the chief cell's storage pool of mature secretory granules in the cytoplasm. Bypass secretion of calcium can be stimulated only by a low circulating concentration of calcium ion and not by other secretagogues for PTH (Fig. 23.10). Degradation of PTH in secretory granules by lysosomal enzymes occurs after prolonged exposure of chief cells to a high-calcium environment.

6. Biological Action

Parathyroid hormone is the principal hormone involved in the minute-to-minute fine regulation of blood calcium in mammals. It exerts its biologic actions by directly influencing the function of target cells primarily in bone and kidney and indirectly in the intestine to maintain plasma calcium at a level sufficient to ensure the optimal functioning of a wide variety of body cells (Fig. 23.11).

In general the most important biological effects of PTH are to (1) elevate the blood calcium concentration, (2) decrease the blood phosphorus concentration, (3) increase the urinary excretion of phosphate by decreased tubular reabsorption, (4) increase tubular reabsorption of calcium, resulting in diminished calcium loss into the urine, (5) increase the rate of skeletal remodeling and the net rate of bone resorption, (6) increase osteolysis and the numbers of osteoclasts on bone surfaces, (7) increase the urinary excretion of Type I collagen metabolites, such as hydroxyproline and collagen telopeptides, (8) activate adenylate cyclase or stimulate increased intracellular Ca^{2+} concentrations in target cells, and (9) accelerate the formation of the principal active vitamin D metabolite (1,25-dihydroxycholecalciferol) (1,25$[OH]_2$D) by the kidney through a trophic effect on the 1-α-hydroxylase in mi-

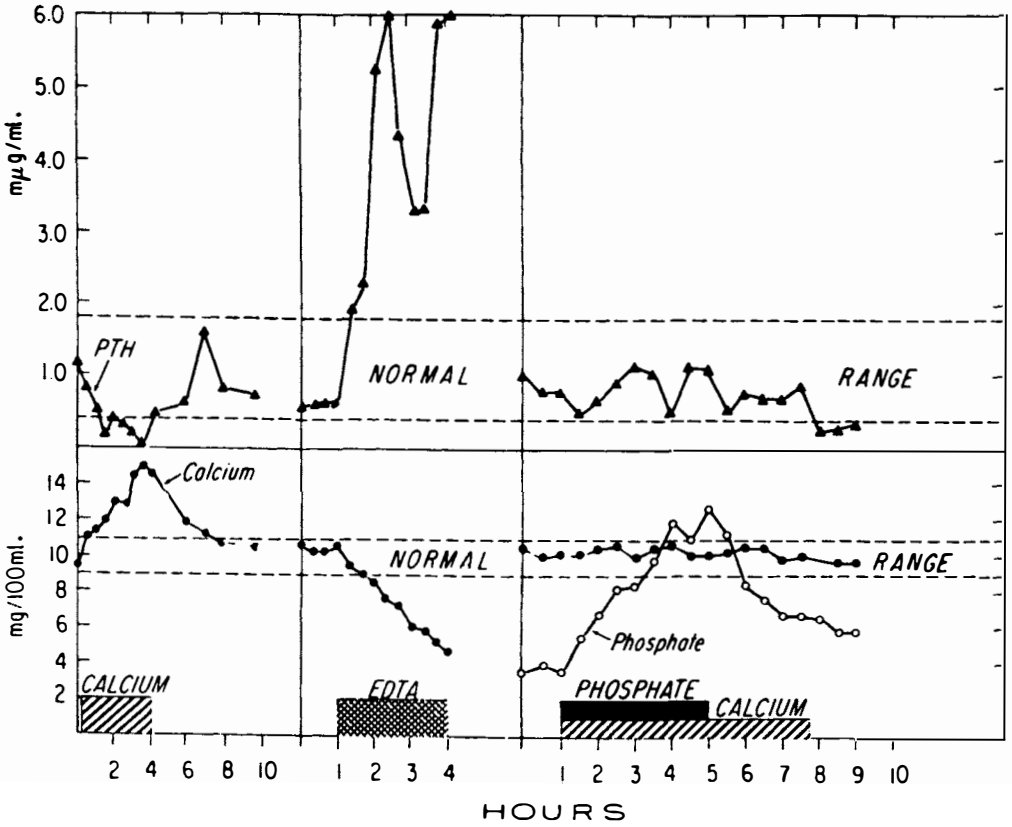

FIGURE 23.9 Changes of plasma immunoreactive parathyroid hormone in response to hypercalcemia induced by calcium infusion, hypocalcemia produced by EDTA infusion, and hyperphosphatemia with normocalcemia in a cow. From Aurbach and Potts (1964).

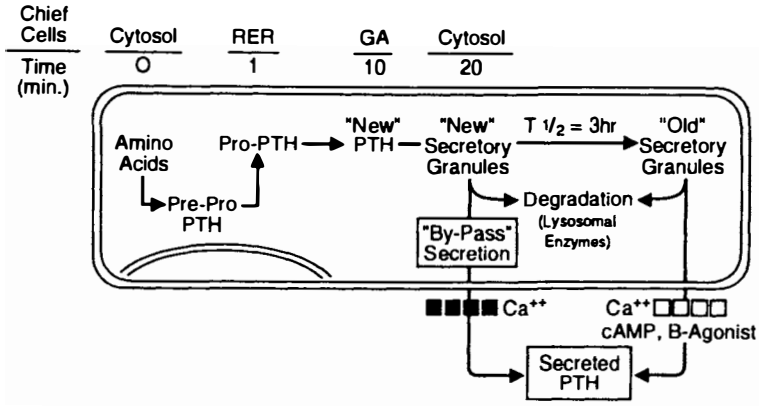

FIGURE 23.10 Bypass secretion of parathyroid hormone in response to increased demand signaled by decreased blood calcium ion concentration. Recently synthesized and progressed active PTH(1–84) may be released directly and not enter the storage pool of mature ("old") secretory granules in the cytoplasm of chief cells. PTH from the storage pool can be mobilized by cyclic adenosine monophosphate (cAMP) and β (B)-agonists (such as epinephrine, norepinephrine, and isoproterenol) as well as by lowered blood calcium ion, whereas secretion from the pool of recently synthesized PTH can be stimulated only by a decreased calcium ion concentration. RER, Rough endoplasmic reticulum; GA, Golgi apparatus. Redrawn from Cohn and MacGregor (1981).

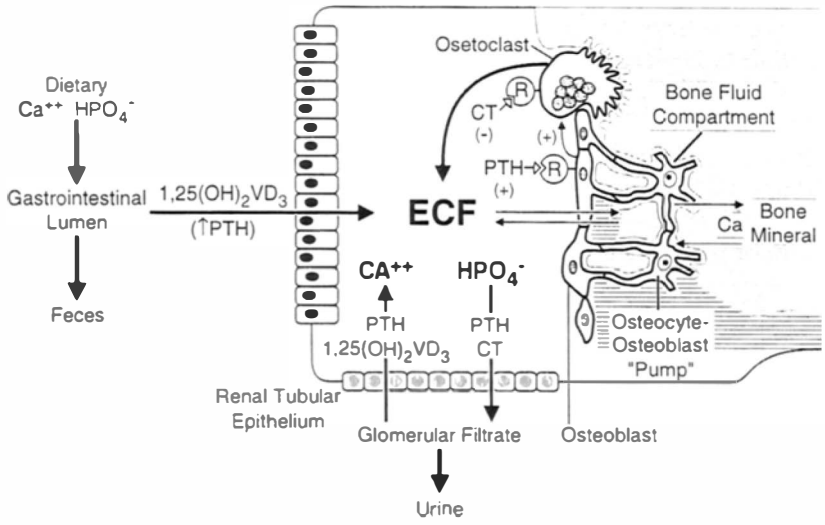

FIGURE 23.11 Interrelations of parathyroid hormone (PTH), calcitonin (CT), and 1,25-dihydroxycholecalciferol [1,25-$(OH)_2VD_3$] in the hormonal regulation of calcium and phosphorus in extracellular fluids (ECF).

tochondria of renal epithelial cells in the proximal convoluted tubules.

An important action of PTH on bone is to mobilize calcium from skeletal reserves into extracellular fluids (Fig. 23.11) (Canalis *et al.*, 1994). The administration of PTH causes an initial decline followed by a sustained increase in circulating levels of calcium. This transitory decrease in blood calcium is considered to be the result of a sequestration of calcium phosphate in bone and soft tissues (Parsons and Robinson, 1971). The subsequent increase in blood calcium results from an interaction of parathyroid hormone with receptors on osteoblasts that stimulate increased calcium release from bone and direct an increase in osteoclastic bone resorption (High *et al.*, 1981a). The mechanisms by which osteoblasts mediate increased osteoclastic bone resorption are currently incompletely understood.

The response of bone to parathyroid hormone is biphasic. The immediate effects are the result of increasing the activity of existing bone cells. This rapid effect of parathyroid hormone depends upon the continuous presence of hormone and results in an increased flow of calcium from deep in bone to bone surfaces through the action of an osteocyte–osteoblast "pump" in order to make fine adjustments in the blood calcium concentration (Fig. 23.11) (Parfitt, 1977).

The later effects of parathyroid hormone on bone are potentially of a greater magnitude of response and not dependent upon the continuous presence of hormone. Osteoclasts are primarily responsible for the long-term action of PTH on increasing bone resorption and overall bone remodeling (Canalis *et al.*, 1994). This is interesting in light of recent findings that have failed to demonstrate receptors for PTH on osteoclasts, but receptors were present on osteoblasts (Segre, 1994). These cells are flat and cover bone surfaces under normal conditions. The initial binding of PTH to osteoblasts lining bone surfaces appears to cause the cells to contract, thereby exposing the underlying mineral to osteoclasts (Rodan and Martin, 1981). The change in shape of osteoblasts associated with PTH may be related to calcium entry into the cell and alteration in microtubule and microfilament function, and appears to be critical to mediation of osteoclastic bone resorption stimulated by the hormone. Bone resorption products, particularly osteocalcin, can attract osteoclast precursors and enhance the resorption process. In addition, osteoblasts elaborate undefined chemical mediators to stimulate osteoclasts directly (McSheehy and Chambers, 1986).

If the increase in PTH is sustained, the size of the active osteoclast pool in bone is increased by activation of osteoclast progenitor cells in the endosteal bone-cell envelope (Heersche *et al.*, 1994). The plasma membrane of osteoclasts in intimate contact with the resorbing bone surface is modified to form a series of membranous projections referred to as the brush "ruffled" border. This area of active bone resorption is isolated from the extracellular fluids by adjacent transitional ("sealing") zones, thereby localizing the lysosomal enzymes and acidic environment to the immediate area undergoing dissolution. The mineral and organic components (e.g., hydroxyproline) released from bone are phagocytized by osteoclasts and transported across the

cell in transport vesicles to be released into the extracellular fluid compartment (Baron, 1996; Roodman, 1996).

Parathyroid hormone also has the potential to serve as an anabolic agent in bone and stimulate osteoblastic bone formation (Canalis *et al.*, 1994). The physiologic role of the anabolic action of PTH *in vivo* is uncertain, but intermittent administration of exogenous PTH has been reported to increase bone mass in humans and animals.

The major effect of PTH under physiologic conditions is exerted on bone cells on endosteal surfaces of cancellous bone and in Haversian canals of cortical bone. In disease states of hyperparathyroidism, the activation of osteoclast progenitor cells occurs in the periosteum as well, leading to the formation of active sites of bone resorption and formation on the periosteal surface. This process results in the characteristic subperiosteal areas of bone resorption seen radiographically in long-standing hyperparathyroidism.

Parathyroid hormone has a rapid (within 5 to 10 minutes) and direct effect on renal tubular function leading to decreased reabsorption of phosphorus and phosphaturia (see Section III on phosphorus metabolism). The site of action of PTH in blocking tubular reabsorption of phosphorus has been localized by micropuncture methods to the proximal tubules of the nephron (Fig. 23.12). In addition, PTH leads to an increased urinary excretion of potassium, bicarbonate, sodium, cyclic adenosine monophosphate, and amino acids.

Although the effect of PTH on the tubular reabsorption of phosphorus has been considered to be of major importance, the ability of PTH to enhance the renal reabsorption of calcium is of considerable importance in the maintenance of calcium homeostasis. This effect of PTH upon tubular reabsorption of calcium is due to a direct action on the distal convoluted tubule (Yanagawa and Lee, 1992). The urinary excretion of magnesium, ammonia, and titratable acidity also are decreased by PTH. The other important effect of PTH on the kidney is in the regulation of the conversion of 25-hydroxycholecalciferol to 1,25-$(OH)_2D$ and other metabolites of vitamin D. The role of PTH as a trophic hormone in the metabolic activation of cholecalciferol will be discussed further in the section of this chapter on vitamin D.

Parathyroid hormone has been shown to promote the absorption of calcium from the gastrointestinal tract in animals under a variety of experimental conditions (Nemere and Norman, 1986; Favus, 1992). This effect is not as rapid as the action on the kidney and is not observed in vitamin D-deficient animals. The increased intestinal calcium transport is due principally to an indirect effect of PTH by its action of stimulating the renal synthesis of the biologically active metabolite of vitamin D (1,25$[OH]_2D$); however, PTH also

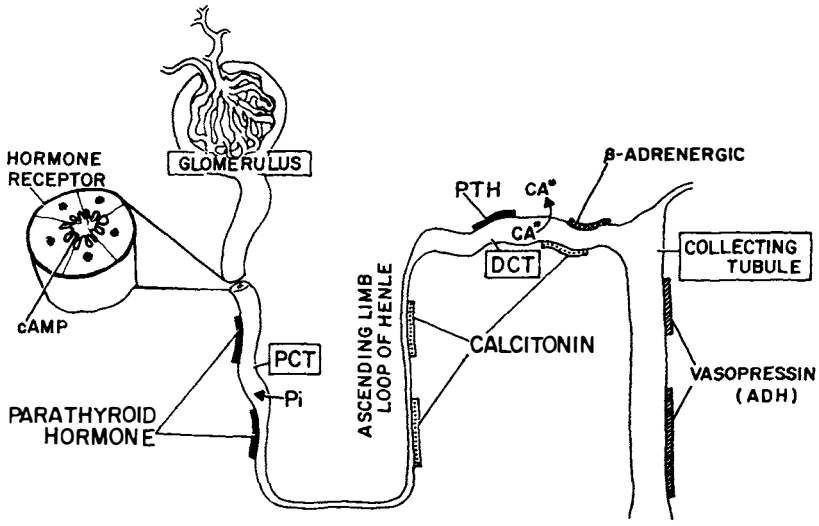

FIGURE 23.12 Distribution of adenylate cyclase-linked hormone receptors (target cells for parathyroid hormone and calcitonin) in the nephron. Parathyroid hormone diminishes tubular reabsorption of phosphorus in the proximal convoluted tubules (PCT), whereas increased calcium reabsorption occurs in cells located in the distal convoluted tubules (DCT). Cells with receptors for calcitonin that are situated in the ascending limb of the loop of Henle and distal convoluted tubules also diminish tubular reabsorption of phosphorus and cause phosphaturia. (Capen, 1989.)

may play a minor role by directly stimulating Ca absorption by intestinal epithelial cells.

7. *Parathyroid Hormone Receptor*

The receptor for N-terminal PTH (1–34), the region important in calcium regulation, has been cloned and sequenced (Abou-Samra *et al.*, 1992; Segre, 1994). It is a 7-transmembrane domain receptor that is expressed in renal epithelial cells and osteoblasts, among other cells. The N-terminal regions of PTH and PTHrP bind this receptor with equal affinity. Binding of PTH or PTHrP to the receptor results in increased levels of both cytoplasmic cAMP and Ca^{2+} by stimulation of adenylate cyclase and the phosphatidyl inositol pathways (Abou-Samra *et al.*, 1992; Coleman *et al.*, 1994). The PTH receptor is also located on many cell types, such as dermal fibroblasts, that are not associated with the action of PTH. It is assumed that the receptor functions as the binding protein for PTHrP in these tissues. Therefore, this receptor may be best termed the PTH/PTHrP receptor. It is not known whether there are distinct receptors for the N-terminal region of PTHrP; however, there are is some experimental data to suggest that alternate receptors may exist for the midregion and C-terminal regions of PTH and PTHrP (Murray *et al.*, 1994).

8. *Subcellular Mechanism of Action*

The calcium-mobilizing and phosphaturic activities of parathyroid hormone are mediated through the intracellular accumulation of 3',5'-adenosine monophosphate (cAMP) or Ca^{2+} in target cells (Fig. 23.13) (Coleman *et al.*, 1994). Binding of PTH to PTH/PTHrP receptors on target cells results in activation of the receptor, binding of the receptor to stimulatory or inhibitory G proteins, and stimulation of adenylyl cyclase or phosphatidylinositol hydrolysis in the plasma membrane. Stimulation of adenylyl cyclase stimulates the conversion of ATP to cAMP in target cells. The accumulation of cAMP in target cells functions as an intracellular mediator or second messenger of parathyroid hormone action to increase permeability for calcium ion. Cytosolic Ca^{2+} concentration also may be increased by the actions of inositol triphosphate to release Ca^{2+} from intracytoplasmic stores or by stimulation of Ca^{2+} transport through transmembrane calcium channels. The resultant increase in cytosol calcium content in combination with cAMP accumulation initiates biochemical reactions in bone cells and renal epithelial cells to conduct the intracellular functions of PTH.

In addition, PTH contributes to the regulation of the rate of formation of the active form of vitamin D by

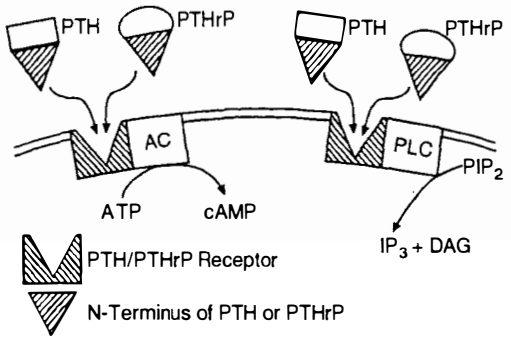

FIGURE 23.13 Mechanism of parathyroid hormone and parathyroid hormone-related protein action. The biologically active N-terminal ends of the hormones PTH and PTHrP bind to specific PTH/PTHrP receptors on the surface of target cells. The receptor–hormone complex is coupled to the catalytic subunit of adenylyl cyclase (AC) and phospholipase C (PLC) in the cell membrane by a nucleotide regulatory protein (G protein). This results in the conversion of ATP to cyclic adenosine monophosphate (cAMP) and phosphatidylinositol to inositol triphosphate (IP_3) and diacylglycerol (DAG). IP_3 stimulates release of Ca^{2+} from intracellular stores. Both cAMP and Ca^{2+} serve as second messengers for polypeptide hormones such as PTH and PTHrP in target cells and result in expression of the biological response of the hormones. (Rosol and Capen, 1992.)

mitochondria in renal tubular epithelial cells. The active metabolites of vitamin D make bone cells more sensitive to the direct effect of PTH ("permissive effect") and greatly enhance the gastrointestinal absorption of calcium, thereby amplifying the effect of PTH upon plasma calcium concentration.

9. *Assays for Parathyroid Hormone*

The metabolism of PTH and the formation of multiple circulating forms of PTH has made development of clinically useful immunoassays challenging (Kronenberg *et al.*, 1994). The principal circulating forms of PTH include intact PTH (1–84) and C-terminal peptides (e.g., PTH 35–84). Parathyroid hormone has two functional domains. N-Terminal PTH (PTH 1–34) is the region of major biological activity in relation to calcium regulation. N-Terminal PTH does not exist in the circulation in a biologically relevant concentration, but administration of exogenous PTH (1–34) will induce the typical actions of PTH on bone and kidney cells (Everhart-Caye *et al.*, 1996). The function of C-terminal PTH peptides is less well understood (Mallette, 1994).

PTH is secreted in two forms: intact PTH (1–84) and C-terminal peptides. PTH (1–84) is the circulating form of biologically active PTH. PTH (1–84) is rapidly removed from the circulation by endopeptidases on Kupffer cells or glomerular filtration, and its half-life is less than 5 minutes (Arnaud and Pun, 1992). Some

of the C-terminal peptides are released from the Kupffer cells back into the circulation and are excreted by glomerular filtration. Therefore, C-terminal PTH has a greater serum half-life than PTH (1–84) and is present in the serum at greater concentrations (50–90% of total PTH) than PTH (1–84), especially in states of hyperparathyroidism. End organs (bone and kidney) also are responsible for degradation of a small fraction of serum PTH (1–84). This involves internalization of PTH–receptor complexes and intracellular degradation by lysosomal enzymes. Rapid removal of PTH (1–84) from the circulation allows the *in vivo* actions of PTH to be controlled by the rate of PTH secretion from the parathyroid chief cells.

Early immunoassays for PTH were single-site radioimmunoassays (RIA) for C-terminal peptides. These assays were suboptimal, because the biologically active form of PTH was not measured. However, they were clinically useful in states of hyperparathyroidism in patients with normal renal function. Midregion and C-terminal RIAs measure both intact PTH and C-terminal PTH, which makes them less clinically relevant (Jorch *et al.*, 1982; Mallette and Tuma, 1984; Flanders and Reimers, 1991). In addition, conditions that reduce glomerular filtration rate, such as renal failure, will result in a large increase in the serum concentration of C-terminal PTH.

Intact serum PTH concentrations are best measured by two-site immunoradiometric assay (IRMA) or N-terminal RIA (Nussbaum and Potts, 1994). Serum intact PTH can be measured in dogs, cats, and horses with assays developed for human PTH (Nichols Institute Diagnostics, San Juan Capistrano, CA; INCSTAR Corp., Stillwater, MN; Diagnostic Products Corp., Los Angeles, CA) because of the cross reactivity of the antisera used in the assays (Torrance and Nachreiner, 1989; Nagode and Chew, 1991; Barber *et al.*, 1993; Cloutier *et al.*, 1993) (Table 23.3). Intact PTH has been successfully measured in dogs or cats with either a human N-terminal RIA or two-site IRMA (Nagode and Chew, 1991; Barber *et al.*, 1993). The correlation between the two assays in dogs is good (Nagode and Chew, 1991). High concentrations of circulating C-terminal PTH have been reported to decrease the measurement of intact PTH in cats, but this can be overcome when the sample is diluted (Barber *et al.*, 1993). Currently, intact PTH is best measured in horses using an N-terminal RIA (L. A. Nagode, personal communication, October 1996).

a. Canine Parathyroid Hormone

The complementary DNA that encodes for canine PTH was cloned and sequenced (Rosol *et al.*, 1995b, 1996). The predicted mature protein consists of 84 amino acids (aa) and has a high degree of homology to bovine, porcine, human, and rat PTH (Fig. 23.14). There are only two substitutions in the first 40 aa of canine PTH compared to those of human PTH at positions 7 and 16. These substitutions are not unique to canine PTH because they also occur in bovine (position 7 and 16) and porcine PTH (position 16) (Kronenberg *et al.*, 1994). Knowledge of the sequence of cPTH will permit synthesis of peptides and development of immunoassays specific for the dog.

B. Parathyroid Hormone-Related Protein

1. Introduction

Parathyroid hormone-related protein (PTHrP) is not strictly a calcium-regulating hormone; however, it was identified in 1982 as an important PTH-like factor that plays a central role in the pathogenesis of humoral hypercalcemia of malignancy (Moseley and Gillespie, 1995). Since its discovery, it has become known that PTHrP is widely produced in the body and has numerous actions in the normal fetus and adult animal independent of its role in cancer-associated hypercalcemia (Gröne *et al.*, 1994; Philbrick *et al.*, 1996). This is in contrast to PTH, which is produced by the parathyroid glands and functions principally in regulation of calcium balance. Some of the actions of PTHrP involve normal regulation of calcium metabolism (Rosol and Capen, 1992; Rosol *et al.*, 1995a). For example, PTHrP functions as a calcium-regulating hormone in the fetus and is produced by the fetal parathyroid gland and placenta (MacIsaac *et al.*, 1991b). In the adult, PTHrP circulates in the blood in very low concentrations (<1 p*M*), but is produced by many different tissues and functions principally as a paracrine cellular regulator. PTHrP may play a role in the transport of Ca into milk during lactation. PTHrP acts as an abnormal systemic calcium-regulating hormone and mimics the actions of PTH in patients with humoral hypercalcemia of malignancy (see Section IV.B on hypercalcemia).

Parathyroid hormone-related protein (PTHrP) is a 139–173 amino acid peptide originally isolated from human and animal tumors associated with humoral hypercalcemia of malignancy (Rosol and Capen, 1992). PTHrP shares 70% sequence homology with PTH in its first 13 amino acids. The N-terminal region of PTHrP (amino acids 1–34) binds and stimulates PTH receptors in bone and kidney cells with affinity equal to that of PTH and results in PTHrP functioning similarly to PTH in patients with humoral hypercalcemia of malignancy (Orloff *et al.*, 1994).

PTHrP not only plays a major role in most forms of humoral hypercalcemia of malignancy (HHM), but

TABLE 23.3 Measurement of Serum Hormone Concentrations

Test	Sample requirements/ handling	Methods	Comments	Reference ranges (OSU values)[a]
PTH, intact	Serum	N-Terminal RIA (Nichols Inst.)	Human assays work well in animals. Commercial assays are no longer available.	23 ± 5 pg/ml (dog) 13 ± 2 pg/ml (cat)
		Two-site IRMA (Nichols Inst.) (Diagnostic Products Corp.)	Human assays work well in animals.	18–122 pg/ml (2–13 pM) (dog)[b] 0–38 pg/ml (0–4 pM) (cat)[b] 2–19 pg/ml (0.2–2.0 pM) (horse)[b]
PTH, midregion, or C-terminal	Serum	RIA	Less clinically relevant; may be increased in animals with renal failure.	Human assays are variable and unreliable in animals.

has been demonstrated in many normal tissues, including epithelial cells of the skin and other organs; endocrine glands; smooth, skeletal, and cardiac muscle; lactating mammary gland; placenta; fetal parathyroid glands; bone; brain; and lymphocytes (Moseley *et al.*, 1991; Gröne *et al.*, 1994; Wysolmerski and Broadus, 1994; Philbrick *et al.*, 1996). Therefore, PTHrP functions as (1) a hormone in an endocrine manner in the fetus, (2) a paracrine factor in many fetal and adult tissues, and (3) an abnormal hormone in an endocrine manner in adults with HHM (Fig. 23.15). It is not known if there is a specific receptor for PTHrP in tissues other than bone and kidney; however, the mid- and C-terminal regions of PTHrP have functions that are independent of its PTH-like effects. Therefore, PTHrP is a polyhormone with multiple biologically active regions whose function depends on enzymatic processing of PTHrP in the serum or tissue of origin (Mallette, 1994). The midregion of PTHrP is responsible for stimulating Ca uptake by the fetal placenta (MacIsaac *et al.*, 1991b) and the C-terminal region can inhibit osteoclastic bone resorption (Fenton *et al.*, 1991b).

2. *Parathyroid Hormone-Related Protein in the Fetus*

a. Fetal Calcium Balance

Fetuses maintain higher concentrations of serum Ca compared to those of their dams. Because fetal parathyroid glands produce low levels of PTH, the mechanism of maintaining increased serum Ca concentrations in fetuses was unknown until recently (Care, 1991). Investigations have demonstrated that PTHrP functions to maintain Ca balance in the fetus (MacIsaac *et al.*, 1991a, 1991b; Abbas *et al.*, 1994). It is the major hormone secreted by fetal parathyroid chief cells and is produced by the placenta to stimulate Ca uptake by the fetus. Thyroparathyroidectomy of sheep fetuses results in a reduction in fetal serum Ca concentration and reduced placental transport of Ca (MacIsaac *et al.*, 1991b). The midregion of PTHrP is the most active portion that stimulates Ca and Mg transport by the placenta.

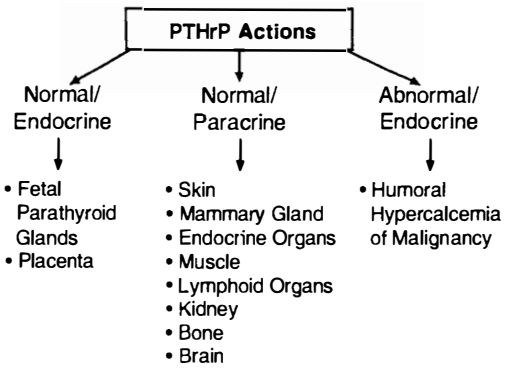

FIGURE 23.15 Actions of parathyroid hormone-related protein (PTHrP). (Rosol and Capen, 1992.)

b. Fetal Bone Development

PTHrP plays a role in differentiation of many tissues during gestation. It is widely expressed in numerous fetal tissues (Campos *et al.*, 1991; Moseley *et al.*, 1991) and is especially important in bone growth and development. Mice with "knock-out" or disruption of the PTHrP genes have decreased cartilage growth, shortened bones, and prematurely ossified bones, and die *in utero* or at birth (Karaplis *et al.*, 1994). Death at the time of birth is due to an inability to respire because the entire rib cage is ossified and rigid, the face is shortened, and the tongue protrudes from the mouth.

PTHrP regulates growth of cartilage at the epiphyseal plate by increasing chondrocyte proliferation and inhibiting maturation of chondrocytes from the proliferative zone to the hypertrophic zone (Vortkamp *et al.*, 1996). PTHrP gene "knockout" mice have short ossified bones at birth due to a lack of cartilage proliferation and early maturation of chondrocytes (Karaplis *et al.*, 1994). PTHrP increases chondrocyte proliferation and thickness of the proliferative chondrocyte zone at the growth plate by inhibiting apoptosis of chondrocytes. Inhibition of apoptosis is dependent on translocation of PTHrP to the nucleus and nucleolus (Henderson *et al.*, 1995). PTHrP contains a nucleolar localization sequence between amino acids 87 and 107. It is unknown whether PTHrP is translocated to the nucleus after secretion from the cell, binding to cell membrane receptors and receptor internalization, or whether translocation represents movement from the point of synthesis in the cytoplasm to the nucleus without exit from the cell (intracrine effect). A rare activating mutation of the PTH/PTHrP receptor in humans (Jansen's chondrodystrophy) results in increased thickness of the proliferating zone of chondrocytes at the growth plate (Schipani *et al.*, 1996).

3. *Parathyroid Hormone-Related Protein in the Normal Adult*

a. Introduction

PTHrP is produced by many tissues in adult animals, including endocrine glands, muscle (smooth, skeletal, and cardiac), brain, lymphocytes, lactating mammary gland, kidney, prostate gland, lung, skin and other simple epithelia, and bone (Capen and Rosol, 1993a; Gröne *et al.*, 1994; Philbrick *et al.*, 1996). The function of PTHrP in most of these tissues is poorly understood, but it probably functions as an autocrine or paracrine regulatory factor, because circulating con-

centrations of PTHrP in normal humans and animals are low (<1 p*M*) (Burtis, 1992; Rosol *et al.*, 1992b). The PTH/PTHrP receptor is often expressed on the same or adjacent cells in tissues that synthesize PTHrP.

b. PTHrP in the Skin

Epidermal keratinocytes produce PTHrP, which plays a role in their proliferation or differentiation (Werkmeister *et al.*, 1993). Keratinocytes do not contain the classic PTH/PTHrP receptor, but PTHrP induces an increase in intracellular Ca^{2+}, which suggests that keratinocytes have an alternative PTHrP receptor (Orloff *et al.*, 1992). The classic PTH/PTHrP receptor is present on dermal fibroblasts (Hanafin *et al.*, 1995). PTHrP production by keratinocytes may act in an autocrine manner in the epidermis and a paracrine manner in dermis. Inhibition of PTHrP action in the skin with PTH/PTHrP receptor antagonists results in increased hair formation and prolonged anagen phase of the hair cycle (Holick *et al.*, 1994).

c. PTHrP in the Mammary Gland

The greatest concentration of PTHrP is found in milk (10–100 nmol/L) and is 10,000- to 100,000-fold greater than that in the serum (Ratcliffe, 1992; Riond *et al.*, 1995a). The function of PTHrP in the mammary gland and in milk is poorly understood at present. Overexpression of PTHrP in the mammary gland during gland development prior to lactation results in glandular hypoplasia due to a reduction in branching morphogenesis of the mammary ducts (Wysolmerski *et al.*, 1995).

Abundant and biologically active PTHrP is produced by alveolar epithelial cells during lactation, which results in the high concentration of PTHrP in milk. Synthesis of PTHrP by the mammary gland abruptly ceases when suckling stops and the gland undergoes involution (Thiede, 1994). PTHrP is enzymatically cleaved in milk, but the N-terminal PTHrP retains biological activity. The mammary gland actively transports calcium from serum into milk, and PTHrP may play a role in stimulating the transport of calcium by alveolar epithelial cells; however, this has not been confirmed in all species (Barlet *et al.*, 1992; Philbrick *et al.*, 1996).

Circulating concentrations of PTHrP may be minimally increased in lactating dams, but PTHrP from the mammary gland likely plays a minor role in systemic calcium balance of lactating animals (Melton *et al.*, 1990; Barlet *et al.*, 1993). No relationship has been demonstrated between PTHrP and the pathogenesis of parturient hypocalcemia and paresis in lactating dairy cattle (Riond *et al.*, 1996). Alternatively, milk PTHrP could have a physiologic function in suckling neonates, such as regulation of growth or differentiation of the gastrointestinal tract (Thiede, 1994). Infusion of PTHrP (1–34) into the mammary artery of lactating sheep resulted in increased blood flow to the mammary gland (Thompson, 1993). This was likely due to relaxation of the smooth muscle in the mammary arteries.

d. PTHrP and Smooth Muscle

PTHrP is widely produced by smooth muscle in the body, including blood vessels, uterus, oviduct of the hen, urinary bladder, and gastrointestinal tract (Philbrick *et al.*, 1996). In general, PTHrP expression is increased when smooth muscle is mechanically stretched; PTHrP induces relaxation of smooth muscle and attenuation of contraction. With progressive distension of the uterus during pregnancy or descent of the ovum in the hen's oviduct, PTHrP expression by the myometrium and myosalpinx increases. PTHrP expression in the urinary bladder smooth muscle is proportional to distension with urine. Both PTHrP and PTH are potent vasodilators and inducers of hypotension due to relaxation of vascular smooth muscle when administered intravenously. PTHrP probably functions as a paracrine regulator of vascular tone, causing vasodilatation and modulating vasoconstriction of other vasoactive compounds.

4. *Assays for Parathyroid Hormone-Related Protein*

Two-site immunoradiometric (IRMA) and N-terminal radioimmunoassays are available for the measurement of human PTHrP (Table 23.3) (Bilezikian, 1992; Kremer and Goltzman, 1994). These assays are useful to measure PTHrP in the dog (see Section IV.B) (Rosol *et al.*, 1992b; Weir, 1992) because of the high degree of sequence homology in PTHrP between species, especially in the first 111 amino acids (Burtis, 1992). An N-terminal RIA for human PTHrP has not proven useful to measure circulating PTHrP in a small number of horses (Rosol *et al.*, 1994). PTHrP concentrations are best measured in fresh or frozen plasma using EDTA as an anticoagulant and with the addition of protease inhibitors, such as aprotinin and leupeptin (Pandian *et al.*, 1992).

The circulating forms of PTHrP are not completely understood, because it rapidly undergoes proteolysis intracellularly and extracellularly after secretion into blood (Pandian *et al.*, 1992). The natural proteolytic cleavage sites of PTHrP (1–141) have not been completely identified (Burtis, 1992; Bowden *et al.*, 1993; Orloff *et al.*, 1994). The forms of PTHrP that are present *in vivo* include an N-terminal peptide, a combined N-terminal and midregion peptide, a midregion peptide, and a C-terminal peptide (Burtis *et al.*, 1994; Yang *et*

al., 1994). The N-terminal peptide extends from amino acid (aa) 1 to 36. The cleavage site may be at the Arg^{37}. The N-terminal peptide also contains three Arg residues at aa 19–21 that could serve as a proteolytic cleavage site. Proteolysis at this site would destroy the PTH-like bioactivity of PTHrP. The midregion of PTHrP extends from the end of the N-terminal peptide to approximately aa 86. There are many Arg and Lys residues between aa 86 and aa 111 that could serve as proteolytic cleavage sites.

Proteolysis of PTHrP makes sample collection and storage important criteria for accurate measurement of circulating PTHrP. The fragments that would be expected to have PTH-like biologic activity *in vivo* include N-terminal PTHrP (1–36), PTHrP (1–86), and intact PTHrP (1–141). The two-site IRMAs measure intact PTHrP (1–141) and PTHrP (1–86) because one antibody binds the N-terminus and one binds the midregion. N-Terminal RIAs measure intact PTHrP (1–141), PTHrP (1–86), and N-terminal PTHrP (1–36). C-Terminal PTHrP accumulates in the serum of human patients with renal failure, which suggests that C-terminal PTHrP peptides are excreted by the kidney as occurs with PTH (Burtis *et al.*, 1990).

5. *Canine Parathyroid Hormone-Related Protein*

The complementary DNA for canine PTHrP has been cloned and sequenced (Rosol *et al.*, 1995b). The PTHrP gene has been reported to be complex with multiple promoters, up to nine exons, and alternate splicing of exons that encode the C-terminal peptides (Gillespie and Martin, 1994). The sequence of the canine PTHrP cDNA indicated that the dog PTHrP gene is more closely related to the human PTHrP gene than are the PTHrP genes in rats, mice and chickens.

The coding region of canine PTHrP predicts a 177-amino acid protein with four regions: signal peptide; N-terminal or parathyroid hormone-like region; midregion; and C-terminal region (Fig. 23.16) (Burtis, 1992; Orloff *et al.*, 1994). The deduced amino acid sequence of the N-terminal region of the mature protein (aa 1–36) is identical in the four mammalian species (dog, human, rat, and mouse) and there is a very high degree of homology in these species of the midregion of PTHrP (Fig. 23.17) (Suva *et al.*, 1987; Yasuda *et al.*, 1989; Mangin *et al.*, 1990; Rosol *et al.*, 1995b). The high degree of interspecies homology indicates the importance of the N-terminus and midregion to the function of PTHrP.

There is less homology of the C-terminal region of canine PTHrP with that region of PTHrP from other species. The function of the C-terminal region is unknown. It has been reported that PTHrP (107–111) and PTHrP (107–139) inhibit osteoclastic bone resorption (Fenton *et al.*, 1991a). Increased urine concentrations of C-terminal PTHrP have been demonstrated in humans and mice with cancer-associated hypercalcemia (Imamura *et al.*, 1991; Kasahara *et al.*, 1992). The circulating concentrations of the C-terminal peptide are increased in patients with renal failure (Burtis *et al.*, 1990). This mimics the finding of increased C-terminal PTH in the serum of patients with renal failure and indicates that the kidney is an important site of excretion of C-terminal PTHrP and that it may have a longer serum half-life than N-terminal or midregion PTHrP.

C. Calcitonin (Thyrocalcitonin)

1. *Development and Structure of Thyroid C Cells*

Calcitonin (thyrocalcitonin, CT) is a more recently discovered hormone than PTH (Copp, 1994). Phylogenetically, the early appearance of calcitonin in primitive elasmobranch fish precedes the first appearance of PTH in amphibians. Calcitonin is secreted by a second endocrine cell population in the mammalian thyroid gland. C cells are distinct from follicular cells in the thyroid that secrete thyroxine and triiodothyronine. They are situated either within the follicular wall be-

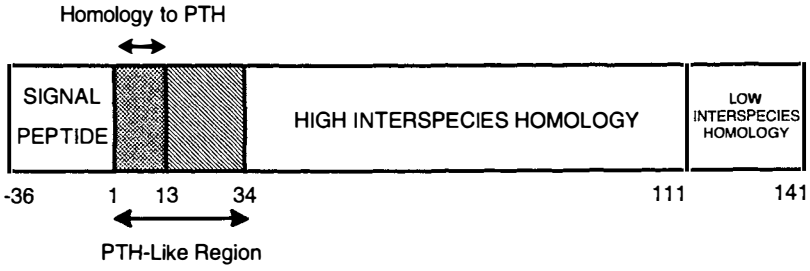

FIGURE 23.16 Different regions of canine PTHrP protein: signal peptide (aa −36 to −1); N-terminal parathyroid hormone (PTH)-like region (aa 1–13), which shares primary sequence homology with PTH; N-terminal PTH-like region (aa 1–34), which binds to the PTH receptor and is identical in dogs, humans, and rodents; midregion with high interspecies homology; and C-terminal region of low interspecies homology.

FIGURE 23.17 Predicted amino acid sequences of the mature form of canine parathyroid hormone-related protein (1–141) and of human, rat, mouse, and chicken PTHrP. Note the high degree of homology in the N-terminal 111 amino acids and complete homology of PTHrP 1–36 (the PTH-like region that binds to PTH/PTHrP receptors) in dogs, humans and rodents. Identical amino acids are represented by dots.

tween follicular cells or as small groups of cells between thyroid follicles. C cells do not border the follicular colloid directly, and their secretory polarity is oriented toward the interfollicular capillaries. The distinctive feature of C cells is the presence of numerous small membrane-limited secretory granules in the cytoplasm (Fig. 23.6). Immunocytochemical techniques have localized calcitonin of C cells to these secretory granules.

Calcitonin-secreting C cells have been shown to be derived embryologically from cells of the neural crest. Primordial cells from the neural crest migrate ventrally and become incorporated within the last (ultimobranchial) pharyngeal pouch. They move caudally with the ultimobranchial body to the point of fusion with the midline primordia that give rise to the thyroid gland. The ultimobranchial body is incorporated into the thyroid near the hilus in mammals, and C cells subsequently are distributed throughout the gland. Although C cells are present throughout the thyroid gland in postnatal life of man and most other mammals, they often remain more numerous near the hilus and point of fusion with the ultimobranchial body. In submammalian species C cells and calcitonin activity remain segregated in the ultimobranchial gland, which is anatomically distinct from both the thyroid and the parathyroid glands.

2. *Chemistry*

Calcitonin is a polypeptide hormone composed of 32 amino acid residues arranged in a straight chain with a 1–7 disulfide linkage (Copp, 1970). It is a smaller molecule than parathyroid hormone (84 amino acids) and is synthesized as part of a larger biosynthetic precursor molecule. Pre-procalcitonin is the initial translational product formed in the rough endoplasmic reticulum (Fig. 23.18). Procalcitonin is transported to the Golgi apparatus where it is converted to calcitonin prior to packaging in membrane-limited secretory granules. Depending upon the need for calcitonin, a proportion of the precursors and active hormone undergo degradation prior to release from C cells. Under certain pathologic conditions (e.g., neoplasia) these neural crest-derived C cells may secrete other humoral factors, including serotonin, bradykinin, ACTH, and prostaglandins (Fig. 23.18).

The calcitonin gene is expressed differently in thyroid (C cells) and neural tissues (Jacobs, 1985). In thyroid C cells the mRNA encodes primarily for pre-procalcitonin (molecular weight: 17,400 Da), whereas in neural tissues there is alternative RNA processing and encoding for pre-procalcitonin gene-related peptide (CGRP) (15,900 Da). CGRP is a neuropeptide composed of 37 amino acids and is concerned with nociception, ingestive behavior, and modulation of the nervous and endocrine systems.

The complete amino acid sequence of calcitonin from porcine, bovine, ovine, canine, salmon, and other animal species, as well as human calcitonin, has been determined (Mol *et al.*, 1991). Synthetic human calcitonin has been prepared and shown to be biologically active. The structure of calcitonin differs considerably between species. The molecules in eight selected species share only eight of the 32 amino acid residues (Fig. 23.19). However, the amino terminal of the calcitonin molecule is similar in all species. It consists of a seven-

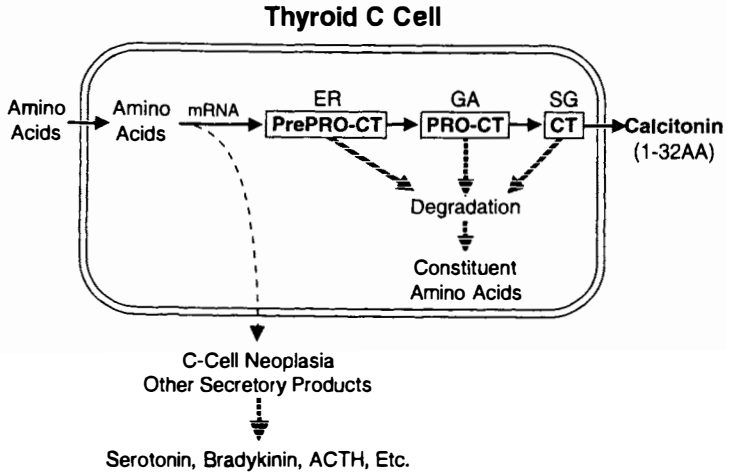

FIGURE 23.18 Biosynthesis of calcitonin (CT) by thyroid C cells. ER, endoplasmic reticulum; GA, Golgi apparatus; SG, secretory granule.

membered ring enclosed by an intrachain disulfide bridge. The complete sequence of 32 amino acids and the disulfide bond are essential for full biologic activity. Salmon calcitonin is more potent in lowering blood calcium on a weight basis than any of the other calcitonins when administered to mammals, including man. The reason for the greater biologic potency of salmon calcitonin in mammals is uncertain, but probably is related to an increased resistance to metabolic degradation or a greater affinity for receptor sites in bone and other target tissues.

3. *Regulation of Secretion*

The concentration of calcium ion in plasma and extracellular fluids is the principal physiologic stimulus for the secretion of calcitonin by C cells (Care, 1992). Calcitonin is secreted continuously under conditions of normocalcemia, but the rate of secretion of calcitonin increases greatly in response to an elevation in blood calcium. Magnesium ion has an effect on calcitonin secretion similar to that of calcium, but these effects are observed only under experimental conditions with nonphysiologic levels of magnesium. When blood Ca^{2+} concentration increases, the intracellular Ca^{2+} concentration in C cells increases, resulting in enhanced calcitonin secretion. C cells express the same Ca^{2+}-sensing receptor as parathyroid chief cells; the receptor is responsible for sensing the extracellular Ca^{2+} concentration and likely contributes to the regulation of calcitonin secretion along with a voltage-sensitive Ca^{2+} channel (Chattopadhyay *et al.*, 1996).

C cells store substantial amounts of calcitonin in their cytoplasm in the form of membrane-limited secretory granules (Fig. 23.6). In response to hypercalcemia, stored hormone from C cells is rapidly discharged into interfollicular capillaries (Capen and Young, 1969). If a hypercalcemic stimulus is sustained, this is followed by an increased development of cytoplasmic organelles concerned with the synthesis and secretion of calcitonin. The endoplasmic reticulum with attached ribosomes is hypertrophied, and the Golgi apparatus is enlarged and associated with prosecretory granules in the process of formation. Hyperplasia of C cells occurs in response to long-term hypercalcemia (Capen and Young, 1969; Collins *et al.*, 1977). When the blood

FIGURE 23.19 Amino acid sequences of calcitonin in different species. Amino acids 1, 4–7, 9, 28, and 32 are shared by all species. The cysteines at positions 1 and 7 form the N-terminal disulfide bridge. Notice the similarities between ovine, bovine and porcine calcitonin, human and rat calcitonin, and chicken and salmon calcitonin. Identical amino acids are represented by dots. Modified from Mol *et al.* (1991).

calcium is lowered, the stimulus for calcitonin secretion is diminished and numerous secretory granules accumulate in the cytoplasm of C cells (Fig. 23.6). The storage of large amounts of preformed hormone in C cells and rapid release in response to moderate elevations in blood calcium probably are a reflection of the physiologic role of calcitonin as an emergency hormone to protect against the development of hypercalcemia.

Calcitonin secretion is increased in response to a high-calcium meal often before a significant rise in plasma calcium can be detected. The cause of this increase in calcitonin secretion could be either a small undetectable rise in plasma ionized calcium or a direct stimulation of certain gastrointestinal hormones by the oral calcium load; the hormones in turn act as secretagogues for calcitonin release from the thyroid gland (Cooper *et al.*, 1972). Gastrin, pancreozymin, and glucagon all have been demonstrated to stimulate calcitonin release under experimental conditions in animals (Care *et al.*, 1970). These findings suggest that gastrointestinal hormones are important in triggering the early release of calcitonin to prevent the development of hypercalcemia following the ingestion of a high-calcium meal (Fig. 23.20) (Care, 1992).

4. *Biological Action*

The administration of calcitonin or stimulation of endogenous secretion results in the development of varying degrees of hypocalcemia and hypophosphatemia. These effects of calcitonin on plasma calcium and phosphorus are most evident in young animals or older animals with increased rates of skeletal turnover. Calcitonin exerts its function by interacting with target cells, primarily in bone and kidney and to a lesser extent in the intestine. The action of PTH and CT is antagonistic on bone resorption (Fig. 23.11) but synergistic on decreasing the renal tubular reabsorption of phosphorus (Fig. 23.12). The hypocalcemic effects of calcitonin are primarily the result of decreased entry of calcium from the skeleton into plasma due to a temporary inhibition of PTH-stimulated bone resorption (Heersche, 1992). The hypophosphatemia develops from a direct action of calcitonin on increasing the rate of movement of phosphate out of plasma into soft tissue and bone (Talmage *et al.*, 1972), as well as from the inhibition of bone resorption. The action of CT is not dependent on vitamin D, because it acts both in vitamin D-deficient animals and after the administration of large doses of vitamin D.

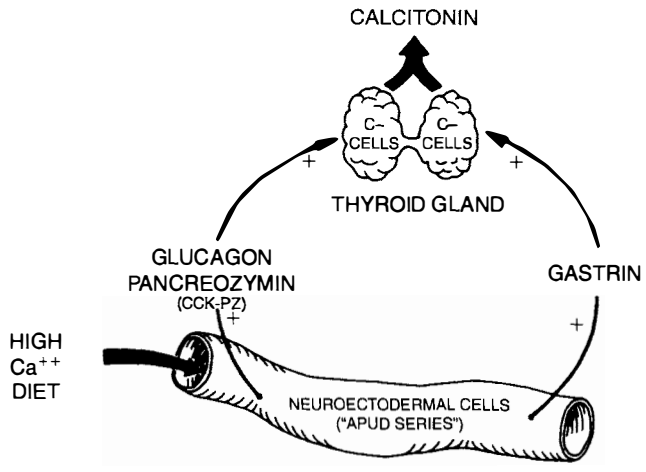

FIGURE 23.20 The gastrointestinal hormone–thyroid C-cell axis provides a mechanism for rapid release of calcitonin from the thyroid in response to a high-calcium diet before a significant elevation in blood calcium occurs. (Capen, 1989.)

The action of calcitonin on inhibiting bone resorption stimulated by PTH and other factors is from blockage of osteoclastic osteolysis (Fig. 23.11). Specific structural alterations are produced in osteoclasts by calcitonin (Chambers and Moore, 1983). Osteoclasts withdraw from resorptive surfaces and the brush border and transitional zone become atrophic (Weisbrode and Capen, 1974; Matthews, 1992). In addition, the rate of activation of osteoprogenitor cells to preosteoclasts and osteoclasts decreases, resulting in decreased osteoclast number. Although CT can block bone resorption completely, the inhibition is a transitory effect. The continuous administration of CT *in vivo* and *in vitro* in the presence of PTH leads to an "escape phenomenon" whereby the effects of PTH on increasing bone resorption become manifest in the presence of CT (Heersche, 1992).

The effects of calcitonin on bone formation are less dramatic. Initially, there appears to be an increase in the rate of bone formation, but the long-term administration of calcitonin appears to lead to a reduction in both bone resorption and formation. Calcitonin-secreting C-cell neoplasms in both bulls and human beings are associated with a low rate of skeletal turnover and densely mineralized bone (Black *et al.*, 1973b). Unfortunately, calcitonin has not proven to be an effective therapeutic agent to induce a long-term increase in bone formation in human patients with postmenopausal osteoporosis. Calcitonin can partially ameliorate the increase in bone resorption that occurs in certain forms of osteoporosis (Lyles *et al.*, 1993; Copp, 1994) or can be used to treat hypercalcemia for a short duration (Dougherty *et al.*, 1990).

Calcitonin and PTH both decrease renal tubular reabsorption of phosphate to cause phosphaturia; however, the adenylate cyclase-linked receptors for calcito-

nin are found in the ascending limb of Henle and the distal convoluted tubule (Fig. 23.12). In addition, calcitonin results in diuresis of sodium, chloride, and calcium. The physiologic significance of calcitonin on renal electrolyte excretion in mammals is uncertain, and this function as a regulator of ionic balance may be more important in primitive vertebrates such as fish. Likewise, the physiologic importance of calcitonin on gastrointestinal absorption of calcium is equivocal.

5. *Physiological Significance*

Calcitonin and parathyroid hormone acting in concert provide a dual negative-feedback control mechanism to maintain the concentration of calcium in extracellular fluids within narrow limits. Present evidence suggests that parathyroid hormone is the major factor concerned with the minute-to-minute regulation of blood calcium under normal conditions. This probably is related to the fact that protection against the development of hypocalcemia by PTH in most higher mammals living in a relatively low calcium–high phosphorus environment is a life-sustaining function. Calcitonin functions more as an emergency hormone to (1) prevent the development of "physiological" hypercalcemia during the rapid postprandial absorption of calcium, and (2) protect against excessive loss of calcium and phosphorus from the maternal skeleton during pregnancy. For example, thyroidectomized cows without a source of calcitonin develop significant hypercalcemia following a high-calcium meal (40 g/day) compared to intact control cows fed a similar diet (Barlet, 1972).

6. *Calcitonin Assays*

Serum calcitonin is best measured by radioimmunoassay. Because of the low degree of homology of calcitonin between species, there is poor cross reactivity of RIAs for calcitonin. There is relatively little need to measure calcitonin in clinical veterinary medicine because of the scarcity of calcitonin-secreting neoplasms or clinical disorders resulting from abnormal blood levels of calcitonin. In humans, RIA for calcitonin is useful to identify functional C-cell (medullary) tumors of the thyroid gland (Ziegler *et al.*, 1996). RIAs for calcitonin are necessary also for experimental investigations of regulation of C cells *in vivo* or *in vitro*. Since the sequencing of canine calcitonin, a canine-specific RIA has been developed and has been used to measure serum calcitonin in dogs (Hazewinkel, 1991).

D. Cholecalciferol (Vitamin D)

1. *Introduction*

The third major hormone involved in the regulation of calcium metabolism and skeletal remodeling is cholecalciferol (vitamin D_3) or irradiated ergosterol (vitamin D_2). Although these compounds have been considered to be vitamins for a long time, they can equally be considered hormones (Bell, 1985). Cholecalciferol is ingested in small amounts in the diet and can be synthesized in the epidermis from precursor molecules (e.g., 7-dehydrocholesterol) through a previtamin D_3 intermediate form (Fig. 23.21). This reaction is catalyzed by ultraviolet irradiation (wavelength 290 to 320 μm) from the sun (Holick, 1981). A high-affinity vitamin D-binding protein (DBP) transports cholecalciferol from its site of synthesis in the skin by the bloodstream to the liver (Holick and Clark, 1978). Carnivores, such as the dog and cat, may be less able to synthesize vitamin D_3 in the skin and are more dependent on dietary sources of vitamin D compared to herbivores and omnivores (How *et al.*, 1994).

In response to prolonged exposure to sunlight, previtamin D_3 is converted to lumisterol and tachysterol (Fig. 23.21). Because the DBP has no affinity for lumisterol and minimal affinity for tachysterol, the translocation of these photoisomers into the circulation is negligible and they are sloughed off with the natural turnover of the skin.

2. *Metabolic Activation*

Vitamin D must be metabolically activated before it can produce its known physiological functions in target cells. Vitamin D_3 from dietary sources is absorbed by facilitated diffusion and bound to an α-2-globulin in the blood for transport. Cholecalciferol from endogenous sources is synthesized in the skin from 7-dehydrocholesterol by a photochemical reaction in the presence of ultraviolet irradiation (Fig. 23.22) (Holick and Clark, 1978). It is bound to a vitamin D-binding protein in the blood and transported to the liver.

The first step in the metabolic activation of vitamin D is the conversion of cholecalciferol to 25-hydroxycholecalciferol (25-OH-CC) in the liver. The enzyme responsible for controlling this reaction is a hepatic microsomal enzyme, referred to as calciferol-25-hydroxylase, associated with the endoplasmic reticulum (Armbrecht *et al.*, 1992). Although 25-OH-CC can exert biologic effects when substantial amounts are present, it primarily serves as a precursor for the formation of more active vitamin D metabolites. Consid-

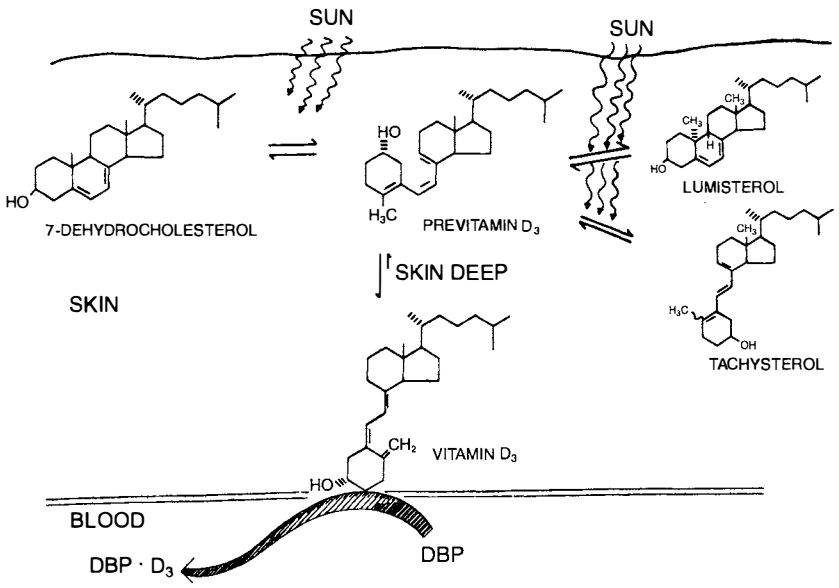

FIGURE 23.21 Prolonged exposure to sunlight results in the photochemical conversion of previtamin D_3 to lumisterol and tachysterol. These photoisomers remain primarily in the epidermis and are lost with the natural turnover of the skin because the vitamin D_3-binding protein has a relatively low affinity for them. From Holick (1981).

erably larger amounts of protein-bound 25-OH-CC circulate than with the more hydroxylated metabolites, such as 1,25-$(OH)_2$D, which are present in extremely low levels in the blood.

This first metabolite of cholecalciferol (25-OH-CC) is transported to the kidney and undergoes further transformation to a more polar and active metabolite (Fig. 23.22) (DeLuca, 1973; Armbrecht *et al.*, 1992). The principal active metabolite of 25-OH-CC formed in the kidney is 1,25-$(OH)_2$D, but other metabolites are formed, such as 24,25$(OH)_2$D. The rate of formation of 1,25-$(OH)_2$D is catalyzed by 25-dihydroxycholecalciferol-1α-hydroxylase in mitochondria of renal epithelial cells in the proximal convoluted tubules. It has been shown that the 1α-hydroxylase enzyme system is a mixed-function steroid hydroxylase similar to those in the adrenal cortex, contains cytochrome P450, and requires molecular oxygen. 1,25-Dihydroxycholecalciferol exerts strong feedback inhibition on the 1α-hydroxylase in the kidney. The conversion of 25-OH-CC to 1,25-$(OH)_2$D is the rate-limiting step in vitamin D metabolism and is primarily the reason for the delay between administration of vitamin D and expression of its biological effects.

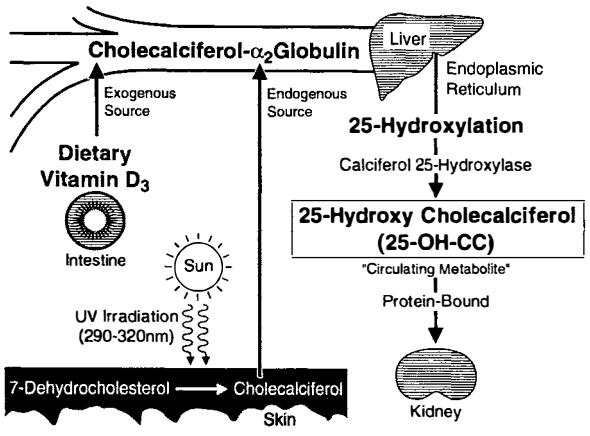

FIGURE 23.22 Metabolism of vitamin D. The initial step of metabolic activation of vitamin D_3 from endogenous and dietary sources is in the liver to form 25-hydroxycholecalciferol.

The control of this final step in the metabolic activation of vitamin D is complex and is regulated by the plasma calcium concentration and its influence on the rates of secretion of PTH and possibly CT (Hulter *et al.*, 1985). The two other major hormones controlling calcium metabolism appear to have opposite effects on this 1α-hydroxylase and formation of 1,25-$(OH)_2$D (Armbrecht *et al.*, 1992). Parathyroid hormone and conditions that stimulate PTH secretion increase the transformation of 25-OH-CC to 1,25-$(OH)_2$D, whereas calcitonin under certain conditions inhibits the conversion. In addition, a low concentration of phosphorus in the blood increases the formation of 1,25-$(OH)_2$D, whereas a high concentration suppresses the activity of the 1α-hydroxylase. Minute-to-minute changes in 1α-hydroxylase activity may result from changes in the

ionic environment of renal mitochondria caused by the accumulation or release of calcium or inorganic phosphate.

The rates of synthesis of 24,25-$(OH)_2D$ and 1,25-$(OH)_2D$ are reciprocally related and controlled by similar factors (Tanaka and DeLuca, 1974). When 1,25-$(OH)_2D$ synthesis increases, the synthesis of 24,25-$(OH)_2D$ declines, and vice versa. For example, feeding a high-calcium diet decreases the formation of 1,25-$(OH)_2D$, and 25-OH-CC is diverted to form primarily 24,25-$(OH)_2D$, a metabolite that is much less active in stimulating intestinal calcium transport. 24,25-$(OH)_2D$ may play a role in bone formation (Ornoy *et al.*, 1978) and egg hatchability (Henry and Norman, 1978), and, with 1,25-$(OH)_2D$, may exert negative feedback control on the parathyroid gland (Fig. 23.23).

Other hormones may increase the activity of renal 1α-hydroxylase and the formation of 1,25-$(OH)_2D$. Prolactin, estradiol, placental lactogen, and growth hormone enhance 1α-hydroxylase activity (Reichel *et al.*, 1989). Increased secretion of these hormones, either alone or in combination, is important in efficient adaptation to the major calcium demands during life. The physiological adjustments in calcium homeostasis imposed by pregnancy, lactation, and growth may be mediated primarily by an increased intestinal absorption of calcium stimulated by 1,25-$(OH)_2D$.

1,25-Dihydroxycholecalciferol is the major biologically active metabolite of cholecalciferol. It interacts with target cells in the intestine and bone under physiological conditions to enhance the rates of existing reactions and increase calcium mobilization. Its onset of action is more rapid and the degree of potency is much greater than those of either cholecalciferol or 25-OH-CC. A similar two-step process of metabolic activation also occurs with irradiated ergosterol (vitamin D_2).

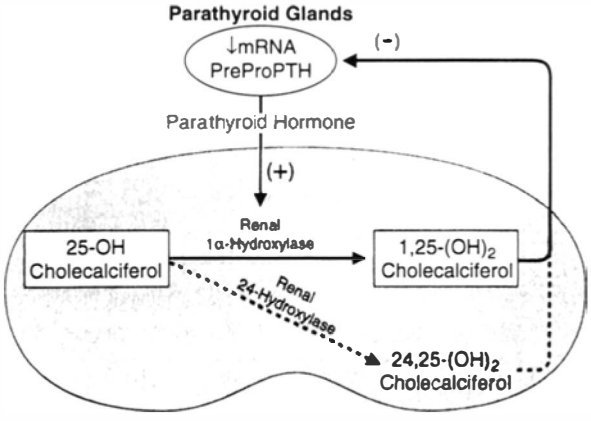

FIGURE 23.23 Negative feedback exerted by vitamin D metabolites on parathyroid chief cells to decrease the rate of parathyroid hormone secretion, which in turn diminishes the rate of formation of additional 1,25-dihydroxycholecalciferol.

3. Chemistry

The chemical structure of cholecalciferol (vitamin D_3) resembles that of other steroid hormones. It is a seco-steroid in which the B ring of the basic steroid nucleus has been opened by breakage of the 9-carbon–10-carbon bond. Photoactivation by ultraviolet irradiation (290 to 320 μm) of 7-dehydrocholesterol in epidermis of the skin results in a cleavage between the 9- and 10-carbons and unfolding of the B ring of the basic steroid nucleus. During metabolic activation of cholecalciferol (or irradiated ergosterol), hydroxyl groups are successively attached to the steroid nucleus by specific hydroxylases at positions 1 and 25 in the liver and kidney to form the hormonal (biologically active) form of vitamin D. In other natural metabolites of cholecalciferol, the two hydroxyl groups are attached at either 24 or 25 and 26 positions.

There are a number of other sterols closely related to cholecalciferol. Vitamin D_2 is formed by the irradiation of the plant sterol referred to as ergosterol. When irradiated ergosterol is ingested and absorbed from the intestine, it undergoes a series of steps of metabolic activation similar to those described for cholecalciferol (vitamin D_3). However, the more active metabolites of ergosterol are 25-hydroxyergosterol and 1,25-dihydroxyergosterol, synthesized by the liver and kidney, respectively. Another related sterol of considerable therapeutic interest is dihydrotachysterol. The A ring of the steroid nucleus in this compound is rotated so that the hydroxyl in position 3 occupies a position sterically equivalent to the hydroxyl position 1 of 1,25-$(OH)_2D$. Dihydroxytachysterol undergoes metabolic transformation to 25-dihydrotachysterol, but subsequent hydroxylation of position 1 does not occur.

4. Biological Action

Vitamin D and its active metabolites function to increase the absorption of calcium and phosphorus from the intestine, thereby maintaining adequate levels of these electrolytes in the extracellular fluids in order to permit the appropriate mineralization of bone matrix. From a functional point of view vitamin D can be thought to act in such a way as to cause the retention of sufficient mineral ions to ensure mineralization of bone matrix, whereas PTH maintains the proper ratio of calcium to phosphorus in extracellular fluids. In addition, a small amount of vitamin D is needed to permit PTH to exert its action on bone ("permissive effect").

The major target tissue for 1,25-dihydroxycholecalciferol is the mucosa of the small intestine. In the proximal part it increases the active transcellular transport

of calcium, and in the distal part the transport of phosphorus. Following synthesis in the kidney, 1,25-$(OH)_2D$ is transported in a protein-bound form to specific target cells in the intestine and bone (Fig. 23.24). Circulating levels of this hormonal form of cholecalciferol are extremely low. Free 1,25-$(OH)_2D$ penetrates the plasma membrane of target cells and initially binds to a cytoplasmic receptor in cells of the intestine (Fig. 23.24) (Walters, 1992). Subsequently, the hormone–receptor complex is transferred to the nucleus and 1,25-$(OH)_2D$ binds to specific receptors in the nuclear chromatin, where it stimulates gene expression leading to increased synthesis of vitamin D-dependent proteins such as calcium-binding protein (CaBP) (calbindin) by intestinal cells (Christakos *et al.*, 1989) (Fig. 23.24). Calbindin has been isolated from several tissues (e.g., small intestine, kidney, placenta, bone, uterus, nervous system, and the shell gland of laying hens) across which significant amounts of calcium are transported.

The absorptive capacity of the intestine for calcium is a direct function of the amount of CaBP present (Wasserman and Fullmer, 1983). Administering vitamin D or feeding low-calcium and low-phosphorus diets has been shown to stimulate the synthesis of CaBP, which contributes to the increased intestinal absorption of calcium. The physiological functions of CaBP are related to the transcellular transport of calcium from the luminal to the basilar border of intestinal absorptive cells and the regulation of intracellular calcium concentration (Fig. 23.24). At the basilar aspect of intestinal absorptive cells, calcium is exchanged for sodium and enters the extracellular fluids.

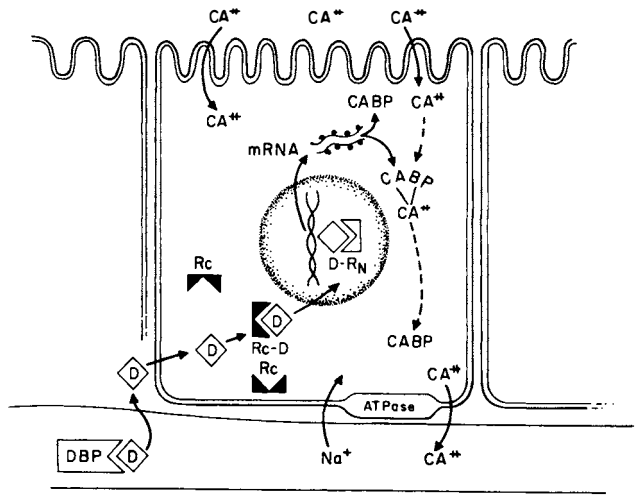

FIGURE 23.24 Molecular mechanisms of action of 1,25-dihydroxycholecalciferol in the intestine. The active metabolite of vitamin D is transported to the intestine by a vitamin D-binding protein (DBP). The hydrophilic steroid penetrates the plasma membrane, binds to a cytoplasmic receptor, and is transported to the nucleus, where it interacts with the nuclear chromatin to increase the formation of mRNA. The mRNA becomes associated with ribosomes on the endoplasmic reticulum and directs the synthesis of new proteins such as calcium-binding protein (CABP, calbindin). The CABP is involved in the transcellular transport of calcium to the basilar aspects of the intestinal absorptive cells, where calcium is exchanged for sodium and enters the extracellular fluid compartment. (Capen, 1989.)

The active metabolites of cholecalciferol also act on bone (High *et al.*, 1981b; Finkelman and Butler, 1985). In addition to its indirect effect on mineralization of bone matrix, vitamin D is necessary for osteoclastic resorption and calcium mobilization from bone. Small amounts of vitamin D or its active metabolite are necessary to permit osteolytic cells to respond to PTH ("permissive effect") under physiologic conditions. 1,25-$(OH)_2D$, 25-OH-CC, and cholecalciferol in pharmacologic doses will stimulate osteoclastic proliferation and the resorption of bone *in vitro* and *in vivo*. 1,25-Dihydroxycholecalciferol is about 100 times more potent on a weight basis in stimulating bone resorption *in vitro* than is 25-OH-CC (Reynolds *et al.*, 1973).

Less is known regarding the action of cholecalciferol and its active metabolites on the kidney. Present evidence suggests that active metabolites of vitamin D stimulate the retention of calcium and phosphorus by increasing proximal tubular reabsorption.

The active metabolites of vitamin D also have a direct effect on the parathyroid gland, in addition to their well-characterized action on intestine and bone. The parathyroids selectively localize 1,25-$(OH)_2D$ and contain specific cytoplasmic and nuclear receptors for the active metabolite of vitamin D (Hughes and Haussler, 1978). Therefore, a negative feedback loop exists whereby vitamin D metabolites (either alone or in combination) directly interact with parathyroid cells to diminish the secretion of PTH, which in turn diminishes the formation of 1,25-$(OH)_2D$ (Fig. 23.23).

It has been recognized that the active metabolites of vitamin D, in particular 1,25-dihydroxycholecalciferol, have many roles in health and disease beyond the regulation of calcium metabolism (Reichel *et al.*, 1989; Walters, 1992). The vitamin D receptor is widespread in most tissues (including hematopoietic cells, muscle, reproductive system, nervous system, endocrine glands, gastrointestinal tract, urinary tract, lungs, and skin), and vitamin D functions to regulate cell growth and differentiation. In general, vitamin D inhibits cell growth and stimulates cell differentiation, but there are exceptions to this paradigm. For these reasons, 1,25-dihydroxycholecalciferol has potential therapeutic value for treatment of psoriasis and certain forms of cancer, among other diseases. Hypercalcemia due to increased intestinal Ca absorption and increased osteoclastic bone resorption are significant side effects

of therapy using the active forms of vitamin D. Therefore, there is considerable interest in developing vitamin D analogs that minimize the calcemic actions of vitamin D, but retain the ability of vitamin D to alter cell growth or differentiation (Bikle, 1992).

5. *Toxicosis*

A disease of cattle known as "enteque seco" in the Argentine and "espichamento" in Brazil is characterized by widespread mineralization of the cardiovascular system, lung, kidney, and other soft tissues (Worker and Carrillo, 1967; Done *et al.*, 1976). A similar disease affects cattle and horses in many other countries worldwide, including the United States. Affected cattle develop a chronic debilitating disease characterized by weight loss, painful gait, kyphosis, polyuria, and dyspnea. The lesions of soft tissue mineralization are remarkably similar to those produced experimentally with large doses of vitamin D (Capen *et al.*, 1966). Studies have shown that ingestion of small amounts of dried leaves from an indigenous plant (*Solanum malacoxylon*) greatly increased the rate of intestinal calcium and phosphorus absorption to produce hypercalcemia and hyperphosphatemia, osteosclerosis, parathyroid atrophy, and hyperplasia of thyroid C cells. Extracts of the leaves of *S. malacoxylon* contain an extremely potent, water-soluble active principle that stimulates the intestinal calcium transport system (de Boland *et al.*, 1976). The active principle has been shown to be 1,25-$(OH)_2$D conjugated to a glycoside. *Cestrum diurnum* ("day-blooming jessamine") also contains substantial amounts of 1,25-$(OH)_2$D and has caused a similar debilitating disease in cattle and horses in the southeastern part of the United States (Wasserman *et al.*, 1975). See also the section on hypercalcemia due to vitamin D or vitamin D metabolites.

6. *Assays for Vitamin D Metabolites*

Most assays for vitamin D and its metabolites employ competitive protein or radioreceptor techniques using vitamin D binding proteins isolated from tissues and tritium-labeled tracers; however, newer ^{125}I-based radioimmunoassays have been developed (Hollis, 1986; Iqbal, 1994; Hollis *et al.*, 1996). 25-Hydroxyvitamin D and 1,25-dihydroxyvitamin D are the most frequently measured metabolites. Because the structures of the common vitamin D metabolites do not vary between species, the same assays can be used to measure serum metabolites in animals and humans. 1,25-Dihydroxyvitamin D is the most potent metabolite in regulating calcium balance; therefore, its measurement is often necessary to understand abnormal calcium regulation. The circulating concentration of 1,25-dihydroxyvitamin D is approximately 25 pg/ml in adult animals and is greater in younger animals (Table 23.3) (Nagode and Chew, 1991). Measurement of serum 25-hydroxyvitamin D is useful for evaluating the potential for dietary vitamin D deficiency or excess, because serum levels are much greater and less tightly controlled compared to those of 1,25-dihydroxyvitamin D. Normal serum concentrations of 25-hydroxyvitamin D are 10–50 ng/ml (Dougherty *et al.*, 1990). Animals that have ingested excess vitamin D may have serum 25-hydroxyvitamin D concentrations 4–20-fold greater than normal (Carothers *et al.*, 1994).

III. PHOSPHATE METABOLISM

A. Introduction

Phosphate in the mammalian body is present predominantly (90%) as hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] in the mineralized matrix of bone, with most of the remaining 10% occurring intracellularly in soft tissues. Phosphate is the major intracellular anion existing in organic (e.g., phospholipids, nucleic acids, phosphoproteins, ATP) or inorganic forms and plays an integral role in many metabolic processes (e.g., energy metabolism, delivery of O_2 to tissues, muscle contraction, and skeletal integrity) (Dennis, 1996). Adequate fluorometric or ion-sensitive methods to measure intracellular phosphate are lacking. Rapid translocations can occur between intracellular and serum phosphate pools, which can dramatically change serum phosphate concentrations. In nonruminant animals on normal diets with adequate amounts of vitamin D, the kidneys are the major regulators of serum phosphate concentration (Yanagawa and Lee, 1992).

B. Serum Phosphate

Serum phosphate is measured as inorganic orthophosphate because the organic forms are not routinely evaluated. Methods for colorimetric determination of phosphate rely on the formation of a complex of phosphate ion with molybdate (Fiske and Subbarow, 1925; Fraser *et al.*, 1987). Although inorganic phosphate is measured, it is often expressed as elemental phosphorus (P_i). The atomic weight of phosphorus is 31, so 3.1 mg P_i/dl serum is equivalent to 1 mmol/liter phosphorus or 1 mmol/liter phosphate. Serum P_i ranges from 2.5 to 6.0 mg/dl (0.8–1.9 mmol/liter) in adult animals; however, serum P_i concentrations are greater in young animals (especially giant-breed dogs) and may be outside the normal range for adult animals. Most serum inorganic phosphate (80%) is in the dibasic

form, HPO_4^{2-}, and the remaining 20% is primarily in the monobasic form, $H_2PO_4^-$. This results in an average valence of serum inorganic phosphate as −1.8, and the milliequivalence of serum phosphate can be estimated by the following calculation: 1 mmol/liter phosphate = 1.8 meq/liter phosphate.

It is important to prevent hemolysis of blood samples, which will artificially increase the measurement of serum phosphate because of the release of intracellular stores. Phosphate circulates as a free anion bound to Na^+, Mg^{2+}, or Ca^{2+}, or bound to protein (10–20% of total serum phosphate). Serum phosphate is an unreliable indicator of body stores and may be higher in younger animals because growth hormone increases renal phosphate reabsorption. Feeding of high-carbohydrate diets or glucose infusions will decrease serum phosphate because of a shift of phosphate intracellularly in response to increased glycolysis and the need for phosphorylated intermediates. High-meat diets may increase serum phosphate as a result of their high phosphate content.

C. Intestinal Phosphate Absorption

Absorption of dietary phosphate is approximately 60–70% and occurs by active transport using a Na/Phosphate cotransporter and by passive diffusion (Favus, 1992; Civitelli and Avioli, 1994). In ruminants the transporter may be coupled to H^+ rather than Na^+ (Shirazi-Beechey *et al.*, 1996). Absorption takes place principally in the forestomachs (ruminants) and duodenum and jejunum (monogastric animals and ruminants) (Care, 1994). Horses may absorb some phosphate from the large intestine (Barlet *et al.*, 1995). The active form of vitamin D, 1,25-dihydroxyvitamin D, increases intestinal phosphate absorption. Low dietary levels of phosphate result in adaptive changes in the intestine that result in increased net phosphate absorption (Schröder *et al.*, 1995). In addition, increased renal production of 1,25-dihydroxyvitamin D and adaption of the kidney to increase renal phosphate reabsorption can compensate for low levels of dietary phosphate.

The source of dietary phosphorus affects its availability (Soares, 1995). Inorganic sources of phosphate and bone and meat meals have high bioavailability (95%). Some diets contain substances or nutrients that can antagonize phosphate absorption, including aluminum and magnesium. Diets high in calcium and fat raise the requirement for phosphorus (Gerloff and Swenson, 1996). Most phosphorus in concentrate sources is in the organic form of phytate, which is poorly utilized in nonruminants. Ruminants have phytase in their rumens to release the phosphate from the sugar skeleton, but nonruminants do not. However, addition of microbial phytase to concentrate diets increases phosphorus bioavailablity for nonruminants. Phytates from different foodstuffs will vary in their digestibility for ruminants.

In ruminants, large amounts of endogenous phosphate enter the gastrointestinal tract from salivary secretions (Care, 1994; Barlet *et al.*, 1995; Shirazi-Beechey *et al.*, 1996). Parotid saliva in ruminants is 16–40 mmol/liter phosphate, and total phosphate secretion by the salivary glands is significantly greater than the dietary supply of phosphate. The endogenous salivary secretion of phosphate is complemented by intestinal phosphate absorption and massive recycling of phosphate, resulting in greater phosphate absorption in the gastrointestinal tracts of ruminants than in those of monogastric animals. Phosphate plays a role as a buffer for volatile fatty acids and as a nutrient for microorganisms in the rumen. High-fiber diets that increase saliva production also increase the total salivary secretion of phosphate. Increased endogenous salivary secretion of phosphate will lead to increased intestinal absorption, but also to increased endogenous fecal loss, resulting in a net loss of phosphate. Ruminants fed a high-roughage diet use endogenous fecal loss of phosphate as the principal mechanism to regulate phosphate excretion. In contrast, ruminants on concentrate diets excrete more phosphate in the urine because of reductions in both saliva flow and endogenous fecal loss. Therefore, the quantity of saliva and regulation of saliva's phosphate concentration are important determinants of phosphate excretion in ruminants.

D. Phosphate Excretion

Renal excretion of phosphate is determined by the glomerular filtration rate (GFR) and the maximum tubular reabsorption rate (TmP) (Yanagawa and Lee, 1992). The majority of renal phosphate reabsorption occurs in the proximal convoluted tubule with small amounts in the distal nephron. Reabsorption is sodium dependent because phosphate transport is performed by a brush-border Na–phosphate cotransporter (Biber *et al.*, 1996). The sodium gradient is maintained by a Na/K ATPase, and therefore phosphate reabsorption is indirectly energy dependent. The regulation of renal phosphate reabsorption can adapt to the body's need for phosphate. Reabsorption is increased with growth, lactation, pregnancy, and low-phosphate diets and is decreased during slow growth, renal failure, or excess dietary phosphorus (Lötscher *et al.*, 1996; Silverstein *et al.*, 1996). The major hormonal regulator is parathyroid hormone, which decreases the TmP and increases renal phosphate excretion (Murer *et al.*, 1996). Other hormones that inhibit Na/P_i cotransport include calcito-

nin, atrial natriuretic peptide, epidermal growth factor, transforming growth factors α and β, and parathyroid hormone-related protein. In contrast, insulin, growth hormone, and insulin-like growth factor I stimulate Na/P_i cotransport by renal epithelial cells (Kempson, 1996).

E. Hypophosphatemia

Hypophosphatemia may impair red and white blood-cell function and lead to muscle weakness, recumbency, intestinal ileus, anorexia, or vomition (DiBartola, 1992; Hodgson and Hurley, 1993; Gerloff and Swenson, 1996). Red blood-cell fragility and hemolysis can be increased by the lack of ATP in the erythrocyte due to the necessity of phosphate for the erythrocytic glycolytic pathway. Intravascular hemolysis is uncommon, but the occurrence of hypophosphatemia in cattle with postparturient hemoglobinuria may predispose erythrocytes to hemolysis when the animals are exposed to hemolytic agents in plants. The production of 2,3-diphosphoglycerate (2,3-DPG) is dependent on phosphate. Erythrocytes with low 2,3-DPG concentrations have increased binding affinity for O_2 and reduced delivery of O_2 to peripheral tissues. This may be responsible for muscle weakness in patients with hypophosphatemia. White blood cells may have decreased chemotaxis and phagocytosis also due to a lack of ATP during hypophosphatemia. The causes of hypophosphatemia include maldistribution secondary to a large carbohydrate load, respiratory alkalosis, metabolic acidosis, catecholamine release, or insulin treatment of an animal with diabetes mellitus. Hypophosphatemia also can be caused by reduced renal reabsorption in animals with primary hyperparathyroidism or renal tubular defects, reduced intestinal absorption during vitamin D deficiency, or oncogenic osteomalacia (see metabolic disease section).

F. Hyperphosphatemia

Hyperphosphatemia leads to a reciprocal reduction in serum ionized calcium concentration because of the mass law interactions between phosphate and calcium ions and because of decreased renal 1,25-hydroxyvitamin D synthesis by the kidney. The clinical signs of acute hyperphosphatemia may be due to hypocalcemia and consist of tetany and soft-tissue mineralization (especially when the serum calcium $\times$ phosphorus product is greater than 70 mg/dl). The principal causes of hyperphosphatemia include massive cellular lysis (e.g., during chemotherapy, rhabdomyolysis, hemolysis), vitamin D intoxication, chronic renal failure (see section on secondary renal hyperparathyroidism), hypoparathyroidism, hypersomatotropism, and hyperthyroidism (Chew and Meuten, 1982; DiBartola, 1992; Yanagawa and Lee, 1992; Brooks, 1995).

IV. METABOLIC DISEASES OF ABNORMAL CALCIUM/PHOSPHORUS METABOLISM

A. Hyperparathyroidism

1. Secondary Renal Hyperparathyroidism

Secondary hyperparathyroidism as a complication of chronic renal failure (CRF) is a metabolic disease characterized by an excessive, but not autonomous, rate of PTH secretion. This disorder is encountered most frequently in dogs and cats but also occurs in other animal species. The secretion of hormone by the hyperplastic parathyroid glands in this disorder usually remains responsive to fluctuations in blood calcium.

The primary etiologic mechanism in this form of hyperparathyroidism is a long-standing, progressive renal disease resulting in severely impaired function. Chronic renal insufficiency in older animals results from interstitial nephritis, glomerulonephritis, nephrosclerosis, or amyloidosis. Several congenital anomalies such as cortical hypoplasia, polycystic kidneys, and bilateral hydronephrosis may result in renal insufficiency in younger animals. When the renal disease progresses to the point at which there is significant reduction in glomerular filtration rate, phosphorus is retained and progressive hyperphosphatemia develops (Fig. 23.25).

The pathogenesis of secondary renal hyperparathyroidism is complex, but it has been recently recognized that 1,25-dihydroxyvitamin D (calcitriol) plays an important role in this disease (Fig. 23.26) (Nagode and Chew, 1992; Felsenfeld and Llach, 1993). Animals with advanced CRF have decreased circulating concentrations of 1,25-dihydroxyvitamin D caused by decreased renal synthesis. Initially, the elevated blood phosphorus depresses the activity of the 1α-hydroxylase in the kidney. In the later stage of chronic renal disease there are decreased numbers of tubular epithelial cells with 1α-hydroxylase activity to produce the active form of vitamin D. Early stages of CRF are often associated with normal concentrations of circulating 1,25-dihydroxyvitamin D (even with the loss of nephrons) because of the correcting effects of increased PTH on renal 1α-hydroxylase that enhance renal tubular synthesis of 1,25-dihydroxyvitamin D.

1,25-Dihydroxyvitamin D is an important regulator of parathyroid chief cell function and acts to decrease PTH mRNA expression, increase expression of the vita-

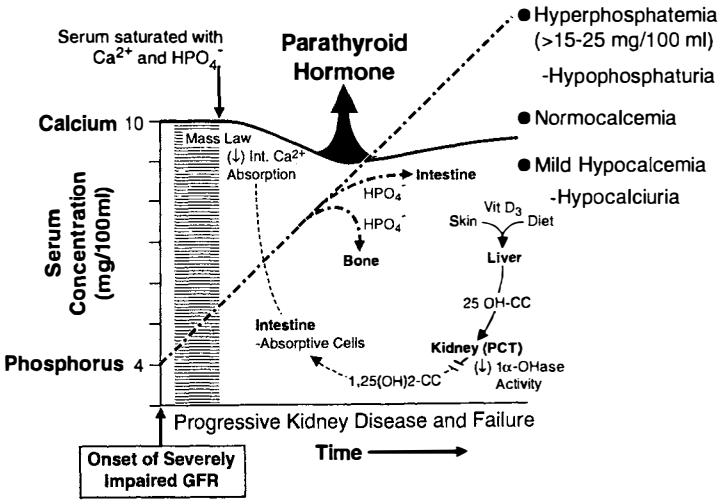

FIGURE 23.25 Alterations in serum calcium and phosphorus during the pathogenesis of secondary hyperparathyroidism associated with progressive renal failure.

min D receptor, and control the set point of chief cell responsiveness to negative feedback by the serum Ca concentration. The function of 1,25-dihydroxyvitamin D serves to complete the endocrine feedback loop with the parathyroid gland to control serum Ca concentration (Fig. 23.8). Decreased circulating levels of 1,25-dihydroxyvitamin D in animals with CRF results in chief cell hyperplasia and increased secretion of intact PTH. The increased circulating PTH correlates with the degree of uremia and has been suggested to play a role in both the clinical signs and progression of CRF by acting as an uremic toxin (Fig. 23.27) (Nagode and Chew, 1992).

The use of dietary phosphorus restriction and intestinal phosphate binders in animals with mild uremia is capable of reducing serum phosphate. Reduced serum phosphate results in decreased serum PTH concentrations because of the removal of phosphate inhibition of 1,25-dihydroxyvitamin D production by the kidneys, but may not return PTH levels to normal (Nagode and Chew, 1992). The oral administration of low doses of 1,25-dihydroxyvitamin D (1.7–3.4 ng/kg) has been shown to normalize serum PTH in dogs and cats with naturally occurring CRF and may reduce the progression of disease (Nagode *et al.*, 1996). Removal of the parathyroid glands did not reduce the progression of

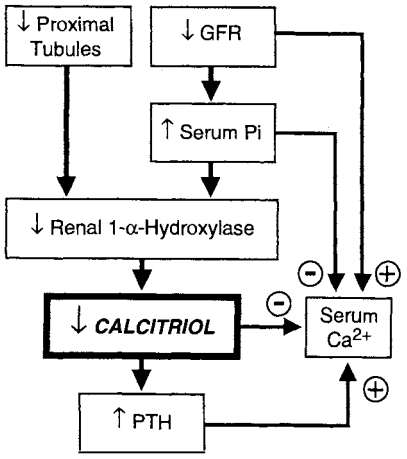

FIGURE 23.26 Hyperparathyroidism and chronic renal failure. Role of 1,25-dihydroxyvitamin D (calcitriol) in the pathogenesis of renal secondary hyperparathyroidism. GFR, glomerular filtration rate, P_i, serum phosphorus, PTH, serum parathyroid hormone. From Rosol *et al.* (1995a).

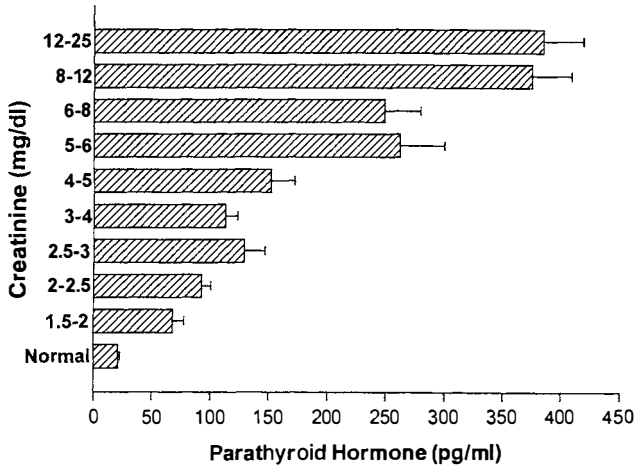

FIGURE 23.27 Relationship of serum N-terminal parathyroid hormone to levels of serum creatinine in 35 normal dogs and 333 canine patients with uremia (mean ± SEM). From Nagode and Chew (1992).

experimentally induced renal failure in dogs; however, serum PTH levels were not as high in the experimental animals as in dogs with spontaneous, advanced renal disease (Finco *et al.*, 1994).

Parathyroid stimulation in patients with chronic renal disease also may be attributed to hypocalcemia that develops in the pathogenesis of the disease. As the phosphorus concentration increases, blood calcium decreases reciprocally (Krook and Lowe, 1964). Impaired intestinal absorption of calcium due to an acquired defect in vitamin D metabolism also plays a role in the development of hypocalcemia in chronic renal insufficiency and uremia. Increased PTH secretion compensates for the mild hypocalcemia, and most animals with CRF are normocalcemic. For a further discussion of serum calcium in animals with CRF, see the sections on hypercalcemia and hypocalcemia.

All four parathyroid glands are enlarged because of organellar hypertrophy initially and cellular hyperplasia later, as compensatory mechanisms to increase hormonal synthesis and secretion in response to the hypocalcemic stimulus. Because the parathyroid gland stores comparatively little preformed hormone, the rate of peptide synthesis appears to be rate limiting for hormonal secretion. Although the parathyroids are not autonomous, the concentration of PTH in the peripheral blood in patients with chronic renal failure may exceed that of primary hyperparathyroidism. A greatly increased number and size of chief cells is required, therefore, to sustain the increased rates of hormonal secretion in patients with long-standing renal disease.

Parathyroid hormone accelerates osteoclastic resorption, results in release of stored calcium from bone, and returns the blood calcium toward normal (Fig. 23.25). The long-standing increase in bone resorption eventually results in the metabolic bone disease associated with chronic renal insufficiency. Progressive glomerular and tubular dysfunction with loss of target cells interferes with expression of the phosphaturic response by the increased circulating PTH in renal disease. Phosphorus is retained and the blood concentration continues to rise in spite of the secondary hyperparathyroidism (Fig. 23.25).

Although skeletal involvement is generalized with hyperparathyroidism, it does not affect all parts uniformly. Bone lesions become apparent earlier and reach a more advanced degree in certain areas. Resorption of alveolar socket bone and loss of lamina dura dentes occur early in the course of the disease. This results in loose teeth that may be dislodged easily and interfere with mastication. Cancellous bones of the maxilla and mandible also are sites of predilection in hyperparathyroidism. Because of the accelerated resorption the bones become softened and readily pliable (i.e., "rubber-jaw disease"), and the jaws fail to close properly. Long bones of the abaxial skeleton are less dramatically affected. Lameness, stiff gait, and fractures after relatively minor trauma may result from the increased bone resorption. Areas of subperiosteal resorption by numerous osteoclasts may disrupt the osseous attachment of tendons, leading to elevation and stretching of the periosteum, bone pain, and an inability to support the body's weight.

2. *Nutritional Secondary Hyperparathyroidism*

The increased secretion of parathyroid hormone with this metabolic disorder is a compensatory mechanism directed against a disturbance in mineral homeostasis induced by nutritional imbalances. The disease occurs in cats (Rowland *et al.*, 1968), dogs, certain nonhuman primates (Hunt *et al.*, 1967), and laboratory animals, as well as in many farm-animal species (Krook and Lowe, 1964; McKenzie *et al.*, 1981; Capen and Martin, 1982; Gilka and Sugden, 1984).

Dietary mineral imbalances of etiologic importance in the pathogenesis of nutritional secondary hyperparathyroidism are (1) a low content of calcium, (2) excessive phosphorus with normal or low calcium, and (3) inadequate amounts of vitamin D. The significant end result is hypocalcemia, which results in parathyroid stimulation. A diet low in calcium fails to supply the daily requirement even though a greater proportion of ingested calcium is absorbed, and hypocalcemia develops (Fig. 23.28). Ingestion of excessive phosphorus results in increased intestinal absorption and elevation of blood phosphorus and can reduce intestinal calcium absorption by forming complexes with calcium in the intestinal lumen. Hyperphosphatemia does not stimulate the parathyroid gland directly, but does so indirectly by virtue of its ability to lower blood calcium when the serum becomes saturated with respect to these two ions. Diets containing inadequate amounts of vitamin D_3 (even with normal levels of vitamin D_2) cause diminished intestinal calcium absorption and hypocalcemia in certain New World monkeys.

In response to the nutritionally induced hypocalcemia, all parathyroid glands undergo cellular hypertrophy and hyperplasia (Capen *et al.*, 1968). Active chief cells stimulated by diet-induced hypocalcemia become larger and more tightly arranged compared to those in parathyroids of normal animals. Because kidney function is normal, the increased levels of PTH result in diminished renal tubular resorption of phosphorus and increased reabsorption of calcium, and blood levels return toward normal (Fig. 23.28). In addition, bone resorption is accelerated and release of calcium elevates blood calcium levels to the low-normal

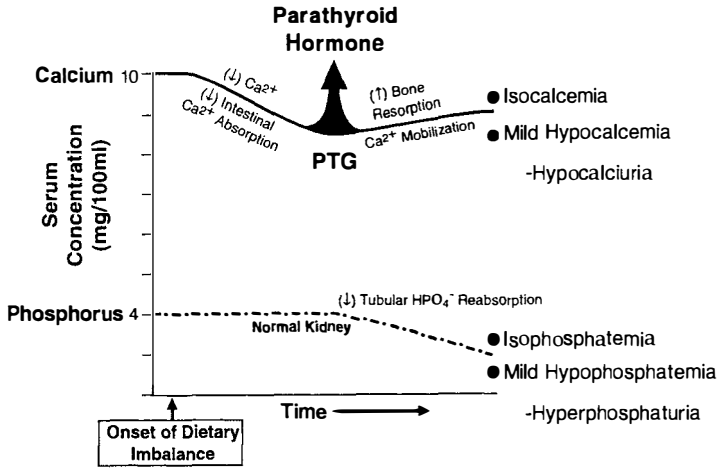

FIGURE 23.28 Nutritional secondary hyperparathyroidism. Alterations in serum calcium and phosphorus in the pathogenesis of nutritional secondary hyperparathyroidism caused by feeding a diet low in calcium or deficient in cholecalciferol but with a normal amount of phosphorus.

range. Continued ingestion of the imbalanced diet sustains the state of compensatory hyperparathyroidism, which leads to progressive development of metabolic bone disease.

Nutritional secondary hyperparathyroidism develops in young cats fed a predominantly meat diet (Pedersen, 1983). For example, beef heart or liver contains minimal amounts of calcium (7 to 9 mg/100 g) and has a markedly imbalanced calcium to phosphorus (Ca : P) ratio (1 : 20 to 1 : 50). An adequate diet for kittens up to 6 months of age should supply 200 to 400 mg calcium. Kittens fed beef heart or liver develop functional disturbances within approximately 4 weeks. Clinical signs are dominated by disturbances in locomotion manifested by a reluctance to move, posterior lameness, and an uncoordinated gait (Rowland *et al.*, 1968). The cortex of long bones is progressively thinned because of increased resorption, and the medullary cavity is widened. Affected kittens become quiet, are reluctant to play, and assume a sitting position or are in sternal recumbency. Normal activities may result in sudden onset of severe lameness due to incomplete or folding fractures of one or more bones. The high content of digestible protein (over 50% on a wet basis) and fat promotes rapid growth in kittens fed beef heart. They appear well nourished and their hair coat maintains a good luster.

In general, kittens are more susceptible and develop more severe skeletal lesions than adult cats fed a similar diet. The disease develops rapidly because the dietary imbalance is wide and the skeletal metabolic rate of kittens is high. Vertebral fractures with compression of spinal cord and paralysis are common complications in kittens but are infrequent in adult cats.

The feeding of a monotonous meat diet to dogs of any age results in secondary hyperparathyroidism with the development of skeletal disease of varying severity by mechanisms similar to those described previously (Saville and Krook, 1969; Krook *et al.*, 1971a). The low calcium content and unfavorable Ca : P of nonsupplemented all-meat diets are unable to fulfill the daily requirements either for growing pups (240 mg calcium and 200 mg phosphorus/lb body weight/day) or adult dogs (120 mg calcium and 100 mg phosphorus/lb body weight/day).

Lameness is the initial functional disturbance in growing dogs and may vary from a slight limp to complete inability to walk. The bones are painful on palpation, and folding fractures of long bones and vertebrae are not uncommon (Goddard *et al.*, 1970; Morris *et al.*, 1971). Clinical signs often are related to resorption of jaw bones in adult dogs. Parathyroid hormone-stimulated resorption of alveolar socket bone results in loss of lamina dura dentes, loosening and subsequent loss of teeth from their sockets, and recession of gingiva with partial root exposure in advanced cases (Krook *et al.*, 1971a).

Secondary hyperparathyroidism of nutritional origin also occurs in collections of aviculturists (domestic and captive birds) (Wallach and Flieg, 1969; Arnold *et al.*, 1974; Long *et al.*, 1983), zoological parks (caged lions and tigers, green iguanas, crocodiles, etc.) (Wallach and Hoessle, 1968; Wallach, 1971; Anderson and Capen, 1976a, 1976b), and laboratory animals used for research (ground squirrels, nonhuman primates, etc.) (Krook and Barrett, 1962; Hunt *et al.*, 1967; Lehner *et al.*, 1976).

In horses the most frequent nutritional imbalance involves the ingestion of excessive phosphorus. This results in increased intestinal absorption of phosphorus, elevation of the blood phosphorus concentration,

and inhibition of intestinal calcium absorption. Hyperphosphatemia does not stimulate the parathyroid gland directly, but does so indirectly by virtue of its ability to lower blood calcium. Horses that develop the disease usually have been fed high-grain diets with below-average-quality roughage. Evidence of high phosphorus intake may be difficult to establish inasmuch as the excess phosphorus may be fed by the owner in the form of a bran supplement added to a grain diet in order to improve the health of the horse. The diet usually is palatable and nutritious except for the unbalanced phosphorus (excessive amounts) and calcium (marginal or deficient) content. A diet deficient in calcium fails to supply the daily requirement even though a greater proportion of ingested calcium is absorbed, and hypocalcemia develops. Occasionally, horses may develop nutritional hyperparathyroidism after pasturing on grasses with a high oxalate content. This results in intestinal malabsorption of calcium (Walthall and McKenzie, 1976). The oxalates form insoluble complexes with calcium in the intestine, resulting in an elevated fecal calcium:phosphorus ratio (2.3:1) compared with horses on a similar calcium and phosphorus intake but without the oxalate-rich plants (fecal calcium:phosphorus ratio 1.2:1). The interference in intestinal calcium absorption results in the development of progressive hypocalcemia that leads to parathyroid stimulation and development of the metabolic bone disease.

Initial clinical signs in horses with nutritional secondary hyperparathyroidism usually include a transitory shifting lameness in one or more limbs, generalized tenderness of joints, and a stilted gait (Krook and Lowe, 1966). The lameness develops as a result of increased osteoclastic resorption of outer circumferential lamellae with disruption of tendinous insertions and bone trabeculae supporting the articular cartilage, resulting in disruption of joint cartilage on weight bearing. Resorption of alveolar socket bone and loss of lamina dura dentes occur early and may result in loose teeth. Later in the course of the disease, severe lesions develop in bones of the skull, especially the maxilla and mandible, resulting in bilateral firm enlargements of the facial bones immediately above and anterior to the facial crests. The horizontal rami of the mandibles are irregularly thickened by a progressive hyperostotic fibrous osteodystrophy ("big head") that develops in horses with nutritional secondary hyperparathyroidism. The hyperostosis of skull bones results from osteoid and fibrous connective tissue deposition in excess of the volume of bone resorbed. The chronic excess intake of phosphorus and increased secretion of PTH result in stimulation of osteoblasts to form osteoid in excess of the amount of bone resorbed by osteoclasts and progressive enlargement of skeletal bones. The hyperostotic fibrous osteodystrophy may impinge upon the nasal cavity, resulting in dyspnea, especially after exertion.

Changes in urine calcium and phosphorus are more consistent and useful in the clinical diagnosis of nutritional secondary hyperparathyroidism in horses. The increased secretion of PTH acts on the normal kidneys to markedly increase urinary phosphorus excretion but decrease calcium loss in the urine compared to normal horses (Joyce *et al.*, 1971). Blood urea nitrogen, serum creatinine, and other parameters used to assess renal function are within normal limits in horses with nutritional hyperparathyroidism. Serum alkaline phosphatase levels often are in the high-normal range or elevated in horses with overt bone disease, reflecting the increased osteoblastic activity in hyperparathyroidism. Under experimental conditions, horses fed a high-phosphorus diet (phosphorus 1.4%; calcium 0.7%) are able to normalize their blood calcium more rapidly following an EDTA-induced hypocalcemia than are controls fed a balanced diet (phosphorus 0.6%; calcium 0.7%), owing to the increased parathyroid activity (Argenzio *et al.*, 1974).

A metabolic bone disorder has been recognized in primates for many years and has received numerous appellations, including cage paralysis, simian bone disease, and osteomalacia. It is now understood that hypocalcemia resulting from either inadequate dietary vitamin D_3 intake in New World laboratory primates housed indoors or excessive phosphorus in the diet of pet monkeys leads to long-term stimulation of the parathyroid glands. The monkeys become inactive, offer less resistance to handling, and have difficulty masticating their food. In the more advanced stages there is maxillary hyperostosis due to osteoid deposition and proliferation of fibrous connective tissue, joint pain, and distortion of limbs by palpable fractures without mineralized calluses. There is radiographic evidence of generalized skeletal demineralization, loss of lamina dura dentes, subperiosteal cortical bone resorption, bowing deformities, and multiple folding fractures of long bones. Cortical bone is thinned because of the activity of increased numbers of osteoclasts. The resorbed bone is partially replaced by the proliferation of immature fibroblasts and neocapillaries.

3. Primary Hyperparathyroidism

Parathyroid hormone is produced in excess of normal in primary hyperparathyroidism by a functional lesion in the parathyroid gland for no apparent useful purpose. This disease is encountered less frequently

in older dogs and cats than is the relatively common secondary hyperparathyroidism.

The normal control mechanisms for PTH secretion by the concentration of blood calcium ion are lost in primary hyperparathyroidism. Hormone secretion is autonomous, and the parathyroid gland produces excessive amounts of hormone in spite of a sustained increase in blood calcium. Cells of the renal tubules are particularly sensitive to alterations in the amount of circulating PTH. The hormone acts on these cells initially to promote the excretion of phosphorus and the retention of calcium (Fig. 23.29). A prolonged increased secretion of PTH results in accelerated osteoclastic bone resorption. Mineral is removed from the skeleton and replaced by immature fibrous connective tissue. The bone lesion of fibrous osteodystrophy is generalized throughout the skeleton but is accentuated in local areas.

The lesion responsible for the excessive secretion of PTH usually is an adenoma composed of active chief cells with interspersed oxyphil and water-clear cells (Krook, 1957; Leav *et al.*, 1976; Capen and Martin, 1977; Sherding *et al.*, 1980; Kallet *et al.*, 1991). Chief-cell adenomas usually are single and result in enlargement of the parathyroid gland. They can be located either in the cervical region near the thyroid or, infrequently, within the thoracic cavity near the base of the heart (Cheville, 1972). Other lesions occasionally associated with primary hyperparathyroidism are primary chief-cell hyperplasia and chief-cell carcinoma (Capen and Roth, 1973; DeVries *et al.*, 1993). C cells in the thyroid gland are usually hyperplastic but are unable to return the blood calcium to normal.

The functional disturbances observed clinically are the result of hypercalcemia and weakening of bones by excessive resorption in long-standing cases. Hypercalcemia results in anorexia, vomiting, constipation, depression, and generalized muscular weakness due to decreased neuromuscular excitability. Lameness due to fractures of long bones may occur after physical trauma. Compression fractures of vertebral bodies can exert pressure on the spinal cord and nerves, resulting in motor and/or sensory dysfunction. Excessive resorption of cancellous bone of the skull resulting in a loosening or loss of teeth from alveolar sockets and hyperostosis of the mandible and maxilla due to proliferation of woven bone have been observed in dogs with primary hyperparathyroidism. Radiographic evaluation reveals areas of subperiosteal cortical resorption, loss of lamina dura around the teeth, soft-tissue mineralization, bone cysts, and a generalized decrease in bone density with multiple fractures. Mineralization of renal tubules and formation of calculi may occur in advanced cases of primary hyperparathyroidism in the dog with substantial elevations of blood calcium (Klausner *et al.*, 1986).

The most practical laboratory tests to aid in establishing the diagnosis of primary hyperparathyroidism are quantitation of total and ionized blood calcium and intact PTH immunoassay. Hypercalcemia is a consistent finding and results from accelerated release of calcium from bone and increased renal calcium reabsorption (although total urine calcium excretion is increased because of increased filtered calcium) (Fig. 23.29). The blood phosphorus is low (4 mg/dl [1.3 mmol/liter] or less) or in the low-normal range because of inhibition of renal tubular reabsorption of phosphorus by the excess PTH. Activity of alkaline phosphatase (an enzyme involved in bone apposition)

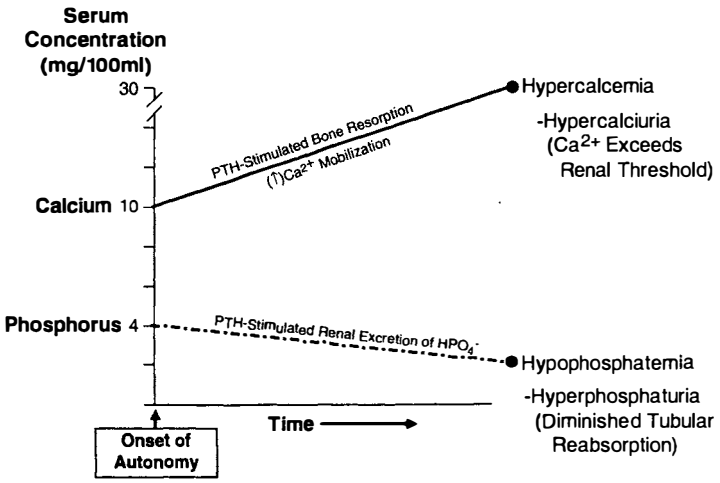

FIGURE 23.29 Primary hyperparathyroidism. Alterations in serum calcium and phosphorus in response to an autonomous secretion of parathyroid hormone in primary hyperparathyroidism.

may be elevated in the serum of animals with overt bone disease. The increased activity of this enzyme results from direct stimulation by PTH and a compensatory increase in osteoblastic activity along trabeculae as a response to mechanical stress in bone weakened by excessive resorption. Serum intact PTH may be increased or in the high normal range (Table 23.3). Normal serum PTH concentration with concurrent hypercalcemia is considered an inappropriate response of the parathyroid gland(s) and is consistent with mild primary hyperparathyroidism.

Successful removal of the functional parathyroid lesion results in a rapid decrease in circulating PTH levels because the half-life of PTH in plasma is less than 10 minutes. It should be emphasized that plasma calcium levels in patients with overt bone disease may decrease rapidly and be subnormal within 12 to 24 hours after operation, resulting in hypocalcemic tetany. Serum calcium levels should be monitored frequently following surgical removal of a parathyroid neoplasm. Postoperative hypocalcemia (5 mg/dl [1.25 mmol/liter] and lower) can be the result of (1) depressed secretory activity of chief cells due to long-term suppression by the chronic hypercalcemia or injury to the remaining parathyroid tissue during surgery, (2) abruptly decreased bone resorption due to lowered PTH levels, and (3) accelerated mineralization of osteoid matrix formed by the hyperplastic osteoblasts but previously prevented from undergoing mineralization by the elevated PTH levels. In some dogs with hypercalcemia and parathyroid adenoma, acute hypocalcemia may occur as a result of spontaneous infarction and necrosis of the adenoma (Rosol *et al.*, 1988b). Infusions of calcium gluconate to maintain the serum calcium between 7.5 (1.88) and 9.0 (2.25) mg/dl (mmol/liter), feeding high-calcium diets, and supplemental vitamin D therapy will correct this serious postoperative complication.

Primary hyperparathyroidism also has been described in German shepherds associated with autonomous chief-cell hyperplasia. The pups develop hypercalcemia, hypophosphatemia, increased iPTH, and increased fractional clearance of inorganic phosphate in the urine (Thompson *et al.*, 1984). Clinical signs include stunted growth, muscular weakness, polyuria, polydipsia, and a diffuse reduction in bone density. Intravenous infusion of calcium failed to suppress the autonomous secretion of parathyroid hormone by the diffuse hyperplasia of chief cells in all parathyroids. Other lesions include nodular hyperplasia of thyroid C cells and widespread mineralization of lungs, kidney, and gastric mucosa. The disease is inherited and may represent an inactivating mutation in the Ca^{2+}-sensing receptor, as occurs in humans with neonatal primary hyperparathyroidism (see Section I.J) (Brown *et al.*, 1995).

B. Hypercalcemia

Hypercalcemia is a common disorder that affects animals. Hypercalcemia has many causes, but is most frequently associated with neoplastic diseases (Chew *et al.*, 1992). Hypercalcemia results from an imbalance of calcium released from bones, calcium excretion by the kidney, and/or calcium absorption from the intestinal tract (Rosol and Capen, 1992). Pathogenic mechanisms of hypercalcemia include (1) excessive secretion of parathyroid hormone (PTH) or parathyroid hormone-related protein (PTHrP), which induce hypercalcemia by stimulating PTH/PTHrP receptors in bone and kidney, (2) excessive absorption of calcium from the intestines due to increased vitamin D or its metabolites, (3) excessive bone resorption due to local bone lesions or abnormal stimulation of osteoclastic bone resorption, (4) reduced renal excretion of calcium, and (5) increased total serum calcium due to increased protein-bound and/or complexed calcium with normal ionized calcium levels (Table 23.4).

The clinical signs of hypercalcemia are similar regardless of its underlying cause and depend on the rapidity of onset of increased serum ionized calcium levels (Rosol *et al.*, 1995a). Animals with serum calcium

TABLE 23.4 Causes of Hypercalcemia

Stimulation of parathyroid hormone receptors
Primary hyperparathyroidism
Secondary renal hyperparathyroidism (uncommon)
Humoral hypercalcemia of malignancy
Excessive intestinal absorption of calcium
Vitamin D intoxication
1,25-Dihydroxyvitamin D intoxication
Granulomatous diseases associated with excessive 1,25-dihydroxyvitamin D production
Hematologic malignancies associated with excessive 1,25-dihydroxyvitamin D production
Excessive bone resorption (independent of PTH receptors)
Immobilization
Hyperthyroidism
Osteomyelitis
Solid-tumor metastases to bone
Hematologic malignancies in bone marrow
Vitamin A toxicity
Reduced renal excretion of calcium
Thiazide diuretics
Hypocalciuric hypercalcemia (familial disease of humans)
Increased protein-bound or complexed serum calcium
Hypoadrenocorticism
Renal failure
Hemoconcentration

values in excess of 16.0 mg/dl (4.0 mmol/liter) generally have the most severe clinical signs. Exceptions to this rule occur, and occasionally animals with severe hypercalcemia have mild clinical signs. Horses (Table 23.1) and rabbits (Hong *et al.*, 1995) have normal total serum calcium concentrations greater than those of other domestic animals, which should be considered before hypercalcemia is diagnosed in these species. Metabolic acidosis will enhance the severity of clinical signs because it will result in an increase in the ionized fraction of serum calcium.

Increased serum Ca^{2+} will induce clinical signs relating to the gastrointestinal, neuromuscular, cardiovascular, and renal systems (Rosol *et al.*, 1995a). Decreased contractility of the gastrointestinal smooth muscle may be associated with anorexia, vomition, or constipation. There may be generalized locomotive weakness due to decreased neuromuscular excitability. Behavioral changes, depression, stupor, coma, seizures, and muscle twitching have been observed in dogs with hypercalcemia. Lameness and bone pain from demineralization of bone or pathologic fractures may be clinical signs with long-standing hypercalcemia. Hypercalcemia results in increased myocardial excitability and diminished ventricular systole, which may result in weakness and syncope associated with cardiac dysrhythmia. There is shortening of the Q–T interval and prolongation of the P–R interval (first-degree heart block). Ventricular fibrillation may develop in severe hypercalcemia (Chew and Capen, 1980). Hypercalcemia may predispose some animals to developing pancreatitis. The pathogenesis of pancreatitis associated with hypercalcemia is unknown, but may be related to degeneration of pancreatic acinar cells and leakage of cytoplasmic enzymes (Cates *et al.*, 1988; Frick *et al.*, 1995).

Polyuria and polydipsia are commonly encountered and may be the reason for an animal owner to seek medical attention. Initially, polyuria and polydipsia are due to impaired renal concentrating ability (Chew and Capen, 1980). The mechanism of this defect is not completely understood, but it appears that hypercalcemia inhibits the antidiuretic hormone-dependent resorption of NaCl in the diluting segment of the nephron (Sejersted *et al.*, 1984). Urine specific gravity is often low (<1.020) and may be hyposthenuric (1.001–1.007). Sodium excretion usually remains unchanged due to the vasoconstrictor effect of hypercalcemia, which results in a reduction of the glomerular filtration rate.

Hypercalcemia also has a toxic effect on renal tubules, either directly or from ischemia induced by vasoconstriction (Chew and Capen, 1980). Renal failure is an important consequence of severe or long-standing hypercalcemia (Kruger *et al.*, 1996). Tubular epithelial cells undergo degeneration, with the collecting system most severely affected. There is mineralization of epithelial cells and basement membranes of tubules. There may be glycosuria due to failure of tubular reabsorption and granular cast formation from degenerate tubular epithelial cells. Azotemia will occur when renal injury is severe, and polyuria and polydipsia will be secondary to renal failure. The magnitude of mineralization and tubular damage may be reduced by phosphate restriction (Harris *et al.*, 1986).

1. Cancer-Associated Hypercalcemia

The most common cause of hypercalcemia in animals and human beings is cancer-associated hypercalcemia (Rosol and Capen, 1992). There are three mechanisms of increased serum calcium induced by neoplasms: (1) humoral hypercalcemia of malignancy, (2) hypercalcemia induced by metastases of solid tumors to bone, and (3) hematologic malignancies (Fig. 23.30).

a. Humoral Hypercalcemia of Malignancy

Humoral hypercalcemia of malignancy (HHM) is a syndrome associated with diverse animal and human malignant neoplasms (Rosol and Capen, 1992). Characteristic clinical findings in patients with HHM include hypercalcemia, hypophosphatemia, hypercalciuria (often with decreased fractional calcium excretion), increased fractional excretion of phosphorus, increased nephrogenous cAMP, and increased osteoclastic bone resorption. Hypercalcemia is induced by humoral effects on bone, kidney, and possibly the intestine (Fig. 23.31) (Rosol and Capen, 1988). Increased osteoclastic bone resorption is a consistent finding in HHM and increases calcium release from bone. The kidney plays a critical role in the pathogenesis of hypercalcemia,

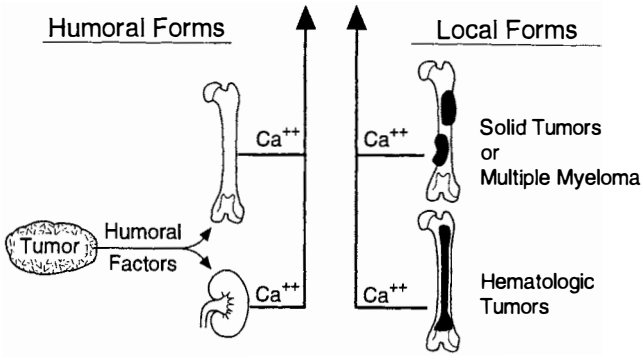

FIGURE 23.30 Pathogenesis of cancer-associated hypercalcemia. Humoral and local forms of cancer-associated hypercalcemia increase circulating concentrations of calcium by stimulating osteoclastic bone resorption or increased tubular reabsorption of calcium. (Rosol and Capen, 1992.)

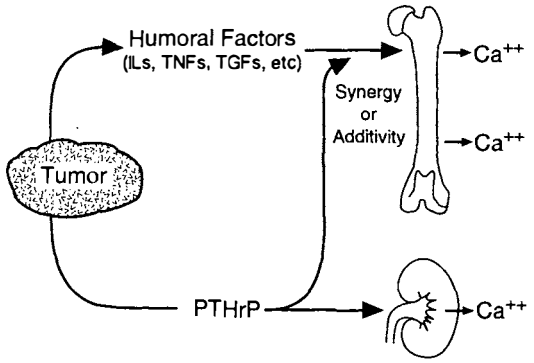

FIGURE 23.31 Humoral factors such as parathyroid hormone-related protein (PTHrP), interleukin-1 (IL-1), tumor necrosis factors (TNF), or transforming growth factors (TGF) produced by tumors induce humoral hypercalcemia of malignancy (HHM) by acting as systemic hormones and stimulating osteoclastic bone resorption or increasing tubular reabsorption of calcium. (Rosol and Capen, 1992.)

because calcium reabsorption is stimulated by PTHrP which binds and activates renal PTH/PTHrP receptors. In some forms of HHM, there are increased serum 1,25-dihydroxyvitamin D levels, which may increase Ca absorption from the intestine (Rosol *et al.*, 1992b).

Malignancies that are commonly associated with HHM in animals include the adenocarcinoma derived from apocrine glands of the anal sac in dogs, some T-cell lymphomas of dogs, and miscellaneous neoplasms that induce HHM in various species, such as cats and horses, in a sporadic pattern (Rosol and Capen, 1988, 1992; Rosol *et al.*, 1994). Excessive secretion of biologically active PTHrP plays a central role in the pathogenesis of hypercalcemia in most forms of HHM; however, cytokines such as interleukin-1 (IL-1), tumor necrosis factor α, or transforming growth factors α and β or 1,25-dihydroxyvitamin D may have synergistic or cooperative actions with PTHrP (Fig. 23.31). Before PTHrP was identified it was well understood that tumors associated with humoral hypercalcemia of malignancy induced a syndrome that mimicked primary hyperparathyroidism due to secretion of a PTH-like factor that was antigenically unrelated to PTH. Purification of the PTH-like activity from the canine anal sac adenocarcinoma and multiple human tumors associated with HHM resulted in the discovery of PTHrP (see section on parathyroid hormone-related protein) (Moseley *et al.*, 1987; Weir *et al.*, 1988a).

PTHrP binds to the N-terminal PTH/PTHrP receptor in bone and kidney, but does not cross-react immunologically with native PTH (Fig. 23.13). PTHrP stimulates adenylyl cyclase and increases intracellular Ca^{2+} in bone and kidney cells by binding to and activating the cell membrane PTH/PTHrP receptors. This results in a stimulation of osteoclastic bone resorption, and in increased renal tubular calcium reabsorption and decreased renal tubular phosphate reabsorption. Interleukin-1 stimulates bone resorption *in vivo* and *in vitro* and is synergistic with PTHrP (McCauley *et al.*, 1991; Rosol and Capen, 1992). Transforming growth factors α and β can stimulate bone resorption *in vitro* and have been identified in tumors associated with HHM, including adenocarcinomas derived from apocrine glands of the anal sac in dogs (Merryman *et al.*, 1989).

i. Canine Adenocarcinoma Derived from Apocrine Glands of the Anal Sac The adenocarcinoma derived from apocrine glands of the anal sac of dogs has been described as consistently fulfilling the criteria for HHM (Meuten *et al.*, 1981, 1983b). This unique tumor appears primarily in middle-aged (mean of 10 years) female dogs with no breed predilection and rarely metastasizes to bone. Clinical signs are referable to hypercalcemia and a mass in the perineum (60% of the cases). Apocrine adenocarcinomas may require rectal palpation to confirm their presence, because their size ranges from 7 mm to 6 × 8 cm. Canine patients with this tumor were reported to have hypercalcemia, decreased levels of immunoreactive PTH, normal levels of prostaglandin E_2 metabolite (13,14-dihydro-15-keto-prostaglandin E_2), and increased urinary excretion of calcium, phosphorus, and cAMP. Bone histomorphometric evaluation revealed a significantly decreased trabecular bone volume and increased osteoclastic bone resorption in lumbar vertebrae from dogs with the adenocarcinoma and hypercalcemia (Meuten *et al.*, 1983b). Parathyroid glands from dogs with the apocrine adenocarcinoma were atrophic or inactive, and there were areas of nodular hyperplasia of C cells in the thyroid glands.

Most dogs with HHM have increased circulating concentrations of PTHrP (Fig. 23.32). Plasma concentrations of PTHrP are greatest in dogs with apocrine adenocarcinomas of the anal sac and sporadic carcinomas associated with HHM (10–100 p*M*) (Rosol *et al.*, 1992b). The serum calcium concentrations in these dogs correlate well with circulating PTHrP concentrations and are consistent with the concept that PTHrP plays a primary role in the pathogenesis of HHM in these dogs (Fig. 23.33).

Some dogs with apocrine adenocarcinomas have inappropriate levels of 1,25-dihydroxyvitamin D (maintenance of normal range or increased) for the degree of hypercalcemia (Fig. 23.34) (Rosol *et al.*, 1992b). This suggests that the humoral factors produced by the neoplastic cells are capable of stimulating renal 1α-hydroxylase and increasing the formation of 1,25-dihydroxyvitamin D even in the presence of increased blood calcium. Plasma immunoreactive PTH was not

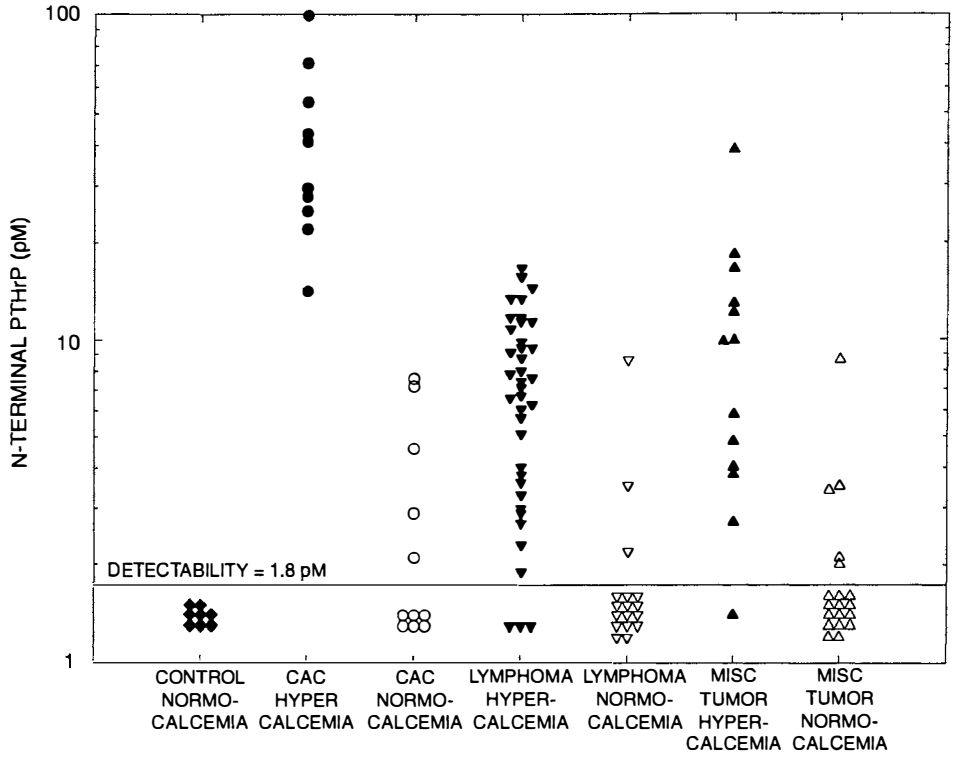

FIGURE 23.32 Circulating N-terminal parathyroid hormone-related protein (PTHrP) concentrations in normal dogs (CONTROL); dogs with hypercalcemia (>12 mg/dl) and anal-sac adenocarcinomas (CAC), lymphoma, or miscellaneous tumors (MISC TUMOR); and dogs with normocalcemia (<12 mg/dl) and anal sac adenocarcinomas, lymphoma, or miscellaneous tumors. From Rosol *et al.* (1992b).

increased in hypercalcemic dogs and was significantly less than that in dogs with primary hyperparathyroidism (Fig. 23.35). Surgical removal or radiation therapy of the adenocarcinoma results in a rapid return to normal of serum calcium and phosphorus, increased serum PTH, and decreased 1,25-dihydroxyvitamin D (Rosol *et al.*, 1992b). Postsurgical survival in dogs with adenocarcinoma and hypercalcemia ranged from 2 to 21 months, with a mean of 8.8 months. Sublumbar metastases occurred in a high percentage (94%) of the dogs and were associated with a recrudescence of the biochemical alterations in serum and urine.

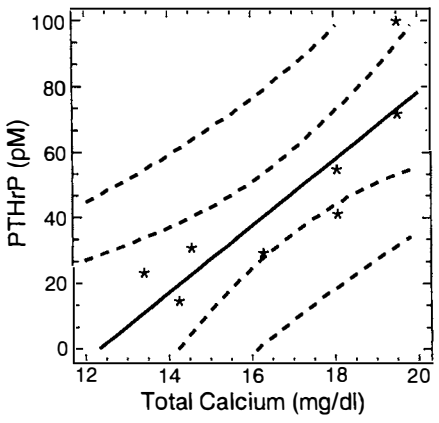

FIGURE 23.33 Regression of PTHrP and total calcium in dogs with anal sac Ca. There was a significant linear correlation (0.87, $P < 0.01$) between serum calcium and N-terminal PTHrP concentrations in dogs with humoral hypercalcemia of malignancy and adenocarcinomas derived from apocrine glands of the anal sac.

ii. Nude-Mouse Model of the Canine Anal Sac Adenocarcinoma A model of HHM has been developed in nude mice utilizing a serially transplantable anal sac adenocarcinoma (CAC-8) derived from a hypercalcemic dog (Rosol *et al.*, 1986). Nude mice with transplanted CAC-8 developed severe hypercalcemia and hypophosphatemia. Serum calcium concentration returned to the normal range in two days after surgical removal of the tumors. Serum 1,25-dihydroxyvitamin D levels were significantly increased and were correlated with serum calcium levels in CAC-8-bearing nude mice. Histomorphometric analysis of lumbar vertebrae revealed increased bone formation and resorption. The adenocarcinoma (CAC-8) produces PTHrP,

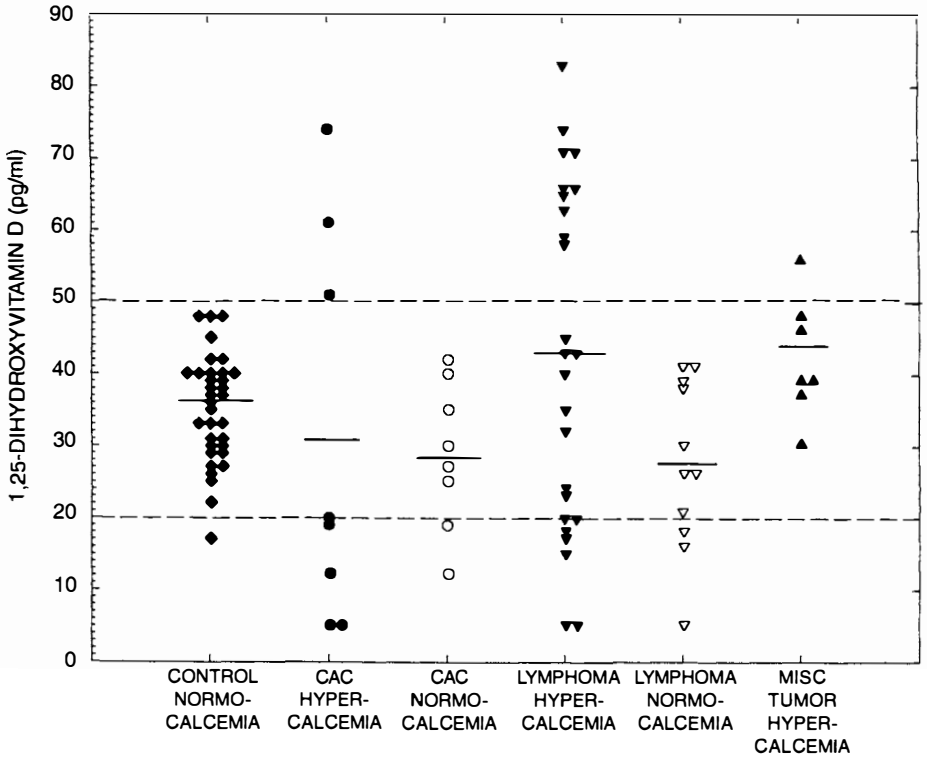

FIGURE 23.34 Serum 1,25-dihydroxyvitamin D concentrations in normal dogs (CONTROL); dogs with hypercalcemia (>12 mg/dl) and anal-sac adenocarcinomas (CAC), lymphoma, or miscellaneous tumors (MISC TUMOR); and dogs with normocalcemia (<12 mg/dl) and anal-sac adenocarcinomas or lymphoma. The normal range was 20–50 pg/ml (dashed lines). Bar = mean. From Rosol *et al.* (1992b).

TGFβ, and TGFα, which may work cooperatively to induce bone resorption and hypercalcemia, but PTHrP is likely to be the central humoral factor in the pathogenesis of hypercalcemia (Rosol *et al.*, 1988a; Weir *et al.*, 1988b; Merryman *et al.*, 1989; Rosol *et al.*, 1990).

Hypercalcemic nude mice with transplanted CAC-8 fed a low-calcium diet (<0.01%) had a significant reduction in serum calcium; however, the serum calcium concentration was not returned to the normal range (Rosol and Capen, 1987). The urine calcium excretion was reduced to control values in the hypercalcemic tumor-bearing nude mice fed the low-calcium diet. This suggested that calcium absorption from the intestine contributes to the hypercalcemia induced by CAC-8. Nude mice with CAC-8 have increased levels of serum 1,25-dihydroxycholecalciferol, which may mediate the effect of dietary calcium intake on serum calcium concentration. However, calcium absorption from the intestine cannot completely account for the hypercalcemia induced by the adenocarcinoma, because nude mice fed the low-calcium diet still had significant hypercalcemia.

Dichlorodimethylene bisphosphonate, a bisphosphonate known to inhibit osteoclastic bone resorption, significantly reduced serum Ca in CAC-8-bearing nude mice, but the serum calcium levels did not reach the normal range for non-tumor-bearing nude mice (Rosol and Capen, 1987). This emphasizes the role of the kidney in the pathogenesis of hypercalcemia in HHM, because complete inhibition of bone resorption was not capable of normalizing serum calcium levels.

iii. Lymphoma Canine lymphoma is associated with hypercalcemia in 20–40% of the cases. Some dogs with lymphoma and hypercalcemia have HHM. Hypercalcemic lymphomas associated with HHM were usually of the T-cell subset (Weir *et al.*, 1988c). The affected dogs have increased fasting and 24-hour Ca excretion, increased fractional P excretion, and increased nephrogenous cAMP. Increased osteoclastic resorption was present in bones without evidence of tumor metastasis. Dogs with HHM and lymphoma may have a pathogenesis of hypercalcemia similar to that occurring in humans with HTLV-I virus-induced lymphoma or leukemia. Neoplastic cells from humans with HTLV-I-induced lymphoma have increased PTHrP production due to stimulation of PTHrP transcription by the virally encoded Tax transcription factor (Prager *et al.*, 1994).

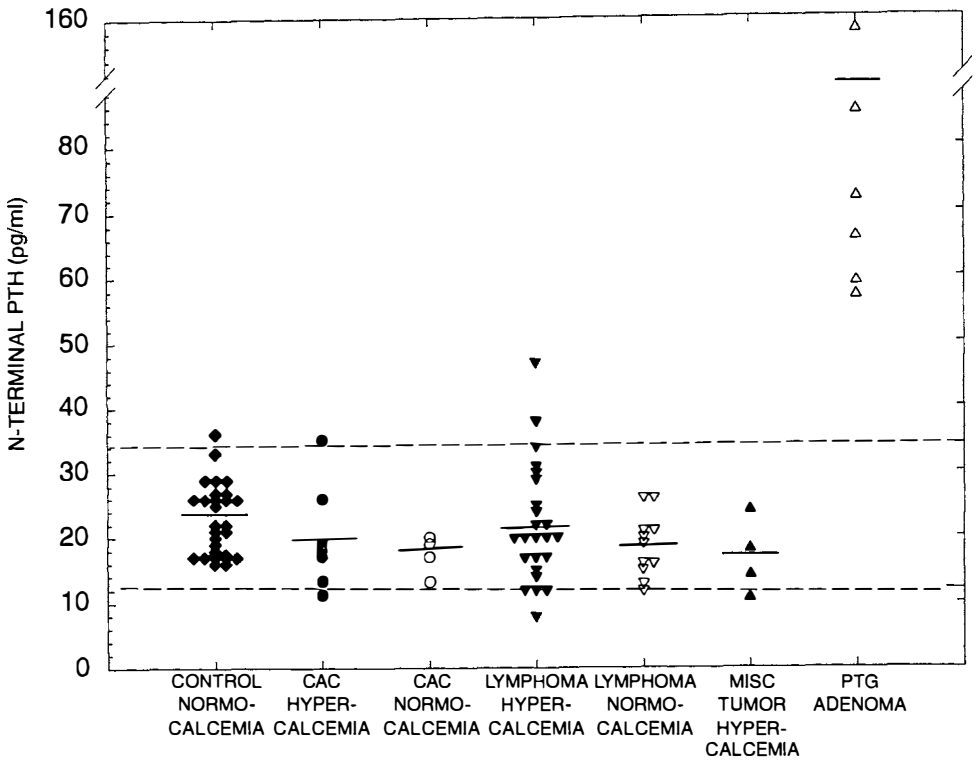

FIGURE 23.35 Serum N-terminal PTH concentrations in normal dogs (CONTROL); dogs with hypercalcemia (>12 mg/dl) and anal-sac adenocarcinomas (CAC), lymphoma, miscellaneous tumors (MISC TUMOR), or parathyroid adenomas (PTG ADENOMA); and dogs with normocalcemia (<12 mg/dl) and anal-sac adenocarcinomas or lymphoma. The normal range was 12–34 pg/ml (dashed lines). Bar = mean. From Rosol *et al.* (1992b).

Most dogs with lymphoma and HHM have significantly increased circulating PTHrP concentrations, but levels are lower (2–15 p*M*) than in dogs with carcinomas and HHM, and there is no correlation with serum calcium concentration (Figs. 23.32 and 23.36) (Rosol *et al.*, 1992b). This indicates that PTHrP is an important marker of dogs with HHM and lymphoma, but is not the sole humoral factor responsible for the stimulation of osteoclasts and development of hypercalcemia. It is likely that cytokines, such as interleukin-1 or tumor necrosis factor, may function synergistically with PTHrP to induce HHM in dogs with lymphoma (Fig. 23.31) (Rosol and Capen, 1992). Some dogs and human patients with lymphoma and hypercalcemia have increased serum 1,25-dihydroxyvitamin D levels which may be responsible for or contribute to the induction of hypercalcemia (Fig. 23.34) (Rosol *et al.*, 1992b; Seymour and Gagel, 1993).

b. Hematologic Malignancies

Some forms of hematologic malignancies present in the bone marrow induce hypercalcemia by the local induction of bone resorption (Rosol and Capen, 1992). This occurs most commonly with multiple myeloma and lymphoma. A number of paracrine factors or cytokines may be responsible for the stimulation of bone resorption. The cytokines most often implicated in the pathogenesis of local bone resorption include interleukin-1, tumor necrosis factor α, and tumor necrosis fac-

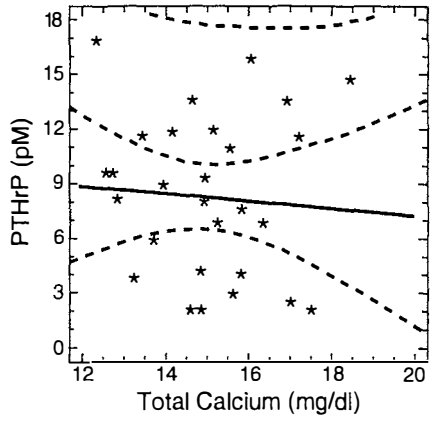

FIGURE 23.36 Regression of PTHrP and total calcium in dogs with lymphoma. There was no correlation between serum calcium and N-terminal PTHrP concentrations in dogs with humoral hypercalcemia of malignancy and lymphoma, which suggests that PTHrP probably functions cooperatively with other cytokines to induce hypercalcemia.

tor β (lymphotoxin) (Martin and Grill, 1992). Other cytokines or factors that may play a role include interleukin-6, transforming growth factors α and β, and PTHrP (Black and Mundy, 1994). Production of low levels of PTHrP by a tumor in bone may stimulate local bone resorption without inducing a systemic response because of increased circulating concentrations of PTHrP. Prostaglandins (especially prostaglandin E_2) also may be responsible for the local stimulation of bone resorption.

Some dogs with lymphosarcoma and hypercalcemia have localized bone resorption associated with metastases to medullary cavities without evidence of increased bone resorption at sites distant from the tumor metastases (Meuten *et al.*, 1983a). Hypercalcemic dogs with lymphosarcoma and bone metastases had decreased serum PTH and 1,25-dihydroxyvitamin D levels; increased excretion of Ca, P, and hydroxyproline; and increased serum prostaglandin E_2 metabolite, 13,14-dihydro-15-keto-prostaglandin E_2. The mediator of local bone resorption has not been identified; however, prostaglandin E_2 may be an important primary or secondary local mediator of bone resorption in these dogs. Other potential mediators include the cytokines, interleukin-1, or tumor necrosis factors.

c. Tumor Metastatic to Bone

Solid tumors that metastasize widely to bone can produce hypercalcemia by the induction of local bone resorption associated with tumor growth. This is not common in animals, but is an important cause of cancer-associated hypercalcemia in human beings (Rosol and Capen, 1992). Tumors that often metastasize to bone and induce hypercalcemia in human patients include breast and lung carcinomas.

The pathogenesis of enhanced bone resorption is not well understood, but the two primary mechanisms are (1) secretion of cytokines or factors that stimulate local bone resorption, and (2) indirect stimulation of bone resorption by tumor-induced cytokine secretion from local immune or bone cells (Garrett, 1993). Cytokines or factors that may be secreted by tumor cells and stimulate local bone resorption include PTHrP (Powell *et al.*, 1991), transforming growth factors α and β, or prostaglandins (especially prostaglandin E_2). In some cases, bone-resorbing activity can be inhibited by indomethacin, which suggests that prostaglandins are either directly or indirectly associated with the stimulation of bone resorption. The cytokines most often implicated in indirect stimulation of bone resorption by local immune cells include interleukin-1 and tumor necrosis factor.

Malignant neoplasms with osseous metastases may cause moderate to severe hypercalcemia and hypercalciuria, but the serum alkaline phosphatase activity and phosphorus are usually normal or moderately elevated. These changes are believed to be due to release of calcium and phosphorus into the blood from areas of bone destruction at rates greater than can be cleared by the kidney and intestine. Bone involvement can be multifocal but usually is sharply demarcated and localized to the area of metastasis.

2. *Miscellaneous Causes*

a. Hypoadrenocorticism (Addison's Disease)

Hypercalcemia (up to 15 mg/dl [3.7 mmol/liter]) occurs in approximately 30% of dogs with hypoadrenocorticism (Peterson and Feinman, 1982; Chew *et al.*, 1992). The elevated serum calcium concentration returns to normal when the disease is treated with adequate corticosteroid replacement therapy. The mechanism of hypercalcemia is not known, but the ionized fraction of serum calcium remains normal, whereas the nonionized fraction increases, and there is inappropriate hypocalciuria for the degree of hypercalcemia. Because the serum ionized calcium concentration is not increased, the hypercalcemia often is not deleterious to the canine patient; however, some of the clinical signs of hypoadrenocorticism (vomiting, anorexia, polyuria, and polydipsia) are similar to those of hypercalcemia.

b. Renal Failure in Horses

The kidneys normally excrete large amounts of calcium into the urine in horses. Horses with renal failure have been reported to be at greater risk for development of hypercalcemia than other species, but this has not been consistently documented (Tennant *et al.*, 1982; Kohn and Chew, 1987). Decreased glomerular filtration of Ca (decreased Ca clearance) may be important in horses that continue to absorb Ca across the intestinal tract. Horses with experimental bilateral nephrectomy develop a striking magnitude of hypercalcemia in association with hypophosphatemia (Tennant *et al.*, 1981), a situation quite different from that in dogs and cats, which develop mild hypercalcemia (or hypocalcemia) and moderate to severe hyperphosphatemia with advancing renal disease.

c. Renal Failure in Dogs and Cats

Hypercalcemia may occur in some dogs in the polyuric phase of acute renal failure (Chew *et al.*, 1992). The mechanism of mild hypercalcemia in the diuretic phase of acute renal disease is not known; however, there may be rapid lowering of serum phosphorus and transient secondary hypercalcemia. The hypercalcemia of acute renal failure resolves without specific treatment.

Mild to moderate hypercalcemia occurs in 10–15% of dogs and cats with chronic renal failure (CRF) (Kruger *et al.*, 1996). The mechanisms underlying the development of hypercalcemia during CRF are less well understood than those for the development of hypocalcemia. Hypercalcemia in dogs and cats with CRF may be due to an altered set point of PTH secretion in parathyroid chief cells (secondary to low 1,25-dihydroxyvitamin D levels) and to excessive secretion of biologically active PTH despite high serum Ca concentrations. Increased secretion of PTH by parathyroid chief cells leads to a stimulation of osteoclastic bone resorption (Ritz *et al.*, 1992). This occurs most often in animals in the late stages of CRF with very high serum intact PTH levels and low serum 1,25-dihydroxyvitamin D levels. Ionized calcium is usually normal at the time of increased total Ca concentration in dogs and cats with CRF, implying increased concentrations of either the protein-bound or the complexed fraction of Ca (Chew *et al.*, 1992). Chronic renal failure can be associated with increased serum concentrations of substances that complex Ca, such as phosphate, citrate, and sulfate. The possible relationship of increased citrate and sulfate concentrations to the magnitude of hypercalcemia has not been determined. Although hyperphosphatemia is common in animals with CRF, its magnitude does not determine whether or not hypercalcemia will develop.

d. Hypercalcemia Due to Vitamin D or Vitamin D Metabolites

Excessive vitamin D, vitamin D-like compounds, or active metabolites of vitamin D will induce hypercalcemia because of increased absorption of calcium from the intestines and stimulation of osteoclastic bone resorption at high dosages. The possible causes of hypercalcemia include (1) intoxication with vitamin D or one of its active metabolites, e.g., excessive dietary supplementation (Harrington and Page, 1983) or ingestion of vermicides, (2) consumption of plants that contain active vitamin D-like substances (Capen, 1992), (3) granulomatous diseases associated with excessive production of 1,25-dihydroxyvitamin D by macrophages, e.g., some dogs with blastomycosis (Dow *et al.*, 1986), and (4) hematologic malignancies associated with excessive production of 1,25-dihydroxyvitamin D, e.g., some lymphomas (see Section IV.B.1.a.iii on hypercalcemia and lymphoma).

The incidence of hypercalcemia due to vitamin D intoxication in small animals has increased because of renewed use of vitamin D (cholecalciferol) as a pesticide and rodenticide (Carothers *et al.*, 1994). The ingested vitamin D is converted to 25-hydroxyvitamin D in the liver and is the major toxic metabolite (Vieth, 1990). 25-Hydroxyvitamin D has a much reduced binding affinity for the vitamin D receptor (500- to 1000-fold) than does 1,25-dihydroxyvitamin D (active form of vitamin D), but is present at such high concentrations that it stimulates hypercalcemia by increasing intestinal absorption of Ca. Only small amounts of the 25-hydroxyvitamin D are converted to the active form of vitamin D, 1,25-dihydroxyvitamin D, which often is present in the circulation at normal to subnormal levels. This is due to inhibition of renal 1-α-hydroxylase by low serum PTH levels, hypercalcemia, hyperphosphatemia, and negative feedback from 25-hydroxyvitamin D that binds to the vitamin D receptor.

The hypercalcemia of hypervitaminosis D is usually accompanied by hyperphosphatemia (because vitamin D also increases intestinal absorption of phosphate in addition to calcium) and normal serum alkaline phosphatase activity. Skeletal disease is not a consistent feature, because the increased concentrations of blood calcium and phosphorus are derived principally from augmented intestinal absorption.

e. Hemoconcentration/Laboratory Error/Artifact

Hypercalcemia may be detected occasionally in dehydrated animals. The magnitude of elevation in blood calcium is mild and is attributed to fluid volume contraction that results in hyperproteinemia and an increased relative concentration of ionized and nonionized calcium. The hypercalcemia rapidly resolves following fluid therapy. The majority of dehydrated animals do not develop hypercalcemia. Small fluctuations in serum calcium are possible after eating.

Technical error is unlikely in the measurement of serum calcium concentrations; however, it is wise to substantiate that hypercalcemia is a repeatable finding by confirmation with a second test.

C. Hypocalcemia

1. Parturition/Lactation-Associated Hypocalcemic Syndromes

a. Parturient Hypocalcemia ("Milk Fever")

Parturient hypocalcemia is a metabolic disease of high-producing dairy cows characterized by the development of severe hypocalcemia, hypophosphatemia, and muscle paresis near the time of parturition. The pathogenic mechanisms responsible for the rapid and precipitous decrease in calcium and phosphorus levels in the blood are complex and involve several interrelated factors (Capen, 1972; Horst *et al.*, 1994). Total and ionized calcium levels decrease progressively beginning several days before parturition (Lincoln and Lane, 1990). Serum magnesium may increase reciprocally as

calcium declines (Riond *et al.*, 1995b). The blood glucose concentration often is increased in response to hypocalcemia because of an interference with the secretion of insulin from beta cells. An adequate amount of calcium ion in extracellular fluids is required for insulin secretion in response to glucose and other secretagogues for insulin (Witzel and Littledike, 1973). The uptake of calcium by beta cells appears to stimulate the contraction of microfilaments, which triggers the peripheral migration of storage granules and release of insulin.

The development of parturient hypocalcemia in dairy cows was considered to be the result of an inadequate response of the parathyroid glands to the substantial demands for calcium imposed by the mineralization of fetal bones and the initiation of lactation. However, ultrastructural studies indicated that parathyroid chief cells in cows with parturient hypocalcemia were capable of responding to the increased demands for calcium by the secretion of stored hormone and hypertrophy of secretory organelles concerned with the synthesis of new hormone (Capen and Young, 1967). Either chief cells were depleted of storage granules, or the secretory granules had migrated peripherally and were fused with the plasma membrane. These structural findings suggest an active secretory response by parathyroid glands in cows with parturient hypocalcemia and are in agreement with biochemical studies (Mayer *et al.*, 1969). An immunoassay was used to measure plasma levels of parathyroid hormone and detected equal or greater levels of hormone in cows with parturient hypocalcemia equal to or greater than those in normal parturient cows (Fig. 23.37). Therefore, the ability of parathyroid glands to respond to the challenge for extra calcium mobilization with increased hormonal synthesis and secretion does not appear to be defective in cows that develop parturient hypocalcemia (Mayer, 1970).

Target cells in bone and skeletal calcium reserves of cows with parturient hypocalcemia are temporarily refractory to the action of the elevated levels of parathyroid hormone. Investigations have shown that the elevation of serum calcium in response to exogenous parathyroid extract is less when the extract is administered prepartum than when it is given postpartum (Martig and Mayer, 1973). Bone turnover, particularly resorption, is low in cows with parturient hypocalcemia, and only a few osteoclasts are present on smooth, inactive trabecular bone surfaces (Rowland *et al.*, 1972). The urinary excretion of hydroxyproline, derived from the breakdown of bone matrix, does not increase significantly during late gestation in cows that develop the disease, as occurs in cows that maintain their serum calcium near normal through parturition

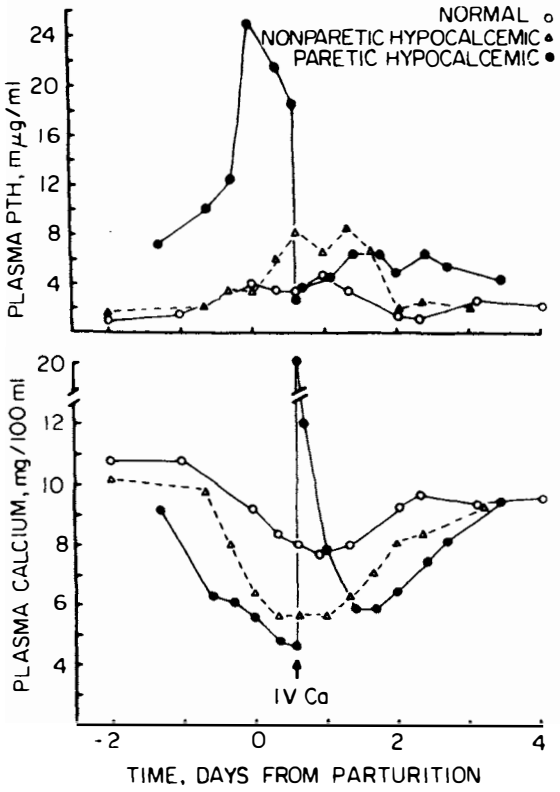

FIGURE 23.37 Development of varying degrees of hypocalcemia in cows near parturition with corresponding increases in plasma PTH levels. The cow developing severe hypocalcemia [below 5 mg/100 ml (1.25 mmol/liter)] had a considerably greater increase in plasma PTH than the moderate rise detected in nonparetic hypocalcemic and normal cows. Note that PTH levels decline rapidly following treatment of the paretic cow with intravenous calcium. From Mayer (1970).

and early lactation (Black and Capen, 1971). A secretion of calcitonin prepartum in certain cows, especially those fed high-calcium diets, may be one factor that contributes to the inability of increased parathyroid hormone levels to mobilize calcium rapidly from skeletal reserves and maintain blood levels during the critical period near parturition. The thyroid content of calcitonin is reduced (14% of control cows) and many C (parafollicular) cells are degranulated (Young and Capen, 1970). Elevated plasma levels of calcitonin have been reported in cows prior to the development of profound hypocalcemia by some investigators (Black and Capen, 1973) but not by others (Mayer, 1971). A syndrome of hypocalcemia analogous to parturient paresis has been induced with long-term intravenous infusion of calcitonin in lactating cows (Barlet, 1968).

The decline in blood calcium may be rapid in certain high-producing dairy cows near parturition and the initiation of lactation. Because bone resorption during the prepartal period often is relatively low owing to a

substantial intake of dietary calcium, there is a relatively small pool of active bone-resorbing cells capable of responding rapidly to PTH. Therefore, when PTH secretion increases because of the rapidly developing hypocalcemia, the increase in activity of the few active osteoclasts present on bone surfaces is insufficient to restore the plasma calcium concentration to normal. The activation of osteoprogenitor cells and the subsequent conversion of preosteoclasts to osteoclasts under the influence of increased PTH with expansion of the pool of active bone-resorbing cells requires time (as long as 48 to 72 hours in an adult cow) and an adequate concentration of calcium in extracellular fluids. If the extracellular fluid calcium falls below a critical level, the increased circulating concentration of PTH may be ineffective in causing an elevation of cytosol calcium in target cells to activate new bone-resorbing cells. Neither an increased endogenous secretion of PTH nor the exogenous administration of parathyroid extract to cows will restore homeostasis once the hypocalcemia is profound. Only the administration of calcium and elevation of calcium in extracellular fluids will restore the responsiveness to PTH, trigger bone resorption, and correct the hypocalcemia.

The composition of the prepartal diet fed to dairy cows is known to be a significant factor in the pathogenesis of parturient hypocalcemia. High-calcium diets have been incriminated in significantly increasing the incidence of the disease (Ender *et al.*, 1962). Conversely, low-calcium diets or prepartal diets supplemented with pharmacologic doses of vitamin D have been reported to reduce the incidence of the disease (Hibbs and Conrad, 1960; Muir *et al.*, 1968).

Although cows fed a high-calcium diet (Ca 150 g:P 25 g/day) have higher blood calcium levels prepartum, they are less able to maintain serum calcium near the critical time of parturition (Black *et al.*, 1973a). Plasma immunoreactive parathyroid hormone levels are lower prepartum than in cows fed a balanced diet (Ca 25 g:P 25 g/day) and decline further at 48 hours postpartum. Inactive chief cells predominate in the parathyroid glands of cows fed high-calcium diets, whereas actively synthesizing chief cells are most numerous in parathyroids of cows fed balanced prepartal diets (Black *et al.*, 1973a). In response to the elevated blood calcium in cows fed high-calcium prepartal diets, thyroid stores of calcitonin are diminished, and C cells are partially degranulated and appear to actively synthesize more hormone (Black *et al.*, 1973a). This stimulation of C cells is accompanied by a decrease in bone turnover near parturition. Trabecular bone surfaces are inactive, and there are few osteoclasts resorbing bone.

A test of the immediately available calcium reserves by EDTA-induced hypocalcemia illustrates the long-term effects of feeding high-calcium and balanced prepartal diets on the function of parathyroid glands and bone. Cows fed a balanced diet respond to the experimental hypocalcemic challenge with a more rapid and greater increase in plasma PTH levels (Fig. 23.38) and the return of blood calcium to preinfusion levels is faster than in cows fed a high-calcium diet. This is accompanied by a marked increase in urinary hydroxyproline excretion, suggesting increased bone-matrix catabolism in response to the PTH secretion. These findings suggest that the long-term feeding of a high calcium diet prepartum will partially suppress chief cells in the parathyroid glands, so that they are less able to respond rapidly by increased PTH synthesis and secretion to a hypocalcemic challenge either induced by EDTA infusion or associated with parturition and the initiation of lactation (Fig. 23.39).

Calcium homeostasis in pregnant cows fed a high-calcium diet appears to be maintained principally by

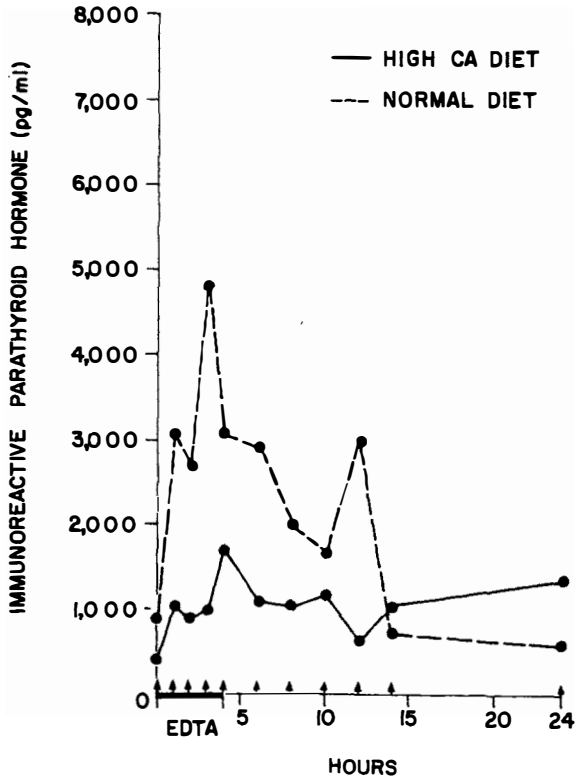

FIGURE 23.38 Parathyroid gland response to experimental hypocalcemia induced by EDTA in pregnant cows fed high-calcium and normal balanced diets. Cows fed the normal prepartal diet responded to the hypocalcemia with a more rapid and greater increase in immunoreactive PTH than cows fed a high-calcium diet. From Black *et al.* (1973a).

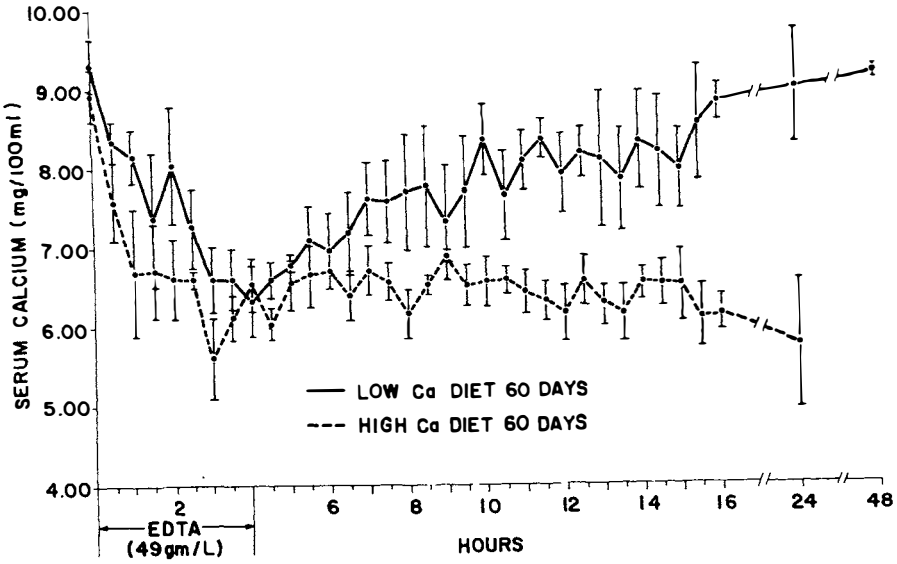

FIGURE 23.39 Immediately available calcium reserves in pregnant cows fed a low-calcium diet compared to those in pregnant cows fed a high-calcium diet prior to parturition. In response to a hypocalcemic challenge provided by EDTA infusion, cows fed the low-calcium diet are able to mobilize calcium from skeletal reserves and return the blood calcium level to the normal range more rapidly than cows fed a high-calcium diet, thereby preventing the development of hypocalcemia. In cows fed the high-calcium diet, chief cells in the parathyroid gland are inactive, and there are few osteoclasts on bone surfaces. Cows fed the low-calcium diet have predominantly actively secreting chief cells in the parathyroids and frequent osteoclasts on bone surfaces. (Capen, 1989.)

intestinal calcium absorption (Fig. 23.40). This greater reliance on intestinal absorption than on PTH-stimulated bone resorption probably is a significant factor in the more frequent development of profound hypocalcemia near parturition in cows fed high-calcium prepartal diets. These cows would be more susceptible to the decreased calcium available for absorption as a result of the anorexia often associated with the high blood estrogen levels at parturition (Muir *et al.*, 1972).

Calcium homeostasis in cows fed balanced or relatively low-calcium diets prepartum appears to be more

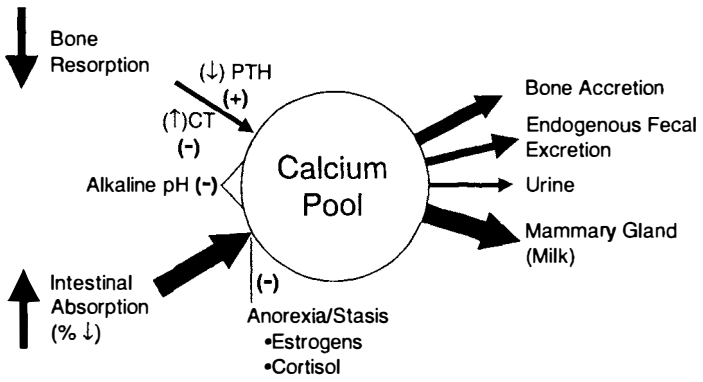

FIGURE 23.40 Calcium homeostasis in cows fed a high-calcium prepartal diet is primarily dependent on intestinal calcium absorption. The rate of bone resorption is low, and parathyroid glands are inactive. Anorexia and gastrointestinal stasis that can often occur near parturition interrupt the major inflow into the extracellular fluid calcium pool. Outflow of calcium with the onset of lactation exceeds the rate of inflow into the calcium pool, and the cows develop a progressive hypocalcemia and paresis. Modified from Mayer (1971).

under the fine control of PTH secretion with the approach of parturition (Yarrington *et al.*, 1977). The higher levels of PTH secreted during the prepartal period by an expanded population of actively synthesizing chief cells results in a larger pool of active bone-resorbing cells to fulfill the increased needs for calcium mobilization at the critical time near parturition and the initiation of lactation (Fig. 23.40). These cows would be less susceptible to the influence of decreased calcium absorption and flow into the extracellular calcium pool resulting from the anorexia and intestinal stasis associated with parturition (Fig. 23.41).

A syndrome biochemically and clinically resembling naturally occurring parturient paresis has been produced experimentally in cows by the prepartal administration of bisphosphonates (Yarrington *et al.*, 1976). These compounds are synthetic analogues of pyrophosphate and are potent inhibitors of bone resorption. When cows with no known history of parturient paresis were fed a low-calcium diet and administered dichlorodimethylene bisphosphonate (CL_2MDP) postpartum, they consistently developed hypocalcemia and hypophosphatemia with muscular weakness, incoordination, and eventually sternal or lateral recumbency (Yarrington *et al.*, 1976). These studies suggest an important role for the skeleton in the maintenance of calcium homeostasis at parturition in dairy cows.

Pharmacologic doses of vitamin D_2 have been administered to dairy cows prepartum to develop an effective method for the prevention of parturient hypocalcemia and paresis. High levels of the parent vitamin D compound are known to increase the rate and quantity of calcium and phosphorus absorbed from the intestinal tract in cattle, to elevate the blood calcium and phosphorus levels progressively after 3 to 5 days, and to increase the net calcium deposition and retention in areas of new bone growth. Because of the inherent difficulty in accurately predicting the date of parturition, however, clinical and pathological evidence of toxicity have been observed in cattle given vitamin D in large doses for an extended period (Capen *et al.*, 1966). These included gastrointestinal stasis, diuresis and anorexia, abnormal cardiac function, reduced rumination, weight loss, and extensive mineralization of the cardiovascular system. The 3- to 5-day delay preceding a significant elevation in blood calcium and phosphorus and the cardiovascular toxicity following administration for extended periods have limited the usefulness of the parent vitamin D compound in preventing the development of hypocalcemia in susceptible cows.

Active vitamin D metabolites appear to be promising in the prevention of parturient hypocalcemia and paresis. The more rapid onset of action (6 to 8 hours), greater potency (up to several hundredfold), and ability to regulate more precisely the magnitude of elevation in blood calcium, thereby minimizing potential toxic effects, are distinct advantages of the principal active metabolite of vitamin D_3 ($1,25\text{-}[OH]_2D$) over the parent vitamin D compound in the development of an effective prophylactic regimen for parturient paresis-

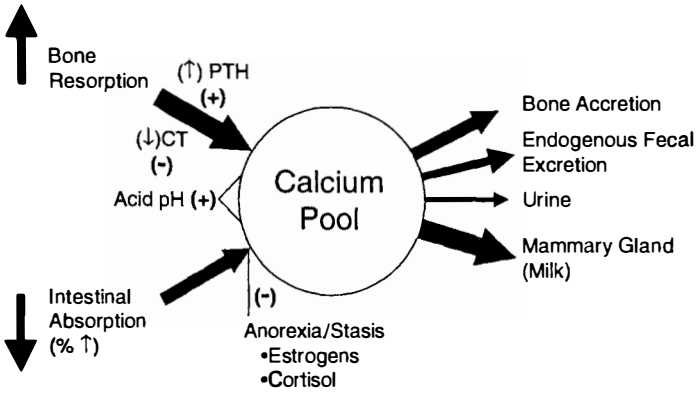

FIGURE 23.41 Calcium homeostasis in cows fed a low-calcium prepartal diet. Bone resorption and intestinal absorption both contribute substantially to the inflow of calcium to the pool in extracellular fluids. The anorexia and gastrointestinal stasis that often occur near parturition may temporarily interrupt one inflow pathway. However, there is more likely to be an adequate pool of active bone-resorbing cells capable of responding to the increased PTH secretion under these dietary conditions to maintain an approximate balance between calcium inflow and outflow, thereby preventing the development of progressive hypocalcemia. Total inflow–total outflow. Modified from Mayer (1971).

susceptible dairy cows. The administration of 1,25-$(OH)_2D$ by the intramuscular route results in a dose-related increase in serum calcium. Approximately 20% of cows with parturient paresis relapse after intravenous calcium therapy. These cows may fail to produce adequate levels of 1,25-dihydroxyvitamin D because of temporary refractoriness of the renal 25-hydroxyvitamin D 1-α-hydroxylase to the rise in serum PTH that occurs in hypocalcemic cows (Goff *et al.*, 1989).

Studies in parturient paresis-susceptible pregnant cows indicate that the intramuscular administration of 600 μg of 1,25-$(OH)_2D$ between 24 and 48 hours prepartum, before a decline in serum calcium and phosphorus had occurred, was effective in maintaining blood levels near the time of parturition. Blood calcium and phosphorus were stable or increasing at parturition and during initiation of lactation (Capen *et al.*, 1979). Blood calcium and phosphorus were stabilized by the injection of a smaller (270 μg) dose of steroid at 48- and 96-hour intervals until the actual time of parturition. Figure 23.42 illustrates the effects on serum calcium of a 600-μg dose of 1,25-$(OH)_2D$, which was administered at 5.5 days prepartum in a Jersey cow, followed after 72 hours by 270 μg of 1,25-$(OH)_2D$. The serum calcium increased progressively for 60 hours following the 600-μg injection, was 10.9 mg/dl (2.7 mmol/liter) at parturition, and remained at 9.3 mg/dl (2.3 mmol/liter) 42 hours postpartum. The serum phosphorus was 6.2 mg/dl (2.0 mmol/L) at parturition and had increased to 7.2 mg/dl (2.3 mmol/liter) at 42 hours postpartum.

b. Puerperal Tetany (Eclampsia in Dogs)

Less is known about the development of hypocalcemic syndromes in animal species other than the cow. Puerperal tetany is most frequently encountered in the small, hyperexcitable breeds of dogs. The clinical course is rapid, and the bitch may proceed from premonitory signs of restlessness, panting, and nervousness to ataxia, trembling, muscular tetany, and convulsive seizures in 8 to 12 hours (Resnick, 1972; Martin and Capen, 1980).

Functional disturbances associated with hypocalcemia in the bitch are primarily the result of neuromuscular tetany, whereas in cows the clinical signs are related to paresis. The occurrence of either tetany or paresis in response to hypocalcemia appears to be the result of basic physiologic differences in the function of the neuromuscular junction of the cow and the bitch (Bowen *et al.*, 1970a). The release of acetylcholine and transmission of nerve impulses across neuromuscular junctions are blocked by hypocalcemia in the cow (but not in the dog), leading to muscle paresis. The dog appears to have a higher margin of safety in neuromuscular transmission, in that the degree to which the endplate potential exceeds the firing threshold is greater in the dog than in the cow. Excitation–secretion coupling is maintained at the neuromuscular junction in the bitch with hypocalcemia. Tetany occurs in the

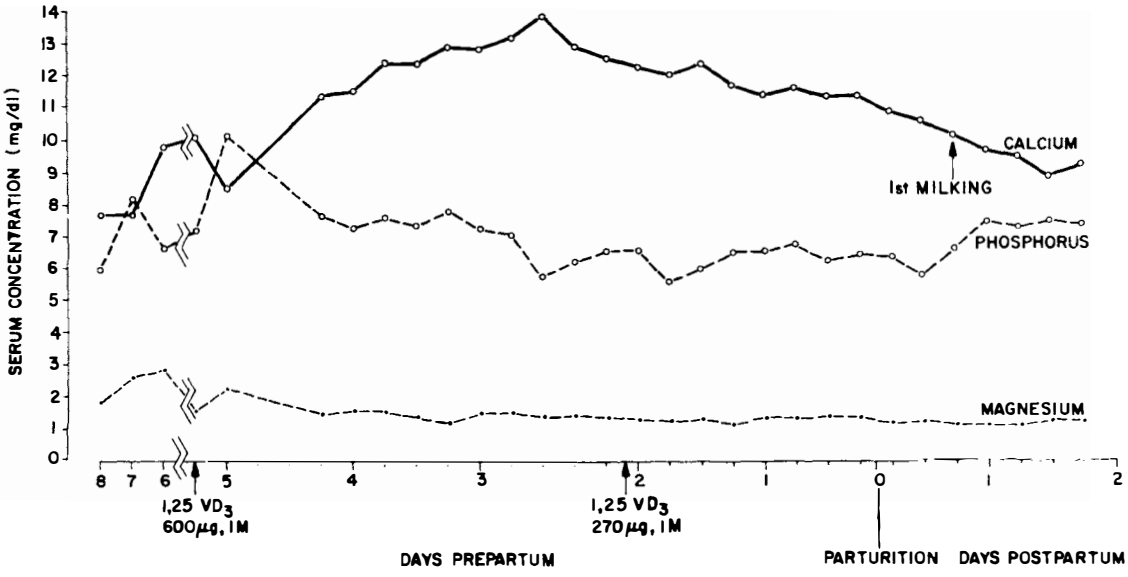

FIGURE 23.42 Effect of two doses (600 and 270 μg) of 1,25-dihydroxyvitamin D separated by a 3-day interval on serum calcium, phosphorus, and magnesium in a parturient paresis-susceptible Jersey cow. From Capen *et al.* (1979).

dog as a result of spontaneous repetitive firing of motor nerve fibers. Because of the loss of stabilizing membrane-bound calcium, nerve membranes become more permeable to ions and require a stimulus of lesser magnitude to depolarize.

There is no evidence to suggest that puerperal tetany (eclampsia) in heavily lactating bitches is the result of an interference in parathyroid hormone secretion. Severe hypocalcemia and often hypophosphatemia develop near the time of peak lactation (approximately 1 to 3 weeks postpartum), probably the result of temporary failure in homeostasis resulting in an imbalance between the rates of inflow to and outflow from the extracellular fluid calcium pool. The administration of intravenous calcium to stop the tetany, combined with temporarily decreasing the lactational drain of calcium by removing the pups, usually corrects the disruption of calcium homeostasis in the majority of bitches. Supplemental dietary calcium and vitamin D have proven useful in preventing relapses in certain bitches with puerperal tetany (Martin and Capen, 1980).

c. Other Species

A number of metabolic disorders characterized primarily by the development of hypocalcemia and associated manifestations occur in several different animal species (including the queen, ewe, goat, mare, sow, and chinchilla). Many of these hypocalcemic syndromes develop near the time of the increased calcium demand associated with parturition and probably are a reflection of a temporary failure of calcium homeostatic mechanisms. A comparable hypocalcemic syndrome associated with parturition does not occur in human beings. The eclampsia that develops in women is related to a toxemia of pregnancy with degenerative changes in the liver, kidney, and placenta, rather than to disturbances in mineral homeostasis.

2. *Primary Hypoparathyroidism*

In hypoparathyroidism, either subnormal amounts of parathyroid hormone are secreted by pathologic parathyroid glands or the hormone secreted is unable to interact normally with target cells. Hypoparathyroidism has been recognized occasionally in dogs, particularly in the smaller breeds such as schnauzers and terriers (Sherding *et al.*, 1980; Hulter *et al.*, 1981; Peterson, 1982; Jones and Alley, 1985). However, the incidence is much less than that of hyperparathyroidism in both dogs and cats.

Several pathogenic mechanisms can result in an inadequate secretion of parathyroid hormone. The parathyroid glands may be damaged or inadvertently removed during the course of surgery on the thyroid gland. If the parathyroid glands or their vascular supply have only been damaged but not removed, functional parenchyma often regenerates and clinical manifestations subsequently disappear.

Agenesis of both pairs of parathyroids is a rare cause of congenital hypoparathyroidism in pups. Idiopathic hypoparathyroidism in adult dogs usually is associated with diffuse lymphocytic parathyroiditis resulting in extensive degeneration of chief cells with partial replacement by fibrous connective tissue. In the early stages of lymphocytic parathyroiditis, there is extensive infiltration of the gland with lymphocytes and plasma cells and nodular regenerative hyperplasia of the remaining chief cells. Later, the parathyroid gland is completely replaced by lymphocytes, fibroblasts, and neocapillaries with only an occasional viable chief cell. The lymphocytic parathyroiditis may develop by an immune-mediated mechanism, because a similar destruction of secretory parenchyma and lymphocytic infiltration has been produced experimentally in dogs by repeated injections of parathyroid tissue emulsions (Lupulescu *et al.*, 1968). Other possible causes of hypoparathyroidism include invasion and destruction of parathyroids by primary (thyroid, salivary, etc.) or metastatic neoplasms in the anterior cervical area. Trophic atrophy of parathyroids occurs with severe hypercalcemia resulting from vitamin D intoxication, ectopic production of parathyroid hormone-related protein by nonendocrine neoplasms, and multifocal osteolytic lesions with release of calcium associated with tumor metastases.

In human beings a variant of the syndrome of hypoparathyroidism (pseudohypoparathyroidism) has been reported in which target cells in kidney and bone are unable to respond to the secretion of parathyroid hormone (Levine *et al.*, 1994). This is due to inactivating mutations in the PTH receptor, the G proteins that couple the PTH receptor to adenylyl cyclase, or the catalytic subunit of adenylyl cyclase in the plasma membrane, resulting in an inability to form cAMP in target cells (Fig. 23.13). Severe hypocalcemia develops in patients with pseudohypoparathyroidism even though parathyroid glands are hyperplastic (Roth and Capen, 1974) and immunoreactive parathyroid hormone levels are elevated.

The functional disturbances and clinical manifestations of hypoparathyroidism primarily are the result of increased neuromuscular excitability and tetany. Bone resorption is decreased and blood calcium levels diminish progressively (4 to 6 mg/dl) (1.0 to 1.5 mmol/liter) because of the lack of parathyroid hormone (Fig. 23.43). Affected dogs are restless, nervous, and ataxic

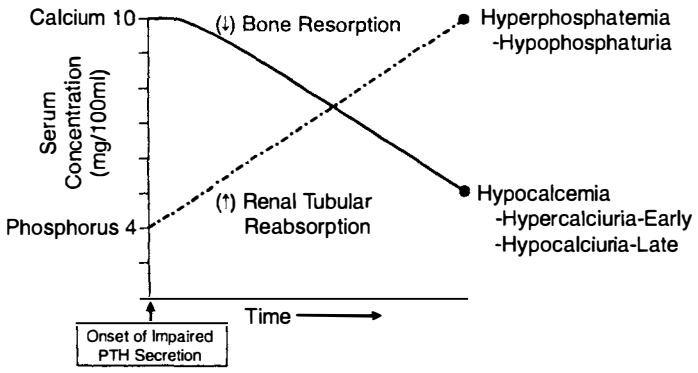

FIGURE 23.43 Hypoparathyroidism. Alterations in serum calcium and phosphorus in response to an inadequate secretion of parathyroid hormone. Progressive increases in serum phosphorus levels and a marked decline in serum calcium levels result in a neuromuscular tetany.

with intermittent tremors of individual muscle groups that progress to generalized tetany and convulsive seizures. Concurrently, blood phosphorus levels are substantially elevated because of increased renal tubular reabsorption.

3. Hypocalcemia and Renal Secondary Hyperparathyroidism

Disturbances in the circulating levels of Ca-regulating hormones occur frequently in animals with chronic renal failure, but most animals remain normocalcemic because of the continued coordination of PTH and 1,25-dihydroxyvitamin D on Ca metabolism. Mild to moderate hypercalcemia occurs in 10–15% of dogs and cats with chronic renal failure, whereas hypocalcemia occur more frequently (Chew *et al.*, 1992). When hypocalcemia occurs, it is largely the result of decreased intestinal absorption of Ca due to decreased serum 1,25-dihydroxyvitamin D. An additional effect can occur because of mass-law interactions of Ca with very high serum concentrations of phosphate as calcium phosphate salts are deposited in soft tissues. Consequently, hypocalcemia usually reflects advanced loss of nephron mass.

4. Hypocalcemia and Exercise

Blood levels of ionized calcium may decrease during intense or prolonged exercise for multiple reasons, including binding to serum proteins, complexation with lactate, changes in calcium-regulating hormones, and losses in the urine, gastrointestinal tract, or sweat. Hypocalcemia may result in increased muscular excitability or tetany and fatigue, and it may contribute to the development of synchronous diaphragmatic flutter in horses. Horses in a 3-day cross-county competition had decreased serum Ca^{2+} concentrations associated with increased serum albumin, total protein, phosphorus, and lactate concentrations (Geiser *et al.*, 1995).

D. Hypercalcitonism and Hypocalcitoninism

Clinical syndromes associated with abnormalities in secretion of calcitonin are recognized much less frequently than disorders of parathyroid hormone secretion in both animal and man (Copp, 1994). The syndromes identified so far have been primarily the result of excess secretion of calcitonin rather than a lack of secretion. A hypersecretion of calcitonin has been reported in human beings and bulls (Black *et al.*, 1973b; Capen and Black, 1974) with medullary (ultimobranchial) thyroid neoplasms derived from C cells. In human beings the syndrome often is familial and affects many individuals in a kindred.

Calcitonin-secreting C-cell neoplasms occur in populations of adult to aged bulls. The chronic stimulation of ultimobranchial derivatives in the thyroid by the high-calcium diets fed to bulls may be related to the pathogenesis of the neoplasm (Krook *et al.*, 1969, 1971b). Cows do not develop proliferative C-cell lesions under similar dietary conditions, probably because of the high physiologic requirements for calcium imposed by pregnancy and lactation. The higher plasma immunoreactive calcitonin levels in bulls than in cows may be related to their greater intake of dietary calcium relative to physiologic requirements (Deftos *et al.*, 1972) (Fig. 23.44).

C-cell (medullary) tumors of the thyroid also occur sporadically in dogs and horses as a firm mass in the anterior cervical region (Leav *et al.*, 1976). Calcitonin activity can be localized to the cytoplasm of tumor cells by immunohistochemical techniques (Leblanc *et al.*, 1991). In addition to calcitonin, medullary C-cell

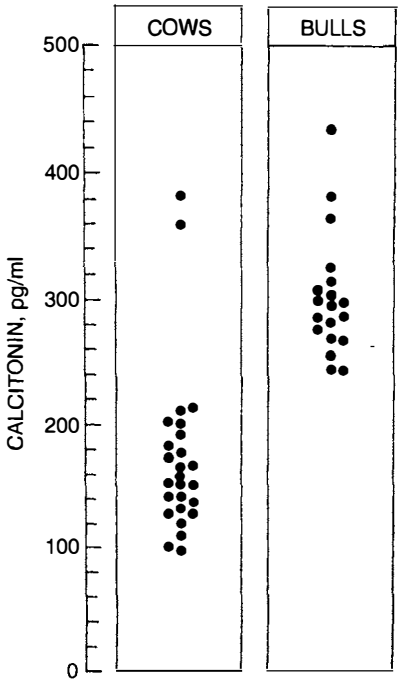

FIGURE 23.44 The higher plasma immunoreactive calcitonin levels in bulls (303 ± 13 pg/ml) than in cows (165 ± 12 pg/ml) may be related to the high dietary intake of calcium relative to physiologic requirements. This prolonged stimulation of calcitonin-secreting C cells by the high calcium intake in the diet has been suggested to be important in the pathogenesis of the more frequent incidence of C-cell (ultimobranchial) neoplasms in older bulls than in cows. From Deftos *et al.* (1972).

tumors may secrete other humoral substances, such as prostaglandins, serotonin, and bradykinin. The incidence of occurrence of C-cell tumors in dogs is uncertain, but it was reported that 7 of 200 thyroid tumors in dogs were derived from C-cells (Zarrin, 1977). They often are firm on palpation because of the presence of large amounts of amyloid in the stroma. Thyroid neoplasms of C-cell origin can be readily differentiated ultrastructurally by the presence of numerous membrane-limited secretory granules in the cytoplasm. Small granules of this type are not present in thyroid tumors derived from follicular cells.

C-cell tumors in both human beings and bulls often are associated with the simultaneous occurrence of pheochromocytomas in the adrenal medulla and neoplasms in other endocrine organs of neural-crest origin (Capen and Black, 1974). Serum calcium and phosphorus levels in adult animals with a chronic excessive secretion of calcitonin usually remain in the low-normal range because of the relatively slow turnover rate of bone. Osteosclerotic changes have been reported in bulls with this syndrome of long-term and excessive calcitonin excretion.

Specific disease syndromes resulting from a lack of calcitonin secretion have not been recognized in either man or animals. However, experimentally thyroidectomized animals are less able than normal to manage a calcium load and may develop postprandial hypercalcemia (Copp, 1969a).

E. Rickets and Osteomalacia

Rickets is a disease of bone that occurs in young animals because of phosphorus or vitamin D deficiency, whereas osteomalacia is a disease of the adult skeleton due to the same causes (Palmer, 1993). Rickets and osteomalacia are characterized by a failure of mineralization and an accumulation or excess of nonmineralized osteoid in areas of bone formation. In rickets there is, in addition, failure of mineralization at the physeal zones of endochondral ossification. This results in thickening of the physis by a zone of proliferating cartilage cells that deforms and bows because it cannot support the body weight. Animals with osteomalacia do not develop widened physes if the deficiency of P or vitamin D occurs after closure of the physis. Osteomalacia is characterized by an accumulation of unmineralized osteoid on trabecular endosteal surfaces and in Haversian systems.

Serum alkaline phosphatase is increased in most forms of rickets and osteomalacia because of an increase in bone-specific alkaline phosphatase. The elevation in serum alkaline phosphatase reflects the increased osteoblastic activity in bone in these diseases. Serum alkaline phosphatase also may be increased in other metabolic bone diseases such as primary and secondary hyperparathyroidism (Delmas, 1995). Bone-specific alkaline phosphatase constitutes the major fraction of total serum activity in young animals, but represents only about 50% of the total activity in adults. There are three genes for placental, intestinal, and bone–liver–kidney alkaline phosphatase isoenzymes. The bone, liver, and kidney forms differ in electrophoretic mobility (even though they are translated from the same mRNA), probably because of different post-translational modifications of carbohydrate side chains. The role of alkaline phosphatase in bone homeostasis is not completely understood. Hypophosphatasia is an inherited autosomal recessive defect in the bone–liver–kidney alkaline phosphatase gene that results in severe rickets in humans. This suggests a function of alkaline phosphatase in the mineralization process that may include (1) the release of local inorganic phosphate and (2) hydrolysis of inorganic pyro-

phosphate, which is an inhibitor of hydroxyapatite crystal formation.

1. Rickets Due to Vitamin D or Phosphorus Deficiency

In young animals, vitamin D is required for the orderly growth and mineralization of cartilage in the physis (growth plate) (Capen, 1985). Young animals fed diets deficient in vitamin D and housed indoors without exposure to ultraviolet radiation develop rickets. In the absence of vitamin D, mineral granules do not accumulate within hypertrophied chondrocytes in the physes of long bones, and there may be a decrease in serum Ca and P levels due to impaired intestinal absorption. Mineralization of the cartilaginous matrix fails to occur, and the physis becomes irregularly thickened as the proliferating chondrocytes and cartilaginous matrix persist because they are not removed by endochondral ossification. Endochondral ossification (vascular invasion and resorption of cartilage with deposition of osseous tissue on residual cartilage septae) requires mineralization of the growth plate. The administration of cholecalciferol, 25-hydroxyvitamin D, or 1,25-dihydroxyvitamin D leads to reestablishment of a normal calcification front in the osteoid on bone surfaces and the physes, often before there is a change in the mineral-ion concentration of extracellular fluids. Secondary hyperparathyroidism may occur as a late manifestation of rickets associated with vitamin D deficiency due to the decrease in serum Ca concentration.

Phosphorus deficiency also will result in rickets because of the failure to maintain an adequate ion product of serum Ca and P at the zones of mineralization in bone. Phosphorus deficiency will not result in hypocalcemia, and serum 1,25-dihydroxyvitamin D levels will be normal or increased.

Rickets seldom occurs in suckling animals unless the dam provides too little milk. Rickets is rare in foals, has been reported in calves and sheep, and occurs in puppies and kittens because of vitamin D or phosphorus deficiency. Rickets may be particularly severe in pigs owing to their rapid growth rate.

2. Rickets Due to Hereditary Defects in Vitamin D Action

Several forms of rickets occur in children, pigs, and laboratory animals because of abnormal metabolism of vitamin D (Liberman, 1996). Vitamin D-refractory syndromes occur in individuals with the morphologic lesions of rickets when fed normal diets in the absence of malabsorption or when exposed to adequate sunlight.

a. Vitamin D-Dependent Rickets, Type I (Hereditary Deficiency in 1,25-Dihydroxyvitamin D Production)

Vitamin D-dependent rickets, Type I, in both pigs and human beings is a familial disease inherited by an autosomal recessive gene (Wilke *et al.*, 1979). Newborn pigs appear healthy and have normal blood calcium and phosphorus concentrations. At 4–6 weeks of age, blood Ca and P decrease, serum alkaline phosphatase activity increases, and clinically detectable rickets develops during the following 3–4 weeks. The pigs develop deformities of bone in the axial and abaxial skeleton, severe pain, and classic lesions of rickets.

In response to the hypocalcemia, plasma immunoreactive PTH levels in pigs with vitamin D-dependent rickets are elevated and serum 25-hydroxycholecalciferol levels are markedly increased (75 ng/ml) compared to those of control pigs (8 ng/ml) (Wilke *et al.*, 1979). Serum 1,25-dihydroxyvitamin D levels are depressed in rachitic pigs (17 pg/ml) compared with levels in normal pigs (47 pg/ml). Homozygous, rachitic animals have no renal 25-hydroxycholecalciferol-1-hydroxylase in kidney homogenates or mitochondrial preparations, which is responsible for the insufficient renal production of 1,25-dihydroxyvitamin D (Winkler *et al.*, 1986). Repeated administration of 25-hydroxycholecalciferol will not significantly change the plasma concentrations of Ca, P, and immunoreactive PTH; however, administration of 1,25-dihydroxyvitamin D daily for 3–4 weeks results in increased plasma Ca, decreased P, and return of immunoreactive PTH and alkaline phosphatase levels to near the normal range.

b. Vitamin D-Dependent Rickets, Type II (Hereditary Defects in the Vitamin D Receptor–Effector System)

Vitamin D-dependent rickets, Type II, is a group of disorders characterized by target organ resistance to 1,25-dihydroxyvitamin D (Liberman, 1996). The disease is characterized by increased serum 1,25-dihydroxyvitamin D levels, hypocalcemia, and secondary hyperparathyroidism, and clinically by rickets or osteomalacia. The disease in humans responds variably to high doses of 1,25-dihydroxyvitamin D. New World primates have a relative end-organ resistance to 1,25-dihydroxyvitamin D and require high levels of vitamin D_3 in their diet. The common marmoset has been shown to represent a model of vitamin D-dependent rickets, Type II (Yamaguchi *et al.*, 1986). Marmosets have increased serum 1,25-dihydroxyvitamin D concentrations compared to those of rhesus monkeys, and some marmosets develop osteomalacia even when on high-vitamin D_3 diets. The resistance to 1,25-dihydroxyvitamin D is likely due to

low affinity binding of 1,25-dihydroxyvitamin D to its nuclear receptor (Gacad and Adams, 1993).

3. *X-linked Hypophosphatemic Rickets*

X-linked hypophosphatemia is a disorder in mice and humans characterized by hypophosphatemia, normocalcemia, decreased tubular reabsorption of phosphorus, and defective mineralization of cartilage and bone (Drezner, 1996). The disease is due to impaired phosphate reabsorption in the proximal convoluted tubules of the kidney. There may be decreased circulating levels of 1,25-dihydroxyvitamin D for the degree of hypophosphatemia. Treatment with phosphorus and pharmacologic doses of vitamin D or one of its metabolites is required.

4. *Osteomalacia Due to Phosphorus or Vitamin D Deficiency*

Osteomalacia literally means "softening of the bones" and is a generalized disease characterized by defective mineralization of osteoid in mature bone (Palmer, 1993). Osteomalacia due to P or vitamin D deficiency results from an interference with mineralization of normal bone matrix (osteoid). In the early stages there is a greater extent of osteoid-covered bone surfaces, and later there is an increase in osteoid seam width. There usually is much less inhibition of bone matrix formation than impairment of matrix mineralization.

Adequate local concentrations of Ca and P are necessary for proper deposition of mineral at the mineralization front. Hypophosphatemia plays a major role in the pathogenesis of osteomalacia. Phosphorus deficiency inhibits normal osteoblast function and reduces the Ca × P ion product. Vitamin D deficiency will also result in osteomalacia that resolves upon adequate supplementation or ultraviolet light exposure. The mechanisms of vitamin D deficiency-induced osteomalacia are not completely understood. The active form of vitamin D, 1,25-dihydroxyvitamin D, stimulates Ca and P absorption from the intestine. In addition, there are receptors for 1,25-dihydroxyvitamin D in osteoblasts, and 1,25-dihydroxyvitamin D stimulates increased expression of alkaline phosphatase and other proteins in osteoblasts. It is likely that proper levels of vitamin D are necessary for adequate Ca and P absorption and normal osteoblast function. The vitamin D metabolite 24,25-dihydroxycholecalciferol may also play a role in the normal mineralization of osteoid (Ornoy *et al.*, 1978).

The presence of osteomalacia is difficult to assess clinically. The diagnosis usually requires an interpretation of bone pain, serum and urine Ca and P concentrations and excretion rates, serum concentrations of vitamin D metabolites, radiography, and most conclusively, histomorphometric analysis of a mineralized bone biopsy.

Osteomalacia also may occur during fat malabsorption syndromes due to inhibition of absorption of Ca and P, and the loss of the fraction (20–30%) of 25-hydroxyvitamin D that undergoes enterohepatic recirculation (Marel *et al.*, 1986). Adults with vitamin D-refractory syndromes, X-linked hypophosphatemia, or Fanconi syndrome will also develop osteomalacia. One of the manifestations of a Fanconi-like syndrome in dogs is a reduction in the tubular reabsorption of P in the kidney (Bovee *et al.*, 1979). Metabolic acidosis is associated with hypercalciuria, loss of skeletal Ca, and renal P wasting, which may induce rickets and osteomalacia (Marel *et al.*, 1986).

5. *Tumor-Induced Osteomalacia*

Benign or occasionally malignant mesenchymal tumors have been associated with a paraneoplastic syndrome in human beings characterized by hypophosphatemic osteomalacia (Lyles, 1996). Tumors reported include hemangioma, fibroma, giant-cell tumor, and hemangiopericytoma. The syndrome is characterized by hypophosphatemia associated with increased fractional P excretion and low circulating levels of 1,25-dihydroxyvitamin D due to inhibition of renal 1α-hydroxylase. It appears that the tumors release a humoral factor that causes phosphaturia and abnormal vitamin D metabolism, because removal of the tumors results in amelioration of clinical signs and of the osteomalacia.

6. *Osteomalacia and Chronic Renal Failure*

Most chronic renal-failure patients develop fibrous osteodystrophy to some degree because of renal secondary hyperparathyroidism; however, a minority of dialyzed human patients develop severe osteomalacia (Marel *et al.*, 1986). Aluminum (Al) accumulation in bone may play a central role in the development of renal osteomalacia. The incidence of renal osteomalacia correlates well with the presence of Al in bone, the content of aluminum in dialysate water, and oral administration of aluminum hydroxide to control hyperphosphatemia by binding intestinal phosphorus. Aluminum is normally excreted by the kidney and accumulates in bone at sites of mineralization. Aluminum may also suppress PTH secretion, which accentuates the osteomalacia; however, administration of Al to dogs did not impair the PTH response to hypocalcemia (Henry *et al.*, 1984).

F. Osteoporosis

Osteoporosis is defined as a reduction in bone density that predisposes bone to fractures due to an imbalance in bone formation and bone resorption. It may occur as a result of malnutrition (starvation or calcium or phosphorus deficiency), during protein-wasting diseases such as parasitism, as a result of local or generalized skeletal disuse, or as an aging change (Palmer, 1993). Osteopenia is defined as a reduction in bone mass without an interpretation on its quality. Many forms of osteopenia occur secondary to endocrinopathies or from excessive or prolonged use of drugs. Age-related osteoporosis is an important disease of humans, but is not a major disease problem in domestic animals (Rodan *et al.*, 1996). There are two types of age-related osteoporosis in humans: Type I or postmenopausal osteoporosis occurs predominantly in women (51–75 years of age) and is associated with loss of trabecular bone, and Type II or senile osteoporosis occurs only slightly more often in women (2:1), is seen in older individuals (>70 years old), and is associated with loss of cortical and trabecular bone. There is a mild, transient increase in bone remodeling in dogs after ovariohysterectomy, but the degree of bone loss associated with ovarian insufficiency is not clinically significant (Boyce *et al.*, 1990).

Bone remodeling in the adult skeleton takes place in discrete foci termed bone remodeling units (BRU). At each BRU bone is first resorbed by osteoclasts and then formed by osteoblasts. The BRU is represented by the formation of osteons in cortical bone and bone structural units in trabecular bone. With advancing age, bone resorption by osteoclasts exceeds bone formation by osteoblasts, resulting in an imbalance in bone remodeling. If bone remodeling is increased, i.e., there are more BRUs, the imbalance will be enhanced. Bone density in humans is at its maximum at about 35 years of age. There is a reduction in bone density of 50 and 35% in trabecular and cortical bone, respectively, over the human lifespan. Bone loss is enhanced after menopause because of the loss of estrogens, or during androgen deficiency in males. The mechanism of action of the sex hormones is not known, but the principal effect of estrogen lack or androgen withdrawal is increased bone resorption. Estrogen deficiency leads to increased activity of local factors in bone that may be responsible for increasing bone resorption. These factors include interleukin-1, interleukin-6, tumor necrosis factor α, and prostaglandins.

The development of osteoporosis also will be enhanced by chronic liver or kidney disease, adrenal glucocorticoid excess, thyroid hormone excess, immobilization, and low calcium intake. Glucocorticoids decrease calcium absorption from the intestine, which results in secondary hyperparathyroidism, and are potent inhibitors of bone formation (Norrdin *et al.*, 1988). Thyroid hormones increase bone remodeling, but may stimulate bone resorption to a greater extent than bone formation (Stern, 1996).

G. Biochemical Markers of Bone Metabolism

One of the most accurate methods to assess bone remodeling, including both formation by osteoblasts and resorption by osteoclasts, is the cancellous bone biopsy (Rosol *et al.*, 1992a; Recker, 1996). This is a technically demanding procedure and requires special facilities for processing and special expertise for evaluation. Recent advances have been made in measurement of circulating biochemical markers of bone turnover (Table 23.5) (Delmas, 1995; Eriksen *et al.*, 1995; Calvo *et al.*, 1996). Some of these markers provide useful indirect measures of bone resorption and bone formation *in vivo*. Bone resorption can be estimated by measuring the serum or urine concentrations of osteoclast-derived enzymes or collagen degradation products. Bone formation can be indirectly evaluated by measuring serum concentrations of osteoblast proteins, enzymes, or precursor peptides released during collagen synthesis.

Because of wide normal variation in the serum markers or lack of bone specificity, individual samples may have limited diagnostic value. However, samples collected over time to monitor changes in concentrations or samples from groups of animals are more valuable diagnostically or in experimental investigations. Most of the serum markers are higher in young animals than in adults because of the rapid turnover of bone during growth. Bone turnover *in vivo* follows a pronounced circadian pattern with increased bone resorption after food intake or during the night (Mühl-

TABLE 23.5 Biochemical Markers of Bone Turnover

Bone resorption: serum markers
Tartrate-resistant acid phosphatase
Bone resportion: urine markers
Pyridinoline and deoxypyridinoline (collagen cross-links) and cross-linked collagen telopeptides
Fasting calcium concentration
Hydroxyproline
Hydroxylysine glycosides
Bone formation: serum markers
Alkaline phosphatase (total or bone-specific isozyme)
Osteocalcin (bone Gla protein)
Procollagen I carboxy-terminal extension peptide

bauer and Fleisch, 1995). Therefore, sample collection should always be at the same time of day.

1. Bone Resorption

a. Tartrate-Resistant Acid Phosphatase

Serum acid phosphatase activity is derived from lysosomes from cells in bone, prostate, platelets, erythrocytes, and the spleen. There are at least six isoenzymes. In bone, acid phosphatase is produced by osteoclasts. Acid phosphatase produced by osteoclasts in bone and macrophages throughout the body is resistant to inhibition by L(+)-tartrate. Serum tartrate-resistant acid phosphatase activity is an insensitive measure of bone resorption because of the lack of osteoclast specificity and the potential for enzyme inhibitors in serum. Future development of immunoassays specific for tartrate-resistant acid phosphatase may be more useful (Price *et al.*, 1995).

b. Pyridinoline and Deoxypyridinoline (Collagen Cross-Links)

Pyridinoline (Pyr) and deoxypyridinoline (D-Pyr) are covalent cross-links between collagen molecules generated from lysine and hydroxylysine and are potentially useful markers of bone resorption (Delmas, 1995). Pyr and D-Pyr are absent from skin, which is an abundant source of collagen. Most Pyr and D-Pyr in serum and urine is likely derived from bone because of the large amount of bone collagen in the body and its constant rate of turnover. Pyr and D-Pyr are not metabolized *in vivo* and are excreted in urine in free form (30–40%) or bound to N-terminal and C-terminal collagen telopeptides (60–70%). Total urine Pyr and D-Pyr can be measured by fluorometry after reverse-phase HPLC purification of hydrolyzed urine (Pratt *et al.*, 1992). Widespread measurement of urinary Pyr and D-Pyr will require development of more convenient assays, such as immunoassays. Immunoassays have been developed for Pyr and D-Pyr-crosslinked collagen telopeptides present in urine and serum, but the clinical utility of these assays is currently under investigation (Delmas, 1995).

c. Fasting Urine Calcium

The concentration of calcium in the urine (corrected for creatinine) of a fasted animal is an indirect measure of bone resorption because of the lack of contribution of calcium absorption from the gastrointestinal tract. This is an insensitive measure and will only detect large increases in bone resorption. Calcium-regulating hormones, such as PTH, also will affect the resorption rate of calcium by the kidneys.

d. Urine Hydroxyproline

Hydroxyproline is present mainly in collagen (representing 13% of the amino acids), but is also present in the C1q fraction of complement. Hydroxyproline is released from collagen during degradation and is not reutilized. Because bone collagen represents 50% of the body's collagen, urine hydroxyproline is an indirect marker of bone resorption. However, it is an insensitive measure of such resorption because 90% of the filtered hydroxyproline is reabsorbed by the kidney and oxidized in the liver. Hydroxyproline can be measured by colorimetric assay of a hydrolyzed urine sample (Kivirikko *et al.*, 1967) or HPLC after hydrolysis and derivatization (Paroni *et al.*, 1992).

e. Urine Hydroxylysine

Hydroxylysine is a unique amino acid present in collagen that is not reutilized after collagen degradation, but is less abundant than hydroxyproline (Delmas, 1995). Hydroxylysine exists in two forms in collagen (galactosyl hydroxylysine and glucosyl hydroxylysine), and the forms differ in proportion in soft tissues and bone. Therefore, assay of urinary excretion of galactosyl hydroxylysine and glucosyl hydroxylysine may be a more sensitive measure of bone resorption than a similar assay for hydroxyproline. The usefulness of measurement of these two compounds is limited by the HPLC technique used in the assay.

2. Bone Formation

a. Alkaline Phosphatase

Total serum alkaline phosphatase activity is a combination of isoenzymes produced in the liver, bone, kidney, placenta, and intestine. The liver and bone isoenzymes represent the greatest fractions. Bone alkaline phosphatase is present in osteoblast cell membranes and is released by an unknown mechanism during bone formation. Measurement of total alkaline-phosphatase activity spectrophotometrically using *p*-nitrophenyl phosphate is an insensitive measure of bone formation because of the contribution of multiple isoenzymes. Bone and liver alkaline phosphatase may be separated by electrophoresis, but this is cumbersome and leads to only minor improvements in the specificity of the assay. Both the liver and bone isoenzymes are encoded by the same gene, but differ in posttranslational glycosylation. This has enabled development of an immunoassay to human bone-specific alkaline phosphatase with a low degree of cross reactivity to other isoenzymes and has increased the usefulness of alkaline phosphatase measurement as a marker of bone formation (Delmas, 1995).

b. Osteocalcin

Osteocalcin (γ-carboxyglutamic acid-containing protein, bone Gla protein) is a vitamin K-dependent protein that is the most abundant noncollagenous protein in bone and is produced by osteoblasts and odontoblasts (Ducy and Karsenty, 1996). It has 49 amino acids and represents 1–2% of total bone protein. The active form of vitamin D, 1,25-dihydroxyvitamin D, is a potent inducer of osteocalcin production by osteoblasts. Measurement of serum osteocalcin by radioimmunoassay is one of the most useful markers of bone formation (Delmas, 1995).

Osteocalcin has a short half-life and is rapidly cleared by the kidney, so serum levels are dependent on renal function. Osteocalcin is quickly degraded in serum *in vivo* and *in vitro* at room temperature. Circulating forms of osteocalcin include the intact peptide, an N-terminal/midregion fragment, and a C-terminal fragment. These forms may interfere with certain radioimmunoassays. Antibodies to osteocalcin cross react between species. Antiserum to bovine osteocalcin can be used to measure human and equine osteocalcin by RIA (Hope *et al.*, 1993). Canine osteocalcin protein has been isolated from bone and sequenced, and a sensitive RIA has been developed (Colombo *et al.*, 1993; Fanti *et al.*, 1993)

c. Procollagen I Carboxy-Terminal Extension Peptide

Collagen Type I constitutes 97% of the collagen in bone. Collagen type I is synthesized as procollagen by osteoblasts during bone formation; it contains peptide extensions at the C- and N-terminal ends that are cleaved during synthesis of collagen fibrils. The procollagen peptides that are released into the circulation have a short half-life and are cleared by the liver. Serum concentrations of C-terminal extension peptides can be measured by radioimmunoassay; however, peptide concentrations are insensitive measures of bone formation and may have a low correlation with bone formation *in vivo* (Delmas, 1995).

V. MAGNESIUM METABOLISM

Magnesium (Mg) is an essential dietary element for animals (Speich and Bousquet, 1991; McDowell, 1992b). Green plants are an excellent dietary source of Mg for animals because of the presence of Mg^{2+} in chlorophyll (Wilkinson *et al.*, 1990). Magnesium metabolism has been studied most extensively in cattle and sheep, because clinical disorders related to magnesium deficiency occur most commonly in those species (Birch, 1990). However, disorders related to magnesium metabolism also are recognized in other animals, including cats, dogs, goats, and horses.

Magnesium ions (Mg^{2+}) and Ca^{2+} bind to negatively charged molecules (e.g., ATP, DNA, RNA), enzymes, and other binding proteins. Mg^{2+} and Ca^{2+} differ only in their radius and polarizability. Mg^{2+} is smaller than Ca^{2+} and binds to many ligands with greater affinity than does Ca^{2+} (Martin, 1990). Interactions between the two ions occur both intra- and extracellularly (Vormann and Günther, 1993). However, different types of interactions occur depending on the binding protein. Such interactions cannot be easily predicted without empirical testing. Depending on the physiological system or binding molecule, Mg^{2+} and Ca^{2+} can interact in the following ways: (1) Mg^{2+} and Ca^{2+} can have similar biological effects, (2) Mg^{2+} and Ca^{2+} can bind to molecules with different affinities resulting in partial synergy or antagonism, (3) the cations can be direct antagonists to each other with no cross-reactivity, or (4) effects can be dependent on Mg^{2+} or Ca^{2+} with no interaction between cations (Vormann and Günther, 1993). The pathophysiology of Mg-related disorders is often complicated by the Ca^{2+} status of the animal, as occurs in cattle with grass tetany. Conditions of hypomagnesemia will lead to exaggerated effects of Ca^{2+} because the antagonistic effects of Mg^{2+} will not be present. In contrast, conditions of hypermagnesemia may produce antagonistic effects on Ca^{2+} metabolism.

A. Distribution of Magnesium in the Body

Magnesium (atomic mass 24.32) is the fourth most prevalent cation in the body, being surpassed by calcium, sodium, and potassium, but ranks second to potassium as a soft-tissue cation and resembles K^+ in distribution (Altura *et al.*, 1987). The body of domestic animals contains 0.05% magnesium by weight, of which 60% is in the skeleton, 38% in the soft tissue, and 1–2% in the extracellular component (Martens and Rayssiguier, 1980). Magnesium content of bone ranges from 4 to 8 gm/kg with a Ca:Mg ratio of 50–100:1 (Meyer and Zentek, 1990). About 70% of bone Mg is removable by treatment with dilute acid and represents Mg bound to the surface of bone crystals, whereas the remaining 30% is an integral part of the bone crystal lattice (Taylor, 1959). Most of the soft-tissue component resides in skeletal muscle (320–420 mg/kg wet tissue) and liver (Al-Khamis, 1995).

Some of the Mg in bone is available for mobilization to soft tissues in young animals when dietary intake is inadequate. Rib Mg content decreased 30% in calves fed Mg-deficient diets (McKim *et al.*, 1984). The adult is less able to mobilize Mg from the skeleton or muscle

during dietary deficiency, and animals may die in tetany with little depletion of bone Mg. Because there is little body reserve available to offset Mg deficiency, a continuous intake of Mg is necessary for health (Wallach, 1987). However, Mg mobilization from bone in adult sheep on Mg-deficient diets may partially protect them from developing clinical signs of hypomagnesemia (Matsui *et al.*, 1994).

Soft-tissue Mg occurs intracellularly at approximately 360 mg/kg compared with the plasma concentration of about 2.4 mg/dl (1.0 mmol/liter). Intracellular magnesium exists in a free ionized form (1%) that is readily exchangeable and a bound form (99%) that is chelated, typically with ATP and apoenzyme proteins. A simple diffusion equilibrium probably exists between the labile, exchangeable form and the Mg^{2+} in the extracellular fluid, whereas a more complex relation occurs between the two intracellular forms.

The blood–brain barrier in neonatal animals permits Mg^{2+} transport, but forms a functional barrier in the postnatal period (Rivera *et al.*, 1991). However, Mg^{2+} concentration in the cerebrospinal fluid (CSF) is usually greater than in the serum, which indicates that Mg^{2+} is actively transported by the choroid plexus (Vormann and Günther, 1993). This is in contrast to the Ca^{2+} concentration in CSF, which is 50% less than serum. The CSF [Mg^{2+}] decreased in proportion to serum [Mg^{2+}] in calves with experimental hypomagnesemia (Sarode *et al.*, 1992). The concentration of Mg in CSF is relatively stable (approximately 2.2 mg/dl [0.91 mmol/liter]) when serum Mg concentration is greater than 1.0 mg/dl (0.41 mmol/liter), but can fall sharply when serum Mg decreases below this level (Meyer and Zentek, 1990).

It is difficult to assess the Mg status of an animal, because plasma Mg (the easiest measured source of Mg) represents less than 1% of total body Mg (Elin, 1987b; Reinhart, 1988; Nowitzki-Grimm *et al.*, 1991; Elin, 1994). Total Mg content of body fluids or tissues can be measured by colorimetric assay, kinetic assay, and atomic or atomic-emission spectrophotometry, and ionized Mg can be measured using an ion-selective electrode (Elin, 1987b; Seiler, 1990; Blanchflower and Kennedy, 1991; Altura *et al.*, 1994; Anderson and Talcott, 1994; Ising *et al.*, 1995). Erythrocyte Mg content can be used to estimate Mg status of the body, but it may not accurately reflect the Mg content of all tissues (Nowitzki-Grimm *et al.*, 1991; Nozue *et al.*, 1991). Mg depletion will lead to a sudden decrease in plasma Mg concentration and a progressive decline in erythrocyte Mg concentration (Mulei and Daniel, 1989; Geven *et al.*, 1990). Magnesium content of mononuclear white blood cells may be a better estimate of Mg status compared to erythrocyte Mg concentration (Elin, 1987a). Measurement of Mg retention by quantifying total urine Mg after parenteral administration is a potentially useful method to assess body Mg status (Martin, 1994). Magnesium balance is principally controlled by absorption from the gastrointestinal tract and excretion by the kidney. There appears to be no primary hormonal control of plasma Mg concentration.

The physiological functions of Mg may be divided into intracellular and extracellular categories.

1. Intracellular Function of Magnesium

Magnesium is essentially an intracellular cation and functions as an activator or a catalyst for more than 300 enzymes in the body, including phosphatases and enzymes that involve ATP (Heaton, 1990). All reactions that utilize ATP require Mg^{2+} because the intracellular substrate is the complex, MgATP. The action of Mg extends to all major anabolic and catabolic processes. Thus, Mg plays a pivotal role in muscle contraction, protein, fat, and carbohydrate metabolism, methyl-group transfer, oxidative phosphorylation, functional properties and stabilization of membranes, cell division, and immune responses. Magnesium regulates ribosomal RNA and DNA structure, thereby affecting cell growth and membrane structure (Günther, 1990). Magnesium is required for maintenance of normal cellular potassium (Ryan, 1993), and Mg deficiency can lead to intracellular K depletion and excessive K excretion (Abbott and Rude, 1993). Magnesium regulates mitochondrial membrane permeability, and one of the earliest ultrastructural changes observed in Mg deficiency is swelling and disruption of mitochondrial cristae (Altura *et al.*, 1987); however, intracellular Mg^{2+} is usually constant in different physiologic or pathophysiologic states.

Total intracellular magnesium can be measured with atomic absorption spectrophotometry, and free intracellular Mg^{2+}, $[Mg^{2+}]_i$, can be measured using a specific Mg^{2+} microelectrode, ^{31}P nuclear magnetic resonance, or Mg^{2+}-specific fluorescent dyes (Fujise *et al.*, 1991; London, 1991; Murphy, 1993). Intracellular free concentrations of Mg^{2+} in nucleated mammalian cells usually range from 0.3 to 3.0 mmol/liter, with the highest levels in myocardial myocytes (2.5–3.1 mmol/liter) and lower concentrations in vascular smooth muscle cells (0.1–1.0 mmol/liter) and erythrocytes (0.3 mmol/liter) (Altura *et al.*, 1987; Fujise *et al.*, 1991; Fenwick and Daniel, 1991). The $[Mg^{2+}]_i$ represents a balance among influx, efflux, and intracellular buffering or chelation (Günther, 1993). In general, Mg^{2+} enters the cell passively and is actively extruded from the cytoplasm (Beyenbach, 1990). Much of the intracellular Mg^{2+} is bound to ATP in the form of $MgATP^{2-}$. Intracellular

Mg^{2+} concentration may be relatively stable, vary between cell regions, or be regulated by various hormones depending on the cell type, but the mechanisms that regulate $[Mg^{2+}]_i$ are poorly understood (Günther, 1986; Romani *et al.*, 1993). Alterations in $[Mg^{2+}]_i$ are slower and last longer than changes in intracellular Ca^{2+}. Therefore, $[Mg^{2+}]_i$ may play a role in the sensitization or desensitization of cellular response systems rather than an acute "on–off" signal as occurs with changes in $[Ca^{2+}]_i$ (Maguire, 1990).

Magnesium deficiency is associated with increased insulin and epinephrine secretion. Insulin increases cellular Mg, and epinephrine decreases cellular Mg; therefore, there is near-normal cellular Mg equilibrium during Mg deficiency. However, insulin and epinephrine can cause cell-membrane depolarization, increased cell Ca and P_i (which may result in cellular calcinosis), and increased cGMP. These effects can be antagonized by the Mg-like effects of taurine, which is mobilized during Mg deficiency. Taurine metabolism may be one of the factors that account for the occurrence of latent clinical disease in states of Mg deficiency (Durlach and Durlach, 1984; Durlach *et al.*, 1987).

2. *Extracellular Function of Magnesium*

Magnesium interacts with extracellular Ca^{2+} by binding to many shared ligands. In general, Mg^{2+} acts as a Ca^{2+} antagonist, and hypomagnesemia is associated with accentuated actions of Ca^{2+}. Mg^{2+} binds to chief cells in the parathyroid glands and inhibits secretion of PTH, but the effect is not as great as that of Ca^{2+}.

Magnesium is important in the production and decomposition of acetylcholine. Low concentrations of Mg or a low Mg^{2+}/Ca^{2+} ratio potentiates the release of acetylcholine at neuromuscular junctions. Therefore, a low concentration of Mg in the extracellular fluid may lead to tetany due to the increased release of acetylcholine at motor end plates. Cholinesterase activity is unaffected by Mg deficiency.

B. Absorption and Excretion

Dietary Mg has a low availability compared to that of dietary Ca. The apparent digestibility of Mg (the percentage of dietary Mg that is not excreted in the feces) ranges up to 40% in ruminants and up to 60–65% in dogs, cats, and horses (Hintz and Schryver, 1972; Meyer and Zentek, 1990). Digestibility of dietary Mg is greater in suckling animals than in adults. The availability of dietary Mg varies considerably depending on type of feed and individual animal variation.

1. *Endogenous Fecal Magnesium (Fecal Mg from Digestive Secretions)*

Magnesium in the feces is not solely unabsorbed dietary Mg, because digestive secretions may contain a considerable amount of endogenous Mg. The apparent digestibility of Mg (food Mg − fecal Mg/food Mg) is a valid estimate of true digestibility only when endogenous Mg in the feces is a small part of total fecal Mg. Endogenous Mg has been estimated in sheep, calves, cattle, and horses, but the estimates varied because of differences in experimental methods (Simesen, 1980). Mean values of endogenous Mg ranged from 0.5 to 5.1 mg/kg body weight/day. Endogenous fecal excretion of Mg is of substantial magnitude in ruminants and may be increased by a greater flow of saliva stimulated by diets high in roughage (Care, 1980). Endogenous Mg excretion may relate to the greater susceptibility of ruminants to hypomagnesemia.

2. *Absorption*

Magnesium is absorbed as a freely diffusing ion, as is calcium, by three mechanisms: (1) paracellular diffusion, (2) paracellular solvent drag, and (3) transcellular active transport (Leonhard *et al.*, 1990; Flatman, 1991; Stojevic *et al.*, 1993). In general, Mg absorption occurs principally in the distal small intestine and colon of monogastric animals and forestomachs of ruminants (Hintz and Schryver, 1972; Meyer and Zentek, 1990; Kayne and Lee, 1993; Stojevic *et al.*, 1993; Rémond *et al.*, 1996). The absorptive efficiency of Mg decreases with increasing Mg concentration of the diet when plasma Mg concentration is normal. Increased dietary Mg will lead to increased serum, erythrocyte and tissue Mg concentrations, especially bone (Chester-Jones *et al.*, 1989, 1990). The concentration of ionized Mg in the small intestine is low because of binding of Mg^{2+} to ingesta. Calves absorb Mg from the large and small intestine until 1 month of age, but once the forestomachs become functional, Mg will be absorbed from this part of the digestive tract (Kolb, 1985). The concentration gradient between the rumenal lumen and blood is too small to account for net Mg absorption, and an active transport process utilizing a Na/K ATPase may be involved (Martens *et al.*, 1978; Martens, 1983; Martens and Käsebieter, 1983), along with passive diffusion down an electrochemical gradient (Care, 1980). Rumen Mg^{2+} absorption may be increased by lower pH (which increases Mg^{2+} solubility) and decreased by microbial sequestration (Kennedy and Bunting, 1991).

The fetus has a plasma Mg concentration that is greater than that of the mother because of active transport of Mg across the placental barrier (Barri *et al.*,

1990). The gradient is dependent on the fetal parathyroid glands in sheep. The midmolecule portion of parathyroid hormone-related protein may be one humoral factor that is involved in stimulating the transport of Mg across the placenta (MacIsaac *et al.*, 1991b). Parathyroid hormone-related protein is produced by both the fetal parathyroid glands and placenta.

The absorption of Mg is increased by the active form of vitamin D (1,25-dihydroxyvitamin D), but the mechanism of the transport is unknown, and Ca and Mg differ in the degree to which absorption is stimulated (Ebel, 1990). However, 1,25-dihydroxyvitamin D administration results in a decreased plasma Mg concentration (Boling and Evans, 1979; Care, 1980). This may be a result of enhanced Mg excretion due to a direct effect of 1,25-dihydroxyvitamin D on tubular reabsorption of Mg, or a secondary effect due to reduced serum PTH concentrations (Fontenot *et al.*, 1989). A common intestinal transport system for Ca and Mg has been hypothesized (Ebel, 1990). Calcium and magnesium interfere with each other's absorption, and high dietary supplementation with Ca decreases the apparent absorption and retention of Mg (Shiga, 1988). In addition, feeding the chelating agent EDTA (which binds Ca in preference to Mg) inhibits the absorption of Ca from the small intestine, but promotes the absorption of Mg in the proximal small intestine in sheep (van't Klooster and Care, 1966). Diets high in phosphate reduce intestinal Mg absorption (Hintz and Schryver, 1972; Ebel, 1990). Increased rumenal concentrations of potassium lead to an increased potential difference across the lumenal epithelial cells and result in reduced Mg absorption (Care, 1988; Martens *et al.*, 1988; Fisher *et al.*, 1994).

3. *Excretion*

The three principal routes of Mg excretion are the gastrointestinal tract, the kidney, and the mammary gland during lactation. Magnesium loss can also occur in animals that sweat. Pregnant animals lose large amounts of Mg during fetal bone development in the latter parts of gestation.

a. Gastrointestinal Tract

Most of the Mg that is excreted is present in the feces. Fecal Mg includes endogenous fecal Mg, which is higher for ruminants than for monogastric animals, and unabsorbed Mg from the diet. Malabsorption syndromes, enteropathies, and cholestatic liver disease can lead to increased intestinal loss of Mg.

b. Kidney

The kidneys play a major role in regulating Mg balance and serum concentration by controlling tubular reabsorption principally in the ascending limb of the loop of Henle (De Rouffignac and Quamme, 1994; Quamme, 1993). Magnesium absorbed in the gastrointestinal tract in excess of body requirements is excreted by the kidney. The tubular reabsorption rate is regulated by dietary availability of Mg, certain hormones, serum concentrations of calcium and magnesium, and urinary calcium excretion (Ryan, 1990). Dietary deficiency of Mg is associated with an increase in renal reabsorption. Fractional Mg clearance is approximately 5–10%, but can vary from less than 1 to 100% depending on the degree of dietary Mg absorption and serum Mg concentration (Fleming *et al.*, 1991; Sutton and Domrongkitchaiporn, 1993). Magnesium appears in the urine when the filtered load exceeds the maximal tubular reabsorptive capacity (Littledike and Cox, 1979). Maximum tubular reabsorption of Mg and filtration rate determine the threshold concentration of Mg in the serum. The renal threshold of serum Mg is 1.8–1.9 mg/dl (0.7–0.8 mmol/liter) in the bovine (Rook and Storry, 1962).

The majority (50–60%) of ultrafilterable Mg is reabsorbed in the thick ascending limb of the loop of Henle, and regulation of renal Mg excretion occurs at this site (Quamme, 1993). Mg is reabsorbed in this segment through the paracellular pathway. Movement of Mg can be controlled by regulation of paracellular permeability and transepithelial voltage. Hypercalcemia and hypermagnesemia inhibit renal reabsorption and increase excretion of Mg. Multiple hormones can increase renal Mg reabsorption and include parathyroid hormone, parathyroid hormone-related protein, calcitonin, antidiuretic hormone, glucagon, β-adrenergic agonists, and insulin (Rizzoli *et al.*, 1989; Ryan, 1990; De Rouffignac *et al.*, 1993). Impaired Mg reabsorption and excess excretion occur with osmotic diuresis (including diabetes mellitus), loop diuretics, hypercalciuria, tubular acidosis, and various toxicities (including aminoglycosides and *cis*-platinum) (Reinhart, 1988; Kes and Reiner, 1990; Sutton and Domrongkitchaiporn, 1993). Excess urinary excretion of Mg could lead to hypomagnesemia, especially if dietary sources are marginal or deficient. Hypermagnesemia may occur secondary to reduced glomerular filtration or chronic renal failure, especially if there is excess dietary intake of Mg.

Urinary Mg concentration can be used as an indicator of dietary supply, but is not representative of current plasma Mg concentration. Magnesium status or adequacy of dietary Mg intake in cattle can be determined more accurately with urinary Mg than with serum Mg. The minimum range of urine Mg indicating adequate herd status is 3.7–9.8 mg/dl (1.5–4.0 mmol/liter) (Horber *et al.*, 1979; Alexander, 1985). The higher range of urine Mg values is present in high-producing

dairy cows fed adequate levels of dietary Mg. If urinary Mg fractional clearance is less than 10% or creatinine-corrected urinary Mg concentration is less than 2.4 mg/dl (1.0 mmol/liter) in dairy cows, then a positive response to Mg supplementation is likely (Sutherland *et al.*, 1986). A serum Mg level of 1.5 mg/dl (0.63 mmol/liter) is regarded as the minimum safe figure for cattle.

Renal antagonism between Ca and Mg may be one of the causes of increased plasma Mg associated with hypocalcemia (Halse, 1984). This may partially explain why (1) some cows with postparturient paresis have plasma Mg levels greater than 2.4 mg/dl (1.0 mmol/liter), (2) plasma Mg decreases when milk fever is treated (Marr *et al.*, 1955), and (3) there is a delay in clinical hypomagnesemia seen in cows with fasting hypocalcemia. Plasma Mg may also be increased in cows during subclinical postparturient hypocalcemia (Dishington, 1975). Phosphate depletion leads to urinary Mg wasting and may result in hypomagnesemia (Ryan, 1990).

c. Mammary Gland

The mammary gland actively secretes Mg into milk, and the ratio of milk Mg : serum Mg is approximately 5:1. The output of Mg in milk is 3–6 mg/kg body weight/day, and the requirements of lactating animals is 20–50 mg/kg body weight/day (Meyer and Zentek, 1990). Milk Mg concentration is steady during lactation in cattle and dogs, but increases in sheep and rabbits. Heavily lactating cows can lose from 2 to 4 g of Mg per day from the mammary gland, which represents a large proportion of dietary Mg absorbed from the gut. Magnesium concentration of milk is stable under conditions of reduced feed or Mg intake or during hypomagnesemia (Meyer and Zentek, 1990). Production increases can be expected from correcting hypomagnesemia in dairy cows (Wilson, 1980; Alexander, 1985). Milk yield significantly decreased in cows 1 week before and after clinical hypomagnesemia (Lucey *et al.*, 1986).

VI. SERUM MAGNESIUM

The method of choice for determination of total Mg in biologic materials is atomic absorption spectrophotometry (Anderson and Talcott, 1994). Colorimetric and kinetic methods also are available for measurement of total serum Mg (Seiler, 1990; Blanchflower and Kennedy, 1991). Serum ionized Mg can be measured with a Mg^{2+}-selective electrode (McGuigan and Blatter, 1989; Altura *et al.*, 1994; Riond *et al.*, 1995b). If a Mg^{2+}-selective electrode is not available, measurement of ultrafilterable Mg may be a satisfactory alternative for evaluating physiologically significant Mg concentrations (Córdova and Pérez-Gallardo, 1993). Changes in serum total Mg often parallel changes in serum ionized Mg.

Serum Mg concentration ranges from 1.5 to 5 mg/dl (0.8–2.1 mmol/liter) depending on species (Table 23.6) About 70–80% of serum Mg is ultrafilterable (free ion or complexed to phosphate, citrate, or other compounds), and the ultrafilterable fraction is independent of the total serum content (Evans and Parsons, 1988). The protein-bound fraction of serum Mg (20%) is bound predominantly to albumin and also to globulins, but serum total Mg concentration is independent of albumin concentration (Evans and Parsons, 1988). Serum ionized Mg concentration represents approximately 70% of total serum Mg and parallels changes in total serum Mg concentration (Riond *et al.*, 1995b). In animals other than cattle, Mg occurs at a higher concentration in erythrocytes than in plasma, and there is no apparent exchange of Mg between plasma, and erythrocytes. Serum Mg varies between breeds of cattle, with lower values in Herefords (1.59 mg/dl, 0.65 mmol/liter) and higher values in Angus (1.91 mg/dl, 0.79 mmol/liter) (Littledike *et al.*, 1995). Plasma Mg may decrease during lipolysis associated with stress, cold, or starvation (Rayssiguier, 1984). Leakage of Mg from tissues into blood after death precludes the use of postmortem blood samples for evaluation of serum Mg concentration.

The validity of using Mg concentration of eye fluids after death to diagnose hypomagnesemia is questionable. Magnesium concentration of aqueous humor after death was reported to have no relationship to serum Mg before death and may actually increase postmortem (Whitaker *et al.*, 1986). It was demonstrated that Mg concentration in bovine vitreous humor (1.8–2.7 mg/dl [0.7–1.1 mmol/liter]) paralleled serum Mg for 48 hours post mortem at temperatures of 4 and 23°C, but decreased at 30°C (Lincoln and Lane, 1985). In contrast, low correlations were demonstrated between Mg concentrations in serum and aqueous or vitreous humor in cows (McCoy and Kennedy, 1994). However, most cows in these investigations were not hypomagnesemic, so the efficacy of using vitreous humor Mg concentrations for evaluation of hypomagnesemia has not been established.

A. Regulation of Serum Magnesium

Serum Mg concentration is less well controlled than that of Ca, and less is known concerning the regulation of serum Mg. There is a reciprocal relationship between Mg and Ca in the serum. Insufficient dietary Mg will lead to hypomagnesemia. Magnesium homeostasis is

TABLE 23.6 Concentration of Magnesium in Animals

Species	Fraction[a]	No. of animals	Concentration (mg/dl) (mean ± 2 SD)	Concentration (mmol/liter) (mean ± 2 SD)	Reference

a result of balance between intestinal absorption and renal excretion with additional regulation by the adrenals, thyroids, and parathyroid glands. However, no endocrine gland exerts a primary regulatory role on plasma Mg. Renal failure may result in an increased serum Mg concentration. In an immature animal the skeleton is a partially labile source of Mg, whereas in the adult the skeleton is largely inert in relation to Mg mobilization.

1. Adrenal Glands

Hyperaldosteronism is associated with a negative Mg balance, hypomagnesemia, and increased excretion of Mg in urine and feces (Simesen, 1980; Charlton and Armstrong, 1989). In adrenal insufficiency, the opposite effect occurs and serum Mg concentration is increased. The effect of mineralocorticoids on Mg homeostasis is secondary to their role in Na and K homeostasis. There is no effect of Mg concentration on aldosterone secretion. Aldosterone has no direct effect on Mg absorption by the rumen (Martens and Hammer, 1981); however, it reduces salivary Na concentration and results in compensatory increases in salivary K concentration that could enhance the inhibition of rumen Mg absorption by diets high in K (Care, 1988; Dua and Care, 1995). Although aldosterone may play a role in the pathogenesis of hypomagnesemia, its presence is not necessary, because hypomagnesemia occurred in adrenalectomized sheep that were changed from dry food to young grass (Care and Ross, 1963).

2. Thyroid Glands

Increased thyroid activity tends to depress the plasma Mg concentration (Simesen, 1980). However, thyroxine is not an important factor in the pathogenesis of hypomagnesemic tetany. Calves fed a milk diet that led to hypomagnesemia developed decreased thyroid activity and increased plasma glucose concentrations (Mulei and Daniel, 1988). Calcitonin has little or no effect on plasma Mg concentration.

3. *Parathyroid Glands*

Elevation of plasma Mg and severe hypomagnesemia inhibit secretion of parathyroid hormone (PTH), whereas moderate hypomagnesemia stimulates secretion of PTH (Mayer and Hurst, 1978; Care, 1980; Shiga *et al.*, 1980; Fiore *et al.*, 1990). However, plasma Ca is the major physiologic control of parathyroid gland function. Parathyroid hormone predominantly increases plasma Ca relative to plasma Mg, although PTH can increase plasma Mg by increasing intestinal absorption, increasing tubular reabsorption, and increasing bone resorption (Care, 1980; Littledike and Goff, 1987). Hypermagnesemia that occurs during postparturient paresis in cattle may be a result of increased PTH levels during hypocalcemia. However, hyperparathyroidism is not associated with increased serum concentrations of Mg (Claeyssens *et al.*, 1990), possibly because of the antagonistic effects of PTH and hypercalcemia on Mg excretion.

The mechanism by which hypomagnesemia results in hypocalcemia is not known; however, hypomagnesemia can impair PTH secretion and induce end-organ resistance to PTH (Abbott and Rude, 1993). Parathyroid hormone activates adenylyl cyclase in bone and kidney, which requires Mg ions. Hypomagnesemia may reduce the target-organ response to PTH (Care, 1980; Rude and Oldham, 1987). Plasma PTH remains normal, decreases, or increases in cows with hypomagnesemia and hypocalcemia, but the PTH present may have reduced physiologic effectiveness. Calves fed synthetic Mg-deficient milk developed decreased plasma Mg, Ca, and P concentrations and no change in plasma PTH or calcitonin concentrations (Rayssiguier *et al.*, 1977). Therefore, hypocalcemia associated with Mg deficiency may be attributed to the lack of PTH secretion associated with decreased serum Ca and lack of responsiveness of target organs to PTH.

VII. DISTURBANCES OF MAGNESIUM METABOLISM

Cattle and sheep are subject to clinical disorders due to Mg deficiency; however, few animals with hypomagnesemia develop clinical signs (Smith and Edwards, 1988; Hoffsis *et al.*, 1989). The disease is often a herd problem and can be classified into a rapidly developing or a slowly developing type (Allcroft, 1954). In calves and beef cattle the disease is generally of the slow type, whereas in milking cattle and sheep the onset is usually rapid. The occurrence usually coincides with the first flush grass in spring. Pregnant and lactating cows are more susceptible to hypomagnesemia because of their increased requirements for Mg.

The cause of multiple clinical signs associated with hypomagnesemic tetany is unknown, but hypomagnesemia is usually asymptomatic. Magnesium is an essential regulator of excitability in the central nervous system and blocks chemical transmission in the peripheral synapses by competitively inhibiting Ca^{2+}-dependent, presynaptic excitation–secretion coupling (Chutkow, 1990). Small decreases in $[Mg^{2+}]$ of the cerebrospinal fluid can lead to generalized convulsions. The depletion of Mg^{2+} in the extracellular fluid may be responsible for the tetanic syndrome in animals with grass tetany because of increased release of acetylcholine at neuromuscular junctions. The major clinical signs of hypomagnesemia are restlessness, muscular twitching, excitement, staggering, salivation, involuntary eye movements, increased sensitivity to strange noises, paresis and tetany, and finally convulsions and death (Chausow *et al.*, 1985; Dua and Nauriyal, 1988).

The onset of symptoms associated with hypomagnesemia cannot be directly correlated with serum Mg concentration. It is likely that serum Ca plays a concomitant role in many cases of hypomagnesemic tetany, because animals with hypomagnesemia are often hypocalcemic (Baker *et al.*, 1979). Cows and steers mobilized Ca less readily during experimental hypocalcemic stress when they were hypomagnesemic (Sansom *et al.*, 1982b). Hypocalcemia associated with hypomagnesemia may be due to reduced feed consumption, but could not be explained by decreased absorption or increased excretion of Ca in hypomagnesemic sheep (Khan *et al*, 1982). Impaired PTH secretion, failure of activation of parathyroid hormone-sensitive adenylate cyclase in bone and kidney, and decreased Ca^{2+} release from bone may also contribute to the development of hypocalcemia (Levi *et al.*, 1974; Rayssiguier *et al.*, 1977; Care, 1980; Reinhart, 1988).

In animals with Mg deficiency, intracellular Mg^{2+} is normal or only slightly reduced. However, secondary effects on cell composition occur and include a loss of K and accumulation of Ca and Na (Heaton and Rayssiguier, 1987). Decreased competition of Mg^{2+} with Ca^{2+} can lead to increased intracellular Na^{+} and Ca^{2+} concentrations, which may be important in the pathogenesis of the clinical signs of hypomagnesemia. Mineralization of blood vessels or soft tissues is a characteristic finding of Mg deficiency in laboratory animals or ruminants (Haggard *et al.*, 1978; Plannells *et al.*, 1995).

A. Hypomagnesemia in Calves

This syndrome has been intimately associated with the feeding of whole milk to calves for an extended period of time and is due to a simple dietary deficiency

of Mg (Caple and West, 1992). The onset of hypomagnesemia is related to the reduction in availability of dietary Mg that occurs with increasing age. Hypomagnesemia may be exacerbated by diarrhea (Groutides and Michell, 1990). Calves suckling beef cows are usually less susceptible to hypomagnesemia because they consume solid food with a higher Mg content (Sansom, 1981). The Mg requirement of growing calves is approximately 16–18 mg/dl (6.6-7.4 mmol/liter of milk (Simesen, 1980), which is greater than the Mg content [12 mg/dl (5.0 mmol/liter)] of cow's milk. The fastest-growing calves show the greatest depression of serum Mg, and characteristic symptoms of hypomagnesemia include excitability, muscle fasciculation, constant movement, stiff gait, twitching of the ears, and intermittent convulsions (Hoffsis *et al.*, 1989; Caple and West, 1992). Tetany may develop when the concentration of serum magnesium decreases to 0.7 mg/dl (0.3 mmol/liter) and death may occur at 0.5 mg/dl (0.2 mmol/liter). However, serum Mg concentration may be increased during the final stages of convulsions, presumably because of the release of Mg by rapidly contracting muscles.

Tetany and sudden death associated with Mg deficiency have been reported in 4-month-old suckling beef calves (Haggard *et al.*, 1978). The cattle were consuming hay and silage with a low Mg content. Deposition of calcium salts occurred in the elastic fibers of arteries in the heart, lungs, and spleen. Treatment with intravenous Mg salts and free-choice Mg-containing supplement was effective in preventing clinical signs and death.

1. Bone–Plasma Relationship

Bone Mg may serve as a source of plasma Mg under conditions of deficiency in calves. Normal bone ash Mg in cattle 6–18 months old is 1.2%, which decreases to 0.66% in cattle greater than three years old (Beighle *et al.*, 1994). Mg content of bone ash is greater in steers (1.0%) than in female cattle (0.65%) (Beighle *et al.*, 1994). Mg in bone ash will be reduced to 0.40–0.48% when plasma levels have declined to 0.7 mg/dl (0.3 mmol/liter) (Smith, 1959). Differences in bone-ash Mg may exist between bones during moderate Mg depletion (Simesen, 1980). Several weeks of oral Mg supplementation or repeated subcutaneous injections of magnesium sulfate (1 g Mg/day) will restore bone ash Mg to normal levels.

Magnesium depletion of bone apparently results from the exchange of Mg by Ca on the bone-crystal surface. Therefore, the Ca/Mg ratio of bone ash is a more sensitive indicator of Mg deficiency than bone Mg content under field conditions (Blaxter and Sharman, 1955).

2. Vitamin D and Serum Calcium and Magnesium

Addition of vitamin D (5–10 IU/kg body weight/day) to milk fed to calves does not prevent hypomagnesemia, but it does prevent hypocalcemia (Simesen, 1980). Calves with moderate hypomagnesemia (1.4–1.5 mg/dl [0.58–0.62 mmol/liter]) and hypocalcemia due to a lack of vitamin D suddenly collapse and remain almost motionless with their necks and legs stiff for periods of a few minutes to half an hour. Calves with only hypomagnesemia demonstrate nervousness, twitching ears, staring eyes, staggering, and inability to stand when serum magnesium concentrations drop below 1 mg/dl (0.4 mmol/liter). Intrarumenal administration of potassium chloride and citric acid to calves can be performed to experimentally induce severe hypomagnesemia and death (Dua *et al.*, 1988; Dua and Nauriyal, 1988).

B. Hypomagnesemia in Adult Cattle

1. Slow Type

Subclinical hypomagnesemia can occur in some animals for a long time, often for months. When serum Mg approaches critically low levels, it is accompanied by mild clinical symptoms such as nervousness and increased excitability. Certain conditions, such as fasting or reduced feed intake, may result in tetany or paresis. Often a combination of several adverse factors is found, but in most cases low dietary Mg and a low plane of nutrition are essential. The incidence of the disease seems to increase with age, and there is a tendency for recurrence in some animals. Plasma Mg and Ca levels are lower in mature than in young cows (McAdam and O'Dell, 1982). Clinical hypomagnesemia occurred in 1% of dairy cows in a survey of England and Wales, and subclinical hypomagnesemia (serum Mg less than 1.9 mg/dl [0.8 mmol/liter]) in 7% of milking cows and 15% of dry cows (Whitaker and Kelly, 1982). Subclinical hypomagnesemia increases the susceptibility to milk fever by decreasing the ability of cows to mobilize Ca in response to hypocalcemia (Sansom, 1983; Kelly, 1988; van Mosel *et al.*, 1991). Serum Mg levels less than 1.9 mg/dl (0.8 mmol/liter) were associated with decreased blood urea N, suggesting that marginal Mg deficiency may cause decreased feed intake (Scott *et al.*, 1980).

a. Seasonal Hypomagnesemia and Winter Tetany

Seasonal hypomagnesemia occurs in the bovine during the winter months and is associated with poor feed quality, cold, wet, or windy periods, and conditions

when heat loss from the body would be the greatest. Supplementary feeding will increase serum Mg, but usually not to normal levels. Clinical hypomagnesemia occurs in animals with very low serum Mg concentrations, or various degrees of hypocalcemia, and coincides with the time of minimal serum Mg concentration.

Persistent low levels of Mg may be found in beef cattle during winter months, but hypomagnesemia is accompanied by few or no clinical symptoms. Some cows may develop moderate incoordination, paresis, or tetany (winter tetany) often associated with recent parturition. Hyperirritability is common. Hypomagnesemia is associated with various degrees of hypocalcemia, and variation in clinical signs may be associated with fluctuations in the Ca/Mg ratio.

b. Effect of Feed Intake

Underfeeding or fasting is effective in lowering serum Mg concentration because of its dependence on dietary Mg and absorption from the intestinal tract. Therefore, any condition associated with a reduction in feed intake will exacerbate a preexisting hypomagnesemic state. Such conditions may include recent parturition, underfeeding, a sudden change in the quality or quantity of the ration, estrus, and weather conditions that reduce grazing or rumination time.

Serum Ca and Mg concentrations decrease in fasting, lactating cows, and starved cows may develop a syndrome similar to milk fever with serum calcium levels as low as 7.0 mg/dl (1.7 mmol/liter) and serum Mg less than 1.0 mg/dl (0.4 mmol/liter). During refeeding, serum calcium concentration quickly recovers to normal values, whereas serum Mg levels remain low during the early stages of refeeding (Fig. 23.45). Energy deficiency will reduce rumen formation of volatile fatty acids and CO_2, which are necessary for normal Mg absorption from the rumen (Martens and Rayssiguier, 1980).

c. Effect of Artificially Low Magnesium Intakes

Lactating cows develop hypomagnesemia and may develop tetany and die, if fed diets with extremely low Mg (about 2 g Mg/day) that are adequate in other nutrients. The occurrence of clinical symptoms is variable between animals, but appears to be more common in animals if serum Mg falls rapidly.

2. Rapid Type: Grass Tetany (Hypomagnesemic Tetany)

Grass tetany is the result of hypomagnesemia often associated with pasturing cattle on spring grass following winter feeding. It occurs most frequently in the first weeks of the grazing season. Grass tetany may also occur sporadically in autumn, especially during wet conditions with relatively low temperatures. After the first frost, the number of cases declines rapidly.

Winter feedstuffs that are deficient in Ca and Mg will lead to increased secretion of PTH and depletion of the mobilizeable bone Mg. Spring pastures that have increased Ca compared to winter feeds will result in increased Ca absorption, reduced secretion of PTH, and reduced bone resorption. This will lead to increased Mg uptake by bone and could result in a rapid reduction of serum Mg concentration that would predispose cattle to the development of grass tetany (Langley and Mann, 1991).

a. Clinical Biochemical Findings

Grass tetany is associated with pronounced hypomagnesemia that is in most cases combined with moderate hypocalcemia. Tetany is not dependent on the concurrent hypocalcemia (Meyer, 1977); however, cows with grass tetany may have lower plasma Ca than asymptomatic, hypomagnesemic cows (Kappel *et al.*, 1983). Low magnesium levels are usually found in clinically normal animals from the same herd. Levels below 1.8 mg/dl (0.7 mmol/liter) are classed as hypomagnesemic, and those below 1.1 mg/dl (0.5 mmol/liter) as severely hypomagnesemic. When blood Mg declines below 1.0 mg/dl (0.4 mmol/liter), appetite decreases. There is a pronounced individual susceptibility to hypomagnesemia. Serum phosphate levels may be normal or low, and there are no consistent alterations in serum Na, K, or Cl levels or in pH of the blood.

Magnesium concentration in the urine can be used as a differential-diagnostic criterion between milk fever and grass tetany. Mg content of the urine is about 50 mg/dl (21 mmol/liter) during milk fever (Sjollema, 1930), whereas during hypomagnesemia the urine has a low Mg concentration [(1.0–3.0 mg/dl) (0.4–1.2 mmol/liter]) (Simesen, 1980). Semiquantitative determinations of urine Mg may be used in the clinical setting, but it is very important to avoid fecal contamination of the urine sample. Postmortem blood samples for diagnostic purposes are of little value, because the Mg level rises rapidly after death. In such cases, analysis of a urine sample carefully removed from the bladder, in connection with analysis of several blood samples from susceptible animals in the herd, may aid the diagnosis. Criteria for Mg in the urine are as follows: >10 mg/dl (4.1 mmol/liter) is adequate; 2.0–10 mg/dl (0.8–4.1 mmol/liter) is marginal; and <2.0 mg/dl (0.8 mmol/liter) is a severe deficiency and an indicator of danger of tetany (McDowell, 1992b).

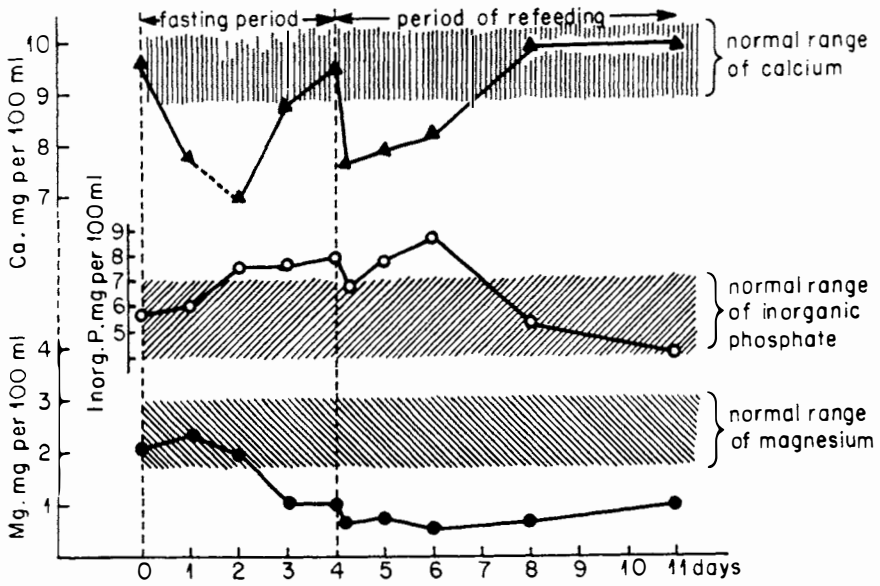

FIGURE 23.45 Changes in serum calcium, magnesium, and inorganic phosphorus during a 4-day period of fasting. From Simesen (1980).

b. Etiological Considerations

The etiology of hypomagnesemic tetany is not completely elucidated, and there are multiple opinions on its pathogenesis. Hypomagnesemia may not be the sole cause of grass tetany. Hypomagnesemic tetany is associated with (1) serum Mg concentration that falls rapidly, within a few days; (2) no depletion of bone Mg in adults; and (3) feeding grass with normal Mg content (Simesen, 1980). A major factor in the pathogenesis of hypomagnesemia is reduced absorption of Mg from the gastrointestinal tract.

The primary change resulting in tetany does not appear to be in the muscle fibers. In hypomagnesemic sheep there were no changes in motor unit potentials evoked from voluntary movements, muscle evoked potentials, nerve conduction velocity, or muscle excitability (Sims *et al.*, 1980). Clinical signs may be more closely associated with the Mg content of cerebrospinal fluid (CSF) than with blood Mg levels. A decrease in blood Mg is followed by a delayed reduction in CSF Mg concentration, which may explain why animals with very low blood Mg levels are symptom free for extended periods of time (Meyer, 1977).

c. Chemical and Mineral Composition of Pasture

The greatest single etiological factor in hypomagnesemic tetany is the decrease in net absorption of Mg from the alimentary tract. The factors responsible for reduced dietary availability of Mg are not clear; however, they may be important only during conditions of marginal supply of Mg (Simesen, 1980). Mineral indices or individual mineral constituents of grass have not demonstrated consistent relationships to hypomagnesemia in grazing cattle. Grass tetany may result either from inadequate intestinal absorption of Mg in the grass, or from substances in the grass completing with Mg absorption. Low serum Mg levels occur when Mg content of the herbage is less than 0.20%, and an increase in serum Mg can be induced by application of Mg-containing fertilizer to the pasture. Hypomagnesemia rarely occurs in cattle grazing clover-rich pastures that are high in Ca and Mg content. Acid rain has the potential to leach Mg from plants and soil (Wilkinson *et al.*, 1990).

Change from winter stall feeds to spring herbage usually involves a decrease in dietary Mg intake and a decrease in availability of dietary Mg. In the spring when young grass is growing rapidly, grass content of K, N, organic acids, and the ratio of K/(Ca + Mg) increase and the percent dry matter decreases (Grunes and Welch, 1989). These conditions predispose animals to the development of hypomagnesemia, especially in lactating cows with increased demand for Mg.

A high N and K content of grass promotes the incidence of hypomagnesemia by inhibiting Mg absorption (Kolb, 1985; Martens and Gäbel, 1986). It is unclear whether high dietary K can directly reduce plasma Mg and result in hypomagnesemic tetany, but dietary K^+ supplementation will reduce Mg absorption in ruminants (Ammerman and Henry, 1987; Beardsworth *et al.*, 1987; Martens *et al.*, 1988). A high-K diet decreased absorption of Mg from the intestinal tract in cows, but the effect was important in the etiology of hypomagnesemia only when dietary intake of Mg was low (Field

and Suttle, 1979). It was reported that a high-K (4%) and low-Mg (0.01%) diet synergistically lowered plasma Mg in sheep (Miller *et al.*, 1982). The additional hypomagnesemic effect of K must have resulted from causes other than reduced absorption of Mg.

The Na/K ratio of rumen contents may be more important than Na and K concentrations (Martens, 1980). The greater the Na/K ratio, the greater the absorption of Mg. Hypomagnesemia was reported in cattle fed a diet with normal Mg content (Luthman and Björkman, 1981), and it was suggested that the Na/K ratio of the fodder or uptake of Mg by body fat may have been important in the pathogenesis of hypomagnesemia. High K concentration of forage (due to fertilization) will reduce Mg absorption in the rumen. Low Na content of spring pastures will increase aldosterone secretion and result in increased K secretion by the rumen and salivary glands. This will further exacerbate the effect of diets high in K content (Dua and Care, 1995).

Grazing of *Phalaris tuberosa* pastures in Argentina is associated with a tendency to induce tetany in cattle. Gradual decreases in serum Mg in cattle were associated with a high K/(Ca + Mg) ratio in the pasture (Cseh *et al.*, 1984). A forage K/(Ca + Mg) ratio greater than 2.2 was a more sensitive indicator of tetanic pasture conditions than Mg content alone (Grunes and Welch, 1989).

Plasma insulin levels were increased in cows on a fescue–bluegrass pasture and were negatively correlated with plasma Mg. In addition, injection of insulin into two cows reduced plasma K and Mg by 20% (Miller *et al.*, 1980). Elevated plasma insulin levels and hypomagnesemia were also present in 10 cows overwintered on pasture with low Mg content and moved to lush pasture with high K content (Ramsey *et al.*, 1979b). In contrast, there was no change in plasma insulin, Ca, or K in hypomagnesemic cows fed fescue pasture fertilized with N and K or hay from a pasture that produced grass tetany in grazing cows (Ramsey *et al.*, 1979a).

d. Rumen Ammonia

Ammonia concentration increases in the rumen of cows during the first few days of grass feeding, but there are conflicting results on the effect of dietary crude protein and rumen ammonia concentration on Mg absorption. It has been suggested that only an acute rise in rumen ammonia may reduce Mg absorption, and that this effect is diminished as the rumen adapts to elevated NH_3 concentrations (Martens and Rayssiguier, 1980). Physiologic concentrations of ammonium ion decreased Mg absorption in an isolated rumen model (Martens *et al.*, 1988). Energy deficiency will also lead to elevated rumen ammonia concentrations.

e. Rumen Aluminum

High concentrations of Al in forage may be associated with an increased incidence of grass tetany, but this is not due to decreased intestinal Mg absorption (Fontenot *et al.*, 1989). Aluminum does not affect Mg absorption, excretion, or retention, but can decrease Mg concentration in serum, bone, and kidney and interfere with Mg-dependent ATP activity (Allen, 1987). Interactions of Al with Ca and parathyroid hormone metabolism may secondarily result in hypomagnesemia (Fontenot *et al.*, 1989). In a series of 32 cows, rumen Al concentration was greater in cows with grass tetany than in subclinical hypomagnesemic and control cows (Kappel *et al.*, 1983). Addition of $AlSO_4$ to the rumen decreased plasma Mg 34% in cows with limited amounts of Mg in the feed. Administration of Al (4 and 8 g/Kg feed) reduced serum Mg 32% in steers (Allen *et al.*, 1980).

f. Trigger Effect

The clinical symptoms of hypomagnesemia may be precipitated by (1) sudden reduction in feed intake, (2) adverse weather, (3) estrus, (4) sudden reductions in dietary Mg, (5) sudden change in diet, (6) transportation, or (7) any stressful environmental stimulus (Simesen, 1980). Muscular fibrillations may be present a few days prior to tetany. Epinephrine-induced lipolysis may result in the sequestration of Mg in fat-cell membranes (Rayssiguier, 1977). Infusion of norepinephrine reduced serum Mg and Ca in sheep, and energy deficiency prolonged these effects (Terashima *et al.*, 1983; Wittwer *et al.*, 1995b).

Cold (2–5°C) and deficient dietary intake of Mg synergistically reduced plasma Mg in sheep (Terashima *et al.*, 1982). Low environmental temperature further reduced plasma Mg in hypomagnesemic sheep on a Mg-deficient diet, but increased plasma Mg in sheep fed a diet with adequate Mg (Hilgers, 1979). Urinary excretion of Mg was increased and serum Mg concentration was decreased in four ewes at an environmental temperature of 8.8°C (Shiga *et al.*, 1979).

In beef cows in Ontario, hypomagnesemia developed 24 hours before introduction to pasture, possibly because of the stress of prepasture handling (Hidiroglou *et al.*, 1981). No grass tetany was observed in these cows, and Mg in mineral feeds did not prevent the hypomagnesemia.

3. Methods of Prevention

The essential aim of prevention is to increase daily intake of Mg. Extra dietary Mg may be provided in multiple forms and by a number of routes (Allen and

Davies, 1981; Mayland and Wilkinson, 1989; Caple and West, 1992; Wittwer *et al.*, 1995a). A practical and cost-effective method of supplementing dietary Mg is to provide free-choice Mg supplements (Robinson *et al.*, 1989). Magnesium alloy bullets have not been useful in preventing hypomagnesemia because of variable rates or too-slow decomposition in the reticulorumen (Stuedemann *et al.*, 1984). Absorption of Mg from the oxide form is more efficient than from sulfate, carbonate, or dolomite forms. Intestinal Mg absorption is greater in Brahman than in Jersey, Holstein, or Hereford cows (Greene *et al.*, 1989). Therefore, selective breeding has the potential to reduce the incidence of hypomagnesemia-related disorders in cattle. In addition, selective plant breeding has the ability to increase grass Mg content (Sleper *et al.*, 1989).

C. Miscellaneous Conditions

1. Hypomagnesemia in Sheep

Clinical symptoms of hypomagnesemia occur in sheep, and the pathogenic factors in the development of hypomagnesemia are similar to those for cows (Kelly, 1979; Caple and West, 1992). There is a marked variation in susceptibility between animals. Ewes with twins are more prone to hypomagnesemia than ewes with single lambs. Plasma Mg increases during the last 3 weeks of pregnancy, but decreases at lambing and for 3 weeks after lambing (Sansom *et al.*, 1982a). This is in contrast to plasma Ca, which is lowest 3–4 weeks prior to lambing due to formation of the fetal skeleton. Sheep are most susceptible to hypomagnesemia at about 2–6 weeks after lambing, which is exacerbated by lush spring pastures (Kelly, 1979).

Magnesium supplementation of ewes with twin lambs did not increase serum Mg concentration from a mean of 1.8 mg/dl (0.7 mmol/liter) and did not alter milk consumption or weight gain of lambs, even though 36% of the ewes had serum Mg concentrations less than 1.7 mg/dl (0.7 mmol/liter) (Bray *et al.*, 1987). Sheep with poor dental health have lower serum Mg concentrations than do flocks with normal dental health (Spence *et al.*, 1985). Old ewes with twins and worn teeth developed postpartum hypomagnesemia and ketosis that resulted in anorexia, blindness, and incoordination (Jopp and Quinlivan, 1981). Treatment was not effective, but feeding good-quality hay served as a preventative.

Transport tetany of lambs occurs within 10 days of arrival at the feedlot (Lucas *et al.*, 1982). Affected lambs develop hypomagnesemia, hypocalcemia, and hyperphosphatemia as a result of fasting and stress.

2. Wheat Pasture Poisoning

Wheat pasture poisoning is a form of hypomagnesemia that occurs during grazing of lush wheat pastures that contain high K and protein. Such rations may induce tetany by interfering with absorption or retention of Mg. Mixed wheat and rye pastures that were associated with tetany had marked increases in K, protein, digestibility, and a peak K/(Ca + Mg) ratio of 3.2 (Bohman *et al.*, 1983b). Plasma Mg concentrations in affected cattle were low (1.7 mg/dl [0.7 mmol/liter]), but were lower 15 days before and 6 days after tetany (1.2 mg/dl [0.5 mmol/liter]) (Bohman *et al.*, 1983a). At the time of tetany, plasma Ca was 4.1 mg/dl (1.0 mmol/liter) and was associated with increased plasma parathyroid hormone and 1,25-dihydroxyvitamin D. Tetany was thus due to hypocalcemia and moderate hypomagnesemia. The hypomagnesemia did not alter PTH secretion or 1,25-dihydroxyvitamin D production in response to hypocalcemia.

3. Effect of Magnesium Administration

The anesthetic level of serum Mg in the ruminant and dog was approximately 14 mg/dl (5.8 mmol/liter) and the lethal level about 20 mg/dl (8.2 mmol/liter) (Bowen *et al.*, 1970b). High serum concentrations of Mg can induce coma, respiratory arrest, and diastolic cardiac arrest. The level of Mg necessary to cause death is much higher when Ca is administered concurrently. The anesthetic or lethal effect of Mg is due to blockade of neuromuscular transmission without depression of the central nervous system (Bowen *et al.*, 1970b). Therefore, infusion of magnesium sulfate should not be used as a method of euthanasia. Clinical administration of magnesium sulfate may be useful therapy for muscular seizures associated with eclampsia (Lucas *et al.*, 1995).

Excessive dietary supplementation with Mg will lead to hypermagnesemia, reduced serum calcium concentration, and potential toxicosis, including diarrhea, weight loss, drowsiness, and death (Thiemann *et al.*, 1987). Sheep fed high levels of Mg (up to 2.4% of the diet) developed diarrhea with no other clinical signs (Chester-Jones *et al.*, 1989), whereas cattle fed up to 4.7% Mg in the diet developed diarrhea and lethargy (Chester-Jones *et al.*, 1990). Administration of $Mg(OH)_2$ to cattle for gastrointestinal disorders has the potential to increase serum Mg concentrations and induce metabolic acidosis (Kasari *et al.*, 1990).

4. Reproduction

Some investigations have provided data to support a role for Mg in fertility and the incidence of retained placenta in cattle. Magnesium supplementation has

reduced the incidence of retained placenta and puerperal endometritis and has increased the conception rate in cows with hypomagnesemia (Krupnik, 1985). Supplementation of cows with Ca and Mg increased conception rates of first inseminations, and the interval from calving to conception was correlated with plasma Mg (Ingraham *et al.*, 1987a). In one study no association was found between hypomagnesemia and retained placenta in cattle (Gibasiewicz, 1984), whereas a reduced incidence of retained placenta in cattle with subclinical hypomagnesemia and supplementation of dietary Mg was reported (Krupnik and Marcinkowski, 1983). Cows supplemented with Mg and Cu had improved fertility, but cows supplemented with Mg or Cu alone did not (Ingraham *et al.*, 1987b). Erythrocyte Mg concentration was correlated with fertility in dairy cows (Mulei *et al.*, 1988).

5. Hypomagnesemia in Goats

Goats grazing fertilized grass pastures with high levels of K and N and low Na developed decreased plasma Mg concentration that was associated with poor growth and decreased milk yield (Rayssiguier, 1984). Experimental hypomagnesemia in goats resulted in tetany, convulsions, and death with hepatic and renal degeneration (Hazarika *et al.*, 1991; Hazarika and Pandey, 1993).

6. Hypomagnesemia and Critical-Care Patients

Critically ill humans have a high incidence of hypomagnesemia, and recent evidence indicates that the same is true for animal patients (Michell, 1991; Martins *et al.*, 1995). The causes include decreased Mg intake in anorectic animals, lack of Mg supplementation to parenteral fluids in animals on long-term fluid therapy or dialysis, excess gastrointestinal loss of Mg, redistribution of Mg intracellularly, or tissue sequestration of Mg. Some drugs can also increase Mg renal loss, including diuretics (e.g., furosemide, thiazides, and mannitol), cardiac glycosides, and aminoglycosides. Magnesium can be shifted intracellularly by administration of glucose, insulin, or amino acids. Renal excretion of Mg is increased in patients with diabetes mellitus, hyperthyroidism, and primary hyperparathyroidism. Hypomagnesemia also may result from excessive catecholamine secretion in critically ill or stressed animals and bacteremia during sepsis (Elisaf and Siamopoulos, 1995).

Magnesium is a vital ion, required for normal myocardial function. Therefore, it is important to prevent hypomagnesemia in cardiac critical-care patients (de Morais and Hansen, 1995; Stepien, 1995). Magnesium is a necessary cofactor for the Na/K ATPase in myocytes. Mg deficiency may be associated with decreased Na/K ATPase activity, which would lead to increased intracellular K^+ concentration, increased Purkinje-fiber excitability, and potential arrhythmia generation. In addition, Mg deficiency is associated with increased circulating levels of macrophage-derived cytokines (interleukin-1, interleukin-6, and tumor necrosis factor α) that potentiate cardiovascular pathology (Weglicki *et al.*, 1992).

Mg concentration is not commonly measured in animal patients, but certain electrolyte abnormalities may occur simultaneously with hypomagnesemia and serve as predictors of hypomagnesemia. These include hypokalemia, hypophosphatemia, hyponatremia, and hypocalcemia (Whang *et al.*, 1984). Hypokalemia is the best predictor of the four electrolyte disturbances.

7. Magnesium-Associated Urolithiasis and Enteroliths

a. Ruminants

Calves fed a diet with excess Mg (1.4% as MgO) had decreased feed intake and growth rate, increased serum creatinine and Mg, and decreased serum Ca (Kallfelz *et al.*, 1987). Calves fed excess Mg or Mg and P (1.6%) developed urinary-tract obstructions due to uroliths composed of calcium apatite, whereas calves fed excess Mg and Ca (1.8%) did not develop urolithiasis. Excess dietary Ca had a protective effect on Mg-associated urolithiasis. Diets with Mg contents greater than 0.35% also may predispose male lambs to urolithiasis (Poole, 1989), but the effect of high dietary Mg is not observed in all investigations (Cuddeford, 1987). Lowering the phosphorus content of diets that are high in Mg and that induce urolithiasis reduces the incidence of urolithiasis (Poole, 1989).

b. Feline

Struvite ($MgNH_4PO_4 \cdot 6H_2O$) urolithiasis predisposes cats to urinary-tract blockage, especially in male cats or cats with lower urinary-tract disease (Buffington, 1994; Buffington *et al.*, 1996). The incidence of struvite urolithiasis in cats is related to the diet (ash and Mg content) and the acid–base status of the animal. Urinary Mg concentration and excretion are highly correlated with Mg intake (Pastoor *et al.*, 1995b). Diets rich in fat and energy decrease dry matter and Mg intake, increase urine volume, and decrease fecal water excretion (Sauer *et al.*, 1985). Increased calcium or phosphate intake will decrease Mg absorption and urinary Mg concentration in cats (Pastoor *et al.*, 1994b, 1995a). Diets high in Mg (especially the alkaline forms, e.g., MgO) and alkaline urine are associated with struvite urolithiasis. The epidemiology of urinary calculi in cats has

changed, with a decrease in struvite calculi and an increase in calcium oxalate calculi (Buffington, 1994). This is likely due to feeding cats diets with low Mg content and to the use of urine acidifiers (methionine and ammonium chloride). Acidifying diets may induce depletion of body stores of potassium and increase fractional excretion of calcium.

Obstructive urinary disease can be induced in cats fed high levels of MgO in dry (0.45% Mg) and moist diets (0.75–1.0% Mg) (Finco *et al.*, 1985). Magnesium homeostasis is maintained by increased urinary excretion of Mg. However, urinary Mg did not correlate well with dietary Mg, possibly because of differences in intestinal absorption of Mg between diets or because of precipitation of struvite in the urinary tract. Urethral obstruction may result from blockage by struvite crystals or uroliths. Not all cats with high urine Mg concentrations developed obstruction, indicating that factors other than Mg ingestion play a role in the development of obstruction. The effect of Mg on struvite urolithiasis depends on urinary pH and the form of Mg in the diet (Buffington *et al.*, 1985, 1990). In cats fed purified diets containing 0.5% Mg, MgO, or $MgCl_2$, the urinary pH was the lowest in the $MgCl_2$-fed group. Urinary struvite crystals were found in all control (0.05% Mg diet) and MgO-fed cats, but not in $MgCl_2$-fed cats. Feeding of $CaCl_2$ to cats will also reduce urinary pH (Pastoor *et al.*, 1994a). Meal-fed cats had higher urinary pH than *ad libitum*-fed cats. Alkaline urine was present in obstructed cats fed MgO and dry diets; however, acid urine was present in obstructed cats fed MgO and moist diets (Finco *et al.*, 1985).

Idiopathic lower urinary-tract disease (feline idiopathic cystitis, FIC) in cats is a common cause of increased frequency and urgency of urination and is associated with sterile urine. The pathogenesis of this disease may be related to abnormal regulation of neuropeptides in the bladder and the induction of neurogenic inflammation (Buffington, 1994; Buffington *et al.*, 1996). Struvite urolithiasis is no longer a frequent symptom in cats with idiopathic lower urinary-tract disease. Experimental or natural Mg-induced urinary obstruction due to struvite urolithiasis differs from idiopathic urinary-tract disease. However, struvite urolithiasis can serve as one predisposing factor in a multitude of factors associated with the pathogenesis of urinary-tract blockage in certain cats with idiopathic urinary-tract disease.

c. Horses

Horses fed high levels of Mg in combination with high protein and phosphate are predisposed to develop ammonium–magnesium–phosphate enteroliths in the colon. In the horse, Mg may be excreted in the colon and can precipitate with high concentrations of phosphate that enter the colon from the small intestine (Blue, 1979; Meyer and Zentek, 1990).

8. Hypermagnesemia

Hypermagnesemia may occur in animals with chronic renal failure, hypocalcemia, cows with parturient paresis, and sheep administered epidermal growth factor (Halse, 1984; Brautbar *et al.*, 1990; Gow *et al.*, 1992b; Riond *et al.*, 1995b). The mechanism of hypermagnesemia in cows with parturient paresis is unknown, but increased renal reabsorption of Mg induced by PTH could play a significant role (Riond *et al.*, 1995b). Hypermagnesemia in sheep administered epidermal growth factor is associated with decreased urinary Mg excretion (Gow *et al.*, 1992a).

CHAPTER

24

The Vitamins

ROBERT B. RUCKER AND JAMES G. MORRIS

I. INTRODUCTION AND BRIEF HISTORY

The concept that food components are linked to tissue growth and repair was evident in the writings of Greek philosophers as early as the fifth century B.C. Nutrition was one of the topics in the Hippocratic collection. The first disease to be recognized as nutrition-related may have been night blindness. An ancient Egyptian medical text, the *Papyrusebers* (written about 1550–1570 B.C.), prescribed "beef liver, roasted, squeezed, placed against the eye" for various eye diseases, including night blindness. In China, liver applied topically to the eye was also used as a treatment for night blindness (Guggenheim, 1981). By the mid-1700s, the curative effects of certain foods had been linked to a number of diseases. James Lynn, a physician in England, assembled his classic treatise that fresh fruits and vegetables seemed effective in curing scurvy. By the 1800s, the association of corn with pellagra was made, and by the 1900s, Eijkman, a Dutch physician working in Java, reported that consumption of polished rice was related to polyneuritis, that is, beriberi. However, the concept that specific diseases could be caused by the lack of a specific compound in the diet did not evolve until the beginning of the twentieth century. Following the success of Pasteur and the "germ theory," many diseases now recognized as nutritional in origin were initially attributed to infectious agents. It was widely held that only the gross constituents of the diet, that is, carbohydrates, protein, fat, and minerals, were needed for complete nourishment. As F. G. Hopkins, one of the founders of nutrition as a science, noted in his 1929 Nobel lecture, "the quantitative data obtained and the attractive circumstance that such data appeared to supply a real measure of nutritional needs . . . caused a feeling that knowledge concerning nutrition was adequate and complete." Nevertheless, the view that small amounts of certain factors seemed necessary for optimal growth and development soon evolved. A foundation was provided from these early studies for the formulation of the vitamin theory. The term vitamin was suggested by Casimir Funk (Funk, 1911) to indicate "vital amines," a class of substances whose lack he proposed as be-

ing responsible for diseases such as scurvy, rickets, pellagra, and beriberi (Guggenheim, 1981; Bender, 1922).

The effort to define the nature of vitamins was first directed at lipid substances that were demonstrated to be essential in the diet of animals. McCollum and Davis at Wisconsin showed that butter or egg yolk, but not lard, supplied a lipid-soluble factor that was necessary for growth in rats. As a consequence of their studies, the first fat-soluble substance with growth-promoting properties (designated as Vitamin A) was reported in the early 1900s, a time considered as the beginning of the "age" of vitamin exploration (Guggenheim, 1981; Darby and Jukes, 1992). Now, there is constant awareness and sensitivity to the possibility of dietary vitamin deficiencies (and excesses). Nutritional deficiencies are not uncommon in animals, particularly animals fed monotonous diets for therapeutic or other reasons. A number of subsidiary and contributory factors may also lead to vitamin-related diseases, in addition to a low concentration of the vitamin in the diet. These factors include interference with normal food intake, loss of appetite (anorexia), impaired absorption or utilization, increased excretion, and the presence of antagonists. Stressful physiological states that increase nutrient demands, such as lactation, may also perturb the vitamin status of animals.

II. DEFINITION, GENERAL PROPERTIES, AND OVERVIEW OF FUNCTIONS

No definition for vitamins is totally satisfactory. As a group of compounds, vitamins have been defined as organic substances present in minute amounts in natural foodstuffs that are essential to normal metabolism, the lack of which in the diet causes deficiency diseases. This definition, however, is not specific and could apply to a number of compounds derived from the secondary metabolism of amino acids, simple sugars, and fatty acids. Table 24.1 lists the vitamins. The compounds listed are categorized as vitamins because in most mammals they represent essential organic compounds not easily classified with the macronutrients. Some may be synthesized, but in insufficient amounts to meet normal needs during critical developmental periods.

Vitamins can also be classified according to chemical and physical properties, such as whether they are soluble in aqueous solution or lipid solvents (Friedrich, 1988). Those vitamins that are soluble in lipid solvents (vitamins A, D, E, and K) are absorbed and transported by conventional lipid transport processes. For water-soluble vitamins, respective solubility coefficients are major factors that dictate ease of absorption. Within physiological ranges of intake, water-soluble vitamins are usually absorbed by active processes. At high concentrations (5–10 times or more the typical requirements), passive processes may also be involved. Further, most vitamins are absorbed in the duodenum. Exceptions are folic acid and vitamin B_{12}. Folic acid is absorbed throughout the upper and mid-intestine; B_{12} is absorbed only in the ileum of some species. The details of these processes will be outlined later. The diversity and complexity of vitamin metabolism and processing, however, should be appreciated at the outset. Vitamins in foods are often present as cofactors or in highly modified forms. Pancreatic and intestinal cell-derived enzymes are required to initiate normal uptake in absorption. Nucleosidases, phosphatases, and peptidases are key factors in processing cofactors to vitamins (Fig. 24.1, Rose, 1996).

Vitamins serve a broad range of functions. For example, some of the actions of vitamin A and vitamin D are best described as consistent with the actions of steroid hormones; derivatives of vitamin A are also important signal transduction mediators. In contrast, vitamin K acts principally as an enzymatic cofactor. Vitamin E is novel in that it acts as a chemical agent scavenging free-radical containing lipids and oxidants, independent of any direct association with an enzyme. In contrast , most of the water-soluble vitamins act as cofactors or serve coenzymes.

The varied functions of vitamins have also complicated the development of a simple system of classification or nomenclature. When the vitamins were originally discovered they were isolated as fractions from selected foods, and as their exact chemical composition was seldom known, a system of letter designations was developed. However, this system became complicated when it was discovered that some of the functions originally ascribed to vitamins were due to other substances, such as one of the essential amino acids. Consequently, the designation of vitamins by letters was not systematically pursued. Similarly, the lack of chemical composition data resulted in a complex system of expressing dosages as arbitrarily defined units, in which a unit was defined in relationship to a biological phenomenon in a given animal model. With advancements in analytical methodology, the chemical structure of vitamins was defined, their functional roles clarified, and assays developed to define an adequate status.

Indeed, the problem of assessing the dietary requirement and adequacy for various vitamins has long plagued nutritionists. Measurements of the concentration in the diet do not account for availability of the vitamin. Four approaches are used to assess the vitamin status of animals: 1) measuring vitamin concentra-

TABLE 24.1 The Vitamins

Vitamin	Function	Relative need per 1000 Kcal or 4180 J	Common sources
Fat-soluble			
Vitamin A	Gene expression, vision, signal transduction	0.3–0.6 μg as retinal equivalents	Plants (carotenes); most organ meats, particularly liver, high in retinyl esters
Vitamin D	Gene expression, signal transduction, calcium metabolism	1–3 μg cholecalciferol, if Ca and P intakes are adequate	Marine fish, eggs, liver oils, meat, UV-irradiated plant and animal sterols
Vitamin E	Antioxidant	2–5 mg	Vegetable and seed oils, green leaves
Vitamin K	Enzyme cofactor for γ-carboxyglutamic acid formation, blood clotting, osteocalcin formation	50–150 μg	Green plants, egg yolk, milk and cheese, bacteria
Water-soluble			
Ascorbic acid	Redox cofactor, antioxidant, antiscurvy	10–40 mg	Citrus fruits, fruits and vegetables in general
Niacin	Redox cofactor, mono- and polyadenylations, antipellagra factor	2–10 mg	Tryptophan-rich foods, milk, meat
Riboflavin (B_2)	Redox cofactor	300–600 μg	Milk, organ meats, eggs, nuts, seeds, fungi, bacteria
Thiamin (B_1)	Carbohydrate metabolism, decarboxylation, transketolation antiberiberi factor	300–600 μg	Seeds, nuts, meat, yeast, bacteria
Pyridoxine (B_6)	Decarboxylation, aldol condensations, transamination	400–600 μg	Yeast, organ meats, wheat germ, vegetables
Pantothenic acid	Acyl and acetyl transport	2–4 mg	Yeast, plants, grains, eggs, organ meats
Biotin	Carboxylation and transcarboxylation	20–40 μg	Yeast, egg yolks, organ meats, bacteria, grains
Folic acid	Single-carbon transfers, antianemia factor, DNA and purine synthesis	75–150 μg	Green plants, organ meats, eggs, cheese
Cobalamin (B_{12})	Single-carbon transfers, mutase reactions, antianemia factor	0.5 μg	Animal products, milk, fish, eggs, meat
Choline	Lipid transport, neural signal transduction	100–150 mg	Meat, cereal, legumes, lecithin, egg yolk
Inositol	Signal transduction	50–100 mg	Meat, milk, grains (oil), legumes

tions in biological fluids, such as blood plasma; 2) administering the vitamin to the animal and measuring urinary excretion of the vitamin or metabolized products, as an index of the saturation of body stores; 3) loading tests, in which the animal is given a compound that requires the vitamin for its metabolism, and 4) urinary excretion of a product is measured; and enzyme stimulation tests, in which rate of a reaction is measured before and after the addition of the vitamin. Examples that are highlighted in subsequent sections are the histidine loading test for the assessment of folate and vitamin B_{12}, and enzyme stimulation tests such as the erythrocyte glutathione reductase and transketolase tests for riboflavin and thiamin, respectively, and the aminotransferase stimulation tests for vitamin B_6.

In the sections that follow, each of the known vitamins and substances that act as "conditional vitamins" will be described. A goal of each section is to provide an overview pertaining to both physiological and biochemical functions of given vitamins. Issues important to nutritional assessment, deficiencies, and effects of excesses will be addressed. For additional references and information, one or two seminal reviews or monographs are cited for each section.

I. FAT-SOLUBLE VITAMINS

A. Vitamin A

1. Introduction

Vitamin A-related deficiency diseases and their cures have been described throughout written history (Guggenheim, 1981). From a modern perspective, the observations by Hopkins, Stepp, and others that a growth-stimulating factor could be extracted from milk into alcohol was a seminal step that eventually led to the identification of vitamin A. The growth-promoting factor was described as being present in egg yolk, but-

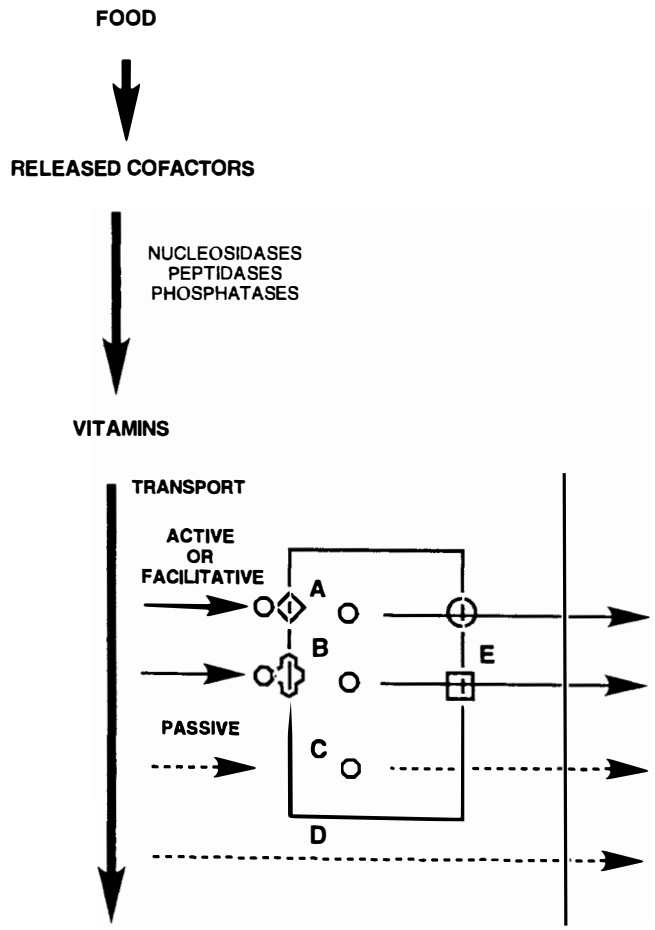

FIGURE 24.1 Steps in vitamin absorption, digestion, and processing. The processing of vitamins requires a number of steps: mastication, hydration, acidification, and the action of numerous enzymes. The vitamins usually enter the body by active or facilitative processes (A or B). At high concentrations the absorption of many vitamins is passive (C) or can occur by pericellular diffusion (D). The uptake of vitamins from the luminal surface maybe facilitative, whereas active transport is often involved for delivery of the vitamin into circulation from the serosal membrane (E). In some cases the transport across the intestinal cell involves packaging into a transport particle, such as chylomicra.

ter, and cod liver oil. In nature, vitamin A is largely present as lipid esters in animal tissues and as provitamin forms of vitamin A in plants. These provitamins belong to the carotenoid family of compounds, for example, β-carotene.

The structures and recommended names of naturally occurring and commercial forms of vitamin A and carotenoids are shown in Fig. 24.2. Once chemical features for the carotenoids and retinoids were resolved in the 1940s and 1950s, studies of their biological function were undertaken and commercial synthesis of vitamin A and vitamin A-like molecules proceeded rapidly.

2. *Proforms of Vitamin A: The Carotenoids*

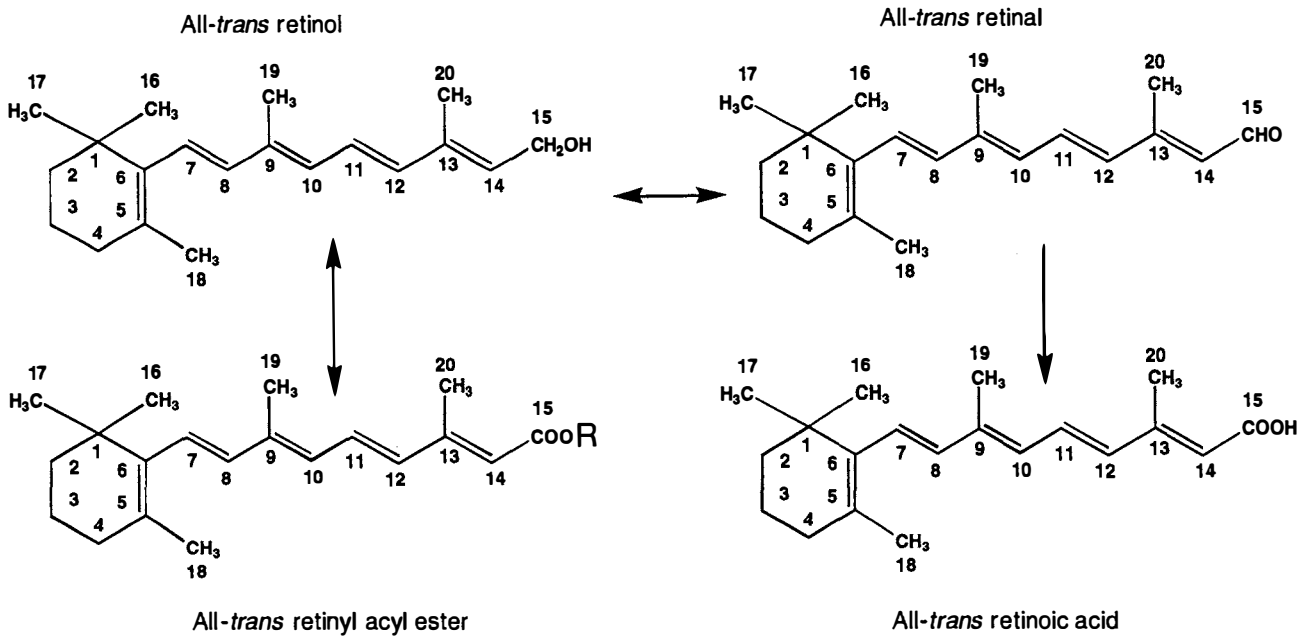
More than 600 carotenoids have been isolated; however, only about 50 appear to have some degree of provitamin A activity. The proforms of vitamin A, the carotenoids, represent an usual class of biological pigments. In plants and prokaryotes, carotenoids serve as mediators of photo-energy-related processes by capturing energy from light. Carotenoids can also quench singlet oxygen and may act as both antioxidants and pro-oxidants. Carotenoids are rich in conjugated double bonds, and besides being designed to interact with light, they are also readily destroyed by intense light, particularly UV light (Sporn *et al.*, 1994). In order to act as a provitamin A, a carotenoid must contain a β-ionone structure (Fig. 24.2).

In plants, carotenoids occur in association with chloroplasts, complexed with protein and other lipids, and provide the main source of provitamin A for animals. The provitamin A potency of plants is largely retained when forage crops are made into hays, but declines with the uptake of oxygen on storage. Grains, with some exceptions (e.g., yellow corn), are minor sources of provitamin A. Among the legume grains, chickpeas and green and black gams are the best sources of provitamin A. The richest source of carotenoid is red palm oil, which contains 500 μg of mixed α- and β-carotene per milliliter. About 7 ml/day of red palm oil can easily meet the nutritional needs of a child or small animal.

3. *Metabolism*

Following ingestion, retinoyl esters in animal products are hydrolyzed to retinol by pancreatic hydrolases (esterases) or lipid hydrolases localized on the surface of the brush border of intestinal cells. Bile and dietary lipid facilitate the absorption process, as retinoyl esters must be part of a lipid micelle to be absorbed. The micellar structures enhance fusion into the microvillus of intestinal cells. Similarly, lipid micelles enhance the uptake of carotenoids into intestinal cells. The bioavailability and digestion of vitamin A and carotenoids are affected by the overall nutritional status and the integrity of the intestinal microvillus. Absorption of physiological doses of vitamin A in most animals is 70 to 90%, but the efficiency of absorption for carotenoids added to diets is 40 to 60%, depending on the type of carotenoid. Carotenoids contained in plant chloroplasts, however, are often very poorly absorbed (less than 10%) because of the low digestibility of chloroplasts and release of carotenoids.

In the intestinal mucosal cell, some carotenoids are oxidized to both carotinals or retinals (Fig. 24.3). Most of the retinal is next reduced by alcohol dehydrogenases to retinol and is reesterified. Retinol and associ-



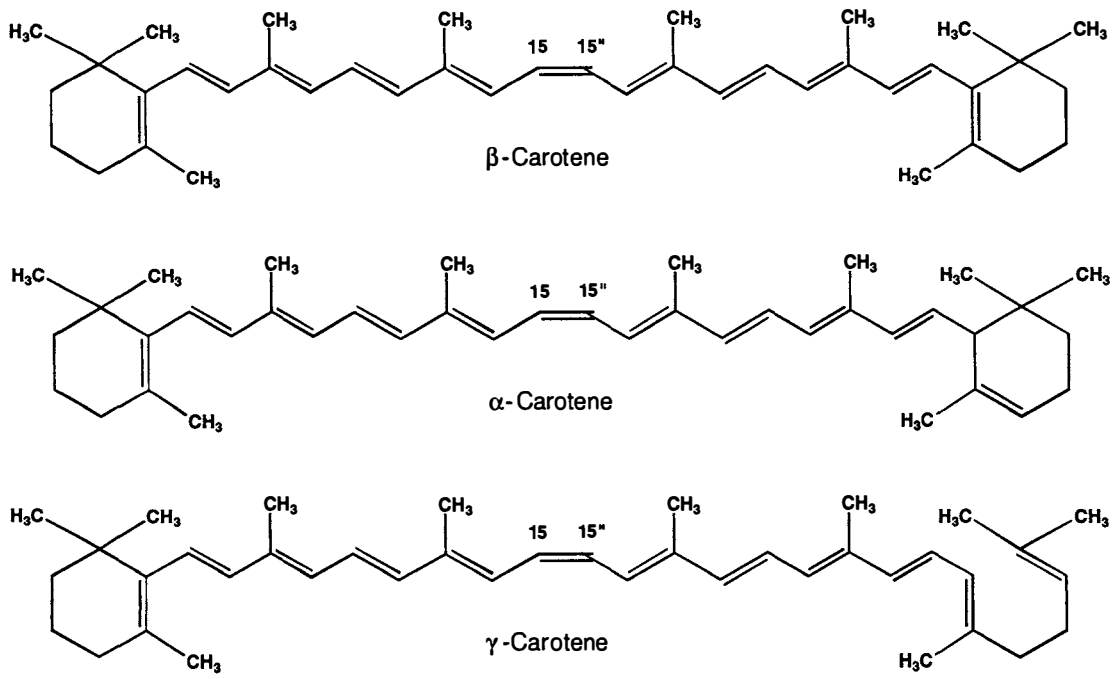


FIGURE 24.2 Structures of common retinoids and carotenoids. The structures for all-*trans* retinol, all-*trans* retinal, all-*trans* retinyl acyl (designated R) ester, and all-*trans* retinoic acid are shown. Note that the oxidation of retinal to retinoic acid is not reversible. β-Carotene is the most potent vitamin A precursor. For vitamin A activity the presence of a β-ionone is essential. β-carotene contains two β-ionone rings. If β-carotene is cleaved at the 15,15′ position, theoretically two retinals are produced. In contrast, α-carotene and γ-carotene result in only one active retinoid when cleaved.

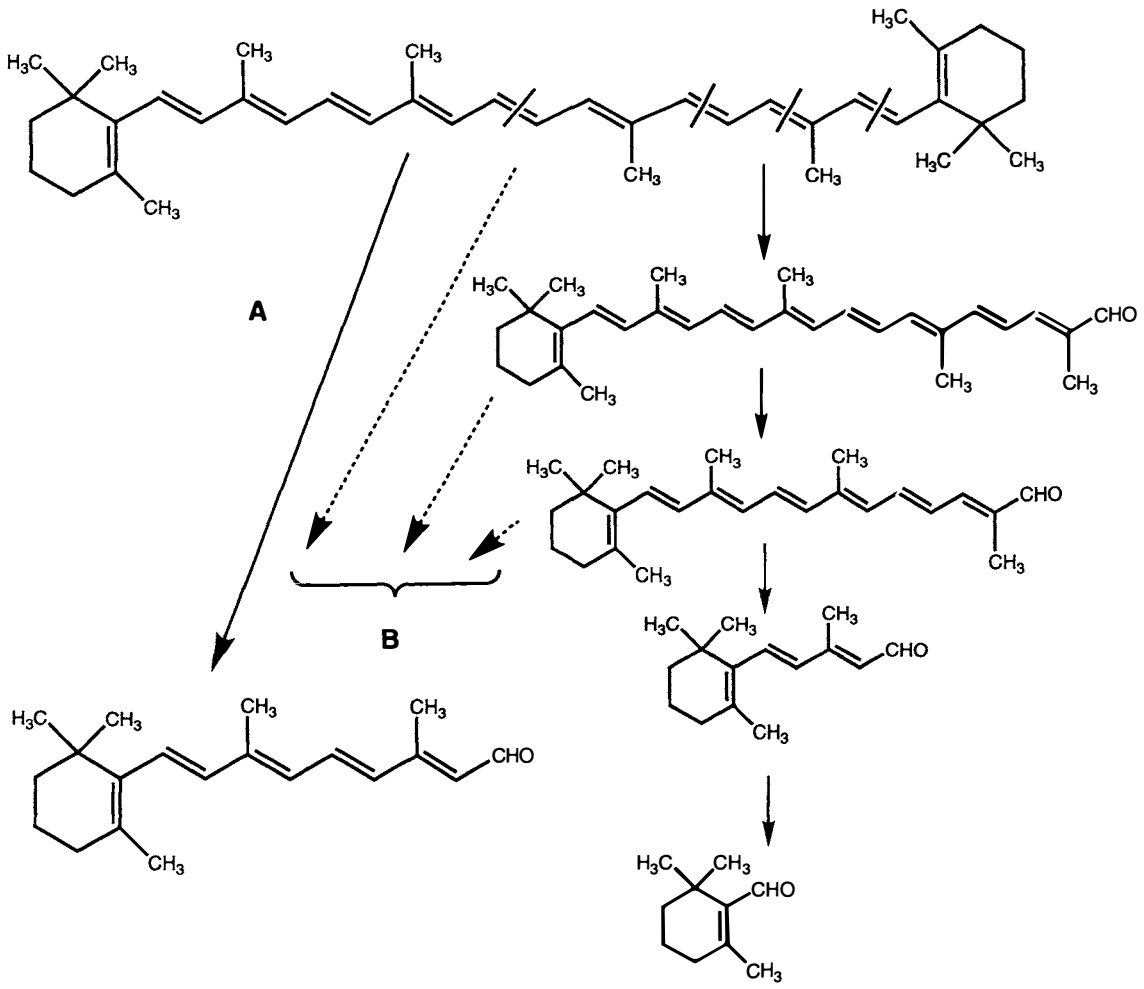

FIGURE 24.3 Cleavage of carotenoids occurs by two distinct routes. Route A represents enzymatic or intrinsic cleavage at the 15,15′ position. However, chemical or extrinsic cleavage (routes designated B) can result at several sites to generate complex mixtures of carotenals.

ated esters are then incorporated into chylomicra, which are released into the lymph. Both intrinsic and extrinsic pathways are proposed for the oxidative cleavage of carotenoids with provitamin A activity to retinal (Sporn *et al.*, 1994; Packer, 1990). Evidence for the intrinsic pathway is based on the direct production of retinal from β-carotene, presumably by the action of a 15,15′-β-carotene dioxygenase. The extrinsic pathway is based on evidence of nonenzymatic chemical cleavage of carotenoids to carotinals.

Chylomicra particles in lymph are carried to the liver, where about 75% of the retinol-derived products are cleared in most animals. In liver, the processing of vitamin A occurs primarily in liver stellate cells, where vitamin A is stored as retinoyl ester, passed on to adjacent parenchymal cells, directed to retinol-binding protein (RBP), a unique retinol-transport protein, or oxidized. Figure 24.4 describes the major feature of vitamin A metabolism in liver cells.

As vitamin A is needed by the body, retinoyl ester in the liver is hydrolyzed and released as retinol bound to RBP, which binds one molecule of vitamin A as retinol per molecule of RBP. When released into circulation, RBP exists as a protein complex with transthyretin, which binds thyroxin. The RBP–transthyretin complex transports vitamin A and thyroxins to their respective target cells. The primary target cells for vitamin A are the epithelial cells.

The association constant (K_a) between retinol and the transthyretin–RBP complex is relatively low, approximately 10^6 M/liter. This association constant is about the same as that for the binding of retinol to other proteins, such as albumin, which does not imply a high degree of specificity. In cell cultures, RBP is not

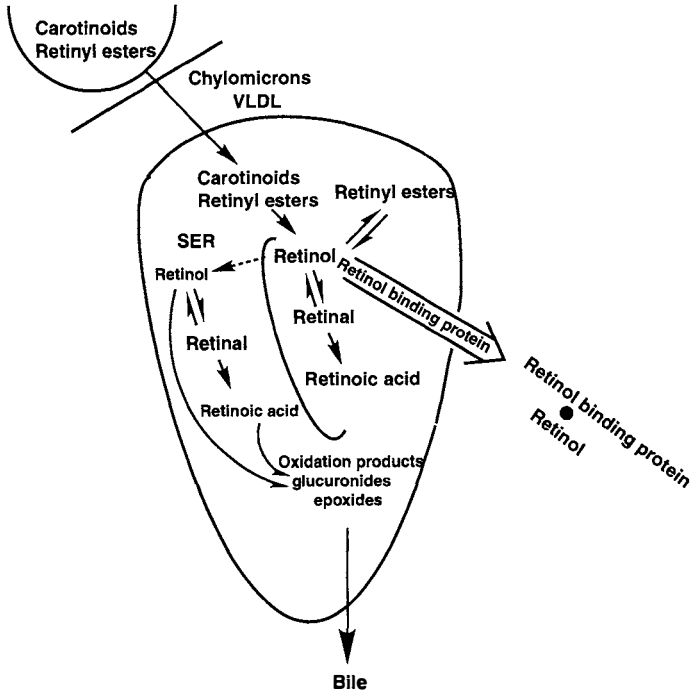

FIGURE 24.4 Major steps in the processing of vitamin A. Carotenoids, retinoids, and retinyl esters associated with chylomicra and VLDL particles are brought to the liver sininoids via the lymphatic system or portal systems in avians and reptiles. Vitamin A is next taken up by liver stellate cells. There is excellent communication between stellate cells and adjacent liver parenchymal cells. Each of these cells produce retinol-binding protein (RBP), which facilitates its transport into secretory pathways that allow delivery of retinol into blood. Excess retinol in cells is stored as retinyl ester (RE). Excess retinol is also oxidized by dehydrogenases in the cytosol, as well as by microsomal oxidases associated with the smooth endoplasmic reticulum (SER). The SER oxidase system results in a variety of oxidation products as well as retinyl glucuronides. Some of these products are delivered via the bile into the intestine. Drugs such as alcohol and barbiturates stimulate microsomal oxidase activity and can cause depletion of retinol.

essential for retinol uptake. However, RBP is designed for binding retinol in a hydrophobic pocket within the protein that most likely protects retinol from oxidation and destruction during transport (Packer, 1990).

Inside the targeted cells, vitamin A, as retinol, interacts with cellular binding proteins that function to control its subsequent metabolism, for example, oxidation to retinal and to retinoic acid. Some of these cellular binding proteins are also a part of the superfamily of glucocorticoid–retinoid–thyroxine transcriptional factors. It is the role of such proteins in transcription and regulation that makes vitamin A important to so many facets of cellular regulation.

Oxidation of retinoids in liver cells proceeds by two pathways, the principal one being cytosolic and involving one of the alcohol dehydrogenase isozymes. The other pathway involves so-called "microsomal oxidases," which may be induced by dietary excess, including alcohol, and many drugs. High doses of phenobarbital or ethanol cause depletion of liver retinol by induction of a microsomal oxidase system that promotes retinoid oxidation. Some of the oxidized products are sufficiently polar to be excreted in the urine. However, the major route of disposal is bile.

4. Functions

The major roles of Vitamin A are in cellular differentiation, tissue growth, and vision (Sherman, 1986). In quantitative terms, only a small fraction of the total vitamin A requirement is involved in the visual process because of extensive recycling of retinal. In vision, vitamin A, as a component of rhodopsin, facilitates the efficient transfer of energy from photons of light to electrochemical signals (Fig. 24.5). The events leading

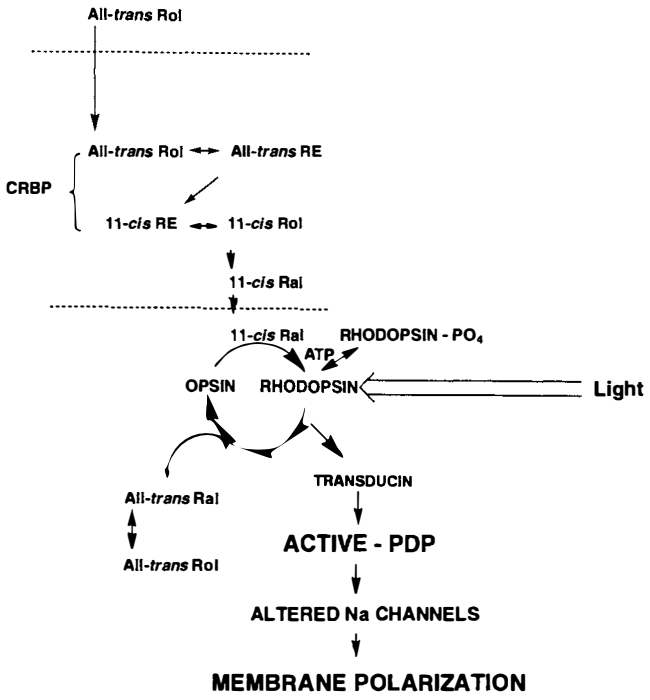

FIGURE 24.5 Vitamin A and vision. When all-*trans* retinol enters the rod cell, it first combines with cytosol retinoid binding protein (CRBP). Retinal and the all-*trans* retinal ester are capable of isomerization. Reactions involving all-*trans* retinal and retinyl esters occur by pathways that utilize CRBP–retinoid complexes as substrates. *cis*-Retinal reacts with opsin to form rhodopsin. The multiple arrows from rhodopsin back to opsin represent conformational changes in rhodopsin upon stimulation by light. The activated rhodopsin interacts with transducin, which in turn activates phosphodiesterase, which eventually causes a decreases in cGMP. This sequence of reactions causes an alteration in sodium channels and alters membrane polarization to activate optic nerve signal propagation. A number of additional events aid in controlling the process, such as inactivation of rhodopsin by phosphorylation.

up to the propagation of this signal are as follows: Vitamin A, as 11-*cis* retinal, forms a protonated Schiff base by binding to a lysine residue at position 296 of the membrane-bound protein opsin to yield rhodopsin. When a photon of light strikes rhodopsin, *cis–trans* isomerization occurs and the process results in a highly strained form of rhodopsin (bathorhodopsin), which is next converted to metarhodopsin with subsequent deprotonation. The deprotonated metarhodopsin interacts with transducin (one of the proteins in the transmembrane G-protein family). This interaction causes a subunit of transducin to bind GTP, stimulating cGMP phosphodiesterase activity. This results in a decease in cGMP, which constitutes a significant amplification of the initiating event, the conversion of light-derived energy through 11-*cis* to *trans* isomerization of retinal and specific changes in protein conformation.

The local decrease in cGMP results in changes in cation flux (Na and Ca ions) across rod cell membranes, resulting in more ionic calcium in the cytosol. The increase in calcium blocks the sodium channel and initiates depolarization, the firing of cells of the optic nerve. Further, metarhodopsin is phosphorylated during these final steps and interacts with a protein designated as arrestin. The metarhodopsin–arrestin complex inhibits the transducin response and causes the release of all-*trans* retinal and the return to rhodopsin (opsin), thus completing the cycle.

In dietary vitamin A deficiency there is an inability to appropriately saturate opsin with 11-*cis* retinal to form rhodopsin and its subsequent complexes, which in turn decreases the sensitivity of the visual apparatus so that light of low intensity is not perceived, leading to the clinical condition of nyctalopia or night blindness.

5. *Growth and Cell Differentiation*

As work on the role of vitamin A in growth progressed, it was soon recognized that in addition to retinal, retinol and its esters, retinoic acid would support growth and many features of normal development, but not vision, for which retinol (retinal) is essential. It is now appreciated that much of the growth-related response of deficient animals to vitamin A is related to maintenance of epithelial cells. With vitamin A deficiency, mucus-secreting cells are replaced by squamous, keratin-enriched cells (Sucov and Evans, 1995; Sherman, 1986).

Within cells, all-*trans* retinol associates with cytosolic retinol-specific binding proteins (CRBPs), and the resulting complexes become vehicles for subsequent processing . For example, all-*trans* retinol may be oxidized and isomerized to 13-*cis* retinoic acid, which subsequently binds to retinoic-acid-specific cytosolic binding proteins, which act as transcription factors in protein regulation and cellar differentiation.

In response to very low doses of retinoids, epithelial cells undergo a "terminal differentiation." Vitamin A derivatives control the expression of various proteins important to mucus formation and cytoskeletal integrity, such as keratin and transglutaminase, and the rate of cell cycling. In response to an abnormally low level of retinoids, cells lose their normal columnar shape, become flattened or squamous, and increase their cytosolic content of keratin (stabilized by transglutaminase-catalyzed cross-links). In dermis, this process results in a protective outer layer, scales, and other specialized surfaces. However, where the primary function of the epithelial cell is provision of a moist surface or absorption, squamous overkeratinization leads to loss of func-

tional integrity. Lack of protective mucous secretions facilitates the establishment of infections of the lungs and other tissues that depend on a mucus barrier. In the intestine, keratinization induces premature sloughing of enterocytes and malabsorption.

A number of hypotheses have been proposed for a gradient delivery of retinoids to epithelial cells, which help explain why some epithelial cells undergo terminal differentiation, whereas others undergo cell cycling and periodic turnover. However, much is still required to clearly define the process. Other cells that are responsive to retinoids include phagocytic cells and cells associated with the immune response; for example, the normal proliferation of the B cells and T cells requires vitamin A.

6. Requirements

The appearance, signs, and symptoms of vitamin A deficiency in a number of animal species have been described in detail. For any given animal, the requirement for vitamin A depends upon age, sex, rate of growth, and reproductive status. For optimal maintenance, the allowance for many animals ranges from 100 to 200 I.U. per kilogram of body weight per day (one I.U. is equal to 0.3 μg of retinol). In young animals, however, a more precise method of expressing the vitamin A requirement is on an energetic basis. In animal feeds, 4000 to 10,000 I.U. per kilogram of feed is considered adequate in the United States to provide vitamin A requirements for most animals.

Pathological conditions that influence vitamin A status include malabsorption, including pancreatic insufficiency and cholestatic disease; cystic fibrosis; liver disease; and kidney disease. Many forms of liver disease interfere with the production or release of RBP, which results in a lower plasma level of vitamin A. Renal failure can result in loss of RBP in urine. Factors that impair lipid absorption and transport also influence vitamin A status.

7. Evaluation of Vitamin A Status of Animals

The vitamin A status of animals may be evaluated on the basis of physiological, clinical, and biochemical procedures. Clinical testing for night blindness and elevation of CSF pressure have been used to indicate vitamin A insufficiency. The concentrations of retinol and its esters are readily measured in biological samples by HPLC using various detectors and provides an indication of the vitamin A status. As the concentration of retinol in plasma is well maintained until liver reserves are grossly depleted, plasma retinol is not a reliable index of vitamin A reserves. Analysis of biopsy samples of liver provides a useful index of reserves. In many carnivores , the plasma contains, in addition to retinol, equal or greater concentrations of retinyl palmitate and retinyl stearate. Plasma retinol concentrations in excess of 30 μg/dl generally indicate that vitamin A is not limiting. In most species, liver concentrations of 100 μg retinol/g liver indicate adequate status.

8. Pharmacology and Toxicity

Vitamin A and various retinoids are used increasingly to treat skin disorders (acne and psoriasis) and certain forms of cancer (Sporn *et al.*, 1994; Gillian, 1992). Retinoyl-β-glucuronide and hydroxyethyl retinamide are commercial preparations of retinoids that have such activity, but are less toxic than retinoic acid. The mechanisms by which these agents function most probably relate to the complex pathways involved in epithelial and epidermal cell differentiation.

Vitamin toxicities may be classified under three broad categories: acute, chronic, and teratogenic. When a single dose of vitamin A (greater than 100 milligrams) is injected into animals in the 20–50 kg weight range, symptoms such as nausea, vomiting, increased cerebral spinal fluid pressure, and impaired muscular coordination result. A lethal dose of vitamin A (100 mg) given to young monkeys has been reported to cause coma, convulsions, and eventual respiratory failure.

Chronic toxicity may be induced by intakes of vitamin A in amounts 10 times the normal requirements. Intakes of vitamin A in this range can lead to alopecia, ataxia, bone and muscle pain, and pruritis. Although cats have a high tolerance to excessive intakes of vitamin A, naturally occurring hypervitaminosis A occurs in cats that are given a diet based largely on liver. Affected cats exhibit skeletal deformations, particularly exostoses of the cervical vertebra, which precludes effective grooming. Vitamin A is also a powerful teratogen. A single large dose during pregnancy (in the 50- to 100-mg range) for an animal weighing 20–50 kg can result in fetal malformations. Chronic intakes (exceeding 10 times the requirements for given animals) can also be teratogenic. Carotenoids, unlike retinoids, are generally nontoxic, and many animals routinely ingest gram amounts of carotenoids on a daily basis with no deleterious effects.

B. Vitamin D

1. Introduction

Sir Edward Mellanby in 1921 reported the induction of rickets in dogs through dietary manipulation. He discovered that the disease could be corrected with cod

liver oil. McCollum in 1922 reported that the curative factor in cod liver oil was not vitamin A , but appeared to be another fat-soluble substance. This substance was later identified as vitamin D, based on the ability to inactivate the vitamin A factor in cod liver by mild oxidation, but in the process retain the antirachitic activity (Bender, 1992).

2. *Sources, Functions, and Metabolism of Vitamin D*

The D vitamins are a family of 9,10-secosteroids that differ only in the structure of the side chain attached to carbon-17. The two forms of vitamin D significant in veterinary medicine are ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3). The differences in the side chain result in the vitamins having disparate potencies with some species of animal and differing in toxicity when consumed in large amounts. These two forms of vitamin D are produced in a two-step reaction when their respective sterols, ergocalciferol and 7-dehydrocholesterol, absorb ultraviolet radiation and undergo photolysis, which is then followed by thermal isomerization. Excessive ultraviolet radiation of the sterols produces inactive compounds (Fig. 24.6). Under most circumstances, animals can synthesize sufficient quantities of cholecalciferol if they receive adequate exposure to ultraviolet light of wavelength 280–320 nm, particularly when the calcium and phosphorus requirements of the animal are met. As vitamin D_3 is produced at one site (skin) and acts at other sites including bone and intestine, it fulfills the definition of a prohormone (Diplock, 1985).

In most animals, 7-dehydrocholesterol is abundant in skin, being the ultimate precursor for cholesterol, which is synthesized *de novo* from acetate. However, the skin of cats and dogs and possibly other carnivores contains only small quantities of 7-dehydrocholesterol, which does not permit adequate synthesis of vitamin D, and these animals are solely dependent on the diet for this vitamin.

With the exception of animal products, most natural foods contain low vitamin D activity. Fish, in particular saltwater fish such as sardines, salmon, and herring, and fish liver oils contain significant to large quantities of vitamin D. Many plants also contain hydroxylated ergosterol derivatives, some of which have potent vitamin D activities (Collins and Norman, 1991).

Initially, vitamin D was assumed to be a cofactor for reactions that served to maintain calcium and phosphorus (as phosphate). When isotopes of calcium became available, it was soon appreciated that there was considerable time lag between the administration of vitamin D, and its effect on calcium-related metabolism. This lag was shown to be due to the conversion of vitamin D to an active form. Investigations throughout the 1960s and 1970s led to the sequence of events outlined in Fig. 25.6 (Wasserman and Fullmer, 1995). For example, the kidneys were identified as the site of 1, 25-dihydroxycholecalciferol (calcitriol, 1,25-$(OH)_2D_3$) production. This discovery, together with the finding that 1,25-$(OH)_2D_3$ is found in the nuclei of intestinal cells, suggested that vitamin D was functioning in a manner analogous to that of steroid hormones. The production of calcitriol is normally closely regulated through feedback control by 1,25-$(OH)_2D$ and parathyroid hormone (PTH) of the activities of the 25-OH-D 1α- and 25-OH-D 24-hydroxylases. A fall in plasma calcium triggers the release of PTH from the parathyroid gland, which stimulates 1α-hydroxylase production and leads to increased output of calcitriol from the kidney. A separate hydroxylase, which catalyzes 24,25-$(OH)_2D_3$ production, is activated under eucalcemic and hypercalcemic states. Whether 24,25-$(OH)_2D_3$ has unique activity is controversial. There is evidence that 24,25-$(OH)_2$-D_3 is required for some of the biological responses attributed to vitamin D. Norman and co-workers have shown that hatchablity in chickens is markedly improved if both 1,25-$(OH)_2D_3$ and 24,25-$(OH)_2D_3$ are administered into eggs containing viable embryos from hens rendered rachitic (vitamin D-deficient) prior to egg production. The two major sites of action of calcitriol in relation to calcium homeostasis are bone, where it acts rapidly in concert with PTH in response to hypocalcemia, and intestine, where the response time is longer.

Calbindin, a calcium-binding protein, is a major product synthesized in intestinal cells in response to calcitriol (Balmain, 1991; Norman *et al.,* 1987). Calbindin influences the movement of calcium across the intestinal cell. Binding of calcium to this protein allows the intracellular concentration of calcium to be elevated. The hormone forms of cholecalciferol also stimulate the production of the calcium- and sodium-dependent ATPases, which reside on the basal-lateral membrane surface of the intestinal cell, thus facilitating the vectorial movement of calcium out of the cell into circulation. In addition, recent evidence also indicates that 1,25-$(OH)_2D_3$ can stimulate secondary messenger systems, such as protein-kinase- and adenyl-cylase-controlled dependent messenger systems.

In addition to 1,25-$(OH)_2D_3$ and 24,25 $(OH)_2D_3$, more than 20 other hydroxylated intermediates and end products have been identified. Clearly defined functional roles for these products have not been elucidated.

In addition to intestinal cells, the osteoblasts of bone are a key target of vitamin D metabolites and play a major role in short-term calcium homeostasis. In addi-

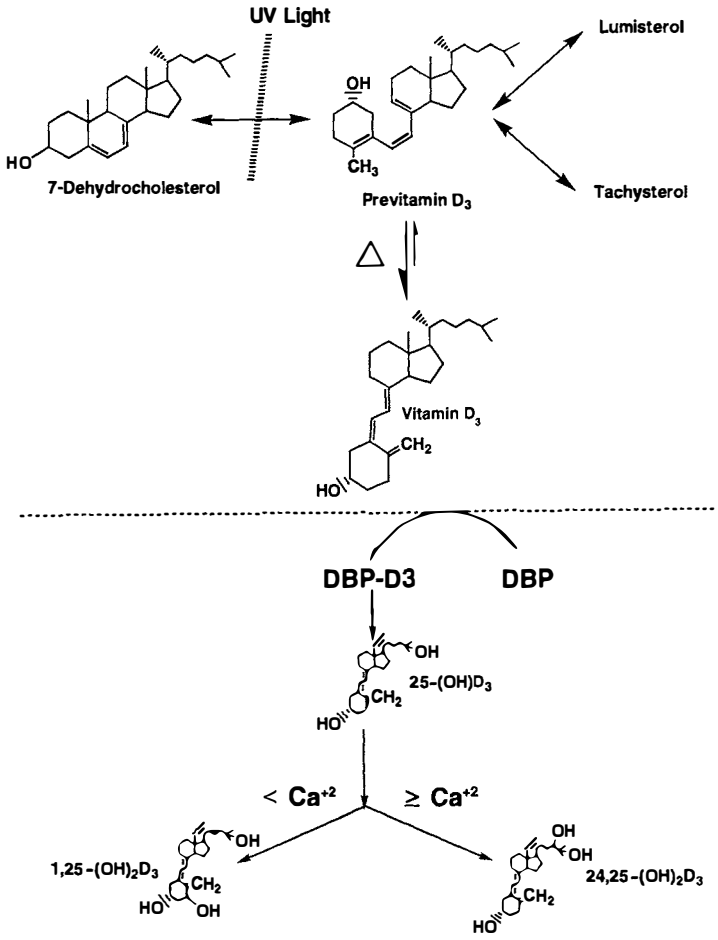

FIGURE 24.6 Vitamin D metabolism. 7-Dehydrocholesterol in skin can be converted to pre-vitamin D by the action of UV light. At body temperature pre-vitamin D spontaneously is converted to vitamin D_3. Related derivatives, such as lumisterol and tachysterol, are also formed. Vitamin D-binding protein (DBP) aids in transport of vitamin D_3 from skin to the liver, where vitamin D_3 is converted to 25-hydroxy-vitamin D_3. In the kidneys, in response to a hypocalcemic state, 1α,25-dihydroxycholecalciferol production occurs. Under a eucalcemic or hypercalcemic state, 24,25-dihydroxycholecalciferol production occurs.

tion, 1,25-$(OH)_2$D is indirectly required for normal bone mineralization during skeletal growth and remodeling of bone. Vitamin D receptors (VDR) in bone are located in osteoblasts and progenitor cells of bone; they control synthesis and secretion of a number of bone-specific proteins in osteoblasts, such as osteocalcin, osteopontin, collagen, and alkaline phosphatase. Although osteocalcin and osteopontin synthesis have been shown to be regulated at the transcriptional level of their respective genes, for the most part vitamin D metabolites attenuate the action of polypeptide hormones such as PTH or calcitonin, which stimulate bone resorption and accretion respectively. Of these two processes, maintaining bone resorption is the most important, because under normal conditions the serum calcium and phosphate ion concentrations are at levels that favor bone apposition or accretion.

3. *Other Functions of Vitamin D*

Vitamin D receptors (VDRs) have been found in a large number of cell types, ranging from skeletal muscle cells to cells important to immune and phagocytic functions, such as macrophages. In pancreatic β cells, 1,25-$(OH)_2D_3$ has also been observed to be important to normal insulin secretion. Vitamin D increases insulin release from isolated perfused pancreatic cells. Moreover, vitamin D metabolites can suppress immunoglobulin production by activated B-lymphocytes. T cells are also affected by vitamin D metabolites. 1,25-

$(OH)_2D_3$ exhibits permissive or enhancing effects on T-cell suppressor activity (Norman, 1995).

A specific transport protein delivers 1,25-$(OH)_2D_3$ and other active forms of vitamin D to targeted cells. The active form of vitamin D then interacts with receptor proteins, which in turn signal enhanced expression of selected proteins. Even in a tissue such as the intestine, VDR represents only about 0.001% of the total protein. Recently, the total size of the deduced amino acid sequence of the VDR protein has been determined for rats as 423, and for humans as 427. The cysteine-rich DNA-binding domain of the amino terminus is 100% conserved between these species, and the steroid-binding domain at the carboxyl terminus is 93% conserved.

4. *Requirements and Toxicity*

Most animals require 5 μg or less of vitamin D per 1000 Kcal of diet. When intake exceeds 5 to 10 times this amount, there is a risk of toxicity, characterized by hypercalcemia and calcification of soft tissues, particularly in the blood vessels of the lung, kidney, and heart. Acute doses of vitamin D (100 times the requirement) can eventually result in a negative calcium balance, because bone resorption is accelerated. Some plants (*Solanum malacoxylon, Cestrum diurnun,* and *Trisetum flavescens*) contain compounds with vitamin D activity (mostly glycosylated forms of 1,25-dihydroxyvitamin D), and consumption of these plants by grazing animals causes an induced vitamin D toxicity and calcinosis manifested by deposition of calcium in soft tissues. Rodenticides containing cholecalciferol as the active ingredient have resulted in toxicity in companion animals that ingest the bait directly, or ingest carcasses of rodents that have ingested the bait (Collins and Norman, 1991).

5. *Assessment of Vitamin D Status*

Reliable assays for the measurement of vitamin D, calcidiol, and calcitriol in plasma are available. Calcitriol occurs in picomolar concentrations (normal values 40 to 150 pmol/liter or 17 to 63 pg/ml) and has a half life of about 4–6 hours in humans. Concentrations of vitamin D in plasma after oral administration are in the nanomolar range ("normal" values range from 0 to 310 nmol/liter or 0 to 120 ng/ml). Vitamin D has a half-life of 24 hours, so the plasma concentration reflects immediate intake rather than overall status. In contrast, 25-OH vitamin D has a half-life of about 3 weeks. It provides the useful index of vitamin D status and is the measurement of choice. Plasma concentrations of 25-OH vitamin D of 20–150 nmol/liter or 8 to 60 ng/ml cover the normal range for most animals. Much higher levels than these have been observed in cats given diets containing high levels of cholecalciferol without apparent deleterious effects.

C. Vitamin E

1. *Introduction*

In the early 1920s, Herbert Evans and Kathryn Bishop observed that rats failed to reproduce when fed diets containing rancid lard, unless they were supplemented with lettuce or whole wheat (Machlin, 1980). Later it was found that germ oil, particularly wheat germ oil, contained an active principle that seemed responsible for improving reproductive performance. These early studies provided yet another function for a fat-soluble substance. By the early 1930s, it was recognized that this substance was a factor that differed from vitamin A or vitamin D. The compound was designated as vitamin E by Sure, and later as α-tocopherol, from the Greek word "tokos" meaning childbirth or reproduction. By 1940, a number of compounds in the tocopherol family had been identified and purified. With elucidation of tocopherol structures and eventual chemical synthesis (Fig. 24.7), studies demonstrating that embryonic failure resulted from vitamin E deficiency quickly followed. Pappenheimer, Olcott, and others observed that muscle degeneration was also a common deficiency symptom. Next, other signs and symptoms were identified, including oxidative diathesis and encephalomalcia in chickens and liver necrosis and hemolytic anemias in other vitamin E-deficient animals (Guggenheim, 1981).

2. *Chemistry, Metabolism, and Sources*

The principal dietary sources of tocopherols are plant oils. Tocopherols are unique among the vitamins as they act primarily at a chemical level as antioxidants, that is, they do not serve as cofactors or appear to be involved directly as a specific factor in cellular regulation. Primarily, vitamin E protects unsaturated fatty acids in the phospholipids of cell membranes. The quinone moiety of tocopherols is capable of quenching free radicals, such as free radical of hydrogen ($H^{\cdot}$), superoxide radicals ($O_2^{\cdot}$), hydroxyl radicals ($OH^{\cdot}$), and other lipid-derived radical species ($LOO^{\cdot}$). Vitamin E is very reactive, and in the course of its action as a free-radical scavenger it is sacrificed; however, in this process it inhibits the formation of lipid-derived oxidation products (Marks, 1977).

Cell membranes contain vitamin E at a concentration of approximately 1 mg per 5–10 g lipid membrane, a concentration sufficient to retard membrane-lipid oxidation. Membrane lipids are constantly engaged in

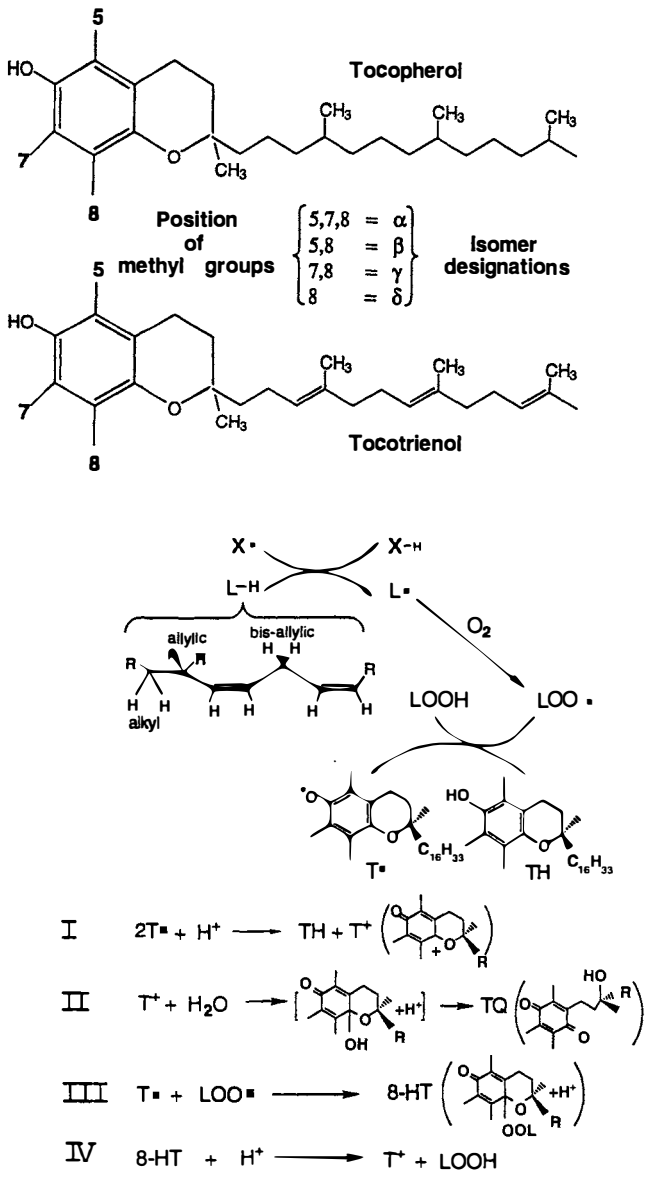

FIGURE 24.7 Vitamin E. The two principal forms of vitamin E, tocopherol and tocotrienol, are shown. Methyl groups are found at the 5, 7, or 8 positions. Tocopherol is the most potent of the various forms of vitamin E in biological systems. Some of the basic mechanisms involving free-radical quenching are also shown. Vitamin E is particularly important in quenching free radicals that generate from the allelic and bis-allelic unconjugated bonds found in membrane polyunsaturated lipids. Resolution of the vitamin E and various known intermediates in the process are given in steps I and IV.

the process of turnover and repair. By prolonging the initiation time before a free-radical chain reactions occurs, vitamin E gives cells time to replace damaged membrane lipids through the process of normal cell turnover.

With regard to absorption and transport, tocopherols first partition into the intestinal micelles prior to absorption (Kayden and Traber, 1995). Following absorption, vitamin E is transferred into the lymph associated with chylomicrons and intestinally derived VLDL particles, similar to other fat-soluble vitamins. Vitamin E is cleared from chylomicrons and VLDL by the lung and the liver. From the liver, most of the vitamin E is found in association with VLDL and LDL particles. Although no specific plasma or serum carrier protein for vitamin E has been unequivocally elucidated, phospholipid transfer protein, which accelerates exchange and transfer of vitamin E between lipoproteins, has been shown to have high specificity for the α-tocopherol form of vitamin E. Phospholipid transfer protein may thus determine the types of tocopherols that are returned to the liver from plasma via HDL- and LDL-derived lipoproteins. For example, the α-tocopherol form of vitamin E is preferred, and the LDL particles contain the highest concentration of vitamin E. From the perspective of human nutrition, this is important in that high concentrations of vitamin E protect the LDL particle from oxidation. It has been proposed that oxidized LDL particles are important mediators of vascular disease (Traber and Packer, 1995).

Vitamin E enters cells by processes similar to those for LDL uptake. LDL membrane receptors, through receptor-mediated endocytosis, appear responsible for vitamin E uptake. Once in cells, vitamin E is incorporated into lipid membranes. About 40% of vitamin E is found in nuclear membranes; the remaining 60% is divided among lysosomal, mitochondrial, and outer cell-wall membranes. From a pharmacological perspective, vitamin E has been associated with improved immune response, improved meat quality, and improved wound healing (Bendich, 1993; Liu *et al.*, 1995).

3. *Requirements*

The nutritional status of vitamin E is often difficult to assess. A number of factors can influence the concentration of tocopherols in cells. Vitamin E acts as the last line of defense for lipid oxidation, primarily residing in lipid membranes. Consequently, enzymes such as superoxide dismutases, catalase, glutathione peroxidase, and related systems for oxidant defense can moderate the absolute need for vitamin E. Further, high dietary intakes of polyunsaturated dietary fats increase the vitamin E requirement because of their eventual deposition in cell membranes and higher susceptibility to oxidation.

4. *Evaluation of Vitamin E Status*

Tocopherols in biological tissues can be measured by HPLC. Although α-tocopherol can be separated readily from other tocopherols, the separation of the β and γ isomers is difficult. For nutritional assessment

of vitamin E, the current indices are based on changes in total tocopherol concentrations in plasma and serum. Measurement of tocopherol concentration in erythrocytes may be an even better indicator for tissue vitamin E than plasma or serum levels. The platelet concentration of vitamin E is also a sensitive measure of vitamin E intake. Moreover, in the experimental setting the measurement of adipose levels of tocopherols seems to be a reliable index for assessing long-term vitamin E status. As in other cells, vitamin E partitions primarily into the membrane lipid compartments of adipose cells. Thus, the concentration of vitamin E per adipose tissue mass may even increase when there is loss of non-membrane stored triglycerides. Because plasma tocopherol concentration, is affected by lipid concentration, an α-tocopherol/total lipid ratio of 0.6 to 0.8 mg/g total lipids has been suggested as indicating adequate nutritional status. Functional tests such as the erythrocyte hemolysis in the presence of 2% peroxide have also been used to indicate status.

D. Vitamin K

1. Introduction

In 1929, Henrik Dan reported what was first thought to be an essential role for cholesterol in the diet of chickens. He noted that chicks fed diets that had been extracted with nonpolar solvents to remove sterols developed subdural and muscular hemorrhages, and that blood seemed to clot at a slower rate. These studies were extended by MacFarland, who observed clotting defects in chicks fed diets based on lipid-extracted fish or meat meals. MacFarland showed that this defect could not be reversed by providing any of the other known vitamins. As a consequence, hemorrhagic disease in chicks was associated with a new factor, designated as vitamin K. Later it was demonstrated that hemorrhagic disease in chicks could be reversed by extracts of alfalfa. In the 1940s it became clear that substances synthesized by bacteria also contained vitamin K activity (Friedrich, 1988; Bender,1992). As this work progressed, information also became available regarding a compound in spoiled clover and grasses that seemed to cause hemorrhagic disorders in cattle and serve as antagonist to vitamin K (Fig. 24.8).

2. Function and Metabolism

With the isolation and identification of vitamin K, an understanding of the mechanism of its action evolved, though not without controversy. At first there was the problem of reconciling how compounds present in the spoiled sweet clover acted as vitamin K antagonists. A number of questions were also raised regarding the structural requirements for vitamin K activity. Now it is appreciated that a number of compounds in the 1,4-naphthoquinone series—even relatively simple compounds such as menadione—possess vitamin K activity. Menadione combines with isoprenoids arising from the cholesterol synthesis pathway, resulting in an active phylloquinone. Dietary phylloquinones are transported to liver by chylomicrons and intestinal VLDL particles and from liver by VLDL and LDL. Studies of vitamin K clearance show that the total pool of vitamin K in the body is replaced rapidly; within hours to days, in contrast to the slower turnover of the other fat-soluble vitamins (weeks to months).

The mechanism of action for vitamin K became clear after it was demonstrated that the formation of γ-carboxyglutamic acid residues (GLA) in thrombin and other proteinases associated with the blood clotting cascade was vitamin K dependent (Suttie, 1995). The formation of GLA residues is a key, as they serve as calcium-binding sites in the proforms of proteinases associated with blood coagulation. Calcium binding is a requisite for their eventual activation. In this regard, vitamin K serves as cofactor for microsomal carboxylases that are responsible for GLA formation. The vitamin K-dependent carboxylase utilizes oxygen and bicarbonate as substrates. The reaction only occurs if glutamic acid is a part of a polypeptide with the correct sequence for specificity. Only the reduced form of vitamin K serves as a cofactor (Fig. 25.8), so a reductase system is necessary for vitamin K regeneration, and one of the intermediate forms is a vitamin K epoxide. As this pathway was resolved, it became apparent that many of the vitamin K antagonists functioned as inhibitors of reductases important for vitamin K regeneration.

GLA residues are also found in bone proteins. The GLA-containing proteins in bone (osteocalcins) appear to be involved in the regulation of new bone growth and formation. The presence of GLA protein in bone helps to explain why administration of the vitamin K antagonist at levels that cause hemorrhagic diseases also may result in bone defects, particularly in neonates. The mineralization disorders are characterized by complete fusion of the proximal tibia growth plate and cessation of longitudinal bone growth (Suttie, 1995).

3. Nutritional Requirements

The establishment of the dietary requirement for many animals has been difficult, in part due to (1) the short half-life of vitamin K, (2) the fact that large amounts of vitamin K may be synthesized by intestinal bacteria, and (3) the extent to which different

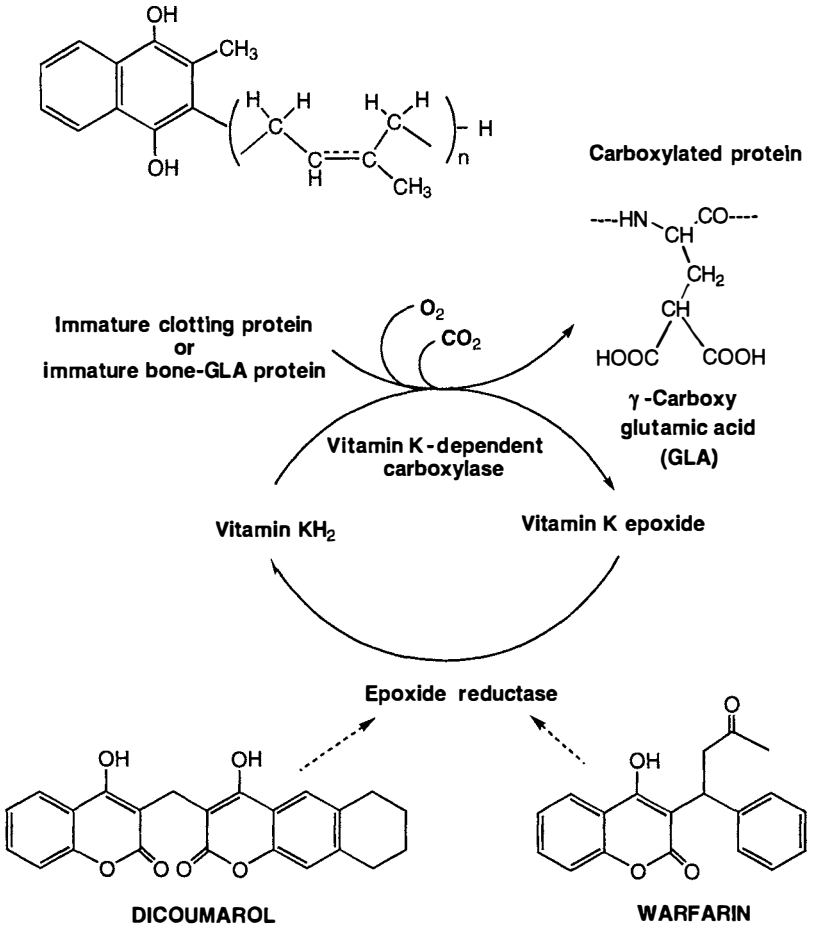

FIGURE 24.8 Vitamin K and its functions. Vitamin K consists of compounds with the general structure shown. Forms of vitamin K in the phylloquinone series (K_1) have a saturated side chain of isoprene units. In the menaquinone series, the isoprene side chain is unsaturated. The isoprene side chain can be as long as 20 carbons in length. Vitamin K functions as a cofactor for microsomal carboxylases, which act on immature clotting proteins in the liver or immature proteins in developing and metabolic active bone to cause the formation of γ-carboxyglutamic acid. During the course of carboxylation, vitamin K is converted to vitamin K epoxide. The epoxides may be converted back to vitamin K. The site of action of vitamin K antagonists such as dicoumarol and warfarin is the reductase regeneration system.

animal species practice coprophagy. Birds tend to have relative high requirements for vitamin K; thus, chickens are often used as experimental animals in vitamin K studies. Recent work suggests that the vitamin K requirement is dependent upon the relative content of vitamin K epoxide reductase activity. A low level of epoxide reductase activity can result in an increased requirement for vitamin K (Suttie, 1995). Ruminal microorganisms synthesize large amounts of vitamin K; thus, ruminants do not need an external source.

Recent assessments of nutritional requirements suggest that small animals should obtain approximately 500–1000 μg as phylloquinone per kg diet. Oxidized squalene and high intakes of vitamin E may act as vitamin K antagonists. Insufficient vitamin K can also occur with antibiotic therapy, treatment with coccidiostatic drugs, or long-term parenteral hyperalimentation without vitamin K supplements. Poultry and swine diets are regularly supplemented with menadione, but the need to supplement the diet of other species is questionable. Few hazards have been attributed to long-term ingestion of vitamin K in amounts of 1–10 mg per kg diet as phylloquinone. However, menadione in amounts corresponding to 10–100 mg per kg diet may act as a pro-oxidant, and high dietary concentrations produce hemolysis. Phylloquinone (vitamin K_1) rather than menadione should be used parenterally to treat animals that have ingested warfarin or other

anticoagulants. Menadione, being water-soluble, produces hemolysis.

IV. WATER-SOLUBLE VITAMINS

We have chosen to organize the discussion of water-soluble vitamins based on physiological function. Most vitamins serve eventually as enzymatic cofactors. For example, niacin, riboflavin, and ascorbic acid serve primarily as redox cofactors (Friedrich, 1988; Combs, 1991). The roles of thiamin, pyridoxine (vitamin B_6), and pantothenic acid (as a component of coenzyme A) are distinguished because of their unique importance to carbohydrate, protein and amino acid, and acyl and acetyl transport, respectively. Biotin, folic acid, and vitamin B_{12} (cobalamin) will be discussed in relationship to their roles in single-carbon metabolism.

A. Ascorbic Acid

1. *Introduction*

Ascorbic acid functions primarily as a cofactor for microsomal mono-oxygenases (hydroxylases) and oxidases. In most animals, ascorbic acid is synthesized from glucose in the liver or kidney (Fig. 24.9). In some animals, however, a deficiency of gulonolactone oxidase, the last step in ascorbic acid synthesis, results in the need for a dietary source . Because of its importance in humans, vitamin C deficiency (scurvy) often determined the course of history. Outbreaks of scurvy influenced the outcome of military campaigns, explorations, and the ability to survive long ocean voyages. It was the search for the anti-scurvy factor that eventually lead to the isolation of ascorbic acid.

2. *Chemistry*

Ascorbic acid is the most powerful reducing agent available to cells and is of general importance as an antioxidant, because of its high reducing potential (Friedrich, 1988). However, under some conditions ascorbic acid can also act as an pro-oxidant. Ascorbic acid is 2,3-enediol-L-gulonic acid. Both of the hydrogens of the enediol group can dissociate, which results in the strong acidity of ascorbic acid ($pK_1 = 4.2$). Enediols are also excellent reducing agents; the reaction usually occurs in a stepwise fashion, with monodehydroascorbic acid as a semiquinone intermediate. This intermediate then disproportionates to ascorbic acid and dehydroascorbic acid. Dehydroascorbic acid is not as hydrophilic as ascorbic acid, because it exists in a deproteinated form. As such, this form of ascorbic acid can move easily across cell membranes. The dehydro form, however, is easily cleaved by alkali—for example, to oxalic acid and threonic acid.

3. *Absorption, Tissue Distribution, and Metabolic Functions*

Dietary ascorbic acid is absorbed from the duodenum and proximal jejunum (Friedrich, 1988). Measurable amounts can also cross the membranes of the mouth and gastric mucosa. Although some controversy exists regarding the relationship between ascorbic acid intake and the intestinal absorption of ascorbic acid, most careful studies indicate that within the physiological ranges of intake (20–400 mg per kg dry food), 80–90% of the vitamin may be absorbed.

In tissues, the highest concentration of ascorbic acid is found in the adrenal and pituitary glands, followed the liver, thymus, brain, and pancreas. Cellular uptake of ascorbic acid occurs by both active and simple diffusion processes. In diabetic animals, the ascorbic acid content of tissue is often depressed, which suggests that factors responding to hypergylcemic states can compromise ascorbic acid status.

Ascorbic acid is maintained in cells by several mechanisms. Ascorbate reductases maintain L-ascorbic acid in the reduced form, which prevents leakage from the cell as dehydroascorbic acid. Significant amounts of ascorbic acid, particularly in fish, may also exist as the 2-sulfate derivative. In rats, about 5% of a labeled dose of ascorbic acid is recovered in urine as 2-*O*-methyl ascorbic acid. The ability to modify ascorbic acid as the 2-sulfate or 2-*O*-methyl derivative as well as to oxidize ascorbic acid has considerable impact on the ability of cells to compartmentalize or modulate functional ascorbic acid levels. In the neonate, glutathione is important to ascorbate recycling and regeneration (Fig. 24.10). An argument can be made for a dietary need for ascorbic acid in the neonates of some species in which the adult does not normally have a dietary requirement. For example, the levels of glutathione are relatively low in neonate rat and mouse tissue. Ascorbate is oxidized to dehydroascorbic acid, which is further catabolized; hence the need for continual replacement.

As a cellular reducing agent, ascorbic acid plays a number of very important roles. It serves as a cofactor for mixed-function oxidations that result in the incorporation of molecular oxygen into various substrates (England and Seifer, 1986). Examples include the hydroxylation of proline in collagen, elastin, C1q complement, and acetylcholine esterase. Hydroxylases (monooxygenases) and some P450-dependent hydroxylases

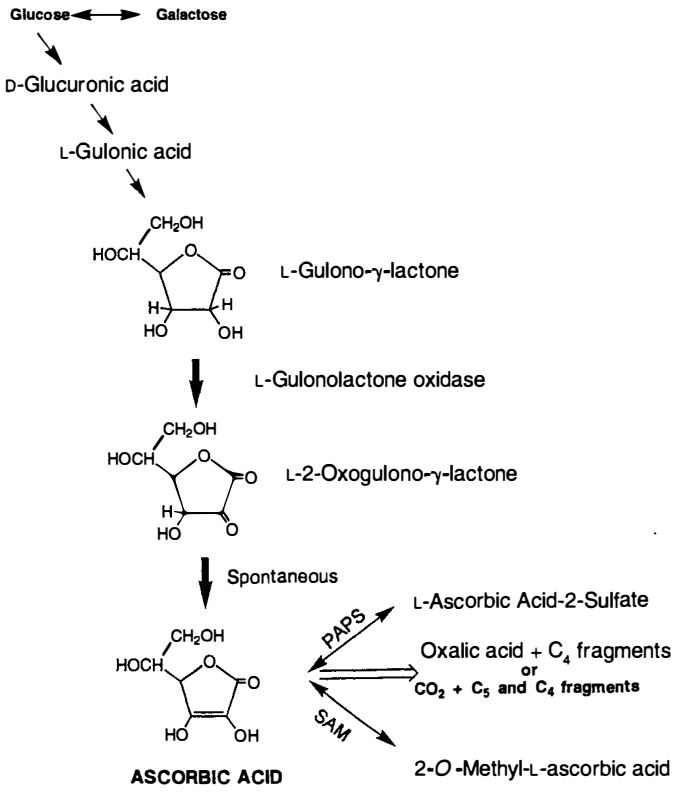

FIGURE 24.9 Ascorbic acid. Ascorbic acid is synthesized in most animals by conversion of glucose through the direct oxidative pathway to L-gulono-γ-lactone and eventually to L-2-oxogulonyl-γ-lactone, which spontaneously oxidizes to ascorbic acid. Also shown are important steps in the metabolism of ascorbic acid. Many cells are capable of converting ascorbic acid to L-ascorbic acid 2-sulfate or to 2-0-methyl-L-ascorbic acid. Phosphoadenosyl phosphasulfate (PAPS) is a requisite cofactor for L-ascorbic acid 2-sulfate synthesis. *S*-Adenosyl methionine (SAM) is the cofactor for 2-methyl-L-ascorbic acid formation. When ascorbic acid is in excess in cells, catabolic enzymes that decarboxylate and cleave ascorbic acid are induced.

that carry out the hydroxylation of steroids, drugs, and other xenobiotics also utilize ascorbic acid as a reductant. Moreover, the hydroxylation steps in the biosynthesis of carnitine and the hydroxylation of tyrosine in the formation of catecholamines represent other important catalytic functions of ascorbic acid. Most of the enzymes involved in these processes are metal-requiring enzymes, in which the role of ascorbic acid is to maintain the metal (usually Cu or Fe) in a reduced state (Fig. 24.11).

Ascorbic acid also been suggested to play a number of regulatory roles. Ascorbic acid influences histamine metabolism in some animals, particularly humans. There is an inverse correlation between ascorbic acid levels and serum histamine levels. Further, steps in the transcriptional regulation of certain proteins, such as the fibrillar collagens, also appear to be influenced by the presence or absence of strong reducing agents such as ascorbic acid (England and Seifer, 1986).

4. Requirements and Toxicity

Ascorbate is synthesized by most animals, with the exception of primates, guinea pigs, some snakes, fruit-eating bats, birds such as passerines, and salmonid fish. For these animals, impaired collagen synthesis is a principal feature of ascorbate deficiency, which is evidenced by capillary fragility, bleeding gums, delayed wound healing, and impaired bone formation. In fish kyphosis, scoliosis and gill pathology also occurs. Connective-tissue lesions are primarily a result of underhydroxylated collagen (at specific prolyl and lysyl

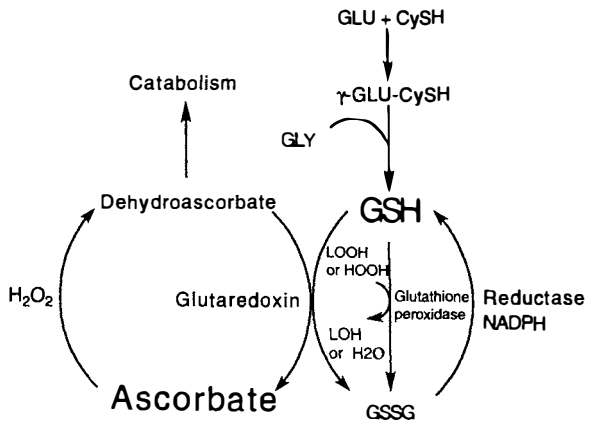

FIGURE 24.10 The relationship between glutathione and ascorbic acid. Glutathione is the most important cosubstrate for reactions catalyzed by glutathione peroxidase. Glutathione (GSH) is also important in maintaining ascorbic acid in its reduced form by serving as a cosubstrate for glutaredoxin.

residues) being abnormally susceptible to degradation. In addition, the inability to deal with metabolic stress requiring normal adrenal gland function and the reduced ability to metabolize fatty acids (carnitine synthesis) contribute to signs of scurvy.

To maintain the functions requiring ascorbate, most animals generate 10–60 mg of ascorbic acid per 1000 Kcal utilized in the course of normal metabolism. Similarly, requirements for ascorbic acid, when needed in the diet, range from 50 to 250 mg per kg diet. When ascorbic acid is consumed in gram amounts (per kilogram of diet), gastrointestinal distress and bleeding may occur. Also, when fed in excess of metabolic need, tissue levels of ascorbic acid are homoeostatically maintained. Homeostasis occurs through the induction of ascorbic acid decarboxylases and cleavage enzymatic activity, which results in enhanced degradation of ascorbate to CO_2 plus ribulose or oxalic acid plus threonic acid. These conversions are probably to protect cells against nonspecific and Fenton reactions.

B. The B Vitamins: Niacin

1. Introduction

Throughout out the 18th and 19th centuries, the disease pellagra was prevalent in western Europe and the southern region of the United States. This disease would eventually become associated with the consumption of corn (maize). Through the elegant work of Goldberger and others, pellagra was then linked to a dietary deficiency of niacin. Dogs played an important role as models for pellagra, as they exhibit a condition designated "black tongue" when given a diet similar to one that produced pellagra in humans. Black tongue is characterized by initial reddening of the mucosa of the lips and mouth, which progresses to necrosis of the mucosa accompanied by ropy saliva, a fetid odor, and diarrhea (Henderson, 1983).

Niacin deficiency is a consequence of consumption of foodstuffs, such as corn, that are low in bioavailable niacin and the amino acid tryptophan. Tryptophan is important to niacin status, because niacin can be generated upon tryptophan degradation (Fig. 24.12). Although niacin deficiency is observed infrequently in free-ranging animals, it nevertheless is a good example of a vitamin-related disease that occurs from consuming a monotonous diet. In corn, the bioavailability of niacin is poor unless the corn (maize) grain is finely ground and processed under alkaline conditions, for example, ground in the presence of limestone. This was not the practice in the human populations of western Europe and the southern United States that developed pellagra, although it was the practice in Central and South America. Normally, niacin is derived from food by hydrolysis of NAD (nicotinamide adenosyl dinucleotide) and NADP (nicotinamide adenosyl phosphodinucleotide) to niacin by the action of pancreatic or intestinal nucleosides and phosphatases (Fig. 24.1). As most animals consume diets that contain adequate tryptophan and available NAD and NADP, niacin deficiency is usually not a problem. An exception to this generalization is cats. In this species the degradation of tryptophan does not proceed along a pathway that leads to nicotinic acid, even though all the enzymes for the pathway are present. High activity of the enzyme picolinic carboxylase at a branch point in the pathway results in diversion from eventual NAD production. For cats and probably all other felids, but not dogs, available niacin is an obligatory dietary factor.

2. Functions

NAD and its phosphorylated form, NADP, are two coenzymes derived from niacin. Both contain an unsubstituted pyridine 3-carboxamide that is essential to function in redox reactions with a chemical potential near −0.32 V. Virtually all cells are capable of converting niacin to NAD. Most enzymes that require NAD are oxidoreductases (dehydrogenases) that aid the catalysis of a diverse array of reactions, such as the conversion of alcohols and polyols to aldehydes or ketones (Fig. 24.13). The most common mechanisms involve the stereospecific abstraction of a hydride ion (H:) from the substrate with its subsequent transfer. Cells generally delegate NAD to enzymes in catabolic path-

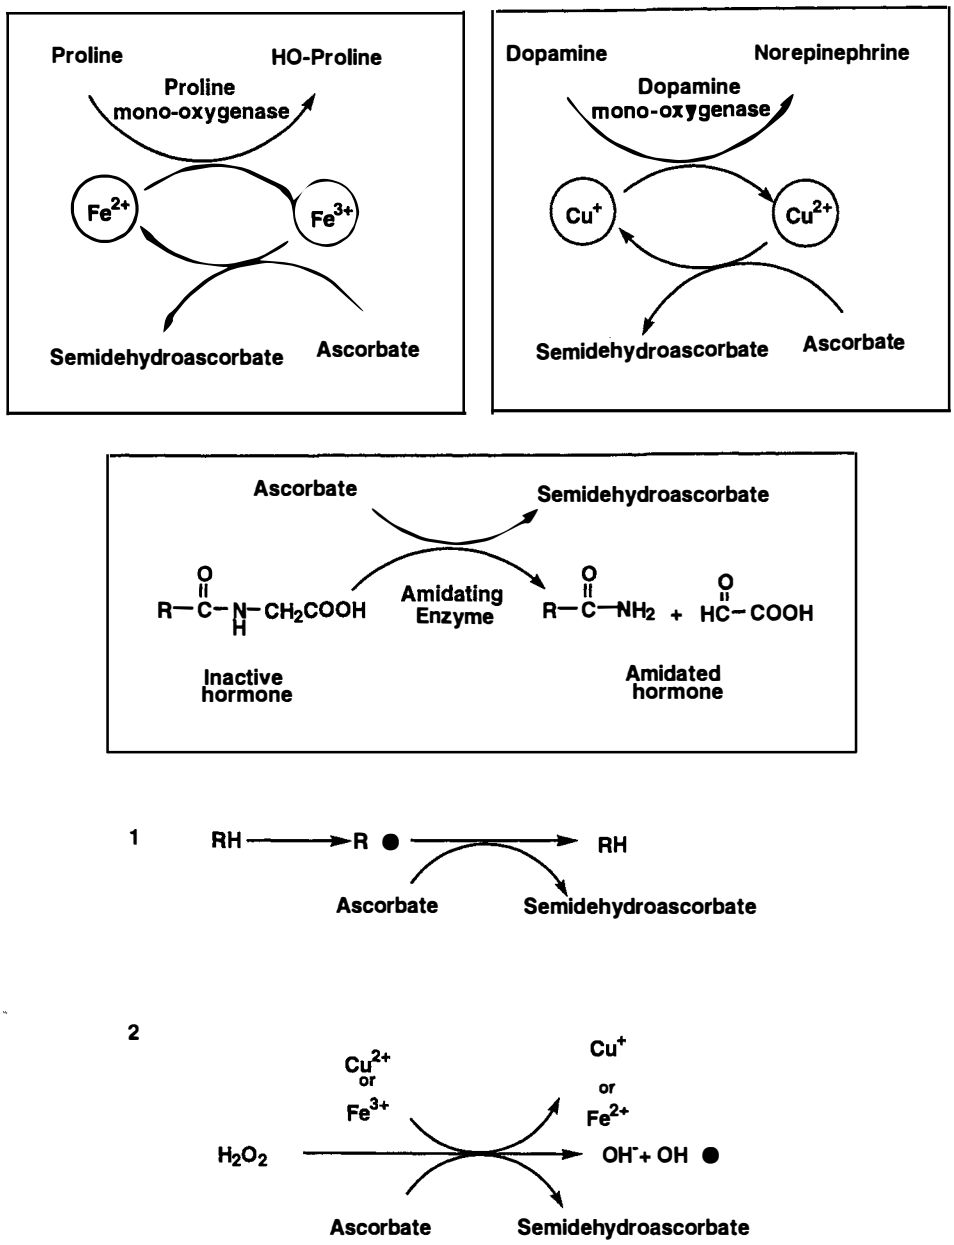

FIGURE 24.11 Selected functions of ascorbic acid. Ascorbic acid is a common mono-oxygenase cofactor. Shown are reactions typical of those for prolyl hydroxynase (mono-oxygenase), dopamine dehydrogenase, and amidating enzyme. Further, ascorbic acid can act as a reductant (reaction 1) or pro-oxidant (reaction 2).

ways, whereas NADP is utilized in synthetic pathways. An additional and equally important function of NAD is its role as a substrate in poly- and monoribosylation reactions. Mono- and polyribosylations are important to many cellular regulatory functions. Enzymes that undergo monoribosylation can become activated or deactivated upon addition of ADP–ribose. Somewhat analogous to phosphorylation, ribosylation represents another example of covalent modification as a regulatory control. In the nuclei of cells, polyribosylation of histones precedes the normal process of DNA repair. This latter phenomenon is important in that pellagra-related lesions of skin following exposure to UV light. UV damage of epidermal cell DNA is an underlying mechanism for the dark-pigmented lesions associated with pellagra. Lack of niacin and therefore NAD is thought to be contributing factor to the skin lesions because of the inability of cells to carry out polyribosy-

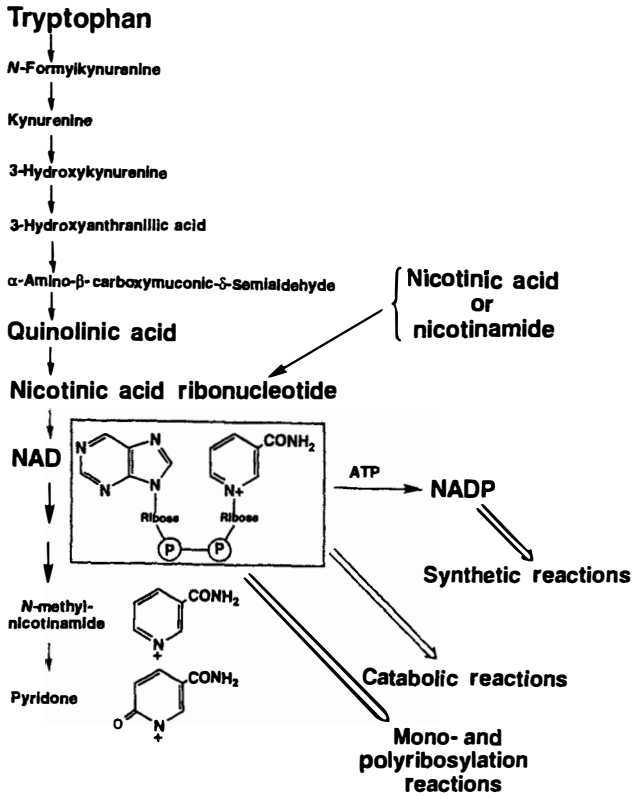

FIGURE 24.12 Metabolism of tryptophan to niacin and NAD. NAD may be derived from tryptophan through the quinolinate pathway. Tryptophan, however, is not a precursor for NAD in those animals that divert α-amino-β-carboxymuconic-δ-semialdehyde to alternative products, e.g., picolinic acid, rather than toward quinolinic acid formation. For example, in cats, nicotinic acid or nicotinamide is needed for NAD production. Note that the phosphorylated form of NAD (NADPH) is used primarily for synthetic reactions. NAD serves as a cofactor for catabolic reactions and as a substrate in mono- and polyadenylation reactions. When NAD is degraded, the nicotinamide component can be methylated or oxidized to pyridone. In birds, more complex conjugated forms of nicotinamide are observed (not shown).

lation reactions. It is this nonredox function of NAD that accounts for the rapid turnover of NAD in cells. Some estimates suggest that as much as 40 to 60% of the NAD in cells is involved in mono- or polyribosylation reactions (Weiner and Eys, 1983; Poirier and Moreau, 1992).

3. *Requirements and Pharmacology*

Niacin is needed in amounts corresponding to 10–25 mg/kg of diet. Depending on species, the conversion of tryptophan to niacin produces about 1 mg of niacin for every 60 mg of tryptophan degraded. In some animals, e.g., cats, high levels of the enzyme picolinic carboxylase causes conversion of α-amino-β-carboxymuconic-δ-semialdehyde to picolinic acid rather than quinolinic acid; cats therefore have an obligatory requirement for niacin (*see* Fig. 24.12). Niacin (nicotinamide) is relatively nontoxic, although nicotinic acid can cause vasodilation when consumed in excess of 100 mg per kg diet. Consequently, there are a number of therapeutic uses for pharmacologic doses of niacin-derived compounds, when increased blood flow is desirable.

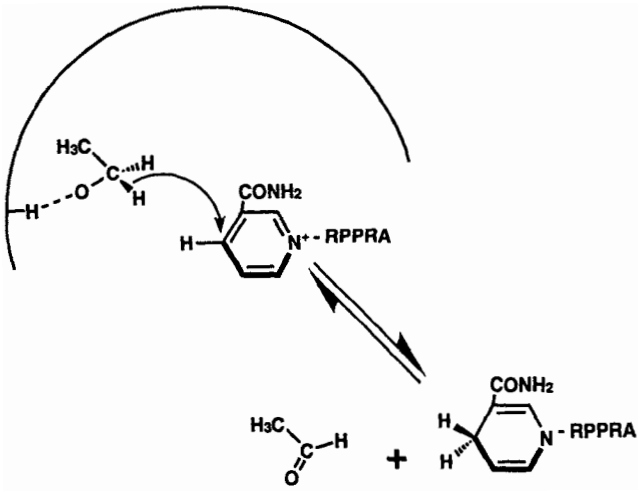

FIGURE 24.13 Role of NAD in the oxidation of ethanol to acetaldehyde.

4. *Determination of Niacin Status*

A nicotinamide loading test has been used to determine niacin status of patients. The patient is given an oral dose of nicotinamide and the urinary excretion products, which are species dependent, are measured. For humans, monkeys, dogs, rats, and swine, largely methylated products are produced.

C. The B Vitamins: Riboflavin

1. *Introduction*

Riboflavin was one of the first of the B vitamins identified (Fig. 24.14). Originally, it was thought to be the heat-stable factor responsible for the prevention of pellagra. Riboflavin is present in tissue and cells as FAD (flavin adenine dinucleotide) and FMN (flavin adenine mononucleotide). FAD and FMN are cofactors in aerobic processes, usually as cofactors for oxidases, although FAD also can function in anaerobic environments as a dehydrogenase cofactor (Cooperman and Lopez, 1991). Many flavin-containing proteins are found in the smooth endoplasmic reticulum of cells, for example, as microsomal enzymes.

2. *Functions*

Enzymes containing flavins are distinguished because they are capable of transferring hydrogen directly to molecular oxygen with the formation of hy-

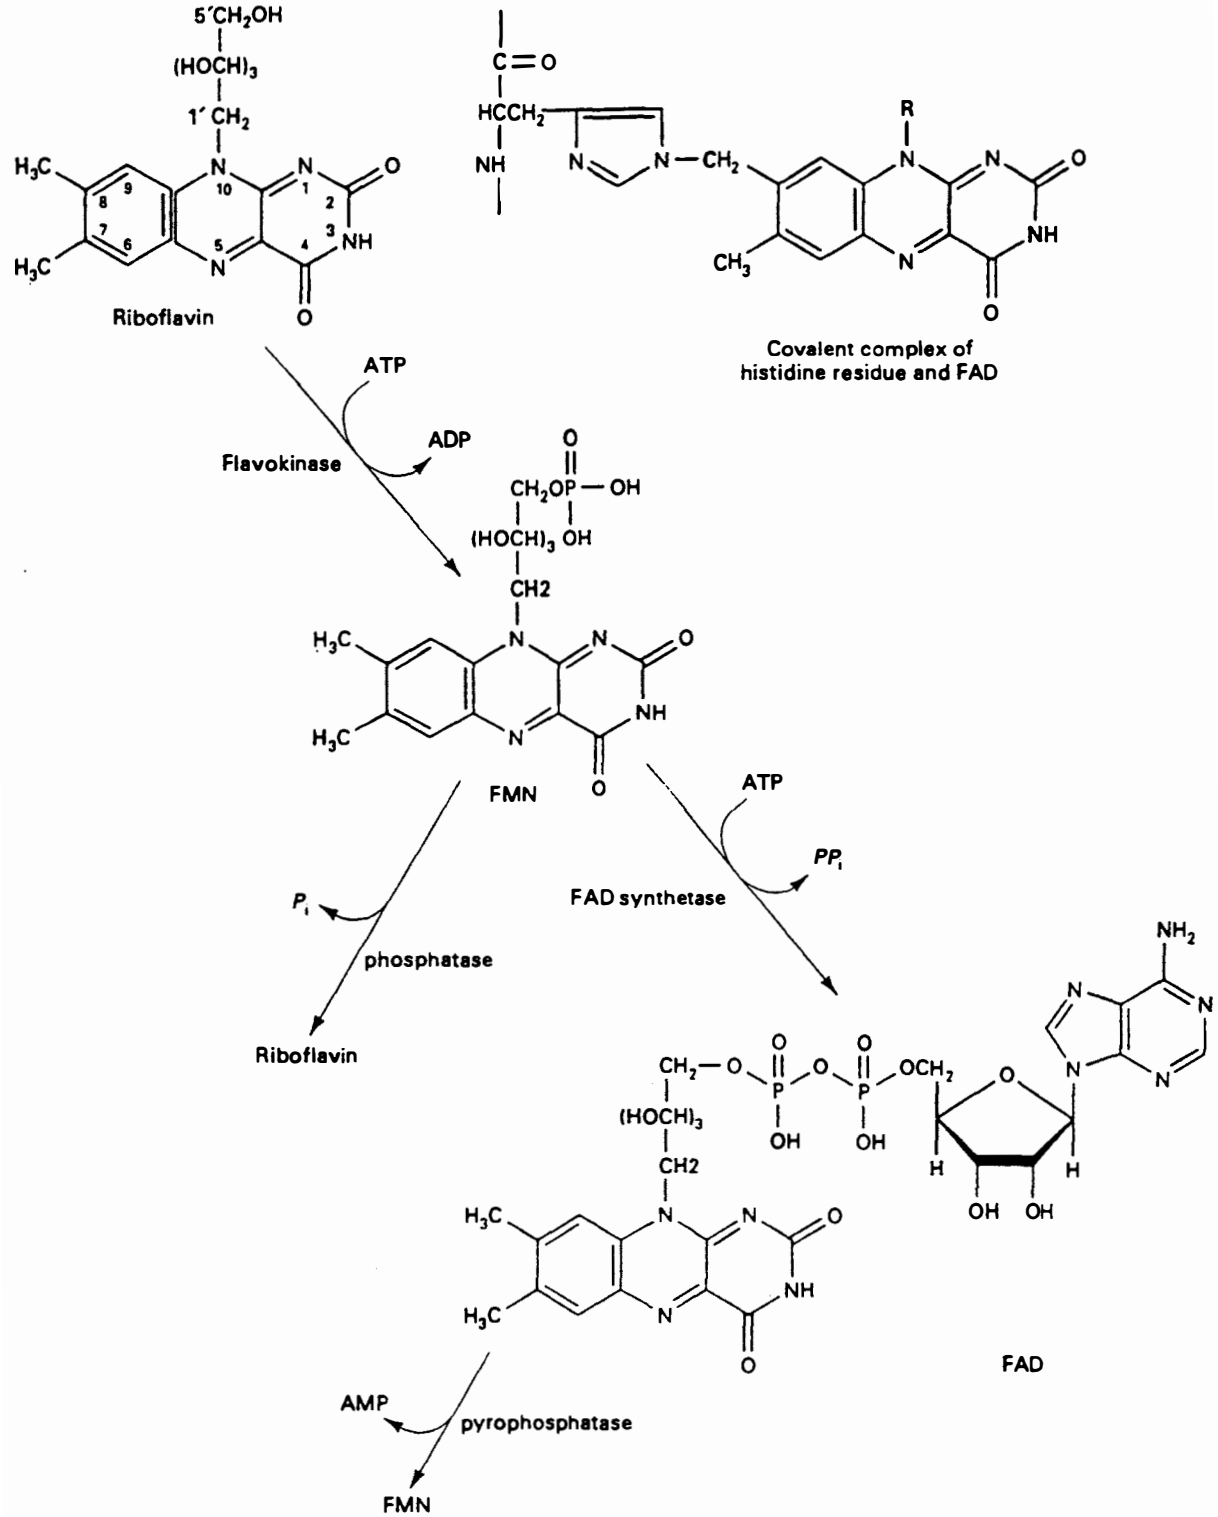

FIGURE 24.14 Riboflavin metabolism. The major forms of riboflavin found in cells are flavin adenine mononucleotide (FMN) and flavin adenine dinucleotide (FAD). In some enzymes, riboflavin may also be covalently bound to the enzymes that it serves, for example, succinic dehydrogenase.

drogen peroxide as a product. Oxygen preferentially participates in reactions involving one electron, one hydrogen transfer proceeding in a stepwise manner. The chemical characteristics of riboflavin are ideally suited for such reactions. Riboflavin-containing cofactors permit biological systems to carry out a range of redox reactions utilizing mechanisms that involve ion hydride transfers (via NAD or NADP), radical hydrogen ion transfers (via FMN or FAD) or ascorbic acid, and one-electron plus one-proton transfers (via FMN or FAD).

3. Metabolism and Requirements

FMN and FAD in foods is hydrolyzed in the upper gut to free riboflavin. Riboflavin is absorbed by active processes and is transported in blood to target tissues in association with albumin. Once in cells, riboflavin is phosphorylated to FMN. FMN is also released from cells and may bind to albumin for reutilization by other cells. Active-transfer mechanisms are responsible for the uptake of FMN. In this regard certain drugs, such as penicillin and theophylline, can displace riboflavin from binding proteins that are important to its transport. Urine is the major route of excretion for riboflavin, although some FAD is excreted in bile.

Requirements for riboflavin are lower than those for niacin or ascorbic acid, primarily because riboflavin is tightly associated with the oxidases and dehydrogenases it serves as cofactor. Riboflavin turnover is dependent on the turnover of the proteins to which it is associated. In some cases, FMN is covalently bound, such as in succinic dehydrogenase. Therefore, in most animals the half-life of riboflavin is several weeks to several months, in contrast to days to several weeks for niacin. Most small animals require 2–6 mg riboflavin per kg diet.

Riboflavin deficiency signs include lesions of the oral cavity, the lips, and the angle of the mouth (cheilosis), inflammation of the tongue (glossitis), and accompanying seborrheic dermatitis. In severe cases of riboflavin deficiency, the filiform papillae of the tongue are lost and the tongue changes color from its usual pink to magenta. Anemia and increased vascularization of the eye are present in some animals with riboflavin, deficiency. As grains are a poor source of riboflavin, deficiencies frequently occur in animals given diets predominantly based on cereal grains. One of the more striking and specific signs of riboflavin deficiency in birds is "curled toe syndrome." Curled toe paralysis has been of economic significance to the broiler industry. In young animals, growth failure, loss of feathers, or alopecia has also been observed.

4. Determination of Riboflavin Status

The erythrocyte glutathione reductase activity coefficient (EGRAC) is the preferred clinical test of riboflavin adequacy. This is an enzyme stimulation test and measures the reduction of oxidized glutathione by the enzyme glutathione reductase with and without the addition of exogenous FAD. In humans a ratio of 1.0 to 1.3 is normal and a ratio between 1.3 and 1.8 indicates deficiency. In dogs a ratio of greater than 1.3 has been taken to indicate deficiency.

D. B Vitamins Directed at Specific Features of Carbohydrate, Protein, or Lipid Metabolism

1. Thiamin

a. Introduction

Studies of thiamin played an important role in the development of early concepts of the function and importance of vitamins. The demonstration by the Dutch medical officer Christian Eijkman that polyneuritis, which was associated with human beriberi, could also be produced in an experimental animal by dietary manipulation presaged the use of animal models in the study of vitamins (Friedrich, 1988). Eijkman and his colleagues fed a diet of polished rice, presumably low in thiamin, to chickens and observed the characteristic feature of head retraction. The focus on rice and the observation that there appeared to be a curative principle in rice bran led to the eventual isolation of thiamin. This sequence of discoveries formed the basis of the discovery of vitamins as precursors to cofactors and their roles as regulators (Sable and Gubler, 1982).

b. General Functions

Thiamin in cells occurs either as the pyrophosphate (TPP) or the triphosphate, TPPP (Fig. 24.15). There are two general types of reactions wherein TPP functions as a magnesium-coordinated coenzyme for active aldehyde transfer reactions (Fig. 24.16). One example is the decarboxylation of α-keto acids, designated as a transketolase reaction. Decarboxylation of α-keto acids occurs twice in the tricarboxylic acid cycle (TCA): in the conversion of pyruvic acid to acetyl-CoA and in the conversion of α-ketoglutarate to succinyl-CoA. The other reaction of TPP is the facilitation of the transformation of "ketols" (ketose phosphates) in the pentose phosphates pathway. In this pathway, NADP is reduced to NADPH, an essential reducing agent for synthetic reactions (see the discussion of niacin). A deficiency of thiamin impairs metabolism of carbohydrates because of defective TCA cycle regulation. Further,

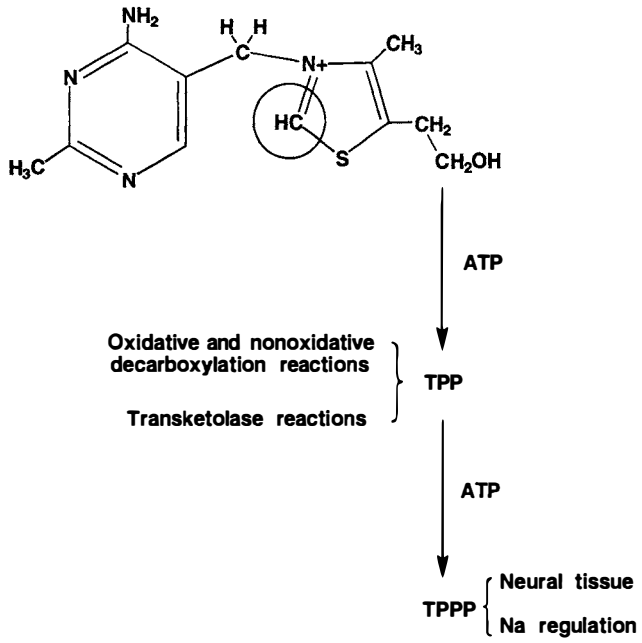

FIGURE 24.15 Thiamin. The five-membered (thiazole) ring of thiamin contains the (-N = CH − S-) arrangement of atoms called an ylid. The ylid arrangement results in a carbon with considerable negative charge, that is a carbanion. The circled carbon essentially acts as an electron-rich center for reactions that are commonly characterized as decarboxylations and transketolations. The cofactor form of thiamin is either as the diphosphate (TPP) or the triphosphate (TPPP). TPP predominates in neural tissue.

perturbations in the pentose phosphate-related carbohydrates pathway lead to decreased production of NADPH, which affects synthetic processes such as fatty acid biosynthesis (Bender, 1992).

TPPP predominates in neural tissue and in brain. In the brain, TPPP is proposed to be involved in sodium gating processes, that is, the flux of sodium ions across neuronal cell membranes. This aspect of thiamin metabolism may be related to the psychosis and impairment of neuromuscular control that is observed in humans with thiamin deficiency.

c. Requirements

Thiamin status should be routinely considered in disease assessment, because a number of factors influence thiamin availability and may induce a deficiency. Because thiamin is heat and alkali labile, extensive destruction of thiamin can occur in the various steps of food processing and preservation. Canning, which involves prolonged elevated temperatures and often alkaline conditions, can result in very low recoveries of thiamin in the final product. Thiamin can also be destroyed enzymatically by thiaminases, which are abundant in the flesh of some fish, particularly spoiled fish, and bacteria associated with fermentation processes. Thiamin deficiency has been observed in fish-eating birds, when spoiled or uncooked fish has been fed. Thiaminase activity is strikingly high in tuna and sardines, catalyzing the inactivation of milligram quantities of thiamin per hour per gram of fish muscle. Thiamin deficiency induced by thiaminases has also been reported in foxes fed uncooked fish products and in cats both given fresh fish, as well as in cats given canned cat food that has suffered excessive processing losses.

In herbivores, thiamin deficiency has occurred following ingestion of bracken fern (*Pteridium aquilinum*), horsetail fern (*Equisetum arvense*), or nardoo (*Marsilea drumen*), which contain thiaminases. In both herbivores and simple-stomached animals, predominant characteristic of thiamin deficiency is polioencephalomalacia. Primarily, lesions of the brain are hemorrhages of the periventricular gray matter and pathology of the inferior colliculi, medial vestibular, and lateral geniculate nucleii. A relationship between excessive production of hydrogen sulfide in the rumen of cattle and sheep and polioencephalomalacia has been demonstrated. The bioavailability of thiamin in foodstuffs is reduced by high levels of tannins. As a general requirement, animals should receive from 4 to 10 mg of thiamin per kg dry food (Combs, 1991).

d. Determination of Thiamin Status

Traditionally, the erythrocyte transketolase saturation test, which is a measure of the stimulation of the transketolase reaction, has been used to assess thiamin status. A stimulation of greater than 16% has been taken as deficiency. A more sensitive test, however, is the measurement of thiamin phosphorylated esters in plasma: The level of these esters declines in plasma before any change occurs in erythrocyte transketolase values. Thiamin loading tests that measure the urinary excretion of thiamin following an oral dose of thiamin have also been used, but lack the sensitivity of the measurement of esters in blood (Sable and Gubler, 1982).

2. *Pyridoxine*

a. Introduction

Vitamin B_6 is a collective term for pyridoxine, pyridoxal, and pyridoxine (Fig. 24.17). Pyridoxine is most abundant in plants, and pyridoxal and pyridoxine are most abundant in animal tissues (Combs, 1991; Dakshinamurti, 1990). Each of these compounds can be interconverted. The active form pyridoxal (B_6 PLP) is phos-

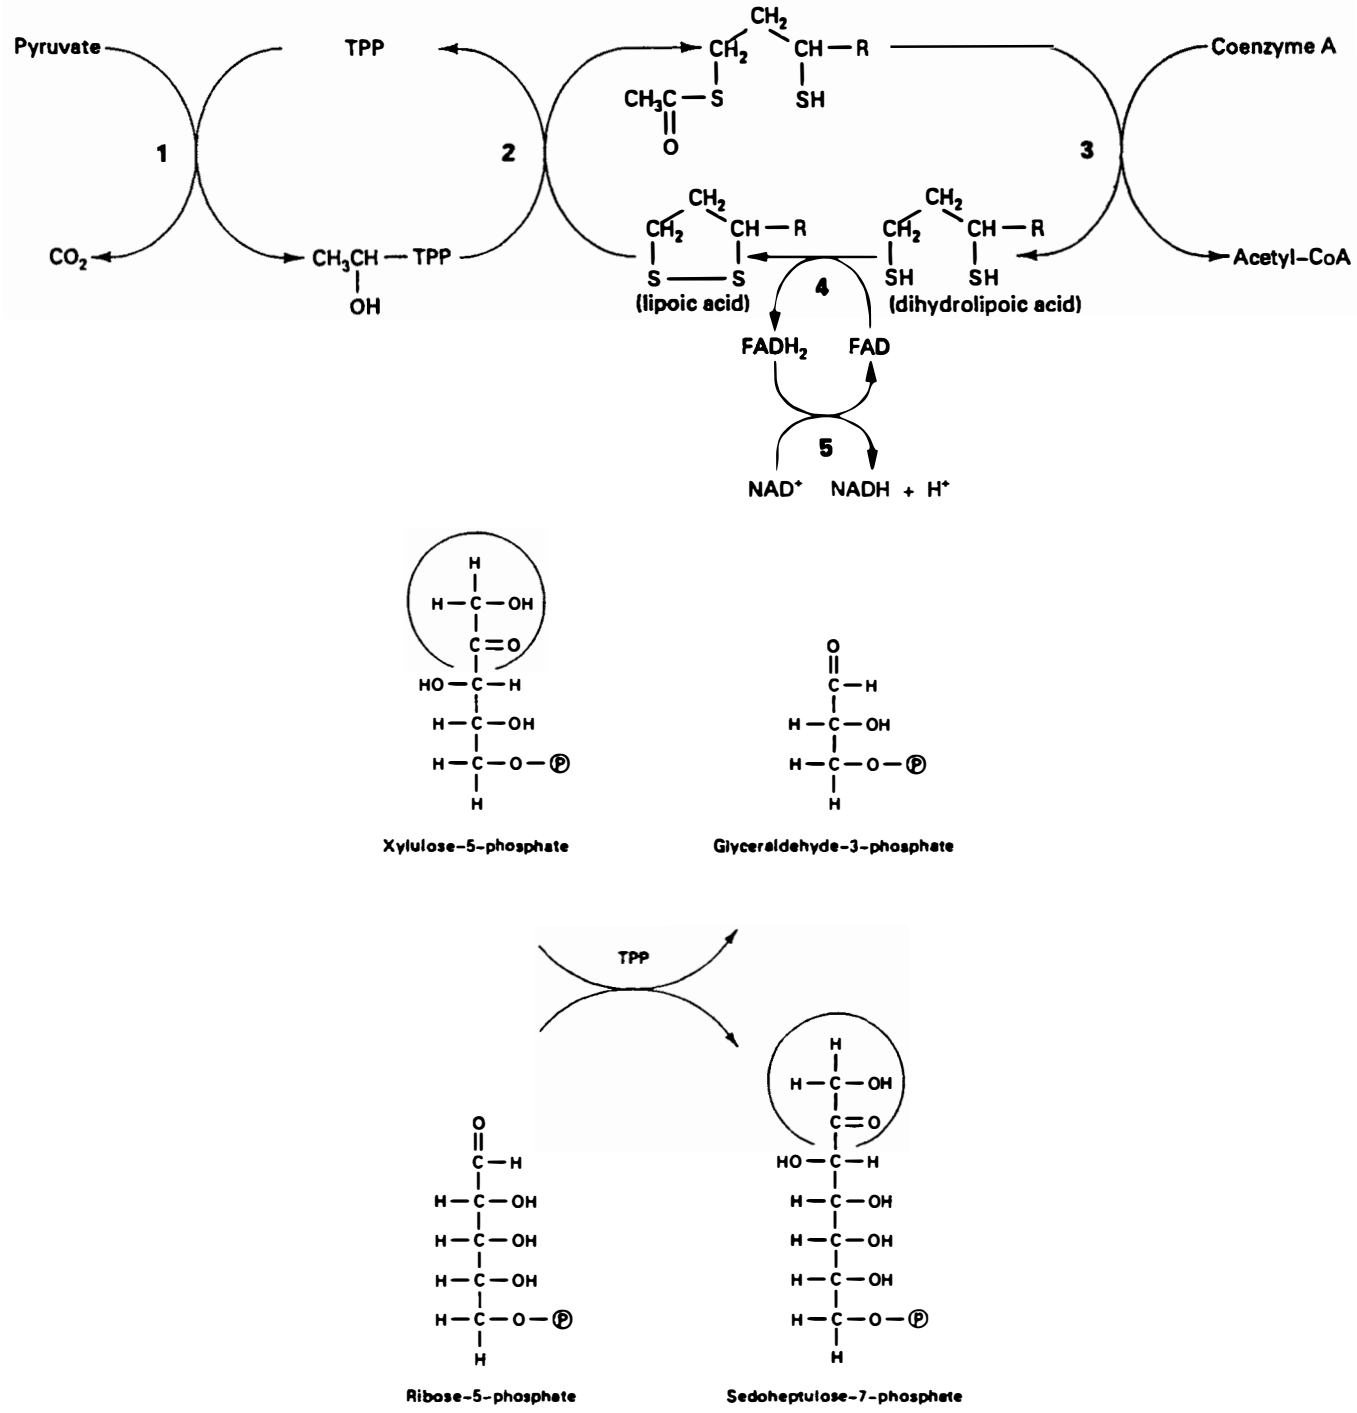

FIGURE 24.16 Reactions involving thiamin. The oxidative decarboxylation of pyruvic acid, and the transketolation reaction, such as the formation of sedoheptulose-7 phosphate and glyceraldehyde-3-phosphate from xyulose-5-phosphate and ribose-5-phosphate, are classic examples of reactions involving thiamin.

phorylated. When pyridoxal-5-phosphate is in excess, it can be converted to pyridoxic acid, which is excreted.

The reactions carried out by vitamin B_6 fall into three general categories related to the metabolism and interconversion of amino acids (Bender, 1992; Coburn *et al.*, 1984; Coburn, 1994). The most common of these reactions is the transaminase reaction. Transaminations are essential to the interconversion of amino acids

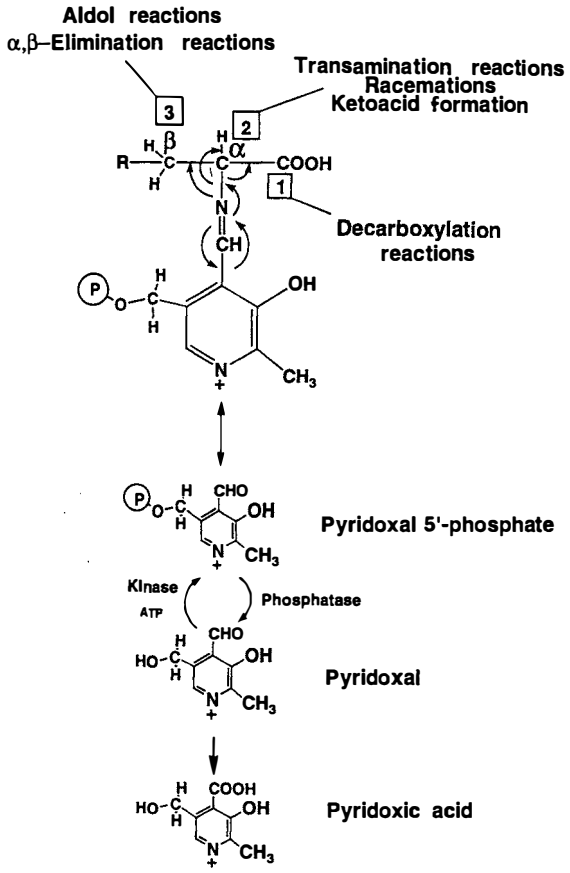

FIGURE 24.17 Vitamin B_6. Vitamin B_6 is a collective term for pyridoxal and the amidated and reduced derivatives pyridoxamine and pyridoxine (structures not shown). The active form of pyridoxal is phosphorylated and carries out decarboxylation reactions, transamination reactions (including racemations and keto acid formations and aldol reactions (including α–β elimination reactions).

and corresponding α-keto acids. The transamination mechanism also applies for reactions important to producing racemic amino acid mixtures, for example, the conversion of L-alanine to D-alanine, and α,β-addition or elimination reactions. Examples of α, β-elimination reactions are the conversion of serine to pyruvic acid and the conversion of homocysteine plus serine to cystathionine. The basic feature of the transamination-type mechanism involves electron withdrawal from the α-carbon, resulting in a proton liberation that sets the stage for substitution and addition reactions (Fig. 24.17).

The second most common reaction involves electron withdrawal from the α-carbon and carboxylic acid group carbon, which facilitates decarboxylation. Decarboxylation reactions include the conversions of tyrosine to tyramine, 5-hydroxytryptophan to serotonin, histidine to histamine, and glutamate to γ-aminobutyric acid (GABA). The convulsions associated with vitamin B_6 deficiency are attributed to insufficient activity of PLP-dependent L-glutamate decarboxylase, leading to a deficit of the inhibitory neurotransmitter GABA.

A third type of reactions involves electron withdrawal from the α- and β-carbons of amino acids. This sets the stage for hydride condensations or aldol reactions. A good example of an aldol reaction is the conversion of serine to glycine with the transfer of the β-carbon (as formaldehyde) to another vitamin cofactor, tetrahydrofolic acid. An excellent example of an hydride condensation is the formation of α-aminolevulinic acid, the first step in heme biosynthesis.

Another important function of vitamin B_6 (as pyridoxal 5'-phosphate), independent of amino acid metabolism, is its role in glycogen phosphorylase (Fig. 24.18). Glycogen phosphorylase catalyzes the hydrolysis of ether (α-1,4) bonds in glycogen to form glucose-6-phosphate. Ether bonds are best catalyzed through acid-mediated mechanisms. The acid proton in this instance is derived from the phosphate group of pyridoxal 5'-phosphate. This important mechanism was elucidated relatively recently. Previously, it was speculated that the association of vitamin B_6 with glycogen phosphorylase was primarily some type of storage mechanism (Palm *et al.*, 1990; Coburn, 1994).

b. Metabolism and Requirements

The requirement of vitamin B_6 by animals is positively related to their intake of protein and amino acids (Coburn,1994). Vitamin B_6 deficiency is rarely seen in animals, as most diets provide adequate amounts. Normally, vitamin B_6 is needed in amounts that range from 2 to 6 mg/kg diet. Ruminants and many herbivores meet a substantial part of their vitamin B_6 requirement from intestinal microbial synthesis. Drug-induced vitamin B_6 deficiency can occur following administration of the tuberculostatic drug isoniazid (isonicotinic acid hydrazide). This drug forms a hydrazone derivative with pyridoxal or pyridoxal phosphate that inhibits the pyridoxal-containing enzymes. Patients receiving long-term isoniazid therapy respond to the administration of supplemental vitamin B_6. Penicillamine (β,β-dimethylcysteine) used in the treatment of Wilson's disease also induces a vitamin B_6 deficiency because of the formation of an inactive thiazole derivative. A naturally occurring antagonist to vitamin B_6, linatine (1-amino-D-proline), is present in flax seed and forms a stable product with pyridoxal phosphate. The most important signs of B_6 deficiency relate to defects in amino acid metabolism. Neurological signs occur as

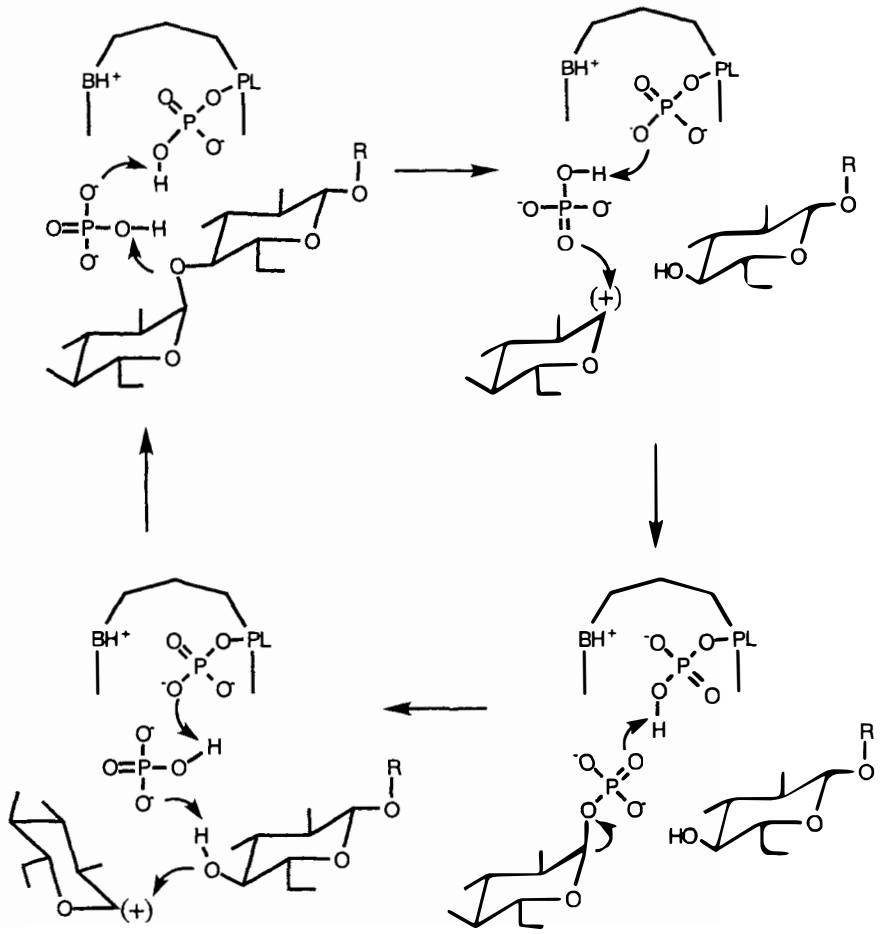

FIGURE 24.18 The role of vitamin B_6 in glycogen phosphorylase. Glycogen phosphorylase catalyzes the hydrolyses of ether bonds in glycogen to form glucose-6-phosphate. Ether bond cleavage is best catalyzed by acid-mediated mechanisms. In this case the acid proton comes from the phosphate group of pyridoxal-5-phosphate.

result of reduced synthesis of important biogenic amines from amino acid precursors, and anemia is a consequence of decreased heme synthesis. Some animals, such as cats, have a marked oxaluria when deficient in vitamin B_6.

c. Determination of Vitamin B_6 Status

A number of tests have been used as an index of vitamin B_6 status. These include measurement of the activities of enzymes that require pyridoxal phosphate as a coenzyme, such as kynureninase and aminotransferases. However, the most sensitive method involves the direct measurement of pyridoxal and/or pyridoxal phosphate in plasma. The relative ratio of these two forms and their response to dietary intake of pyridoxine depends on the species of animal.

3. Pantothenic Acid

a. Introduction

Pantothenic acid was discovered in 1933 by Roger William, who observed that it was an essential growth factor for yeast and lactic acid bacteria. Later, Elvehjen, Jukes, and others demonstrated pantothenic acid to be essential for animals. Pantothenic acid is a component of coenzyme A (Fig. 24.19). Pantothenic acid (as a part of phosphopantothene) is also present at the active site of acyl carrier protein (ACP), a component of the fatty acid synthesis complex, as phosphopantoteine. Both forms are present in foods. Consequently, absorbed pantothenic acid must first be released from coenzyme A and ACP, steps that involve the actions of peptidases and nucleosidases (Combs, 1991; Fox, 1991).

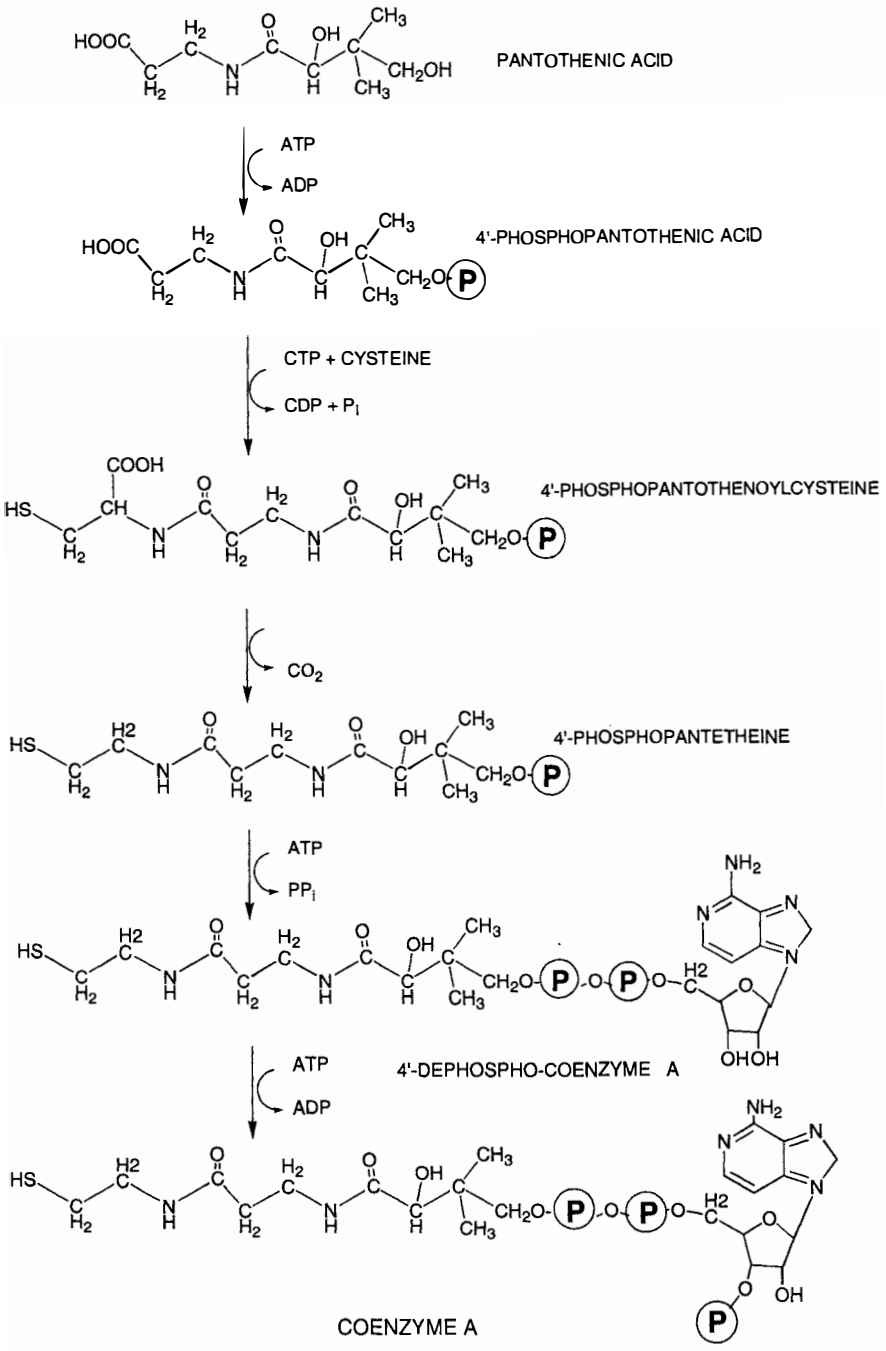

FIGURE 24.19 Pantothenic acid and coenzyme A.

b. Metabolism Functions and Requirements

CoA is the principal moiety for the vectoral transport of acyl and acetyl groups in synthetic and catabolic reactions, and a deficiency is characterized by impaired acetyl and acyl metabolism. The ability to utilize fatty acids as fuels is compromised. There is also an increased production of short-chain fatty acids and ketone bodies, which can lead to severe metabolic acidosis. In addition, dermal lesions occur because of impaired fatty acid metabolism. For most animals, the requirement for pantothenic acid is 10–20 mg per kg diet.

c. Assessment of Pantothenic Acid Status

Because of the widespread occurrence of the vitamin in foods, deficiencies are extremely rare. Urinary output of pantothenate is directly proportional to dietary input and has been used as an index of adequacy. For humans, mean excretion is 4 mg/day, and <1 mg/day is abnormally low.

E. Vitamins Involved in Single-Carbon Metabolism

1. Biotin

a. Introduction

Biotin functions in enzymatic carboxylation reactions as a cofactor for the CO_2-fixing enzymes: acetyl-CoA carboxylase, which is essential for fatty acid synthesis; propionyl-CoA carboxylase, which participates in odd-chain fatty acid metabolism; and pyruvate carboxylase (Bonjour, 1991), which is involved in the formation of oxaloacetate, an important obligatory step in reverse glycolysis and gluconeogenesis. Biotin is also involved as the coenzyme in the carboxylation of β-methylcrotonyl-CoA (a product of leucine metabolism).

b. Metabolism and Requirements

Biotin is found in highest concentrations in the liver. In food, biotin is present in relatively high concentrations in cereals, including soybeans, rice , barley, oats, corn, and wheat. Biotin is covalently bound to the enzymes that it serves as cofactor; the chemical linkage is to a peptide bond between the carboxylic acid moiety on biotin and the ε-amino function of peptidyl lysine in the enzyme. The biotin–enzyme peptide bond requires an ATP-dependent step (Fig. 24.20).

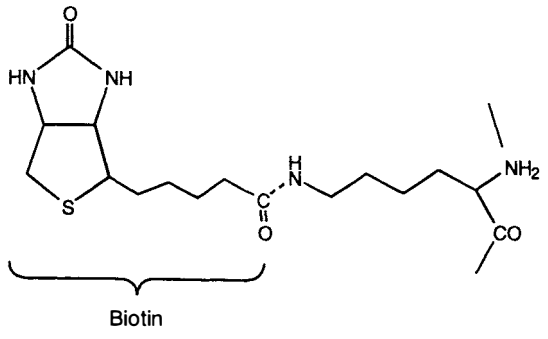

FIGURE 24.20 Biotin. Biotin is covalently bound in carboxylases and transcarboxylases by peptidyl linkage between the carboxylic acid moiety of biotin and the ε-amine function of peptidyl lysine. The biotin–lysine adduct is called biocytin. Biocytin can be cleaved by the enzyme biocytinase to generate free biotin.

When biotin-containing carboxylases are degraded, biotin is released as biocytin. Biocytinase is an important liver enzyme, that catalyzes the cleavage of the peptide linkage between biotin and lysine to release free biotin for reutilization. In the absence of the enzyme, biotin deficiency occurs in the newborn. The biotin requirement of animals is relatively low (in the microgram per kilogram range), which is due to at least three considerations. Biotin is covalently attached to a limited number of enzymes that it serves as a cofactor, it is extensively reutilized, and some biotin is produced by the gut microflora. Nevertheless, nutritional problems associated with biotin status can occur. Biotin and biocytin have a high affinity for certain proteins, particularly avidin in egg white. The consumption of raw egg albumin can induce biotin deficiency because the strong association of biotin with avidin renders dietary biotin unavailable. Ingestion of significant quantities of raw egg white by fur-bearing animals and pigs has lead to the condition described as "egg-white injury."

Biotin deficiency leads to impairment of gluconeogenesis and fat metabolism. Biotin deficiencies can also induce severe metabolic acidosis. The inability to carry out fat metabolism also markedly affects the dermis with biotin deficiency. Alopecia and dermatitis are characteristics of biotin deficiency in most animals and birds.

c. Assessment of Biotin Status

Deficiencies of biotin in the absence of consumption of raw egg white (avidin) are rare. Biotin has been measured in biological samples by microbiological assay methods following proteolytic digestion. Functional measurements of carboxylase activity (e.g., propionyl-CoA carboxylase) in liver samples have confirmed deficiencies in experimental animals.

2. Folic Acid and Vitamin B_{12}

a. Introduction

Knowledge of folic acid and B_{12} evolved from efforts to better understand macrocytic anemias and certain degenerative neurologic disorders (Brody *et al.*, 1991; Friedrich, 1988). The Scottish physician Combe recognized in the early 1800s that a certain form of macrocytic anemia appears related to a disorder of the digestive organs. In classic studies by Minot and Murphy, Castle, and others, it became clearer that the disorder was associated with gastric secretions and in some cases could be reversed by consuming raw or lightly cooked liver. Through careful clinical investigations and inferences, Castles postulated the existence of an intrinsic factor in gastric juice that appeared to combine

with a dietary extrinsic factor to modulate the severity of the anemia (Bender, 1992; Combs, 1991).

In parallel studies, folic acid was also associated with macrocytic anemia. Large-scale efforts by a number of pharmaceutical companies throughout the 1940s and 1950s and careful clinical and basic studies at academic institutions eventually led to the isolation of folic acid and vitamin B_{12} and our current understanding of the novel interactions between these two vitamins, as well as the complexity of their chemistry and unique features associated with absorption and transport.

b. Chemistry and Functions

The structures of folic acid and vitamin B_{12} are given in Fig. 24.21 and Fig. 24.22. Folic acid is a member of a family of compounds with a pteridine moiety. In the case of folic acid, the pteridine moiety is conjugated by a methylene bridge to *para*-aminobenzoic acid, which in turn is joined to glutamyl residues by a peptide linkage. An overview of one-carbon transfers involving tetrahydrofolate (THF) coenzymes and their metabolic origins is given in Fig. 24.21. The reactions include the generation and utilization of formaldehyde, formimino, and methyl groups. For these conversions to occur, folic acid must be in its completely reduced state. The reductions occur at positions 5, 6, 7, and 8 to form a tetrahydrofolic acid (THFA). Reduction brings the nitrogens at positions 5 and 10 closer together and changes the electrochemical properties of both, which facilitates the formation of the various THFA single-carbon derivatives that are involved in the metabolic conversions shown in Fig. 24.18. The formyl, methanyl, and methylene forms are utilized for purine synthesis and important steps in thymidy-

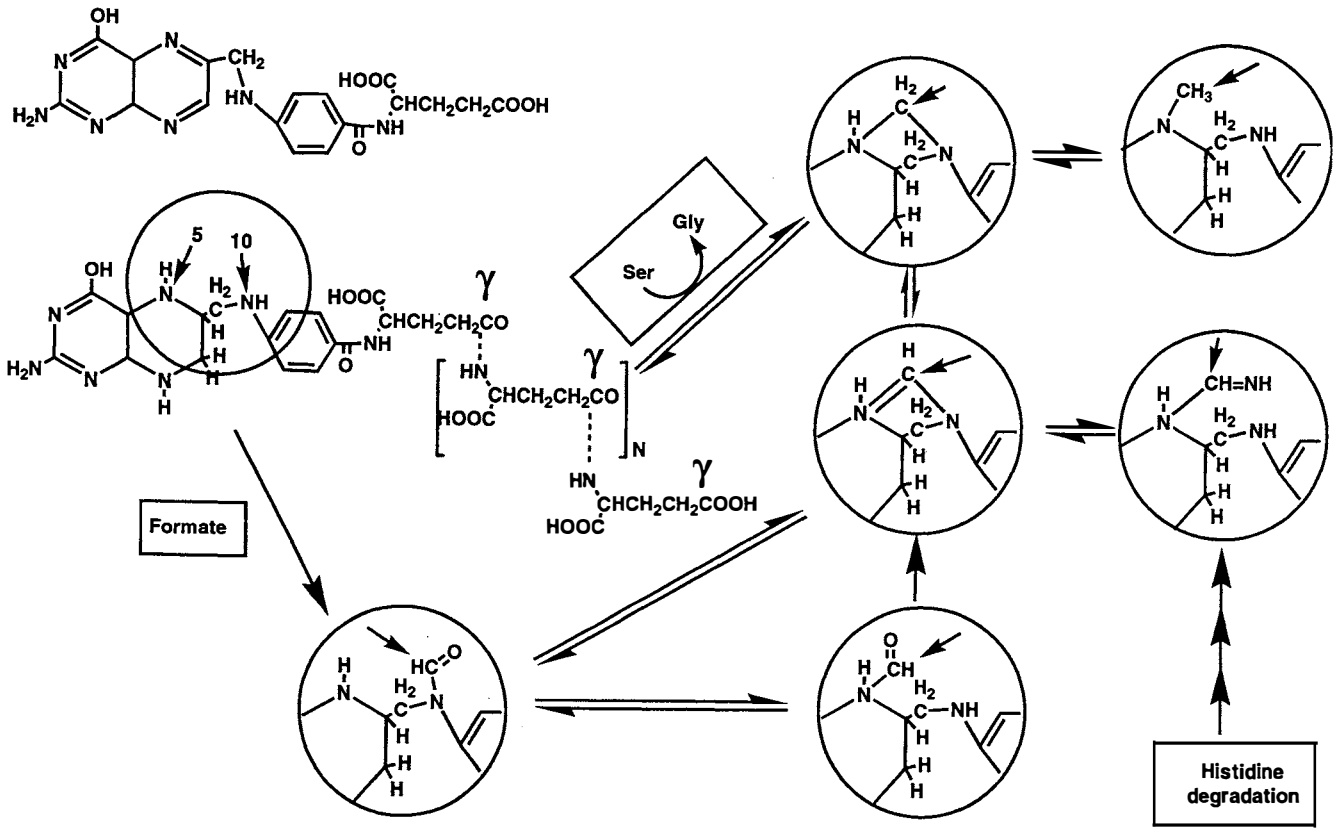

FIGURE 24.21 Folic acid. Structure of oxidized and reduced tetrahydrofolic acid (THFA) are shown. The 5 and 10 positions of the molecule are highlighted because these sites are important to single-carbon transfer. Folic acid is found in foods as γ-linked polyglutamyl folic acid (*n* ranges from 3 to 5 units). In the intestine, γ-peptidases (also referred to as conjugases) cleave the polyglutamyl residues to the single glutamate (as shown for the oxidized structure of folic acid). Single carbon units can enter into THFA by a number of routes. Formimino groups can arise from glycine and histidine degradation. Cylization results in N^5,N^{10}-methenyl THFA. Reduction of this product results in N^5,N^{10}-methylene THFA. This product can also be derived directly from an aldol-type condensation reaction arising from the conversion of serine to glycine (see Fig. 24.17). This step represents a major source of single carbon units. Subsequently, all of the forms of methylated THFA may be ultimately reduced to N^5-methyl THFA.

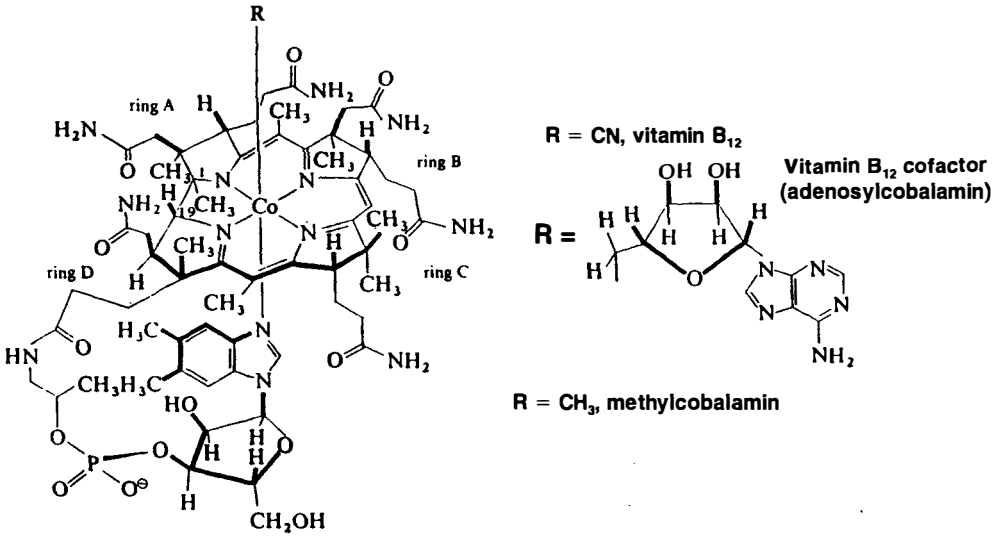

FIGURE 24.22 Structure of vitamin B_{12}. At the position designated as R, vitamin B_{12} can be methylated or coordinated with H_2O or a deoxyadenosyl moiety (see text). Commercial preparations of vitamin B_{12} are complexed with cyanide, for example, cyanocobalamine.

late (i.e., DNA-related) synthesis. These reactions are essential to cell division and proliferation and so are of obvious importance to animals. Folate also participates in reactions involved in the interconversion and catabolism of amino acids. Much of the folate in the body is in the form of methyl-THF, but for the transfer of methylene groups required for purine synthesis, folate has to be to in the form of THF. Removal of the methyl group from methyl-THF, and its eventual transfer to homocysteine, is effected by vitamin B_{12} and represents an important interaction between these two vitamins (Fig. 24.23).

Two vitamin B_{12} coenzymes participate in mammalian metabolism (Bender, 1992): vitamin B_{12} in the methylated form in the THFA–homocysteine transmethylase system, in which a methyl group is transferred from methyl THFA to homocysteine; and in the adenosylated form as 5-deoxyadenosylcobalamin, as a coenzyme of methylmalonyl-CoA mutase. In this reaction, methylmalonyl-CoA is converted to succinyl-CoA for ultimate use as a metabolic fuel (Fig. 24.24). This reaction is essential for the delivery of carbon from odd-chained fatty acids into the TCA cycle. In the absence of vitamin B_{12}, methylmalonic acid accumulates in blood and is excreted in the urine. This reaction of is particular significance to some herbivores and ruminants, which depend heavily on propionate, an odd-chain fatty acid, as a major gluconeogenic precursor.

c. Metabolism

Steps in the absorption, transport, and utilization of folic acid and vitamin B_{12} are more complex than for other water-soluble vitamins. In the case of folic acid, the conjugated glutamyl residues must be remove for effective absorption, for example, to monoglutam tetrahydrofolate. The enzymes in the intestinal cel that carry out the hydrolysis of conjugated glutam residues are commonly referred to as conjugases. Sp

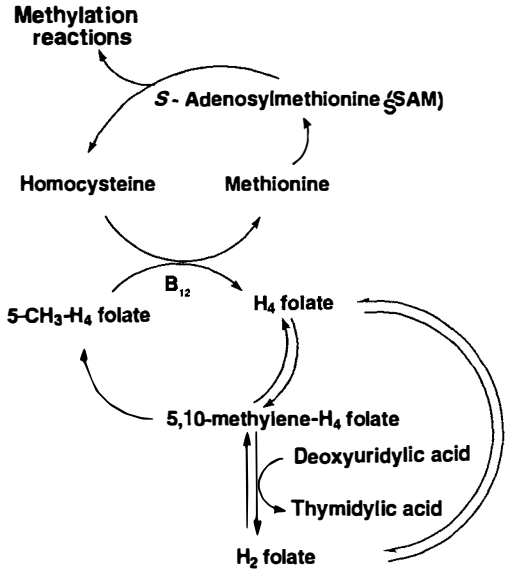

FIGURE 24.23 Interactive reactions involving THFA and vitam B_{12}. N^5, N^{10}-methylene THFA is important for thymidylic acid form tion from deoxyuridylic acid. The single carbon unit of other forr of THFA, such as the formyl and N^5,N^{10}-methenyl derivatives, a ultimately transferred through vitamin B_{12} to form methionine fro homocysteine. Methionine can be activated by ATP to produce adenosylmethionine. This intermediate is important to methylati of phospholipids and DNA, and to production of methylated forr of various amino acids and carbohydrates.

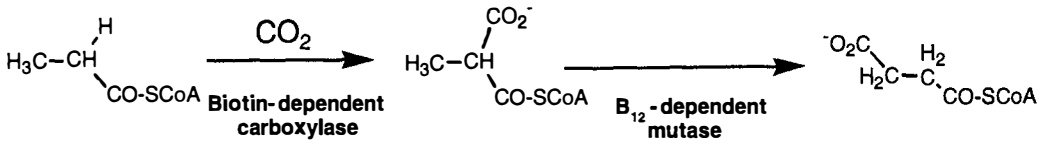

FIGURE 24.24 A vitamin B_{12}-dependent mutase reaction.

cific serum transport proteins exist for folic acid, and cellular uptake is by active processes . As folic acid is found in circulation primarily as methyl tetrahydrofolate, reduction and methylation are important steps in the eventual transfer of folic acid across intestinal cells into circulation.

For B_{12}, the steps important to processing involve first release of B_{12} from foods under acidic conditions (Ellenbogen and Cooper, 1991). Vitamin B_{12} then binds to proteins produced by cells of the gastric fundus (and also by the pancreas and salivary gland in some species). Two proteins have been identified, which are usually designated as R protein and intrinsic factor. Vitamin B_{12} first binds to R protein and is apparently released in the intestinal lumen by the action of pancreatic and intestinal proteinases and peptidases, to allow vitamin B_{12} to bind to intrinsic factor. The vitamin B_{12}–intrinsic factor complex then interacts with receptors on the intestinal brush border localized in the midgut, that is, the ileum.

Interference with R-protein intrinsic-factor production, inflammatory disease affecting the ileum, or overproduction of intestinal microflora can adversely affect the availability of vitamin B_{12}. With bacterial overproduction, there is competition between the host and bacteria for vitamin B_{12} and production of bacterial proteins that bind B_{12} and interact with its uptake. Gut bacteria can also be a source of B_{12}. Many animals obtain vitamin B_{12} through coprophagy. In ruminants, vitamin B_{12} is synthesized in large quantities by ruminal bacteria provided an adequate concentration of cobalt is present in the diet.

Once vitamin B_{12} is taken up by luminal cells, it is transported into the lysosomes where the vitamin B_{12}–intrinsic factor complex is degraded and the vitamin B_{12} is released and vectorally directed for release into plasma. Vitamin B_{12} is transported in plasma by one of at least three specific transport proteins, transcobalamins I, II, or III. The transcobalamins transport vitamin B_{12} to cells where it is again transferred into targeted cells by endocytotic mechanisms.

d. Requirements and Deficiency

The requirements for folic acid range from 1 to 10 mg per kg diet for most animals. There are some conditions in which the folic acid requirements are conditionally high, such as when either natural o pharmacological folic acid agonists are present in th diet. With the discovery that THFA is required fo DNA synthesis, a number of antimetabolites that func tion as inhibitors of folic acid reductase were devel oped in the 1950s and 1960s. The best example is meth otrexate, which ultimately inhibits the proliferatior and regeneration of rapidly replicating cells. Cell divi sion is blocked in the S phase because of impaired DNA synthesis. As a consequence, drugs such as meth otrexate are widely used in cancer chemotherapy, particularly for tumors of the lymphoreticular system.

The requirement for vitamin B_{12} for most animals is in the range of 2–15 μg per kg diet. Although deficiencies of folic acid and vitamin B_{12} are uncommon in free-ranging nonruminant animals, diseases of the stomach, proximal duodenum, or ileum and pancreatic insufficiency can affect folic acid and vitamin B_{12} absorption, respectively.

Deficiencies of both vitamin B_{12} and folic acid produce clinical signs of macrocytic anemia and dissynchronies in growth and development owing to the importance of folic acid to purine and DNA synthesis. Chronic deficiencies of either folic acid or B_{12} can also promote fatty liver disease and indirectly influence extracellular matrix maturation stability by causing abnormal elevations in homocysteine. Such signs and symptoms are attributable to both THFA and B_{12} deficiencies because of the integral relationship between vitamin B_{12} and THFA regeneration. Dietary intakes of folic acid sufficient to maintain functional THFA levels can mask the initial signs of vitamin B_{12} deficiency, such as macrocytic and megaloblastic anemia. Prolonged vitamin B_{12} deficiency in humans results in serious neurological disorders, such as degeneration of the myelin sheath.

e. Assessment of Vitamin B_{12} and Folate Status of Animals

The independent roles of vitamin B_{12} in propionate metabolism and folate in histidine metabolism provide the basis for methods of assessment of their adequacy, independent of their mutual role in methyl transfer. Vitamin B_{12} in a component of the coenzyme of methylmalonyl-CoA mutase that catalyzes the conversion of L-methylmalonyl-CoA to succinyl-CoA. Ad-

ministration of a loading dose of valine (1 g/kg body weight), which is a precursor for methylmalonyl-CoA, results in excretion of methylmalonic acid in urine in the vitamin B_{12}-deficient animal. Similarly, in histidine metabolism THF is required for the removal of the formimino group from formiminoglutamic acid. When a folate-deficient animal is given a loading dose of histidine (0.2 g/kg body weight) there is an enhanced urinary excretion of formiminoglutamic acid.

V. VITAMIN-LIKE COMPOUNDS

Vitamin-like compounds are products derived from carbohydrate, amino acid, or fatty acid metabolic pathways. These compounds primarily perform specialized transport functions or are associated with signal transduction mediators in cells. A nutritional case can be made that in some animal species, these compounds have important "conditional" requirements, that is, developmental periods may be identified in which a dietary source is required to maintain balance.

A. Lipotropic Factors

Nutritional requirements exist for a number of compounds at specific periods in development, particularly neonatal development, and periods of rapid growth. These compounds typically perform specialized transport functions particularly in relation to fatty acids. Apart from specific amino acids such as methionine, examples include choline, inositol, and carnitine.

1. Choline

Choline plays a key role in methyl group metabolism, carcinogenesis, and lipid transport and is a component of lecithin (Chan,1991). Choline is generally the major source of methyl groups in the diet, but can also be synthesized *de novo* from ethanolamine when methionine, dimethylcysteine, or betaine are in adequate supply. Formation of betaine from choline provides an important sources of labile methyl groups for transmethylation reactions. Sufficient amounts of choline are normally produced if the diet contains adequate amounts of precursors; however, in young growing animals a positive growth response can occur upon addition of choline, commercially available as trimethyl hydroxyethylammonium chloride or as the bitartrate (Fig. 24.25).

Choline is one of the precursors of acetylcholine Choline is also a component of sphingomyelin and lecithin (see Fig. 24.25). The most abundant source of choline in the diet is lecithin. The primary sign of a choline deficiency is fatty liver. In monkeys, dogs, and rats it has also been shown that prolonged choline

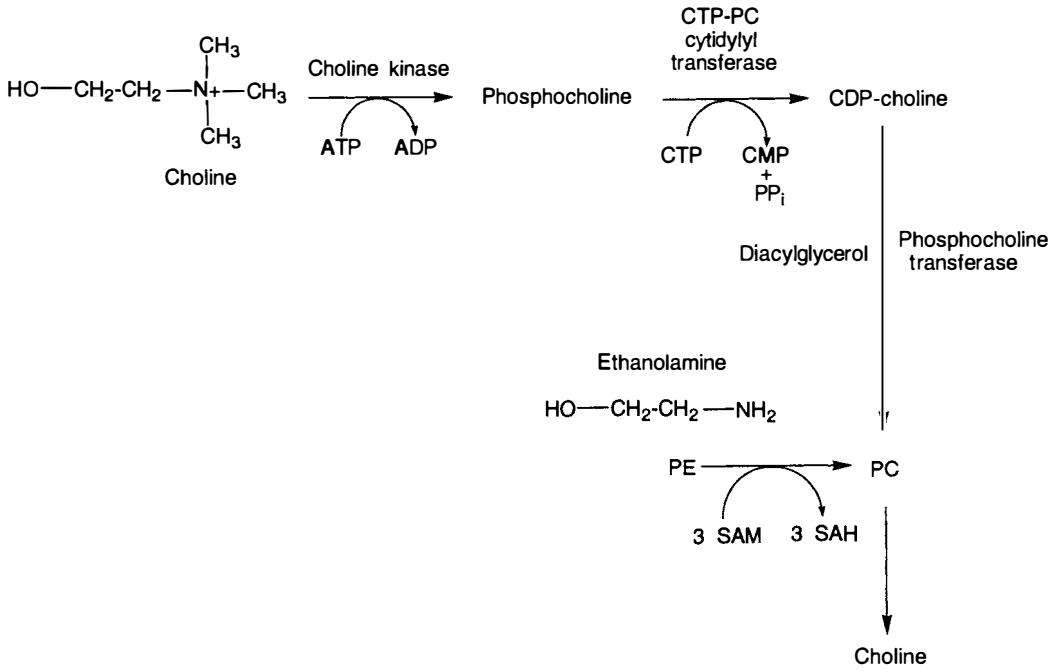

FIGURE 24.25 Choline and phosphatidylcholine (PC). Choline is essential for phosphatidylcholine (PC) synthesis. PC is one of the major phospholipids found in membranes and in circulating lipid particles. PC may be synthesized by several pathways. Choline as phosphocholine may be transferred directly to diacylglycerol following activation. PC may also be derived from diacylglycerol ethanolamine. In this pathway diacylglycerol ethanolamine is methylated by SAM to form PC.

deficiency results in cirrhosis. In mice and rats, prolonged deficiency ultimately results in hepatocellular cancer, a unique example of nutrition deficiency resulting in neoplasm. The dietary requirement for choline is dependent on the total sum of methyl donors in the diet, particularly methionine. Often, 500–1000 mg of choline are added per kilogram of diet.

2. *Inositol*

Inositol is also a component of phospholipids, and as with to choline, a dietary deficiency results in a fatty liver if the compound is limiting (Holub, 1987). Inositol is synthesized from glucose-6-phosphate after cyclization. In some animals, particularly gerbils and hamsters, a nutritional need for inositol can be demonstrated when they are given diets containing coconut oil. Myoinositol is plentiful in most foodstuffs. The estimated daily intake for large animals can be as high as 1 or 2 grams per day. Inositol is particularly important in signal transduction and phospholipid assembly. Plasma levels of inositol are increased during renal disease and nephrectomy. Otherwise, there is constant turnover due to incorporation and release from phospholipids.

3. *Carnitine*

Oxidation of fatty acids requires their transportation from the cytosol into the mitochondrial matrix where they undergo β-oxidation (Borum,1986). Carnitine plays a major role in this transport process by accepting activated fatty acids at the outer mitochondrial membrane Carnitine comes from both the diet and synthesis from peptidyl lysine (Fig. 24.26). After release of trimethyl lysine, the next steps involve its ascorbic acid-dependent hydroxylation. This step sets the stage for cleavage followed by a second hydroxylation step. These steps are not carried out efficiently in some neonates. Given the importance of carnitine to β-oxidation of long-chain fatty acids, carnitine deficiency can have profound effects on lipid utilization. An inherited carnitine deficiency has been recognized in some breeds of dogs.

Meats and dairy products, in contrast to plant foods, are well supplied with carnitine. Cereal grains, besides being low in carnitine, are also generally low in the precursors of carnitine: lysine and methionine.

4. *Taurine*

Although taurine (Fig. 24.27) is not generally considered a vitamin, the requirement for taurine by some animals is of the similar order as that for choline (Sturman, 1992). Taurine, or 2-aminoethanesulfonic acid, is present in all animal tissues and is one of the principal free amino acids in cells. Some tissues such as the retina, olfactory bulb, and granulocytes have particularly high concentrations of taurine. Taurine and/or glycine are used by many animals as conjugates for the bile acids. Some of the taurine excreted in the bile

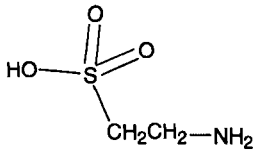
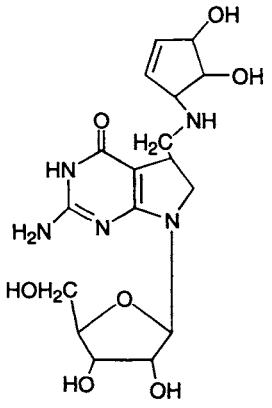
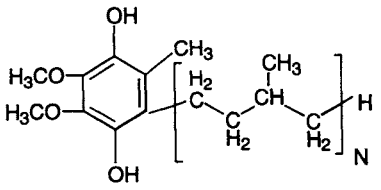
Inositol



Taurine



Queuosine



Coenzyme Q (reduced state)

FIGURE 24.27 Inositol, taurine, queuosine, and coenzyme Q.

is returned to the liver in the enterohepatic circulation. Most animals can synthesize adequate amounts of taurine from the oxidation of cysteine, to provide for the daily loss in the enterohepatic circulation. However, some animals, particularly domesticated and wild felids, and human infants do not synthesize adequate amounts of taurine. Dogs normally synthesize sufficient taurine to be independent of a dietary need for taurine; however, when dogs are given diets low in sulfur amino acids, taurine may become limiting. Cats are particularly susceptible to taurine deficiency. Defective synthesis in cats is a result of low activity of two enzymes in the synthetic pathway, cysteine dioxygenase and cysteinesulfinic acid decarboxylase, and an obligatory requirement for taurine to conjugate bile acids. A wide array of clinical signs have been described in taurine-deficient cats, including central retinal degeneration, reversible dilated cardiomyopathy, reproductive failure in queens, teratogenic defects, and abnormal brain development in kittens.

Dietary concentrations of taurine required to maintain adequate levels in plasma and whole blood are a function of type of diet, which affects the extent of microbial degradation that occurs in the enterohepati circulation. For most expanded diets, 1 g taurine/k dry matter is adequate, but canned diets may requir concentration up to 2.5 g taurine/kg dry matter.

5. Assessment of Taurine Status

Plasma and whole blood concentrations of 40 an 300 μM of taurine appear to be adequate in cats fo reproduction, which is the most demanding physiolog ical state for taurine.

B. Other Cofactors and Potential Vitamins

The following compounds are highlighted becaus of their known roles as coenzymes in prokaryotes an potential roles as probiotics (growth-promoting sub stances) in higher animals. These compounds includ queuosine, coenzyme Q, pteridines (other than foli acid) such as biopterin and the pteridine cofactor fo the Mo–Fe flavoproteins, lipoic acid, and pyrroloqu noline quinone.

1. *Queuosine*

Queuosine is included because it represents a novel product arising from a microbe–host interaction. Queuine is the nucleoside base that is modified to queuosine (Fig. 24.27). Queuosine resembles guanidine and is preferably utilized in some tRNAs. The importance of this interaction has yet to be fully understood. Germ-free animals survive without a source of queuine or queuosine (Farkas, 1980).

2. *Coenzyme Q*

Although claims have been made for a dietary requirement for coenzyme Q, more work is needed to fully clarify a true nutritional role for this compound. Ubiquinone or coenzyme Q is found in mitochondria. Coenzyme Q (Fig. 24.27) is structurally similar to vitamins E and K. Quinines are ideally suited to interact with cytochromes to effect the flow of electrons in the mitochondrial respiratory chain. Coenzyme Q can be synthesized and is easily absorbed from the intestine by the same route as other fat soluble vitamins. However, there is no known requirement for coenzyme Q in higher animals.

Of the lipophilic substances with redox cycling capacity, the ubiquinones (coenzyme Q) are a group of ubiquitous 2,3-dimethoxy-5-methyl benzolquinones substituted at position 6 with terpenoid chains of varying lengths. In mitochondria, coenzyme Q affects two-electron processes and helps initiate two single-electron transfers through semiquinone intermediates. Coenzyme Q is found mainly in the mitochondrial intermembrane. Although there is no apparent dietary requirement for coenzyme Q, it is present in food and promoted for various putative health benefits. After absorption from the intestine, coenzyme Q is transported by the same transport system as vitamin E and vitamin K.

3. *Pteridines*

In animals, tetrahydrobiopterin is an important redox cofactor, best known for its role at the catalytic site for phenylalanine hydoxylase (Kaufman, 1993). Tetrahyhydrobiopterin is presumably made in sufficient quantities from pathways important to guanine synthesis. A related pteridine cofactor is the molybdenum pteridine cofactor found in xanthine and other sulfur oxidases (Fig. 24.28). The importance of molybdenum to the synthesis of the molybdenum pteridine cofactor is the basis for molybdenum being an essential element.

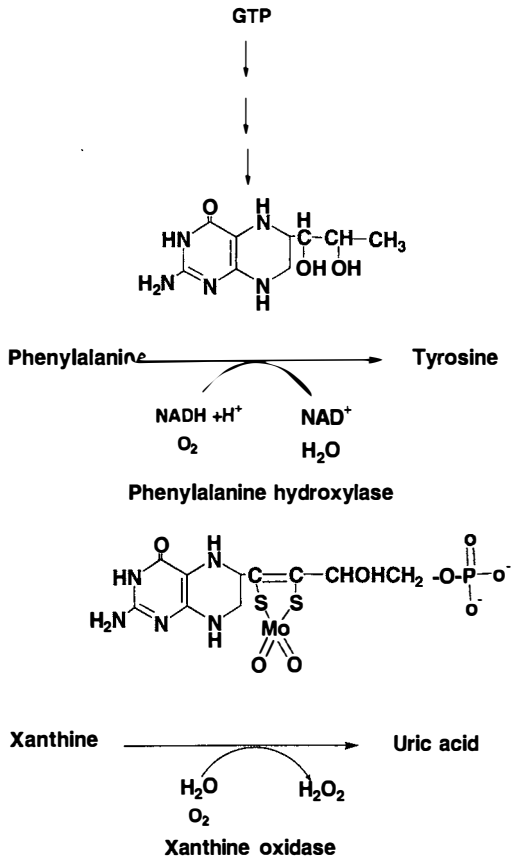


FIGURE 24.28 Biopterin (found in phenylalanine hydroxylase) and the molybdenum cofactor (found in xanthine oxidase).

4. *Lipoic Acid*

Lipoic acid is presumably made in the livers of most animals (Bender, 1992). This coenzyme is linked by amide linkage to lysyl residues within transacetylases. Lipoyl moieties functions in the transfer of electrons and activated acyl groups from the thiazole moiety of thiamin pyrophosphate to CoASH (Fig. 24.16). In this process the disulfide bond is broken and dihydrolipoyl transiently generated. Reoxidation is required to reinitiate this cycle. Although most reactions in biological systems may be described as nucleophilic in nature, reactions involving oxidized lipoic acid involve electrophilic mechanisms owing to the oxidized state of the two sulfur atoms in lipoic acids.

5. *Pyrroloquinoline Quinone*

Pyrroloquinoline quinone (PQQ) (Fig. 24.29) is a recently identified cofactor that was originally isolated from methylotrophic bacteria (Smidt *et al.*, 1991). PQQ is utilized in bacteria as a redox cycling cofactor. It has been shown to be present in mammalian tissue; however, its primary function is still not clear. PQQ

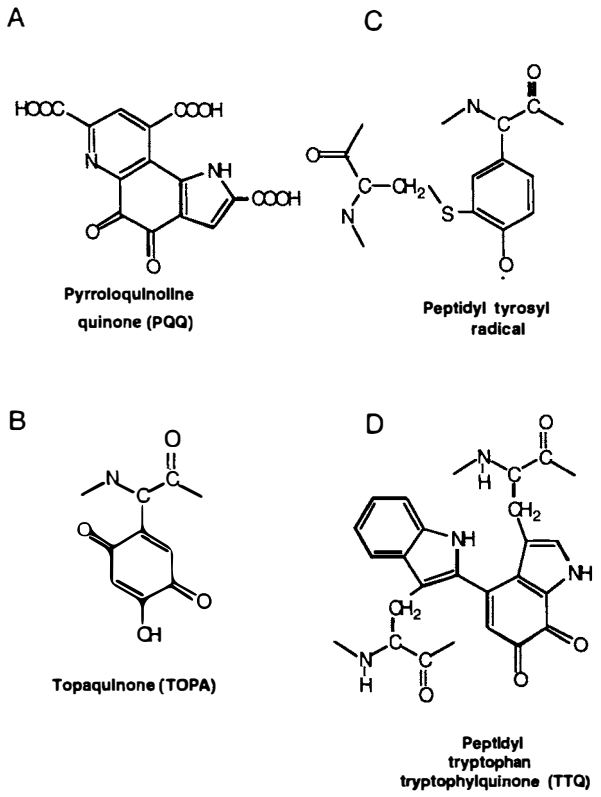

FIGURE 24.29 Quinone cofactors. Pyrolloquinoline quinone (PQQ) is a dissociable redox cofactor important to the metabolism of methylotrophic bacteria. It has growth-promoting properties in animals (a). TOPA is found in mammalian amine oxidases (b). The tyrosyl radical is at the active site of ribonucleotide reductase (c). TTQ, derived from tryptophan, is found in methylamine dehydrogenase in prokaryotes (d).

in amounts corresponding to 300 or more micrograms per kilogram diet is a potent growth stimulant in mice fed chemically defined diets. If there is a more universal nutritional need for PQQ, however, it has yet to be established. The growth response in mice only occurs in offspring from dams that have been nutritionally deprived of PQQ throughout their adult lives. Nevertheless, knowledge of PQQ's functions may prove to be important. It has the potential of serving as a cofactor. PQQ may also be viewed as similar to some of the bioflavonoid compounds, such as guerncin, rutin, and catechin, that appear to have health promoting benefits because of their ability to also act as redox cycling agents and/or antioxidants.

VI. CONCLUSIONS

The goals of this chapter were to highlight selected functions of vitamins and to develop concepts and principles relative to vitamins that may aid in clinical assessment. Vitamins represent a diverse array of molecules, which have equally diverse functional roles in an array of organisms and species. However, there are many common themes and similarities that have practical significance. For example, when expressed on an energy basis, vitamin requirements are often of the same order across species. Differences in requirements between species are usually due to unique pathways for production, degradation, or disposal. Ascorbic acid and niacin are examples of vitamins that cannot be synthesized by some animals and therefore are true vitamins. Similarly, there is a dietary requirement for vitamin D in cats and dogs, but the requirement is conditional for most other species. Taurine is an example of a nutrient where continual enteric degradation and loss results in a nutritional need.

Vitamin deficiencies are often the result of animals consuming monotonous diets, that is, diets based on a limited number of food sources. In nonruminant animals, the consumption of diets composed of a restricted array of foods clearly increases the probability of vitamin deficiency. Further, young and growing animals may have relatively higher need for some nutrients. Many species have a requirement for vitamins during the neonatal period that later in life may be produced in adequate amounts, for example, choline, carnitine, or inositol. There are also numerous possibilities for interactions that can have deleterious physiological consequences. The processing of foods can result in substantial losses of natural and added vitamins such as thiamin, and the presence of thiaminase (as in raw fish) is another potential source of loss. Although single vitamin deficiencies of the fat-soluble vitamins occur naturally, frequently multiple vitamin deficiencies of the B complex are encountered. Foods that are poor sources of one of the B vitamins tend to be poor sources of several B vitamins.

With respect to functions, vitamins evolved to serve unique and complex roles: as cofactors, as signaling agents in cells, as regulators of gene expression, and as redox and free-radical quenching agents. As is the case for any substance that is essential to a given function, all vitamins at some point in development can be viewed as limiting nutrients, the absence of which results in specific deficiency signs and symptoms.

Lysosomal Storage Diseases

MARK HASKINS AND URS GIGER

I. LYSOSOMAL BIOLOGY

In 1955, de Duve *et al.* named the cytoplasmic particles that contain a series of hydrolytic enzymes lytic bodies, or "lysosomes." These organelles have a single lipoprotein membrane and contain several dozen different acid hydrolase enzymes (Holtzman, 1989), which typically catalyze catabolic reactions $A-B + H_2O \rightarrow A-H + B-OH$. Lysosomes and their "housekeeping" enzymes function in degrading many substrates that are found in all nucleated mammalian cells. Deficiencies of these enzymes lead to lysosomal accumulation of these substrates, thereby causing disease.

In normal cells, most lysosomal hydrolases are synthesized as preproenzymes on rough endoplasmic reticulum (ER) ribosomes. Through a signal-recognition particle complex, the enzymes are translocated into the lumen of the ER, where high-mannose oligosaccharides are added (Fig. 25.1; reviewed in Kornfeld and Sly, 1995). These oligosaccharides are trimmed and the glycoprotein moves to the Golgi apparatus, where further shortening occurs. Further posttranslational modification results from the action of two enzymes that add a mannose-6-phosphate (Man-6-P) marker. The Man-6-P moiety can be recognized by two similar integral membrane glycoprotein receptors that transfer the enzyme to the lysosome. These two receptors are (1) small and cation-dependent for binding, and (2) large and cation-independent, which in some species also bind insulin-like growth factor II. Both receptors appear responsible for the transport of the enzymes from the Golgi apparatus via clathrin-coated vesicles to the prelysosomal/endosomal compartment. Once the lysosomal enzymes dissociate, the receptors recycle to the Golgi apparatus.

A proportion of the Man-6-P modified enzyme in the Golgi may also leave the cell via secretory granules (Fig. 25.1). Different enzymes appear to be secreted from cells in varied amounts (Dobrenis *et al.*, 1994). Thus, the level of activity in serum of any particular enzyme is related to how much is secreted and its stability at plasma pH. Secreted enzyme can also ultimately reach the lysosome because the cation-independent receptor is present in the plasma membrane on some cells such as fibroblasts (Kaplan *et al.*, 1977; Distler *et al.*, 1979; Natowicz *et al.*, 1979). Thus, enzymes that connect with this receptor can be internalized and transferred to lysosomes. This pathway provides the mechanism for therapy for lysosomal storage diseases discussed later.

Although posttranslational glycosylation is common to most lysosomal enzymes, other modifications or activator proteins are necessary for the function of a subset of the hydrolases. For example, the eight lysosomal sulfatases undergo an additional co- or posttranslational modification, which converts a cysteine

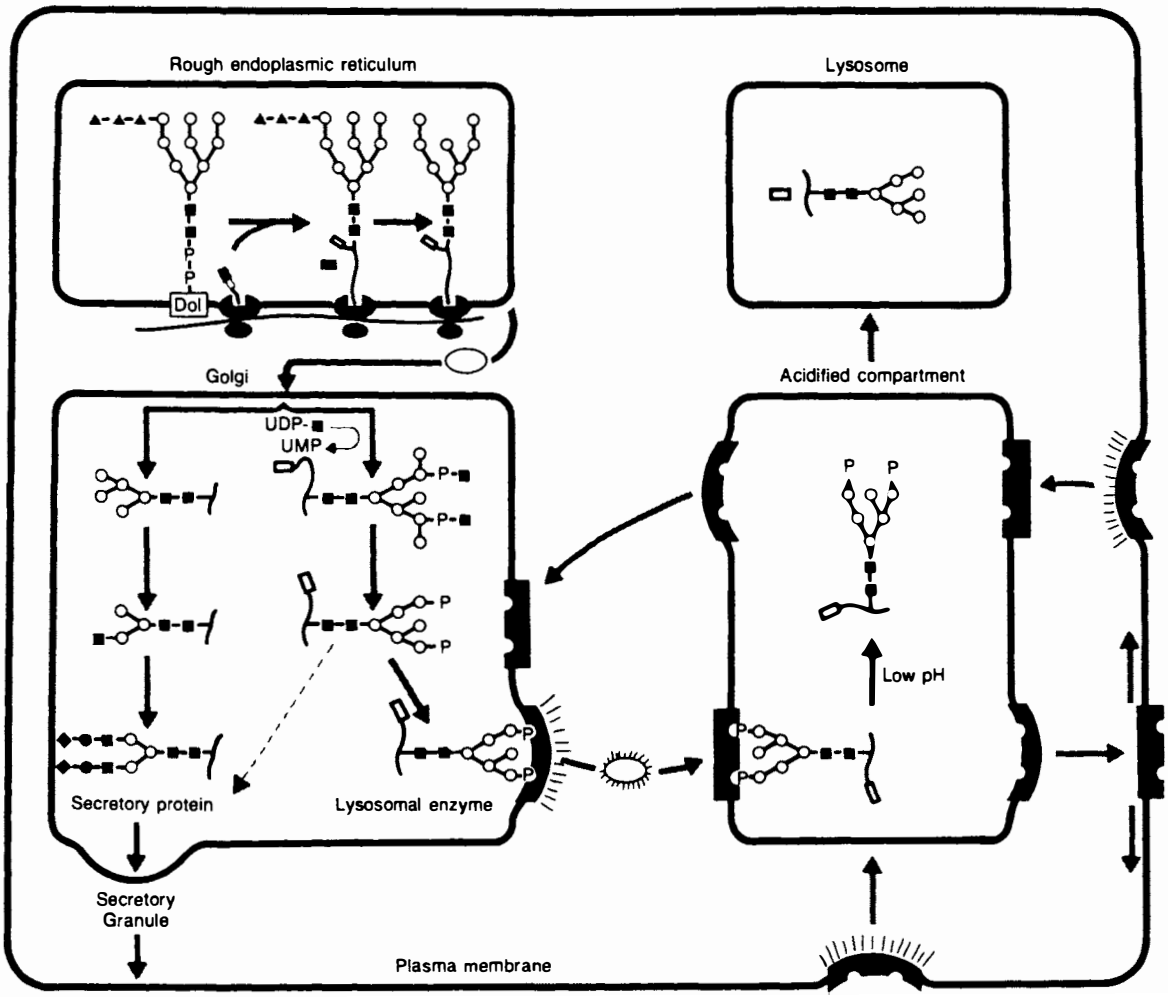

FIGURE 25.1 Schematic diagram of how lysosomal enzymes are processed and delivered to the lysosome. (From Kornfeld, S., 1987. Trafficking of lysosomal enzymes. *FASEB J.* **1,** 463, with permission.)

residue common to all known eukaryotic sulfatases to 2-amino-3-oxopropionic acid (Schmidt *et al.*, 1995). The absence of this conversion results in multiple sulfatase deficiency. The degradation of sphingolipids with short hydrophilic head groups requires sphingolipid activator proteins (SAPs), which are small, nonenzymatic glycoproteins (reviewed in Sandhoff *et al.*, 1995). Deficiency in activity of SAPs is also known to cause lysosomal storage diseases.

Lysosomes function in degrading large complex substrates that have been taken into a cell by endocytosis, or autophagy (the degradation / turnover of a cell's own molecules). The endosome containing the substrates fuses with a primary lysosome, producing a secondary lysosome, which contains the mixture of hydrolases and substrates. Degradation of most substrates occurs by the activity of a series of hydrolases in a stepwise fashion, each step requiring the action of the previous hydrolase to modify the substrate, thereby permitting catabolism to proceed to the next enzyme step in the pathway. If one step in the process fails, further degradation ceases. For example, the glycosaminoglycans, formerly known as mucopolysaccharides, are long molecules of repeating subunits and are, as part of proteoglycans, a component of the ground substance of the extracellular matrix. The series of hydrolases that are responsible for the stepwise degradation of one of the glycosaminoglycans (GAGs), dermatan sulfate, are illustrated in Fig. 25.2. Each enzyme works sequentially. Each of the enzymes in this pathway has been described as deficient in a domestic animal (Table 25.1).

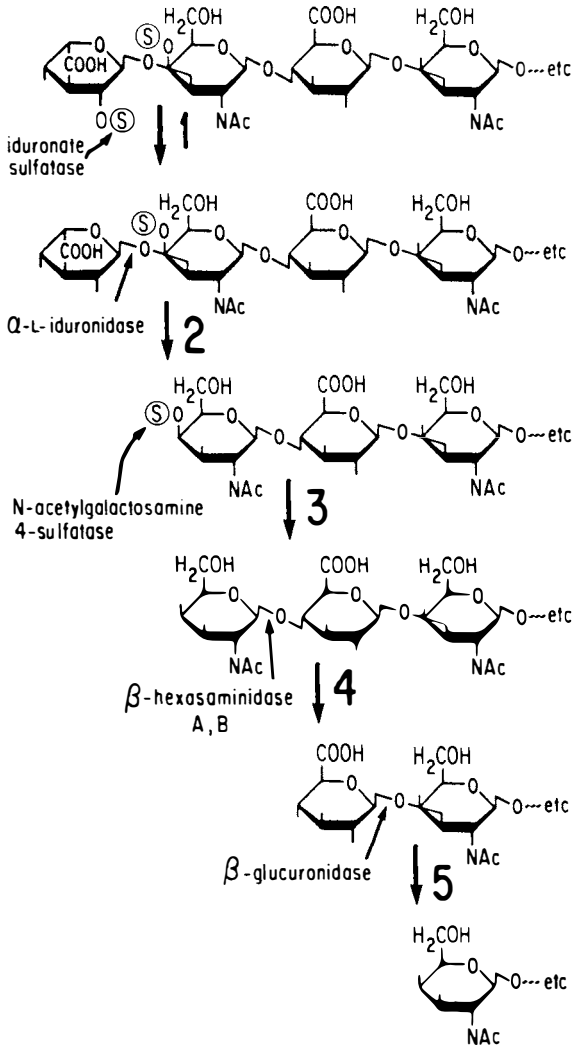

FIGURE 25.2 The stepwise degradation of the glycosaminoglycan dermatan sulfate by a series of lysosomal enzymes, all of which have been determined to be deficient in activity in domestic animals. [From Neufeld, E. F., and Muenzer, J. (1995). The mucopolysaccharidoses. *In* "The Metabolic and Molecular Bases of Inherited Disease, Seventh Edition, Vol. II. (C. R. Scriver, A. L. Beaudet, W. S. Sly, and D. Valle, eds.), p. 2467. McGraw Hill, Inc., New York, with permission.]

II. LYSOSOMAL STORAGE DISEASES

The lysosomal storage diseases (LSDs) are defined as a group of individually rare genetic disorders of cellular catabolism. The earliest detailed clinical reports of a LSD were in humans by Tay (1881) and Sachs (1887). Eighty one years later the stored material in this disease (Tay–Sachs disease) was defined as G_{M2} ganglioside (Svennerholm, 1962); seven years later the enzyme that is deficient in activity (β-hexosaminidase A) was defined (Okada and O'Brien, 1969; Sandhoff, 1969). Isolation of the cDNA coding for the alpha subunit of β-hexosaminidase A was reported 15 years later (Myerowitz *et al.*, 1984, 1985; Korneluk *et al.*, 1985), which was quickly followed by the identification of the first of more than 50 mutations responsible for Tay–Sachs disease (Myerowitz and Hogikyan, 1986, 1987) and the cloning of the gene (Proia and Soravia, 1987).

Most LSDs are inherited as autosomal recessive traits and result from mutations in the coding sequence of one of the acid hydrolases located in the lysosome. Point mutations, deletions, and other alterations in sequence may occur anywhere along the length of DNA coding the enzyme protein. Each individual alteration will produce a unique change in the protein.

The consequence of such a genetic abnormality is the reduction or elimination of the catalytic activity of the particular enzyme. This reduction in enzyme activity results in the accumulation within the lysosome of the substrate of that enzyme (Fig. 25.3), hence the name lysosomal storage disease. The reduction in the amount of product of the metabolic pathway does not appear to produce disease. LSDs are classified by the primary substrates that accumulate and are defined by the individual enzyme that is deficient in activity. For example, the mucopolysaccharidoses (MPSs) are a group of diseases resulting from defective catabolism of glycosaminoglycans. Each of the MPSs is caused by impaired function of one of 10 enzymes required for normal glycosaminoglycan degradation. In humans, these disorders were initially defined by clinical phenotype, then by the particular glycosaminoglycan(s) (heparan, dermatan, chondroitin, and keratan sulfates) present in the urine of patients. Now, in addition to being defined by the enzyme that is deficient in activity, many of the diseases are subdivided by the particular mutation in the coding sequence of the gene responsible for the defect.

Different mutations of the same gene may produce (1) very similar diseases, as seen in two families of cats with MPS VI (McGovern *et al.*, 1985), or (2) somewhat different diseases, as is seen in humans with MPS IH and MPS IS, with and without CNS disease, respectively (Neufeld and Muenzer, 1995). Affected individuals either may be homozygous for the same mutation in both alleles, or may be heteroallelic (having one mutation in the allele on one chromosome and a different mutation in the allele on the other chromosome). In addition, if the substrates being stored in different diseases have similar pathologic effects, mutations of different lysosomal enzyme genes may produce very similar diseases. This has been described in humans with MPS III A–D, each caused by a different enzyme deficiency, yet all have a very similar phenotype (Neu-

Mucopolysaccharidosis III D (Sanfilippo D syndrome)	*N*-Acetylglucosamine 6-sulfatase	Nubian goat (Thompson *et al.*, 1992; Friderici *et al.*, 1995)
Mucopolysaccharidosis VI (Maroteaux–Lamy syndrome)	*N*-Acetylglucosamine 4-sulfatase (arylsulfatase B)	Siamese cat (Cowell *et al.*, 1976; Jezyk *et al.*, 1977; Haskins *et al.*, 1979c, 1980; McGovern *et al.*, 1985; DiNatale *et al.*, 1992) Domestic short-haired cat (Giger *et al.*, unpublished) Miniature pinscher dog (Neer *et al.*, 1992, 1995) Miniature schnauzer dog (Thrall, personal communication) Welsh corgi dog (Giger *et al.*, unpublished) Rat (Yoshida *et al.*, 1993a,b, 1994)
Mucopolysaccharidosis VII (Sly disease)	Beta-glucuronidase	Mix-breed dog (Haskins *et al.*, 1984; Schuchman *et al.*, 1989) Gus mouse (Birkenmeier *et al.*, 1989; Vogler *et al.*, 1990; Sands and Birkenmeier, 1993) Cat (Gitzelmann *et al.*, 1994)
Sphingomyelinosis A and B (Niemann–Pick A and B diseases)	Acid spingomyelinase	Siamese cat (Chrisp *et al.*, 1970; Wenger *et al.*, 1980; Snyder *et al.*, 1982; Yamagami *et al.*, 1989) Miniature poodle dog (Bundza *et al.*, 1979) Mouse[a]

[a] Mutation analysis (Horinouchi *et al.*, 1993) has shown that the two mouse models previously described (Pentchev *et al.*, 1980, 198 Miyawaki *et al.*, 1982) lack a molecular defect in the acid sphingomyelinase gene. Consequently, they represent sphingomyelinosis C or D

feld and Muenzer, 1995). Animals with LSDs very closely resemble their human counterparts.

Several animal species were diagnosed clinically and pathologically as having a lysosomal storage disorder (included in Table 25.1) before this group of diseases was defined by deficiencies in hydrolase activity. The first definitive discovery of an enzyme deficiency in a nonhuman animal species was G_{M1} gangliosidosis in a Siamese cat by Baker *et al.* in 1971. Since then, naturally occurring LSDs defined by a deficiency in lysosomal enzyme activity have been recognized in cats, cattle, dogs, goats, mice, pigs, rats, and sheep (Table 25.1). Notably, although there are estimated to be more than 5 million horses in the United States and although the horse is a closely observed species, an LSD has not been documented in horses.

It is important to recognize that there is a group of diseases that apparently involve the lysosome, but which at present have not been defined as being caused

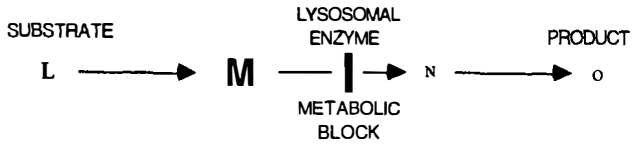

FIGURE 25.3 Metabolic consequences of an enzyme deficiency. The reduction in catalytic activity of the enzyme that converts M to N results in the accumulation of M within the lysosome.

by a defect in hydrolase activity or transport: ceroi lipofucinosis (Batten disease), sphingomyelinosis ((Niemann–Pick disease C), and Chediak–Higashi syr drome (Table 25.2). Two of the subcategories of ceroi lipofucinosis have recently had an enzyme (palmitoy protein thioesterase: Vesa *et al.*, 1995) and gene (CLN gene: Lerner *et al.*, 1995) associated with them in hu mans. The animals listed in Table 25.2 have not y been characterized with respect to the basic defect.

An additional group of storage diseases result fro defects in glycogen metabolism and do not involv lysosomal enzymes (Table 25.3). Although they are n LSDs, they are presented here for completeness an to avoid confusion. Note that glycogenosis type II an LSD and is included in Table 25.1. Several mous models of LSDs have now been created by gene knocl out technology (Table 25.4). In creating a knockou the phenotype has ranged from essentially no diseas to being fatal soon after birth. New knockout mode of LSDs will continue to be created in mice to provic more information about the pathogenesis of these d bilitating disorders, and for evaluating therapy.

III. PATHOGENESIS

In LSDs, the continued presentation of substrates the cell for degradation results in storage and the pr duction of large lysosomes. By electron microscopy, l

Ceroid lipofuscinosis	Palmitoyl-protein thioesterase; CLN3 gene	Australian cattle dog "blue heelers" (Cho *et al.*, 1986; Wood *et al.*, 1987) Border collie dog (Taylor and Farrow, 1988) Chihuahua dogs (Rac and Giesecke, 1975) Cocker spaniel dogs (Fankhauser, 1965; Beck, 1974; Nimmo Wilkie and Hudson, 1982) Dachshund dogs (Cummings and de Lahunta, 1977; Vandevelde and Fatzer, 1980) Dalmatian dog (Malkusch, 1982; Goebel *et al.*, 1988) English setter dog (Koppang, 1969, 1973, 1979, 1988) Saluki dogs (Appleby *et al.*, 1982) Tibetan terrier dog (Riis *et al.*, 1992) Yugoslavian shepherd dog (Bichsel and Vandevelde, 1982) Siamese cat (Green and Little, 1974) Devon cattle (Harper *et al.*, 1988) South Hampshire sheep (Jolly *et al.*, 1980b, 1988, 1989, 1992) Swedish sheep (Järplid and Haltia, 1993)
Sphingomyelinosis C (Niemann–Pick C disease)	Unknown defect in cholesterol transport.	Cat (Lowenthal *et al.*, 1990; Munana *et al.*, 1994) Mouse previously classified as type A (Pentchev *et al.*, 1980; Miyawaki *et al.*, 1982, 1986) Mouse (Adachi *et al.*, 1976; Tanaka *et al.*, 1988; Goldin *et al.*, 1992; Ohno *et al.*, 1992; Butler *et al.*, 1993; Higashi *et al.*, 1991, 1993) Boxer dog (Kuwamura *et al.*, 1993)
Chediak–Higashi syndrome	Unknown	Cats (Kramer *et al.*, 1977) Cattle (Padgett *et al.*, 1964) Foxes (Nes *et al.*, 1983) Killer whales (Taylor and Farrell, 1973) Mice (Lutzner *et al.*, 1967) Mink (Leader *et al.*, 1963)

sosomes within the cytoplasm can be seen as membrane-bound inclusions containing the stored substrate (Fig. 25.4). However, in some LSDs, the substrates that accumulate may be lost during tissue processing. The swollen lysosomes become large enough to be seen by light microscopy (Fig. 25.5). The accumulation of the primary substrate for a particular enzyme pathway may then interfere with other lysosomal hydrolases necessary for different degradative pathways (Kint *et al.*, 1973), thus leading to the secondary accumulation of these additional substrates. As substrates accumulate, the lysosomes swell and occupy more and more of the cytoplasm (Fig. 25.6). This increase in the number and size of lysosomes may obscure the other cellular organelles, and may deform the nuclear outline. As the process continues, the affected cells swell, leading to organomegaly. With the exception of the central nervous system (CNS), and cartilage and bone, the pathophysiology of these disorders is predominantly related to the increase in the cell, tissue, or organ size. For example, in the mucopolysaccharidoses, storage of glycosaminoglycans within the cells of the mitral heart valve causes these normally fusiform cells to become rounded (Fig 25.6). This, in turn, causes the valve leaflet and cordae tendinea to become thick (Fig. 25.7), interfering with normal cardiac function and producing a murmur. Stor-

age within the cells of the cornea (Fig. 25.8) results in reflection and refraction of light, producing the cloudiness observed grossly and by ophthalmoscopy (Fig. 25.9).

In many LSDs, the central nervous system contains swollen neurons (Fig. 25.10) and lysosomes which contain lamellar substrate (Fig. 25.11). The pathogenesis of the CNS lesions includes the development of meganeurites and neurite sprouting, which appear correlated with alterations in ganglioside metabolism (Purpura and Baker, 1977, 1978; Purpura *et al.*, 1978; Walkley, 1988; Walkley *et al.*, 1988, 1990, 1991; Siegel and Walkley, 1994). Gangliosides, whether stored as a primary substrate (in G_{M1} and G_{M2} gangliosidosis) or secondarily (in MPS I) appear to stimulate neurite sprout development. The presence of new neurites and their synapses apparently plays a role in the CNS dysfunction of these diseases.

I-cell disease (named for the inclusions seen in cultured fibroblasts; Tondeur *et al.*, 1971) is an exception to the usual pathogenesis of LSDs (reviewed in Kornfeld and Sly, 1995). As is frequently observed, exceptions can provide new information about normal processes. Studies of fibroblasts from patients with this disease were

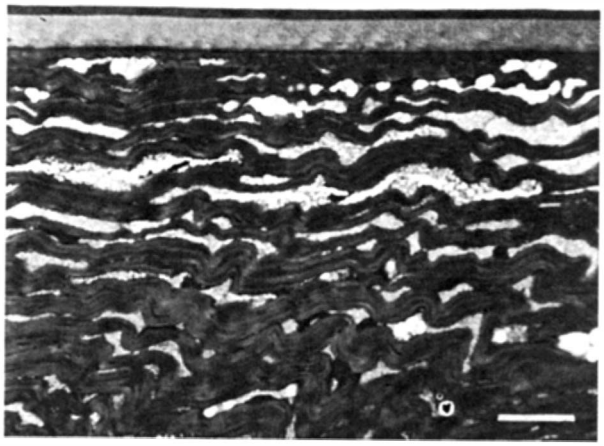

FIGURE 25.8 A light micrograph of the posterior cornea from a cat with MPS VI illustrating the highly vacuolated keratocytes. Bar = 25 μm.

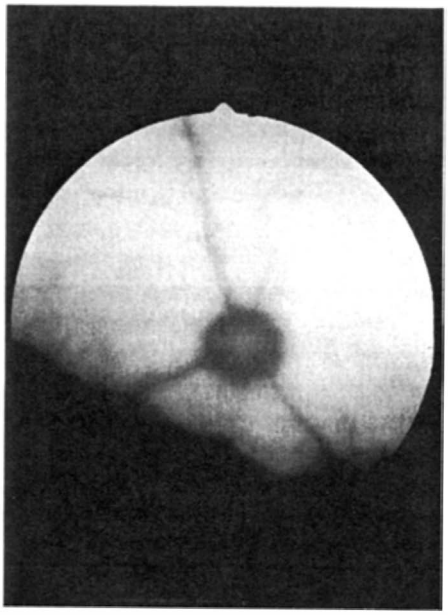

FIGURE 25.9 The appearence of the retina with indistinct optic disc and vessels of an MPS I cat as seen through the cloudy cornea.

seminal in providing insight into the Man-6-P transport system (Hickman and Neufeld, 1972). This disorder results from a failure in the first enzyme in the pathway responsible for the posttranslational phosphorylation of the mannose moiety of most lysosomal hydrolases (Reitman *et al.*, 1981; Hasilik *et al.*, 1981). The consequence of a defect in this phosphotransferase enzyme is production of lysosomal enzymes that lack the signal responsible for efficiently directing the enzymes to the lysosome by the Man-6-P receptor-mediated pathway. Thus, little of the enzyme reaches the lysosome, and large amounts are secreted extracellularly into the plasma. Because the phosphotransferase activity has

FIGURE 25.11 A electron micrograph of the lysosomes in a neuron from a cat with MPS I showing the lamellar inclusions. These inclusions are not typical of glycosaminoglycans, but rather represent glycolipids that accumulate secondary to the primary substrate storage. Bar = 0.5 μm.

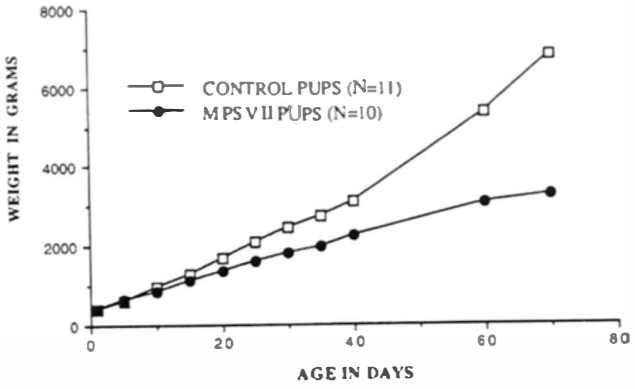

FIGURE 25.12 Growth retardation often seen in animals with lysosomal storage disorders. ●, pups with MPS VII (N = 10); □, control pups (normal littermates; N = 11).

been difficult to measure, the diagnosis of I-cell disease has usually been reached by demonstrating the low intracellular activity of most lysosomal enzymes, and consequent high enzyme activity in serum. Although a clinical and pathologic phenotype that combines all of the lysosomal storage diseases would be expected in I-cell disease, this does not occur. I-cell is a severe disease in children and cats, most of the pathology is found in mesenchymally derived cells; Kupffer cells and hepatocytes are essentially normal (Martin *et al.*, 1975, 1984). Mental retardation is present in children, and death is common before 8 years of age; however, there is relatively little CNS pathology (Nagashima *et al.*, 1977; Martin *et al.*, 1984). All cell types examined to date have been deficient in phosphotransferase activity, yet many organs (including liver, spleen, kidney, and brain) have normal intracellular lysosomal enzyme activities. This observation indicates that there is either an intracellular Man-6-P-independent pathway to lysosomes, or that secreted enzymes are internalized by cell surface receptors that recognize carbohydrates on enzymes, such as mannose, which is not phosphorylated (Waheed *et al.*, 1982). A Man-6-P-independent pathway to the lysosome has been demonstrated for β-glucocerebrosidase and acid phosphatase (Williams and Fukuda, 1990; Peters *et al.*, 1990).

IV. CLINICAL SIGNS

As a group, these disorders are usually chronic and progressive and have a wide spectrum of clinical severity, even within a particular disease. The predominant clinical signs are related to the CNS, skeleton, eye, cardiovascular system, and organomegaly. Most LSDs can be divided clinically into those with and without CNS involvement. Head and limb tremors that progress to gait abnormalities, spastic quadriplegia, seizures, and death are commonly observed. The disorders in animals with marked clinical signs of CNS disease include fucosidosis, galactosylceramide lipidosis, G_{M1} and G_{M2} gangliosidosis, α- and β-mannosidosis, MPS III A and D, and sphingomyelinosis A and B.

Other clinical signs associated with lysosomal storage disorders are associated with failure to thrive, growth retardation (Fig. 25.12), umbilical hernia, corneal clouding, hepatosplenomegaly, cardiac murmurs, and skeletal abnormalities including facial dysmorphia and vertebral, rib, and long-bone deformities (Fig. 25.13). The MPS disorders, in general, affect more organ systems than the other diseases. The age of onset and severity of clinical signs is usually relatively consistent within a disease in animals; however, some variability can exist even in a family having the same

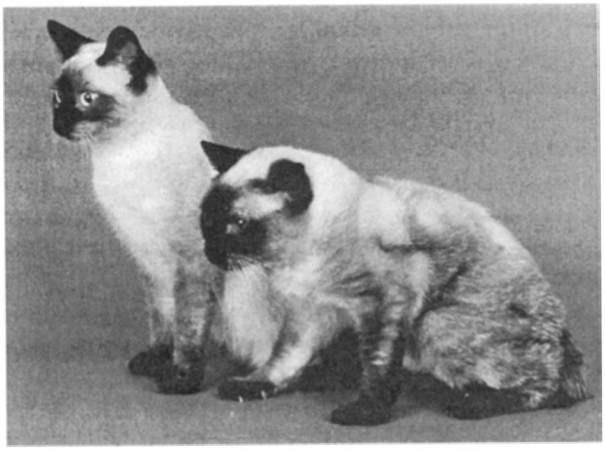

FIGURE 25.13 A normal Siamese cat next to a littermate with MPS VI. Note the outward manifestations of the skeletal abnormalities: flattened facies, small size, low posture associated with fusion of the cervical and lumbar spine.

TABLE 25.5 Diseases in Animals in Which a Mutation in the Coding Sequence of the Relevant Enzyme Has Been Determined

Disease	Deficient enzyme	Species and selected references
Fucosidosis	Alpha-fucosidase	Springer spaniel dog (Skelly *et al.*, 1996)
Galactosylceramide lipidosis	Galactosylceramidase (galactocerebroside beta-galactosidase)	Cairn terrier dog, West highland white terrier dog (Wenger, 1995, personal communication)
G_{M2} gangliosidosis	Beta-hexosaminidase A and B	Korat cat (Muldoon *et al.*, 1994)
Alpha mannosidosis	Alpha-mannosidase	Angus and Gallway cattle (Nilssen, 1995)
Beta mannosidosis	Beta-mannosidase	Anglo-Nubian goat (Haithcock *et al.*, 1995; Jones, 1995, personal communication) Saler cattle (Chen *et al.*, 1994)
Mucopolysaccharidosis I	Alpha-L-iduronidase	Domestic cat (Schuchman, 1995, personal communication) Plott hound dog (Menon *et al.*, 1992)
Mucopolysaccharidosis III D	*N*-Acetylglucosamine 6-sulfatase	Nubian goat (Cavanagh *et al.*, 1995)
Mucopolysaccharidosis VI	Arylsulfatase B	Rat (Kunieda *et al.*, 1995) Siamese cat (Yogalingam *et al.*, 1996)
Mucopolysaccharidosis VII	Beta-glucuronidase	GUS mouse (Sands and Birkenmeier, 1993) DSH cat (Fyfe *et al.*, 1996)

mutation. In research colonies of dogs and cats with LSDs kept in a relatively consistent environment, the explanation for varied clinical signs rests with the variable genetic background upon which the mutation is expressed.

Most LSDs are manifest within four months after birth, with some evident before weaning and fewer with adult onset (canine MPS IIIA). In severely affected animals, death often occurs before weaning. In research colonies, heterozygous matings are expected to produce, on average, 25% affected offspring. However, because of neonatal death, significantly fewer affected offspring reach weaning age.

In humans with LSDs, although not always consistently, specific mutations in some diseases have been associated with a particular pattern of clinical severity and progression. Null mutations that produce little RNA or unstable RNA resulting in no enzyme protein synthesis usually have a severe phenotype. Although specific mutations have recently been identified for several LSDs in animals (Table 25.5), there is still not enough information to be useful in prognosis.

V. DIAGNOSIS

The approach to a diagnosis of an LSD includes a complete history and physical examination with evaluation of the chest, abdomen, CNS, skeleton, and eyes. Laboratory tests should include a complete blood count with evaluation of granulocyte and lymphocyte morphology, skeletal radiographs, and urine screening for abnormal metabolites, particularly glycoaminoglycans. It may be helpful to establish a fibroblast culture from a skin biopsy, and to perform a liver biopsy. The disease may progress quickly, and the diagnosis may follow a complete postmortem examination.

A pedigree analysis should be performed as part of the history to determine information about the inbreeding of the parents and the presence of other family members with similar clinical signs or that died early. As most LSDs are inherited as autosomal recessive traits, parents are often related and are carriers (heterozygotes), but are clinically (phenotypically) normal. On average, one-fourth of the offspring of heterozygous parents are affected, two-thirds of unaffected offspring are carriers, and other relatives may also be affected (Fig. 25.14).

Abnormal metabolites may be found in urine, and their presence points toward specific metabolic pathways that warrant further evaluation. A metabolic screen of urine (Fig. 25.15; Jezyk *et al.*, 1982; Giger and Jezyk, 1992) for GAGs is a relatively simple and inexpensive approach to identify the mucopolysaccharidoses and some cases of gangliosidosis (toluidine blue spot test; Fig. 25.16). Thin-layer chromatography of urinary oligosaccharides is helpful in identifying mannosidosis. Urine samples to be evaluated should be kept refrigerated or frozen and sent on ice to an appropriate laboratory.[1]

A final diagnosis for LSDs requires the demonstration of a particular enzyme deficiency. Enzyme assays

[1] One such laboratory is the Metabolic Screening Laboratory Section of Medical Genetics, Veterinary Hospital of the University of Pennsylvania, 3900 Delancy Street, Philadelphia, PA 19104-6010 A complete history including signalment of the animal should be included with the samples.

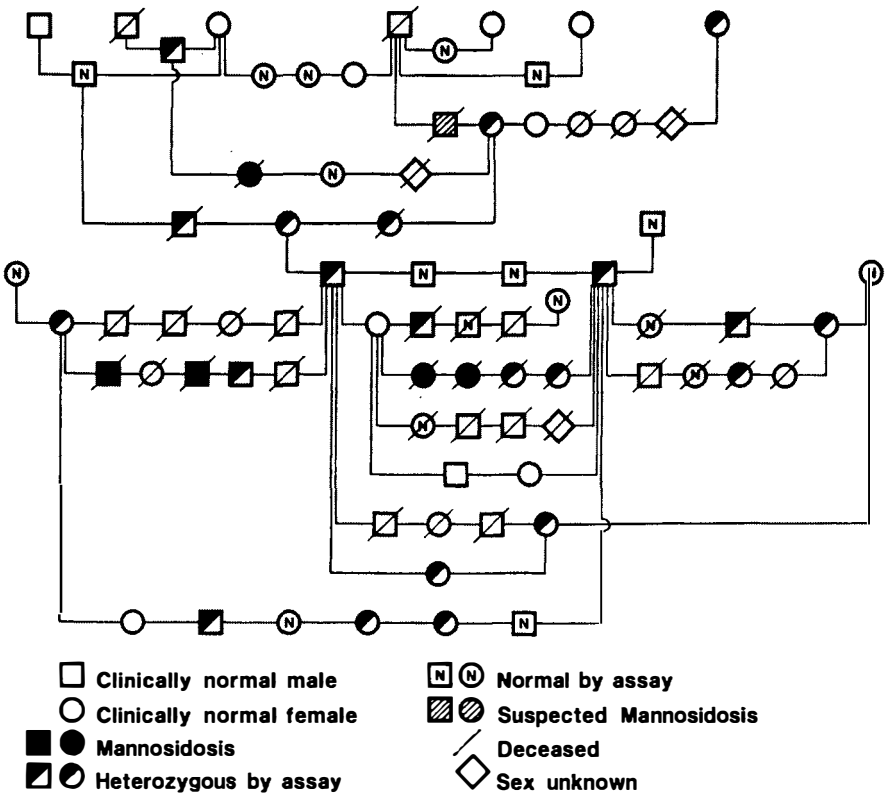

FIGURE 25.14 The pedigree of a family of cats with alpha-mannosidosis.

using artificial substrates can usually be performed on serum, white blood cells, cultured fibroblasts, or liver. Generally, there is a profound deficiency in activity of the enzyme, making the diagnosis straightforward. In addition, the activities of other lysosomal enzymes in the cells or tissues are frequently higher than normal. The biochemical status of the clinically normal parents should be evaluated when possible. In an autosomal recessive disease, heterozygous parents are expected to have half-normal activity of the enzyme in question because each parent carries one normal and one mutant allele. Although in a population heterozygotes (carriers) have on average half-normal activity, there is a marked overlap between the ranges for enzyme values from normal and obligate heterozygous animals (Fig. 25.17). Thus, accurate detection of an individual as normal or a carrier may be difficult with enzyme assays, and can best be achieved by molecular tests for the specific mutation in those diseases and families where the abnormality is known at the gene level (Table 25.5).

An animal suspected of having an LSD that dies or requires euthanasia should have a complete postmortem examination, including the central nervous, skele-

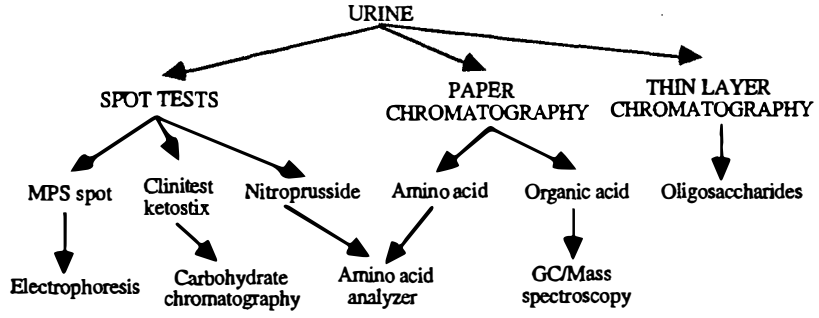

FIGURE 25.15 The scheme used to detect metabolic diseases, including some lysosomal storage disorders, by examining compounds present in urine.

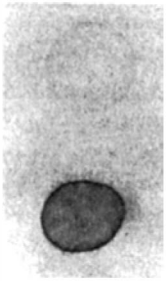

FIGURE 25.16 The results of a urine spot test detecting abnormal amounts of glycosaminoglycans in the urine of animals with MPS.

tal, and ocular systems. The liver should be frozen as quickly as possible for subsequent accumulated substrate and enzyme determinations, and DNA analysis. Fibroblast cultures can be established from skin, linea alba, or pericardium (using sterile technique) for future studies that may require living cells. Liver, brain, and other tissues should be preserved in formalin, and samples should be taken for thin section and electron microscopy (in gluteraldehyde), particularly from the liver and the CNS.

VI. THERAPY

The combination of secretion of lysosomal enzymes by cells and uptake of enzymes by diseased cells via the Man-6-P receptor system forms the basis for the present approaches to therapy for the LSDs. Providing a source of normal enzyme to abnormal cells will permit that enzyme to be taken up by the plasma membrane receptor, resulting in delivery of the normal enzyme to the lysosome where it can catabolize stored substrate. At present, the approaches to deliver normal enzyme to abnormal cells include (1) the parenteral injection of purified recombinant normal enzyme produced in Chinese hamster ovary cells (Barton *et al.*, 1990; Shull *et al.*, 1994), (2) heterologous bone-marrow transplantation, which provides normal bone marrow and bone-marrow-derived cells that release normal enzymes continuously (Haskins *et al.*, 1991), and (3) approaches to gene therapy where a viral vector is used to transfer a copy of the normal enzyme cDNA to a patient's own cells, which then act as a source of normal enzyme (Wolfe *et al.*, 1990, 1992). The amount of enzyme secreted by normal cells will affect the degree of correction achieved; the more enzyme is secreted, the more is available for uptake by diseased cells.

Acknowledgments

The authors wish to thank to Dr. Donald Patterson for his vision and for establishing the first Section of Medical Genetics in a veterinary school, Dr. Peter Jezyk for developing a metabolic screening laboratory for animals, Dr. Gus Aguirre for his contributions to the understanding of ocular disease, Mr. James Hayden of Bio-Graphics for the illustrations, Ms. Ping Wang for enzyme analyses, and Ms. Cathy Just, Ms. Margie Weil, and a cadre of veterinary students for animal care. Supported by NIH grants RR 02512, DK 25795, EY 07705, and NS 33526.

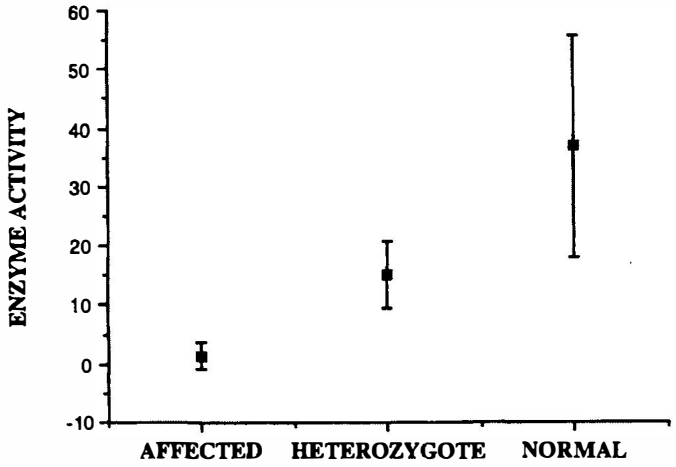

FIGURE 25.17 Mean serum alpha-mannosidase activity of a colony of related cats, illustrating the overlap that exists between normal and heterozygous animals. Although heterozygote detection is possible in a population, detection is more difficult for an individual. Molecular techniques will overcome these difficulties in carrier detection. (Error bars: ±2 SD.)

CHAPTER

26

Tumor Markers

BRUCE R. MADEWELL

I. INTRODUCTION

A tumor marker, in the broadest sense, might be considered a laboratory measurement of a substance or a process that provides clinically useful information with regard to tumor diagnosis and patient management. Tumor markers might be unique attributes of neoplasms, or may reflect the neoplastic process by a high level of expression relative to that of normal cells. Ideally, a marker of cancer should be sensitive, specific, and noninvasive; allow identification of affected patients and/or those at risk for the disease; reflect tumor burden; have value as a prognostic indicator; be predictive of tumor recurrence; and serve as an aid for the selection of an effective treatment strategy. Cancer markers should also accurately reflect the disease process, rather than any side effects of medication or treatment; be well understood with regard to any possible influences of the patient's age and gender; be reproducible in measurement and have a clear normal range; and be rapidly responsive to changes, thus reflecting current disease load.

Very few tumor markers have been described that fulfill these idealistic criteria in human medicine, and fewer have undergone rigorous clinical appraisal; few putative tumor markers have been described in veterinary medicine. However, the explosion in new information based on data from immunology and cell and molecular biology has now provided methods for critically examining biological processes associated with cancer, and to contrast those cellular perturbations with those of homeostasis. Those tumor markers that are convincingly demonstrated to distinguish normal from neo-

plastic cells will then enter clinical appraisal, and perhaps a few will emerge as ideal markers of cancer.

A partial list of *serum tumor markers* is provided in Table 26.1. Categorically, these putative markers include oncofetal proteins, hormones and ectopic hormones, enzymes, immunoglobulins, tumor-associated antigens, and miscellaneous markers. In this chapter, we will also examine the application of new technologies to neoplasms of importance to animals, using the broadest definition of tumor "marker" as an alteration in a cellular attribute that has been shown to be associated with a given tumor type providing a profile for risk assessment, clinical diagnosis, clinical staging, or therapeutic approaches. In particular, we will examine the advances made in *immunohistochemistry* for the evaluation of poorly differentiated neoplasms. *Flow cytometry* will be examined for measurement of DNA ploidy and cell proliferation in clinical samples of tumors, or, using specific immunologic probes, as a method for identification of subpopulations of cells or the detection of tumor cells in heterogenous clinical specimens. The *cytogenetic* changes that have been described in companion-animal neoplasms will be reviewed. New *DNA diagnostic technology*, based on isolation of RNA, DNA, or protein from tumor cells and the analysis of these components for structural or quantitative abnormalities, will also be reviewed with respect to its contemporary application in veterinary medicine.

II. SERUM TUMOR MARKERS

A. Oncofetal Proteins

Carcinoembryonic antigen (CEA) and *alpha-fetoprotein (AFP)* are the classic oncofetal proteins used as tumor markers. Oncofetal proteins are substances that appear to originate within tumor cells and enter the circulation as a result of secretion by the tumor or as breakdown products of tumor cells. These proteins are normally present during variable periods of embryonic or fetal life, do not disappear entirely during adult life, and reappear with certain neoplasms. In human patients the oncofetal protein CEA has been the most widely studied marker. It was discovered in 1965 by raising antisera against a colon carcinoma, and it is now known to belong to a family of cell surface glycoproteins that are found in various malignancies (Bates 1991). CEA is used most often as a marker of neoplasm of the lung, colon–rectum, breast, pancreas, ovary, and prostate gland. CEA has had little application as serum tumor marker for cancer in veterinary practice.

AFP is synthesized by the yolk sac and fetal liver of almost all mammals (Yamada *et al.*, 1995). AFP serves, in human cancer patients, as a marker of nonseminomatous testicular cancer and hepatocellular carcinoma. In animals, AFP was detected in cattle with hepatocellular carcinoma and in fetuses (Kithier *et al.* 1974). A more recent evaluation of AFP as a serum marker in dogs using reagents specific for human AFP revealed only rare elevations in association with various naturally occurring malignancies (Hahn and Richardson, 1995), but serum AFP concentrations were greatly elevated in dogs with experimentally induced hepatic tumors (Lowseth *et al.*, 1991). Canine AFP was recently purified from amniotic fluid, and an ELISA developed for canine AFP; that study also revealed that AFP levels in newborn puppies are higher than those measured in newborn cattle, pigs, and human infants (Yamada *et al.*, 1995).

TABLE 26.1 Categories of Tumor Markers

Oncofetal proteins: Carcinoembryonic antigen, alpha-fetoprotein
Hormones: Hormones and ectopic hormones, human chorionic gonadotropin (hCG)
Enzymes: Prostatic acid phosphatase, alkaline phosphatase, lactate dehydrogenase
Immunoglobulins
Tumor-associated antigens: CA-125, prostate-specific antigen (PSA)
Others: Fibronectin, sialic acid, acute-phase proteins, tissue polypeptide antigens

B. Hormones and Ectopic Hormones

1. Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) is used commonly in human medicine as a marker of gestational trophoblastic neoplasia; β-hCG serves as a nearly ideal tumor marker and is elevated in virtually all cases of trophoblastic neoplasia. Recent data provides optimism that β-hCG may be a definitive biomarker for cancer. Complete β-hCG is present in cell membrane of cultured fetal and cancer cells. Its expression in cancer defines the metastatic aggressiveness of the tumor in which it is found. Of fundamental importance is that cells from nonembryonic tissue or benign neoplasms, unlike cancer or fetal cells, do not express β-hCG. Therefore, the presence of β-hCG becomes a definitive phenotypic expression of malignant transformation not only in trophoblastic tumors or tumors of germ cell origin, but also in a wide range of solid tumors (Regelson, 1995). I am not aware of applications of hCG for assessment of animal tumors, perhaps a re

flection of the fact that gestational trophoblastic neoplasms are rarely diagnosed in domestic animals.

2. *Serum Parathyroid Hormone*

Measurements of parathyroid hormone are useful for study of clinical disorders of calcium metabolism. Elevation of serum parathyroid hormone concentration at the time of hypercalcemia is strong evidence for the presence of primary hyperparathyroidism (Chew *et al.*, 1995). Although primary hyperparathyroidism is relatively uncommon in dogs and cats, descriptions of both adenomas and carcinomas of the parathyroid glands are recorded in the literature and should be considered in the differential-diagnostic evaluation of any dog or cat with persistent hypercalcemia.

3. *Parathyroid Hormone-Related Protein*

The hypercalcemia of malignancy is one of the most frequently recognized paraneoplastic syndromes in animals. Hypercalcemia associated with malignancy results either from the stimulation of local bone resorption associated with neoplasms metastatic to the skeleton, or via the release of humoral factors that act systemically to increase osteoclastic bone resorption, and to increase calcium resorption from the kidneys or calcium absorption from the GI tract (Rosol and Capen, 1992). The ectopic production of parathyroid hormone per se by tumors is rare. Instead, there is now substantial evidence that inappropriate production of parathyroid hormone-related protein (PTHrP) by tumors can explain most of the clinical and pathologic findings in patients, both animal and human, with the humoral hypercalcemia of malignancy. Parathyroid hormone-related protein was named for its amino acid homology and pathophysiologic mimicry of the actions of PTH (de Papp and Stewart, 1993). However, although data show clear evidence for an association between increased activity of PTHrP and hypercalcemia in dogs with adenocarcinomas derived from the apocrine glands of the anal sac, malignant lymphoma, and miscellaneous other carcinomas, there appears to be a variety of systemically acting humoral factors, such as cytokines, released by tumors that alter calcium metabolism (Rosol and Capen, 1992).

4. *Thyroxine/Thyroglobulin*

Measurement of serum thyroxine concentration, or use of the thyroid-stimulating hormone response test, is used to establish a diagnosis of a functional thryoid neoplasm. It has been reported that approximately 20% of thyroid tumors in dogs are functional (Loar, 1986). In a more recent publication, it was reported that up to 70% of dogs with thyroid carcinomas had high serum concentrations of thyroglobulin, although there was no clear relationship between the thyroglobulin and thyroxine concentrations of those dogs (Verschueren and Goslings, 1992).

Elevation of serum thyroxine is diagnostic of hyperthyroidism in the cat, although single serum throxine measurements may give equivocal results. The serum triiodothyronine (T3) suppression test can be used to confirm hyperthyroidism in these cases (Peterson *et al.*, 1990). Most cats with clinical evidence of hyperthyroidism will not have an underlying carcinoma, however, but rather an adenoma or adenomatous hyperplasia of the thyroid gland.

5. *Adrenocorticotropin/Cortisol*

Plasma cortisol concentration, or alteration of that concentration using adrenocorticotropin (ACTH) stimulation and/or dexamethasone inhibition, is used in a variety of procedures for diagnosis and monitoring of dogs and cats with hyperfunctioning adrenocortical tumors. Similarly, the measurement of ACTH may facilitate the diagnosis of spontaneous adrenal disorders, both primary and secondary to pituitary dysfunction. The specific mechanics of conducting these tests and the interpretation of their results are reviewed elsewhere (Kempainen and Clark, 1995). Some of these same diagnostic methods have been applied to the diagnosis of hyperadrenocorticism associated with adrenal gland tumors in ferrets (Gould *et al.*, 1995).

6. *Sex Steroid Hormones/Hormone Receptors*

In veterinary practice, measurements of sex steroid hormones in plasma have been utilized most frequently for characterization of equine granulosa cell tumors (Stabenfeldt *et al.*, 1979). The granulosa cell tumor is the most commonly recognized ovarian tumor in the mare and is frequently associated with clinical signs resulting from high plasma testosterone or estrogen concentrations (Meinecke and Gips, 1987). Less frequently, plasma progestins are elevated. However, there are considerable differences in the steroid hormone profiles among affected horses reflective of dynamic changes within the neoplastic granulosa and ovarian stroma cells.

Measurements of plasma estradiol have also been used recently to characterize the functional activity of adrenocortical tumors in ferrets (Lipman *et al.*, 1993).

There have been a multitude of manuscripts in the veterinary literature over the past 20 years regarding estrogen and/or progesterone receptor concentrations in dogs and cats with mammary tumors; those studies are reviewed elsewhere (Donnay *et al.*, 1995). The mea-

surements have generally been made from cytosol fractions prepared from fresh mammary tumors, and more recently using immunohistochemistry. Estrogen and progesterone receptors can be detected in normal mammary tissues, and in the dog, it has been determined that ER concentrations were decreased in malignant mammary tumors compared to those in normal mammary tissues, whereas PR concentrations tended to be higher than those detected in the normal gland (Donnay *et al.*, 1995). Poorly differentiated tumors tended to have lower receptor concentrations than those found in benign or well-differentiated tumors; and this was particularly true in those neoplasms that were of large size and associated with a high rate of growth.

C. Enzymes

1. Lactate Dehydrogenase, Serum Alkaline Phosphatase, Prostatic Acid Phosphatase

Patients with malignant disease often have increased lactate dehydrogenase (LDH) activity in serum, although it is usually a nonspecific increase in animals. In human patients, the isoenzyme LDH-1 is elevated in germ cell tumors (teratomas, testicular seminomas, ovarian dysgerminomas). Similarly, alkaline phosphatase measurements assist nonspecifically in the diagnosis of hepatobiliary disease and bone disease associated with increased osteoblastic activity. Prostatic acid phosphatase (PAP) is an enzyme secreted by the normal prostate gland. PAP levels increase in the serum of human patients with advanced prostate cancer, and abnormal levels indicate that the tumor has spread beyond the prostatic capsule. In general, the serum level increases with progressive stages of disease. Although PAP can be localized in the canine prostate gland using immunohistochemical procedures (Aumuller *et al.*, 1987), serologic detection of this secretory antigen has not been described in dogs in association with prostatic disease.

D. Immunoglobulins

Measurement of serum immunoglobulin concentrations in the plasma hyperviscosity syndromes probably represents the oldest and most consistent use of serum tumor markers in clinical veterinary medicine. In monoclonal disorders such as multiple myeloma or Waldenstrom's macroglobulinemia, recognition of a characteristic electrophoretic pattern of serum on cellulose acetate membrane provides evidence for a monoclonal protein (M-protein, monoclonal, myeloma), although it must be remembered that hypergammaglobulinemia is not seen in all cases of myeloma, and indeed, there may be hypogammaglobulinemia anc a normal-appearing electrophoretic pattern. Further cellulose acetate electrophoresis may not detect smal monoclonal proteins. The monoclonal spike detectec on serum or urine protein electrophoresis can thei be assayed qualitatively by immunoelectrophoresis t determine the specific antibody class of the parapro tein, and the protein can then be quantitated by singl radial immunodiffusion or other quantitative methods These markers, therefore, are used to facilitate diagno sis as well as providing a convenient measure for moni toring patients undergoing therapy.

E. Tumor-Associated Antigens

1. CA-125

The tumor-associated antigen CA-125 has been use clinically in human medicine to monitor patients witl epithelial ovarian carcinomas; CA-125 is not speci fic for ovarian cancer, however, and CA-125 level may also be elevated in patients with nongynecologi cal tumors and in certain other conditions such a the first trimester of preganancy and endometriosi (Helzlsouer *et al.*, 1993). I am unaware of applicatio of CA-125 as a marker for animal neoplasms.

2. Prostate-Specific Antigen

Prostate-specific antigen (PSA) is a tumor associated antigen and is raised in the serum of huma patients with several conditions, including cancer c the prostate, benign prostatic hyperplasia, and prosta titis. It is used along with the digital rectal examinatio for screening patients for prostatic cancer, and it is als used to monitor patients with prostatic cancer afte therapy. It is often used in conjunction with serur measurement of prostatic acid phosphatase. PSA ca be detected by immunohistochemistry in canine pros tate tissues using anti-human PSA antibodies, but is not detected in the serum of dogs with prostati disorders (McEntee *et al.*, 1987).

F. Miscellaneous Serum Tumor Markers

1. Fibronectin

Fibronectin is one of the extracellular matrix prc teins. It is a large glycoprotein found in an insolubl form in connective tissue stroma and basement mem branes. It is also present in soluble form in plasm One study of plasma fibronectin concentrations fro dogs with a variety of neoplasms revealed dogs wit both high and low plasma concentrations (Feldman *al.*, 1988a). Fibronectin concentrations were also exan

ined in peritoneal effusions from dogs with a variety of intra-abdominal tumors; those data suggested that decreased fibronectin concentrations in peritoneal effusions were associated with a hypercoagulable state (Feldman *et al.*, 1988b).

2. *Sialic Acid*

Serum lipid-associated sialic acid levels have been used as tumor markers because of a rather consistent alteration of glycolipids, glycoproteins, and glycosyltransferases associated with their synthesis in tumor tissues. In one study, serum lipid-associated sialic acid levels were elevated in 22 of 24 dogs with cancer (Kloppel *et al.*, 1978), whereas in another study increased levels were also observed in dogs with malignant tumors compared to levels in healthy dogs, those with nonneoplastic conditions, and dogs with benign tumors (Poli *et al.*, 1986).

3. *Acute-Phase Proteins*

The acute-phase proteins (APP) are those proteins whose plasma concentration rises 25% or more following tissue injury or infection These proteins are elevated in a wide variety of acute and chronic diseases, including cancer. The best-studied human APP include ceruloplasmin, complement components C3 and C4, α_1-acid glycoprotein (AG), α_1-proteinase inhibitor (α_1-anti-trypsin), α_1-anti-chymotrypsin, haptoglobulin (Hp), fibrinogen (Fbn), C-reactive protein (CRP), and serum amyloid A (SAA). There has been some application of these APPs in veterinary medicine as markers for animals with cancer. α_1-Acid glycoprotein (AGP, oromuscoid) is categorized as an APP. Serum concentrations of AGP are increased in human patients with a variety of neoplasms, but like other APPs, its concentration in serum is also increased by acute and chronic inflammatory disorders. In the dog, serum AGP concentrations were shown to be increased in dogs with hematopoietic and nonhematopoietic tumors at the time of diagnosis (Ogilvie *et al.*, 1993). In that study, high serum concentrations of AGP in dogs with malignant lymphoma decreased significantly following induction of clinical remission with anticancer chemotherapy, suggesting a role for these measurements in monitoring the course of malignant lymphoma in dogs receiving treatment.

Tumor necrosis factor-α (TNF-α) is a cytokine produced primarily by macrophages. There are data to show that TNF-α may be an important inflammatory cytokine associated with hematopoietic suppression due to feline leukemia virus infection (Khan *et al.*, 1992).

III. FLOW CYTOMETRY

A. DNA Ploidy

The most frequent application of the flow cytometer for animal cancer patients has been for the evaluation of DNA content; these measurements have been made in a variety of canine and feline neoplasms, including those derived from the mammary glands (Hellmen *et al.*, 1988, 1989, 1995; Minke *et al.*, 1990; Rutteman *et al.*, 1988; Alenza *et al.*, 1995), bone (Fox *et al.*, 1990), hematopoietic system (Frazier *et al.*, 1993), urinary bladder (Clemo *et al.*, 1994), thyroid glands (Verschueren *et al.*, 1991), prostate gland (Madewell *et al.*, 1991), and skin (Ayl *et al.*, 1992). These measurements are based on the higher or lower DNA content of tumor tissues, due either to abnormal DNA (aneuploidy) or increased DNA content and cell division, compared to that of nonmalignant tissues. Because many neoplasms are believed to arise from a single abnormal cell, the resultant chromosome constitution is unique and tends to remain stable. The ratio of the abnormal DNA content of tumor tissue to that of normal cells is called the DNA index. The abnormal DNA is therefore useful for tumor diagnosis as well as the recognition of rare neoplastic cells in early or residual disease states.

The widespread application of flow cytometry for analysis of ploidy in human and animal cancer patients has revealed, in general, that normal tissues, reactive tissues, and tissues of benign tumors have diploid (2N) DNA values. Preneoplastic lesions may contain aneuploid DNA values, whereas in established tumors, the percentage of aneuploidy varies with tumor type. For example, in human patients with leukemias, aneuploid DNA histograms are more likely to be associated with acute leukemias than with chronic leukemias. In solid tumors, the percentage of aneuploidy varies considerably with the tumor type, from as little as 45% aneuploidy in patients with ovarian tumors to as high as 98% in patients with sarcomas (Koss *et al.*, 1989).

Another application of the flow cytometer is for estimation of the frequency of dividing cells. Cells synthesizing DNA have a higher DNA content than those not synthesizing DNA; the portion of cells with the higher level is the S-phase fraction. Many tumors will not possess DNA aneuploid populations, and an assessment of the proliferation rate will be the basis for interpreting the histogram as abnormal. Many studies have shown that proliferation indexes obtained by flow cytometric analysis are comparable to those obtained by a labeling index. In one study, the S-phase fraction of canine mammary tumors was determined by flow cytometry; the S-phase fraction was significantly higher in dogs with malignant tumors than in dogs

with benign tumors, and it correlated positively with the histologic grade of malignancy (Alenza *et al.*, 1995).

In flow cytometry, therefore, a specimen can be categorized as having an abnormal (aneuploid) histogram if the DNA content of the population of cells is clearly separated from the normal diploid cell population; if the proliferation index is elevated; and if increased numbers of cells possess DNA in excess of that found in cells in the G_2 phase of the cell cycle (tetraploid).

B. Cell Surface Determinants

Through the development of specific monoclonal antibodies, the flow cytometer also allows characterization of cell populations by cell surface determinants. These reagents allow for the differentiation of both lymphocyte classes and their precursors, as well as many of the lymphocyte subclasses. In addition, monocytes, granulocytes, platelets, and their precursors can be identified. Recently, several laboratories have developed a wide range of well-characterized monoclonal antibodies against canine leukocyte surface antigens (Doveren *et al.*, 1985; Gebhard and Carter, 1992; Moore *et al.*, 1992; Mazza *et al.*, 1993; Cobbold and Metcalfe, 1994; Voss *et al.*, 1994; Watson *et al.*, 1994). The specificities of many of these antibodies were defined in a workshop and a CD classification for canine leukocyte antigens was proposed (Cobbold and Metcalfe, 1994). These monoclonal antibodies developed to normal hematopoietic elements are now being used to characterize the leukemias and lymphomas, thus providing new phenotypic categories that have diagnostic and prognostic relevance. The recent development of monoclonal antibodies to feline myeloid, erythroid, and lymphoid cell lineages should also expedite immunophenotyping of feline hematopoietic neoplasms (Groshek *et al.*, 1994). Further, newly developed antibodies are now being used to characterize solid tumors. For example, hormone receptors can be quantitated on breast tumor cells to assist in treatment planning.

IV. CYTOGENETIC CHANGES

Most advanced neoplasms lose monoclonality and acquire heterogenous genetic constitutions. Cytogenetic analysis examines the gross morphologic features of chromosomes and is best used to detect consistent, nonrandom chromosomal abnormalities such as translocations and deletions. Such abnormalities are informative markers of clonality if they are specific for the neoplasm and are found in sufficient numbers of cells (Nabers, 1994). In human medicine, chromosome studies of tumors have provided important clues to the location of the relevant genes and the mechanisms by which their growth regulatory functions have been altered.

Cytogenetics has been somewhat limited in veterinary medicine because it requires cell culture and the preparation of chromosomes in the metaphase of mitosis, which further serves to make their cellular origin uncertain. Most cytogenetic studies reported in the dog have been compilations of single or few cases; many of these studies are referenced elsewhere (Hahn *et al.* 1994). Both structural and numeric chromosome alterations have been described in canine neoplasms. Very complex structural changes, including centric fusion and resultant aberrant metacentric chromosomes, have been described in dogs with both solid and hematopoietic neoplasms. These changes have generally been inconsistent and have not yet revealed information on pathogenic significance. It is presumed that increasing complexity of the karyotype is probably correlated in some way with tumor characteristics such as rate of growth or degree of invasiveness, but the present data do not provide unequivocal support for that supposition. The presence of double minute chromosomes may reflect gene amplification, and numeric chromosome aberrations may also lead to gene amplification. Probably the best-documented cytogenetic abnormality in animal neoplasms is that associated with the canine transmissible venereal tumor, in which the normal 78 chromosomes are reduced to 58 or 59, with many metacentrics (Makino, 1963; Murray *et al.*, 1969). There have been few descriptions of cytogenetic abnormalities associated with solid tumors (Mayr *et al.*, 1994a, 1993a) including the recent demonstration of trisomy of chromosome 9 in a canine hemangiopericytoma and a partial deletion in chromosome 1 of several other canine hemangiopericytomas (Mayr *et al.*, 1995a).

G-banded cytogenetic analysis was recently done on canine malignant lymphoma specimens in an effort to correlate cytogenetic findings with other variables that might influence treatment responses. In that study numerical chromosomal abnormalities were detected more often than structural abnormalities, and the results of the cytogenetic studies did not correlate with other prognostic variables. The cytogenetic findings did, however, predict the length of first clinical remission and survival time (Hahn *et al.*, 1994).

V. PROLIFERATION MARKERS/APOPTOSIS

Measurement of cell proliferation may provide useful information concerning tumor prognosis and diagnosis. Methods directed at different parts of the cell cycle are available.

A. Mitotic Counts

Counting mitoses is the most traditional morphological method for assessing cell proliferation. The mitotic phase of the cell cycle is easily recognized on routinely prepared histologic sections. Mitotic counts are expressed as the number of mitoses per certain number of high dry microscopic fields, or as the number of mitoses present in a certain number of cells (mitotic index). Mitotic counts give prognostic information for some tumors such as fibrosarcomas in cats. The major flaw of the mitotic count is its lack of reproducibility. Mitotic counts are easy to perform, but errors in interpretation can occur because of delays in fixation, variations in section thickness and in the size of the microscope field used, and difficulties in the recognition of mitoses.

In clinical practice, high mitotic index was demonstrated to affect treatment responses adversely for dogs with synovial sarcoma (Vail *et al.*, 1994), sarcomas of the canine spleen (Spangler *et al.*, 1994), and canine and feline fibrosarcomas (Bostock, 1986).

B. Thymidine Labeling Index and BrdU Incorporation

The synthesis of DNA, or the S phase of the cell cycle, can be measured by labeled DNA precursor incorporation. Tritiated thymidine, or a halogenated thymidine analog, bromodeoxyuridine (BrdU), is used for direct estimation of DNA synthesis; thymidine in tissue sections is revealed with photographic emulsion, whereas the development of specific monoclonal antibodies to BrdU has allowed its immunohistochemical detection in paraffin-embedded sections, allowing simultaneous examination of the morphology of the proliferating cells. The thymidine labeling index is defined as the ratio of the number of positively stained cells to the total number of cells; because this method directly assesses DNA synthesis, it is considered the standard for cell cycle analysis and proliferation studies (Sahin *et al.*, 1993). For BrdU, the S-phase fraction of the cell cycle can be determined by counting nuclei labeled with BrdU, thus providing an accurate estimate of the proliferative potential of a tumor. One problem with assessment of tumor proliferation using the BrdU labeling index is the necessity of infusing patients with BrdU prior to surgery, or the necessity of incubating fresh tissue with BrdU in order to permit its incorporation into tumor DNA.

C. Nucleolar Organizing Regions

Silver staining of proteins associated with nucleolar organizing regions (NORs) of interphase chromosomes may be used on conventional histological sections or cytologic preparations for assessment of proliferation rates (Rose *et al.*, 1994). Nucleolar organizing regions are segments of chromosomal DNA that encode for ribosomal RNA. In normal cells, NORs are usually tightly aggregated in one or more nucleoli; in malignant cells, they desegregate from the nucleoli and tend to disperse throughout the nucleus. Because NORs are related to DNA synthesis and metabolic activities, it is generally agreed that the size and number of NORs reflect nuclear activity. The amount of NOR protein is related to the cell cycle, increasing progressively from Go to S-phase. The NORs can be demonstrated histologically by a simple silver-staining method because of the argyrophilia of their nonhistone acidic proteins. These argyrophilic nucleolar organizing regions (AgNORs) indicate actual or potential transcriptional activity of ribosomal DNA and therefore serve as apparent cytologic markers of cell proliferation; increased numbers of AgNORs may reflect increased tumor-cell turnover or cell ploidy and are generally associated with poor cellular differentiation (Schned, 1993). AgNOR counts are expressed as the number of AgNORs per nuclei, or as the percentage of tumor cells with >5 AgNORs per nucleus. The mean AgNOR count is believed to be a reflection of DNA ploidy, whereas the percentage of cells with >5 AgNORs per nucleus is thought to be a reflection of proliferative activity.

In the dog, mean nucleolar size has been shown to correlate with mitotic index in squamous-cell carcinoma of the skin. In that study, a close correlation was found between mean nucleolar area/cell and mitotic activity, and the mean nucleolar area/cell was significantly higher in canine squamous-cell carcinoma than in canine basal-cell carcinoma (DeVico *et al.*, 1995). In another study, the rate of proliferation of canine perianal tumors determined by quantitative analysis of AgNOR proteins revealed a progressive increase in the rate of proliferation parallel with the histologic features of malignancy (Preziosi *et al.*, 1995a). For dogs with mast-cell tumors treated surgically, AgNOR staining was demonstrated to be a better prognostic indicator than either tumor histologic grade or mitotic index (Bostock *et al.*, 1989). The staining of AgNORs in canine transmissible venereal tumors was also used as a measure predictive of response to vincristine chemotherapy (Harmelin *et al.*, 1995). AgNOR staining of canine mammary tumors revealed high counts in tubular and solid carcinomas, particularly in those tumors showing infiltration of surrounding connective tissues; an unfavorable prognosis following surgery was determined for most dogs that had high AgNOR counts (Bostock *et al.*, 1992). AgNOR staining in feline mammary carcinomas was not shown, however, to correlate with other

tumor attributes, and therefore was not useful for diagnostic or prognostic purposes (DeVico *et al.*, 1995).

D. Proliferation Markers

Methods for detection of cell cycle related antigens are described in Section VI.E.

E. Image Analysis

Another laboratory measure of ploidy, S-phase fraction, and nuclear area is image analysis; this can be accomplished on cytocentrifuge preparations of Fuelgen-stained nuclei extracted from traditionally prepared tissue specimens (formalin fixation, paraffin embedding). Image analysis allows evaluation of individual nuclei, providing both morphometric and densitometric nuclear values. In one study, 90 canine mammary tumors were examined by image analysis (Destexhe *et al.*, 1995). The mean S-phase fraction of malignant lesions was twice that of benign lesions; the mean nuclear surface was smaller in malignant lesions than in benign lesions; and 37% of the malignant tumors were aneuploid. Tumors shown histologically to invade lymphatic vessels were significantly associated with aneuploidy and a high S-phase fraction.

F. Apoptosis

Apoptosis is a "programmed" form of cell death that leads to the clearance of unwanted cells without disruption of tissue structure or function (Savell, 1994). There are several laboratory methods that allow characterization or recognition of apoptosis. One unique attribute is that in apoptosis, there is activation of endogenous endonucleases. These enzymes lead to a characteristic ladder of oligonucleosomal fragments upon electrophoresis, which is in contrast to the smearing of DNA that has been degraded during necrosis because of uncontrolled access of nucleases to DNA. Another feature of apoptosis is the characteristic cellular morphology. The principle morphologic feature in apoptosis is the condensation of nuclear heterochromatin, resulting in the formation of a crescent apposed to the nuclear membrane. Other changes include cell shrinkage, cytoplasmic condensation, and the formation of buds at the cell membrane that later condense into "apoptotic bodies." Another feature of apoptosis is that the process of cell death is not accompanied by inflammation or necrosis because lysosomal enzymes and granule contents are not released by the dying cells. These features are best detected by the electron microscope, but apoptotic bodies can be visualized in histologic sections using hematoxylin-stained cells or fluorescence microscopy and dyes such as propidium iodide or acridine orange.

One method for visualization of apoptotic cells is *in situ* 3′ labeling, which allows detection of DNA double-strand breaks (Kressel and Groscurth, 1995). Another method for detection of internucleosomal fragmentation of DNA is agarose gel electrophoresis followed by ethidium bromide staining, which allows recognition of the highly ordered DNA fragmentation characteristic of apoptotic cells. This apoptotic DNA is characterized as a "DNA ladder" reflective of the regular fragmentation (180–200 bp multiples) of the nuclear genome. Flow cytometry using propidium iodide staining can also be used to detect the reduced DNA or subdiploid cells, characteristic of apoptotic cells compared to diploid (normal) cells.

VI. IMMUNOHISTOCHEMISTRY

The introduction of immunohistochemistry as a routine procedure in many veterinary diagnostic laboratories has improved the objective diagnosis of neoplasms. Immunohistochemistry has emerged as an important tool for tumor typing and has led to an improved understanding of cellular differentiation. Immunohistochemistry allows precise determination of the histogenesis of many neoplasms that would be characterized as undifferentiated on the basis of morphologic examination of the hematoxylin- and eosin-stained tissue. Although most of the antibodies used routinely in the immunohistochemistry laboratory do not recognize unique attributes of neoplasms per se, accurate determination of histogenesis may allow appropriate treatment methods to be used and more reliable estimates of prognosis to be established. Some of the immunohistochemical determinations that are used in veterinary medicine are outlined (Table 26.2) and the following is a brief summary of their applications.

A. Histopathology, Intermediate Filaments, Cytokeratins

The distinction of carcinoma from other undifferentiated or poorly differentiated neoplasms may be difficult. The immunohistochemical markers that are used to characterize tumors derived from epithelium include cytokeratin intermediate filaments (IF), epithelial membrane antigen or the milk-fat globule proteins, and carcinoembryonic antigen. The cytokeratin intermediate filament proteins are a component of the cytoskeleton of mammalian cells. This cytoskeleton contains the thin (4–6 nm) actin-containing microfilaments, the thick (20–30 nm) microtubules, and the

TABLE 26.2 Immunohistochemistry: Utility in Veterinary Medicine

Hormones and hormone receptors:
Somatostatin
Insulin
Glucagon
Thyroglobulin
Gastrin
Calcitonin
Calcitonin gene-related peptide
Parathyroid hormone
Estrogen receptor
Progesterone receptor
Oncoproteins: c-*erb*B-2 oncoprotein, c-*myc* oncoprotein, p53 protein, RB protein
Proliferation markers: Proliferating-cell nuclear antigen (PCNA), Ki-67
Enzymes involved in cytotoxic drug metabolism: P-glycoprotein
Histopathology tumor markers:
Prostatic acid phosphatase
Prostate-specific antigen
von Willebrand factor
Carcinoembryonic antigen
Chromogranin A
Neuron-specific enolase
S-100 protein
Lysozyme
Collagen IV
Smooth-muscle actin
Skeletal myosin
Myoglobin
Synaptophysin
Laminins
Type IV collagen
Histopathology, intermediate filaments: Cytokeratins (pan-cytokeratin, specific molecular weight cytokeratins)
Histopathology, intermediate filaments: Mesenchyme (vimentin, desmin, neurofilaments, glial fibrillary acidic protein)
Histopathology, lymphoid markers:
Leukocyte common antigen
Pan T cell
Pan B cell
Macrophage
IgG, IgM, IgA
Virology:
FeLV
FIV
Papillomavirus

intermediate size (10 nm) intermediate filaments. The intermediate filaments are the most complex in terms of protein structure, and at present there are six distinct classes of intermediate filaments, including the acidic (type I, pH 4.5–5.5) and neutral–basic (type II, pH 6.5–7.5) keratins of epithelia; type III proteins, including vimentin of many mesenchymal cells; the type IV neurofilaments; the type V lamins of eukaryotic cells; and nestin, the type VI protein of neuroectoderma stem cells (Steinert, 1993).

The cytokeratin proteins are unique among the IFs presenting a high degree of diversity of polypeptid units: 20 in human tissues and 22 in bovine and murin tissues. The cytokeratin unit molecule consists of a disulfide-bonded heterodimer between type I and typ II cytokeratin polypeptides. These cytoskeletal compo nents form elaborate cagelike networks around the nu clei of mammalian cells (Steinert, 1993). Cytokeratin IFs are highly correlated with the degree of differentia tion of the tissue; therefore, specific cytokeratin identi fication is useful not only for determining the epithelia histogenesis of tumor specimens, but also for distin guishing glandular from squamous differentiation in dependent of other morphologic features. For epithe lial neoplasms undergoing progression from epithelia dysplasia to carcinoma *in situ* to invasive squamous cell carcinoma, there is concurrent decreased expres sion of high- and low-molecular-weight cytokeratins characteristic of normal differentiated epithelial cells. Well-differentiated squamous cell carcinomas express high-molecular-weight cytokeratins (de las Mulas *et al.*, 1995). The great majority of canine and feline carcinomas will show reactivity of at least a portion of the tumor cells for cytokeratins (Andreasen *et al.*, 1988a; Cardona *et al.*, 1989; Hellmen *et al.*, 1989; Magnol *et al.*, 1985; Rabanal *et al.*, 1989). Panels of cytokeratin antibodies, including antibodies to both high- and low-molecular-weight keratins, however, are often needed in animal specimens to increase the sensitivity of immunohistochemical recognition of epithelial tumors (Sandusky *et al.*, 1991).

Most studies demonstrating expression of cytokeratin intermediate filaments in domestic animal tissues rely on cross reactivities of those proteins with polyclonal or monoclonal antibodies developed against human IFs. Although cross reactivity is often discerned and subsequently used clinically for demonstration of IF proteins in animal tissues, some caution is advised in interpreting the results of these studies: Clear differences in the immunoreactivities of animal and human tissues for many of these diagnostic antibodies have been observed (Vos *et al.*, 1992).

Specific cytokeratins have been proposed as histodiagnostic markers, for some tumors, usually as a consequence of the change in cytokeratin expression during tumorigenesis. A type I (acidic) 57-kDa cytokeratin was proposed as a molecular marker for malignant transformation in canine mammary tumorigenesis, reacting with the basal monolayer of epidermis and ductal carcinomas (Arai *et al.*, 1994).

Using human-derived monoclonal antibodies as well as feline-derived antibodies to cytokeratin pro-

teins, feline cytokeratins in mammary tissues were determined to be highly homologous to patterns of cytokeratin expression in human tissues (Ivanyi *et al.*, 1992). Luminal epithelial cells reacted with monoclonal antibodies specific for cytokeratin IFs consistent with simple epithelia, whereas myoepithelial cells reacted with antibodies specific for cytokeratin proteins in basal cells of stratified epithelia (Ivanyi *et al.*, 1993). Further, cytokeratins typical of stratified epithelia were detected in areas of squamous metaplasia of adenocarcinoma cells, suggesting that these IFs serve as a marker for squamous metaplasia before it can be detected by the light microscope.

B. Histopathology, Intermediate Filaments, Mesenchyme

1. Vimentin

Vimentin intermediate filaments are used to mark nonmuscle sarcomas (Andreasen *et al.*, 1988a). As anticipated, the vaccine-associated sarcomas of cats, predominately fibrosarcomas, are immunoreactive for vimentin IFs, but within this spectrum of soft-tissue sarcomas are tumors that are also reactive for one or more smooth-muscle markers (desmin, smooth muscle-specific actin), suggesting a fibroblastic or myofibroblastic phenotype (Hendrick and Brooks, 1994; Pace *et al.*, 1994). Vimentin expression is lost during the process of differentiation of skeletal muscle and is absent in mature myofibrils of skeletal muscle. Vimentin IFs may be expressed, however, in poorly differentiated rhabdomyosarcomas (Vos *et al.*, 1993).

2. Desmin

Desmin is a cytoskeletal component that holds myofibrils in place; it has been used as a marker for canine leiomyomas and leiomyosarcomas (Andreasen and Mahaffey, 1987). During different stages of development, skeletal muscles express desmin. Skeletal muscle tumors are reactive to desmin antibodies in the dog and cat (Andreasen *et al.*, 1988a; Madewell *et al.*, 1988; Sarnelli *et al.*, 1994), and the botryoid variant of canine rhabdomyosarcoma has also been demonstrated to contain desmin (Andreasen *et al.*, 1988b).

3. Neurofilaments

Mammalian neurofilaments contain at least three distinct subunits. Antibodies to individual or triplet neurofilaments have been shown to react with canine axons and neurons (Vos *et al.*, 1989); neurofilaments are used to demonstrate neural tumors, as well as carcinoid tumors, pheochromocytomas, islet-cell tumors of the pancreas, and others (Mukai *et al.*, 1986).

4. Fibrillary Acidic Protein

Glial fibrillary acidic protein (GFAP), the major subunit of glial filaments, is found not only in glial cells in the central nervous system, but also in some Schwann cells and schwannomas and in some other tissues (Dolman, 1989). In the dog, GFAP reactivity is found in glial cells, predominantly fibrous astrocytes Schwann cells, axons, and cell bodies of some peripheral ganglia (Vos *et al.*, 1989). Some cells in canine ganglioneuroblastomas will stain positively for GFAP (Schulz *et al.*, 1994).

C. Histopathology—Other Markers

1. Carcinoembryonic Embryonic Antigen

Carcinoembryonic embryonic antigen (CEA) is a glycoprotein present in a wide variety of normal and neoplastic tissues. In human beings, adenocarcinomas are frequently positive for CEA, and this feature is used routinely to identify adenocarcinomas derived from the colon, stomach, pancreas, breast, endometrium, thyroid, ovary, and urinary bladder (Ordonez 1989). In animal specimens, curiously, CEA reactivity was detected in a small number of choroid plexus tumors from the dog (Ribas *et al.*, 1989). CEA reactivity has also been demonstrated in the normal canine exocrine pancreas and in some neoplasms of the exocrine canine pancreas (Rabanal and Fondevila, 1992). CEA reactivity was also detected in apocrine gland-derived tumors in the dog (Ferrer *et al.*, 1990).

2. Alpha-Fetoprotein

Using immunohistochemistry, alpha-fetoprotein was detected in only 3 of 11 hepatocellular carcinomas examined in the dog (de las Mulas *et al.*, 1995).

3. Epithelial Membrane Antigen

Epithelial membrane antigen (EMA) or milk-fat globule proteins have not been studied systematically in domestic animals. EMA is a mucin produced in large amounts by epithelial cells of the lactating breast and other glandular epithelia. Antibodies to EMA have been used for detection of acinar cells and carcinomas in human patients. EMA reactivity was demonstrated on the surface of canine salivary glandular epithelium *in vitro* (Strandstrom *et al.*, 1989).

4. Von Willebrand's Factor (Factor VIII-Related Antigen)

Von Willebrand's factor, a part of the factor VIII complex, is restricted to endothelial cells, megakaryocytes, and platelets. In the human being, antibodies to factor VIII-rag (F8RA/vWF) are established as markers of endothelial cells, megakaryocytes, and platelets, and immunohistochemical demonstration of factor VIII-rag is considered a useful adjuvant to conventional stains for the diagnosis of equine, feline, and canine vascular neoplasms (Moore *et al.*, 1986; van Buest *et al.*, 1988; Miller *et al.*, 1992). More recently, canine endothelial cells in normal organs and vascular neoplasms were also shown to express CD31, an adhesion molecule also referred to as platelet endothelial cell adhesion molecule (Ferrer *et al.*, 1995).

Another emerging and very useful application of immunohistochemistry using anti-F8RA/vWF or other vascular markers is to highlight the microvessels within tumors. Some pathology laboratories are now measuring intratumoral vessel density as a prognostic indicator. In some tumors, it has been determined that intratumoral vessel density is a better predictor of disease-free survival than tumor stage, grade, or type (Weidner, 1995). This is based on the knowledge that tumor growth is angiogenesis dependent. For any tumor to grow to macroscopic dimensions, it must induce the surrounding tissue either to share its nutrient supply or to provide an alternative supply. Indeed, the mark of successful malignant transformation involves the ability to induce and expand the vascular network to provide the nutrients needed for cellular transformation.

5. Myoglobin

Myoglobin antibody, although skeletal muscle-specific, is generally of limited value in the diagnostic laboratory because myoglobin is identified only in the most differentiated tumors, which usually do not pose diagnostic difficulty (deLellis and Dayal, 1987), and smooth-muscle tumors are characteristically myoglobin negative (Donner *et al.*, 1983).

6. Actin Microfilaments

Actins are a complex group of proteins; vertebrates possess at least six distinct forms of actin that are tissue specific. Four muscle actins have been identified: cardiac, vascular smooth muscle, enteric smooth muscle, and gamma-actin. Skeletal-muscle tumors are reactive for skeletal-muscle actin (Erlandsen, 1989; Sarnelli *et al.*, 1994), and smooth-muscle tumors stain for smooth-muscle actin (Hanzaike *et al.*, 1995).

7. Skeletal Myosin

Skeletal and cardiac-muscle myosin are referred to as sarcomeric myosin; antibodies that discriminate between smooth and sarcomeric myosins are used for diagnosis of smooth- and skeletal-muscle-derived tumors.

8. Prostate-Specific Antigen and Prostate-Specific Acid Phosphatase

PSA and PSAP are useful markers of genitourinary tumors in the dog; demonstration of PSA and PSAP allows diagnosis of otherwise undifferentiated prostatic carcinomas from carcinomas derived from the urinary bladder or colon (Aumuller *et al.*, 1987; McEntee *et al.*, 1987). A canine prostatic secretory protease has also been described (Aumuller *et al.*, 1987).

9. S-100 Proteins

S-100 is an acidic, calcium-binding protein of uncertain function that is composed of two subunits, designated α and β. Originally isolated from brain and thought to be specific for glial cells, S-100 proteins have subsequently been detected in a variety of nonneuroectodermal tissues (Schmitt and Bacchu, 1989). Reactivity for S-100 has been demonstrated in canine malignant melanoma, including amelanotic melanoma (Sandusky *et al.*, 1985), but immunoreactivity for S-100 proteins has also been detected in canine hemangiosarcoma, liposarcoma, leiomyosarcoma, malignant fibrous histiocytoma, and schwannoma (Rabanal *et al.* 1989; Thoolen *et al.*, 1992; Tanimoto and Ohtsuki, 1992) S-100 reactivity has also been demonstrated in canine myoepithelial cells (Ferrer *et al.*, 1990), but its presence in epithelial cells of the mammary gland in the dog precludes its use as a specific marker for myoepithelial cells (Moller *et al.*, 1994). Although S-100 protein is not a specific marker for melanoma, it is not generally expressed in non-neural-derived epithelium, and therefore it is useful for distinguishing between carcinoma and melanoma. In veterinary specimens, the diagnosis of malignant melanoma is often a challenge Immunohistochemical demonstration of S-100 proteins, vimentin intermediate filaments, and neuron-specific enolase, coupled with negative reaction for cytokeratin, may allow a tentative diagnosis of malignant melanoma (Sandusky *et al.*, 1985). Several monoclonal antibodies have been developed that are specific for human melanoma-associated antigens, but incon-

sistent results have often been obtained when these antibodies are applied to animal specimens. However, two commercially available monoclonal antibodies to human melanoma-associated antigens have been shown to react with the majority of canine melanomas that were formalin-fixed and paraffin-embedded (Berrington *et al.*, 1994).

10. Neuron-Specific Enolase

Enolase is an enzyme involved in the glycolytic pathway of metabolism. Five forms that differ in their unit composition and tissue distribution have been identified (Ordonez, 1993). The enolase γ-subunit, characteristic of neural cells, has been designated neuron-specific enolase (NSE). This enzyme was first described in the brain and later in other neuroendocrine cells and their tumors. For example, medullary thyroid tumors derived from the neural crest thyroidal C-cell system may be immunoreactive for NSE (LeBlanc *et al.*, 1991). Antibodies to NSE also stain melanomas, but lack specificity for their diagnosis (Vinores *et al.*, 1984). Chordomas typically stain for NSE (Dunn *et al.*, 1991). Ganglioneuroblastomas in the dog may also stain for neuron-specific enolase (Mattix *et al.*, 1994).

11. Chromogranin A

The chromogranins are a group of acidic peptides present in the secretory granules of endocrine cells; the major chromogranins are A, B, and C. Chromogranin A is the most abundant of the three, and it has proven useful as a marker for endocrine differentiation (Ordonez, 1993) . Antibodies to chromogranin are used to diagnose tumors derived from the adrenal medulla, islet cells of the pancreas, C-cells of the thyroid gland, parathyroid glands, and anterior pituitary (Wilson and Lloyd, 1984).

12. Type IV Collagen and Laminin

Type IV collagen and laminin are the principal components of basement membranes. Although these membrane components are visualized in tissue sections with stains such as the periodic acid Schiff reaction, immunohistochemical methods allow specific and sensitive identification of these basement membrane components. Many studies have revealed that the basement membrane is either interrupted or absent in invasive carcinomas, and this observation may be used as a prognostic finding. Continuous basement membranes are usually found associated with benign tumors, and in one study of canine mammary neoplasms, most of the malignant mammary tumors examined lacked continuous basement membranes, especially the invasive carcinomas (Pena *et al.*, 1995). A interrupted basement membrane suggests that th basement membrane was formed but then degrade by enzymes such as type IV collagenase associate with tumor invasion. In that same study, it was deter mined that myoepithelial cells were the main sourc of basement membrane proteins in canine mammar tumors. That observation provides foundation for th lower metastatic rate associated with tumors wit myoepithelial proliferation (Pena *et al.*, 1995). In ar other study, laminin expression was examined in tes ticular tumors derived from dogs; fragmentation, los or absence of the basement membrane was associate with tumor invasion and strongly correlated with his tologic classification and proliferative activity (Benaz *et al.*, 1995).

13. Integrins

The name *integrin* was first used to signify the pre sumed role of these proteins in integrating the intra cellular cytoskeleton with the extracellular matri (Schwartz and Ingber, 1994). The β1 integrins are mem bers of the VLA (very late activation) family of trans membrane glycoproteins. The integrins mediate cel to-cell adhesions and interactions between cells an extracellular matrix proteins such a fibronectin, colla gens, and laminin. There are data in human medicin to demonstrate that alterations of the expression c these adhesive proteins may be related to tumc spread. Immunohistochemistry was used to demor strate β1 integrin expression on the surface of canin mammary tumors (Pena *et al.*, 1994). In one study c normal, dysplastic, and neoplastic canine mammar tumors, evidence suggested that β1 expression wa decreased in malignant tumors, and that the decrease expression noted in malignancy was correlated to th metastatic potential of the tumors, thus potentiall serving as a marker of malignancy (Restucci *et al* 1995).

The β2-integrin subfamily contains molecules med ating the adhesion of migrating lymphocytes to endc thelial cells, the extracellular matrix, and epitheli cells. Canine keratinocytes may express β2 integrin such as intercellular adhesion molecules (ICAM-2 which can be detected immunohistochemically. Wit antibodies and procedures applicable to studies of lym phocyte–keratinocyte interactions, the pathogenesis c epidermotropism of lymphocytes in canine mycosi fungoides was examined (Olivry *et al.*, 1995).

14. Amyloid

Antibodies directed at amyloid of immunoglobuli lambda-light chain origin as well as amyloid-A hav been used to identify amyloid in various animal specie

using formalin-fixed, paraffin-embedded tissues. These reactivities have been used to confirm that the amyloid associated with some plasma-cell tumors is of immunoglobulin origin, and have also served as useful markers for plasmacytoid differentiation in some tumors (Linke *et al.*, 1984; Rowland *et al.*, 1991; Rowland and Linke, 1994).

D. Enzymes Involved in Cytotoxic Drug Metabolism

1. P-Glycoprotein

One of the most important mechanisms of cellular resistance to anticancer drugs involves the expression of the plasma membrane P-glycoprotein (Pgp), which is thought to function as an ATP-dependent efflux pump that reduces the cellular concentration of a wide range of chemotherapeutic agents. Pgp can be detected in tumors of every histologic type, and although some studies have been contradictory, several studies on human leukemias, lymphomas, and some childhood solid tumors have demonstrated a strong association between the Pgp expression in tumor samples and clinical outcome (Benchimol and Ling, 1994). Using Western blotting of membrane preparations made from canine lymphoma cells and an antibody to human Pgp, its expression was demonstrated in tumor cells derived from dogs that were resistant to chemotherapy (Moore *et al.*, 1995).

E. Proliferation Markers

Methods for detection of cell cycle related antigens are now available.

1. Ki-67

The monoclonal Ki67 is the prototype, recognizing a nonhistone nuclear protein expressed in proliferating cells in Gl, S, G2, and M, but not in quiescent (G0) cells. Ki67 labeling correlates well with cell proliferation as assessed by tritiated thymidine uptake, and provides a measure of the number of proliferating cells (proliferative fraction). Immunostaining with antibodies to the Ki67 antigen is now well established as a quick and efficient method for evaluating the growth fractions of various tumor types because of its distinctive reaction patterns that exclusively involve proliferating cells (Ross and Hall, 1995). Proliferative activity assessed by Ki-67 monoclonal antibodies in canine testicular tumors provided good correlation with other proliferation markers (Sarli *et al.*, 1994).

2. Proliferating-Cell Nuclear Antigen

Proliferating-cell nuclear antigen (PCNA), also known as cyclin, is a nonhistone nuclear protein associated with DNA polymerase delta, which is present throughout the cell cycle in proliferating cells. The PCNA gene is transcribed in both proliferating and quiescent cells; PCNA mRNA accumulates only in proliferating cells, reaching its maximum during S-phase (Sahin *et al.*, 1993; Rose *et al.*, 1994). The use of monoclonal antibodies to identify PCNA has been validated in the horse, cat, and dog (Theon *et al.*, 1994; Sarli *et al.*, 1994; Preziosi *et al.*, 1995b). In an applied clinical study, it was demostrated that the proliferation rate in squamous-cell carcinoma of the facial skin affected the prognosis of animals treated with radiation therapy (Theon *et al.*, 1995). A significant difference in the values of PCNA indices was reported between benign and malignant growths in both the dog and cat (Sarli *et al.*, 1995).

F. Hormones and Hormone Receptors

Antibodies to insulin, glucagon, somatostatin, pancreatic polypeptide, gastrin, and adrenocorticotropic hormones have proven valuable for the diagnosis of canine and feline pancreatic endocrine tumors and their metastases (O'Brien *et al.*, 1987; Boosinger *et al.*, 1988; Hawkins *et al.*, 1987; van der Gaag *et al.*, 1988). Canine pancreatic endocrine tumors may also be immunoreactive for islet amyloid polypeptide and calcitonin gene-related peptide (O'Brien *et al.*, 1990). Immunoreactivity for insulin, somatostatin, glucagon, and pancreatic polypeptide has also been demonstrated in the equine endocrine pancreas (Furuoka *et al.*, 1989). The normal canine exocrine pancreas contains cells immunoreactive for amylase, carboxypeptidase A, and α-antitrypsin (Rabanal and Fondevila, 1992). These same antibodies are also useful for detection of pancreatic exocrine carcinomas, with most neoplasms reacting for amylase and carboxypeptidase, and fewer immunoreactive for carcinoembryonic antigen and α-antitrypsin (Rabanal and Fondevila, 1992). These markers, therefore, are useful in the dog for distinguishing metastatic carcinomas of the pancreas from tumors derived from other histologic sites.

Immunohistochemical demonstration of thyroglobulin is useful for determining the histogenesis of primary thyroid carcinomas, those tumors arising in ectopic sites such as the heart base, and metastases of presumed thyroid origin (Moore *et al.*, 1984). Thyroid carcinomas with follicular differentiation consistently stain positively for thyroglobulin, whereas those with compact phenotype are less consistently reactive.

Many thyroid neoplasms will react immunohistochemically with neuron-specific enolase as well (Leblanc *et al.*, 1991). Medullary thyroid tumors derived from the neural crest thyroidal C-cell system may be immunoreactive for calcitonin, calcitonin gene-related peptide, and neuron-specific enolase (Leblanc *et al.*, 1991). These parafollicular cells can be distinguished from compact follicular cells of thyroid tumors on the basis of their immunoreactivity for calcitonin (Carver *et al.*, 1995). Medullary thyroid carcinomas in the horse and sheep may also be immunoreactive for calcitonin (van der Velden and Meulenaar, 1986; Renzoni *et al.*, 1995).

Parathyroid hormone immunoreactivity may be used to localize parathyroid glands in tissue sections. Further, using antibodies to parathyroid hormone-related protein, widespread localization of PTHrP was reported in both normal and neoplastic canine tissues; it is a presumed mediator of hypercalcemia of malignancy in dogs, but its widespread localization in normal canine tissues also demonstrates a physiologic role for the protein (Grone *et al.*, 1994).

1. Estrogen Receptor; Progesterone Receptor

The cytosol receptor assays provided evidence for steroid receptor-positive and steroid receptor-negative tumors; using these assays, the prevalence of estrogen and progesterone receptors has been reported to exceed 50% in canine mammary carcinomas, and data suggested that dogs with tumors expressing steroid hormone receptors survived longer than dogs without estrogen receptors or progesterone receptors (Sartin *et al.*, 1992). At the cellular level, however, it is often found that mammary tumors are heterogenous and composed of individual receptor-positive and receptor-negative cancer cells. The availability of specific, monoclonal antibodies for estrogen and progesterone receptors and the development of immunohistochemical methods for the localization of steroid hormone receptors in mammary tumors has resulted in a plethora of articles in human patients that detail close correlation of results with features of tumor grade and histologic types, as well as treatment responses. Although immunohistochemistry has been used to assess steroid receptors in canine mammary tumors, these new biological findings have not yet been extensively correlated with the clinical behavior of the tumors.

2. Epidermal Growth-Factor Receptor

Using immunohistochemistry, epidermal growth-factor receptor (EGF-R) was detected in almost one-half of plutonium-239-induced canine pulmonary neoplasms, but it was also expressed in a smaller percentage of nonneoplastic proliferative lung lesions (Gillett *et al.*, 1992).

3. Oncoproteins

Immunohistochemical staining with specific monoclonal antibodies for proteins of oncogenes or tumor suppressor genes may serve as biomarkers for cancer. Cytologic specimens, exfoliated cells, needle-biopsy specimens, and fixed tissues, including those from hospital archives, can be suitable for examination and could be particularly informative for some tumors. Examples of proteins to which monoclonal antibodies have been produced for immunohistochemistry include p53 and Rb, Bcl-2, BCRA1, c-*myc*, c-*ras*, c-*erb*B-2, and others. Most of these monoclonal antibodies have been raised to human or rodent antigens, although preliminary data in the veterinary literature demonstrate cross reactivities of at least some of these antibodies with specimens derived from domestic animals. These markers can be tested for their ability to function as tumor markers in animals on the basis of *a priori* knowledge of their functions.

G. Histopathology—Leukocyte Markers

Until recently, research on the canine immune system was done using antibodies against human or murine leukocyte antigens, but monoclonal antibodies with specific reactivities to canine and feline leukocyte antigens have been developed in recent years. Leukocyte antigens are currently defined by cluster-differentiation (CD) numbers assigned in international workshops; the specificities of many of the canine antibodies were established at the First Canine Leukocyte Antigen Workshop, and the canine homologs of the human CD antigens were summarized (Cobbold and Metcalfe, 1994). For example, antibodies with specificities toCD45 recognize B and T cells; antibodies to CD3 and CD5 recognize T cells; CD4 reactive cells include T helper-cell subset (MHC-II restricted); CD8 reactive cells include a cytotoxic T-cell subset (MHC-I restricted T cells); Thy-1 reactive cells include peripheral T cells, thymocytes; MHC-II reactive cells include antigen-presenting B and T cells; and monoclonal antibodies to CD21 and mb-1 recognize B cells. Plasma cell tumors have often been distinguished in the immunohistochemistry laboratory by their reactivity for antibodies to canine IgG $F(ab)_2$ and vimentin (Baer *et al.*, 1989).

In the cat, monoclonal antibodies specific for the feline homologs of CD4 (Ackley *et al.*, 1990; Tompkins *et al.*, 1990), CD8 (Klotz and Cooper, 1986; Tompkins *et al.*, 1990), major histocompatibility class II (Rideou

et al., 1990), and a leukocyte common antigen (CD45) have been described (Hunt *et al.*, 1995).

In the dog, the majority of malignant lymphomas are classified as B cell in origin (Teske *et al.*, 1994b). The proliferative lymphocytes in canine mycosis fungoides have been identified as T lymphocytes, although these lymphocytes expressed predominately CD3 and CD8 antigens, in contrast to the predominant CD4 expression of T lymphocytes in human mycosis fungoides (Moore *et al.*, 1994). Other cutaneous lymphoid neoplasms in the dog have been chararacterized by immunohistochemistry; these cutaneous lymphoid tumors predominately involve T lymphocytes, whereas epitheliotrophic lymphomas are exclusively of T-lymphocyte origin (DeBoer *et al.*, 1990; Ferrer *et al.*, 1993; Fivenson *et al.*, 1994; Moore *et al.*, 1990, 1994; Tobey *et al.*, 1994). An equine cutaneous T-cell lymphoma has also been identified (Littlewood *et al.*, 1995).

Several studies demonstrate the value of immunophenotyping for dogs with malignant lymphoma as an aid to predicting response to chemotherapy. Using cytofluorography and monoclonal antibodies to canine or human cell-surface determinants, it was determined that dogs with T-cell tumors had shortened remission and survival times when compared to dogs with B cell-derived tumors (Greenlee *et al.*, 1990). More recently, using immunohistochemistry, an avidin–biotin complex immunoperoxidase technique, and an expanded repertoire of monoclonal antibodies, canine lymphoma cells were categorized as B-cell type, T-cell type, or non-B/non-T cell type (Teske *et al.*, 1994a). In that study, dogs with B cell-derived tumors had significantly longer durations of remission and overall survival times following onset of chemotherapy than those dogs with T cell-derived tumors. Some data are now also evolving in the literature regarding the immunophenotyping of equine lymphomas (Asahina *et al.*, 1994), and the neoplastic cells of sporadic bovine leukosis develop from both B- and T-cell lineages (Asahina *et al.*, 1995).

H. Virology

1. Feline Leukemia Virus

Immunohistochemistry allows detection of specific localization of feline leukemia virus in tissues. Using immunofluorescence, "sequestered" feline leukemia virus (FELV) antigen was detected in localized tissues such as the spleen, intestinal crypt epithelium, or lymphomatous tissues in aviremic cats (Hayes *et al.*, 1989). Similarly, we detected an apparent sequestered FELV infection in a cat with a malignant lymphoma arising in the setting of immunosuppression following renal transplantation (Gregory *et al.*, 1991). In another report, retroviral DNA was detected in both blood and tumor tissue from a cat with an olfactory neuroblastoma, but not in nonneoplastic tissues, including the brain of the affected cat (Schrenzel *et al.*, 1990).

2. Bovine Papillomavirus

Immunohistochemistry is a rapid and reliable screening method for the detection of papillomaviruses in tissues using antisera to papillomavirus group-specific antigen (Sundberg *et al.*, 1984). This method has been used to identify papillomaviruses in a variety of avian and mammalian neoplasms (Sundberg, 1987) for example, using anti-papillomavirus group-specific structural antigens (bovine papillomavirus subgroup A), papillomavirus was detected in cutaneous papillomatosis from a dog (Shimada *et al.*, 1993). Other specific clinical applications of this detection method are referenced (Campbell *et al.*, 1988; Elzein *et al.*, 1991). Detection of papillomavirus group-specific antigen requires that highly differentiated cells contain large numbers of viral particles; in many papillomavirus infections however, the resultant lesions differ in the frequency with which mature virus particles are being produced which alters their immunoreactivity. A negative result therefore, does not necessarily indicate the absence of papillomavirus infection. Other methods, principally based on nucleic acid hybridization and/or the polymerase chain reaction (PCR), are now being used in many research laboratories to investigate further the molecular pathogenesis of the various avian and mammalian papillomaviruses.

VII. CYTOCHEMISTRY

Hematologic diagnosis has traditionally been based on light microscopy supplemented by cytochemistry. New techniques of immunophenotyping, cytogenetics and molecular genetics are providing new classification systems; many of these investigative strategies are now moving into the diagnostic laboratory as new sources of information that have influence on patient management. Cytologic assessment remains of major importance, however, in the diagnosis of acute leukemia; cytochemistry facilitates the diagnosis of the majority of cases of acute myelogenous leukemia and allows a provisional diagnosis of acute lymphoblastic leukemia. The most important cytochemical reactions for neutrophilic differentiation are the myeloperoxidase reaction and the Sudan black C stain. Chloroacetate esterase is also used as a marker for neutrophil differentiation. In the dog and cat, alkaline phosphatase reactivity may indicate acute myeloid leukemia

because normal neutrophils in these species lack alkaline phosphatase reactivity (Jain, 1993). The most important stains for monocytic differentiation are the "nonspecific" esterase (NSE) reactions, such as α-naphthyl acetate esterase. The diffuse cytoplasmic reactivity of monocytes for nonspecific esterases can be inhibited by sodium fluoride; some T-lymphocyte subsets will also show localized cytoplasmic reactivity for NSE, but the reactivity is resistant to fluoride inhibition. The lipase stain is also used as a marker of monocytic differentiation. Myelomonocytic leukemias are identified by simulataneous cytochemical reactivities, typically alkaline phosphatase and non-specific esterase.

VIII. MOLECULAR ONCOLOGY

A. Methods

Increasing data regarding genetic changes that are often specifically associated with particular types of tumors provides the basis for new and effective strategies for diagnostics. These tests can be based directly on the changes in DNA that occur in tumor cells, or on the RNA that is made from that altered DNA. Cytogenetics was the tool used first to examine gross morphologic features of chromosomes, and to characterize the consistent, nonrandom chromosomal abnormalities such as translocations and deletions. These precedent studies provided important clues to the location of relevant genes and the mechanisms by which their growth regulatory functions have been altered. New advances in molecular technology, however, now allow analysis of genes at the nucleotide level; these methods are beginning to be applied in veterinary medicine. Techniques for identifying genetic changes in tumor cells are discussed next.

1. Nucleic Acid Hybridization

Hybridization refers to the base pairing of complementary strands of nucleic acid that leads to the double-stranded molecule. *In situ* hybridization allows identification of nucleic acid sequences within cells that can be components of genes that code for particular proteins. The advantage of *in situ* hybridization is that it allows examination of gene content at the site of expression in the cell, and it can provide evidence of whether or not a specific gene is transcribed within the cell. Reviews of methodologies and applications of *in situ* hybridization are available elsewhere (Mitchell *et al.*, 1992). For cancer diagnosis, *in situ* hybridization provides an opportunity to use complementary nucleic acid sequences to cancer-causing viral genes such as leukemia viruses, immunodeficiency viruses, or th papillomaviruses. *In situ* hybridization has been use extensively in diagnostic pathology and oncology b providing proof that cells synthesize proteins. Wherea immunohisto(cyto)chemistry is used to demonstrat specific tumor-associated proteins by virtue of thei gene expression, *in situ* hybridization provides un equivocal evidence of their synthesis by the neoplasti cells. This application is perhaps best illustrated by th demonstration of expression of specific oncogenes i preneoplasia and overt neoplasms. For example, usin *in situ* hybridization, *erb*-B RNA was detected in a sma number of plutonium-239-induced canine pulmonar neoplasms, demonstrating activation of that oncogen (Gillett *et al.*, 1992).

2. Restriction Enzymes and Restriction Fragment Length Polymorphisms

Restriction enzymes (or endonucleases) are a grou of endonucleases that cleave double-stranded DNA a a specific recognition site (restriction site) determine by the exact DNA sequence. Hundreds of restrictio enzymes with related and different specificities ar now available. Restriction enzymes cut DNA into re producible sizes; however, alterations of that restri tion site (i.e., mutation, deletion) might abolish tha DNA sequence so that the enzyme does not cut tha DNA. Therefore, the uncut DNA fragment will b larger than normal upon electrophoresis. Mutation at sites recognized by restriction enzymes, or polymo phisms at restriction enzyme sites, are extremely usefu for genetic analysis, because mutations at restrictio sites are inherited like any other genetic trait and ca be used for linkage analysis. *Restriction fragment lengt polymorphism* (RFLP) analysis involves application c restriction enzymes to detect polymorphisms linked t cancer-related genes, and it has been used extensivel to examine regions of the genome likely to contai tumor suppressor genes (Rowley *et al.*, 1993).

3. Southern Blots

The Southern blot is a standard technique used fc the identification of specific DNA sequences. Typicall a DNA sequence (i.e., a PCR product, or chromosom DNA that has been digested with a restriction enzym is denatured (to single-strand form) and transferred c blotted to a special membrane, usually nitrocellulos A labeled probe (radioactive or nonradioactive) wi hybridize to a complementary sequence on the mem brane, which can then be detected, for example, b autoradiography or some other imaging procedur Southern blotting was used to detect c-*myc*, c-*erb*B 2, c-*ros*-1, c-*yes*-1, v-*myc*, v-Ki-*ras*, and v-Ha-*ras* prot

oncogenes in genomic DNA from several domestic animal species, including dogs, cats, horses, and cattle (Miyoshi *et al.*, 1991). In another study, using Southern blotting, c-*erb*B-2 and c-*myc* overexpression was detected in canine melanoma cell lines (Ahern *et al.*, 1993). *Northern* blot analysis is a variation of Southern blotting, whereby steady-state levels of a particular RNA transcript (mRNA), instead of cleaved DNA fragments, are separated by electrophoresis without prior digestion and then probed in a hybridization reaction with complementary sequences. Northern analysis can be used to detect both qualitative and quantitative information on mRNA transcripts; for example, it can be used to identify amplified gene expression.

4. DNA Sequencing

Direct sequencing is the primary method for characterizing genes. Although sequencing methods have been simplified in recent years, they are still laborious and time consuming, and therefore of limited clinical use. Direct DNA sequencing is expected to be a routine procedure in specialized clinical laboratories within 10 years (Kant, 1995). Many genes and their mutations associated with cancer are now being elucidated, and a number of autosomal genes, such as the major ones associated with familial breast cancer (*BCRA1, BCRA2*), cumulatively affect large numbers of individuals in the population. The nucleotide sequences of genes relevant to animals with cancer are now being elucidated.

5. Polymerase Chain Reaction

Another approach to examining genetic structure is the polymerase chain reaction. PCR is an *in vitro* method that uses enzyme synthesis to exponentially amplify specific DNA (or cDNA) sequences. Amplification of a gene or gene fragment of interest from virtually any tumor preparation by means of PCR, coupled with improved detection methodologies, has enhanced diagnostic capabilities, allowing characterization of genes responsible for neoplastic transformation and tumor progression.

Applications of PCR for viral agents that may be associated with, or causative of, cancer in animals include its use in the detection of infections with bovine papillomavirus, bovine immunodeficiency virus, feline leukemia virus, and feline immunodeficiency virus (Belak and Ballagi-Pordany, 1993). For the detection of the bovine leukemia virus (BLV), PCR has been used adjunct to indirect (serologic) methods for diagnosis of BLV infection in circumstances where serology may be unreliable, such as during early stages of infection, in animals persistently infected with bovine viral diarrhea virus, or in young calves that have received colostrum from infected dams (Belak and Ballagi-Pordany, 1993). Most of the PCR strategies for detection of BLV infection are based on demonstration of proviral DNA in blood lymphocytes.

B. Genetic Changes in Cancer Cells

The key molecular events associated with carcinogenesis involve oncogenes and tumor suppressor genes. These genes may be altered in premalignant as well as malignant processes; methods are now available to study these genes directly in clinical specimens. For example, mutated p53 genes have been detected in the urine of human patients with cancer of the urinary bladder; mutant *ras* genes in stools derived from patients with pancreatic and colorectal cancer; and both mutant p53 and *ras* genes in sputum from patients with lung cancer (Duffy, 1995). These findings demonstrate that the genetic alterations associated with cancer may be detected in fluids or secretions that had contact with the malignant tissues. Alterations involve changes in both gene structure and gene expression. Oncogenes contribute to tumor formation either because constitutional activation prevents them from following regulatory signals or because structural changes incapacitate their normal signaling function. Proto-oncogenes may be activated by a number of mechanisms.

1. Amplification

Proto-oncogenes may be inappropriately amplified or overexpressed in neoplasms, and these phenomena have become frequent findings in the molecular analyses of various tumors. Amplified oncogenes were first discovered in cells carrying two cytogenetic abnormalities, double minute chromosomes and homogenously staining chromosome regions. The first reports of somatic ampification of a cellular oncogene involved the c-*myc* oncogene in a promyelocytic leukemia cell line and a colonic carcinoma cell line. *Myc* proteins serve as transcription factors. Overexpression of *myc* promotes cell proliferation, and it appears that dysregulation of *myc* confers a growth advantage to affected cells. In human patients, from a clinical perspective, L-*myc* is amplified in patients with non-small-cell lung cancer, and N-*myc* in patients with neuroblastoma. Amplification correlates with a more rapid disease progression and advanced disease state and is an independent prognostic factor for decreased survival time. In human breast cancer, the c-*erb*B-2 (also known as HER-2/*neu*) is amplified consistently in patients with advanced neoplasms, and those amplifications are associated with poor prognosis. There are preliminary data to show that c-*erb*B is also overexpressed in canine malignant melanoma (Ahern *et al.*, 1993).

2. *Mutation*

Mutation is another mechanism of oncogene activation resulting in altered protein product. Single nucleotide substitutions leading to amino acid changes (missense mutations) are responsible for most disease-causing alterations of genes. Point mutations in proto-oncogenes and tumor suppressor genes are relatively common abnormalities in human tumors, and preliminary data are now emerging regarding the occurrence of similar mutations in some animal tumors. In human medicine, many of these mutations have been shown to have considerable significance in disease processes; for some genes, specific mutations have been used to detect minimum tumor burdens either early in the disease course or following cytoreductive treatment. Specific mutations have been used to categorize individuals predisposed to cancer in high-risk families; other mutations have been shown to correlate with patient response to therapy, thus serving as a measure of prognosis. Still others have served to provide evidence for the role of specific environmental carcinogens in tumorigenesis by virtue of the characteristic mutations induced.

Mutations in the *RAS* family of oncogenes occur with high frequency and predictability at certain neoplasms at codons 12, 13, and 61, conferring transforming properties to *ras* p21 proteins. Mutations of *ras* genes have been identified in a wide variety of neoplasms, occurring most frequently in tumors of the pancreas, colon, thyroid gland, and lung, and in myeloid leukemia. For example, Ki-*ras* activation occurs in approximately 30% of human patients with non-small-cell lung cancer; we have determined similar activation of Ki-*ras* in dogs with lung tumors (Kraegel *et al.*, 1992).

3. *Translocation*

Proto-oncogenes may be activated by translocations and inversions. There are two principal consequences of translocations or inversions. In one situation, either the T-cell receptor or an immunoglobulin protein comes to lie near a proto-oncogene, thereby activating it. Alternatively, the break occurs within a gene on each chromosome involved, creating a fusion gene encoding a chimeric protein. The genes involved in activating translocations often encode transcription factors, indicating that altered transcription plays a role in tumorigenesis. Translocation is a common mechanism in human hematopoietic neoplasms, whereby proto-oncogenes located near the break are activated as a result of the translocation. For example, in Burkitt's lymphoma, c-*myc* is placed by translocation under the influence of immunoglobulin enhancers and promoters. Immunoglobulin and T-cell receptor genes are fre quently involved in chromosomal aberrations becaus they are naturally rearranged to generate activ antigen-receptor genes. This process leads, on occa sion, to interchromosomal translocations or inversion as in Burkitt's lymphoma.

One study of 15 dogs with canine lymphoma c leukemia revealed 10 dogs with rearrangements of th immunoglobulin heavy chain gene (IgH), and 4 dog with TCR*B*-chain gene rearrangements. Most c the IgH chain rearrangements were associated wit tumors expressing cell-surface immunoglobuli whereas 3 of 4 dogs with TCR*B*-gene rearrangemen were Thy-1 positive (Momoi *et al.*, 1993).

At present, there are still limited data on the nucleo tide sequences of the (proto-)oncogenes and tumo suppressor genes in domestic animals, their chromo somal localizations, their expression in tissues, an their roles in cellular growth, differentiation, and carc nogenesis. c-*myc* expression was described in canir mammary tumors (Engstrom *et al.*, 1987), and overe pression of c-*myc* was reported in explants of canir malignant melanomas (Ahern *et al.*, 1993). A canir genomic oncogene related to the human c-*yes*-1 onc gene was detected in a canine mammary neoplasm, a well as the genomic DNA from the same dog, sugges ing a role for that oncogene in the early stages of ca cinogenesis (Miyoshi *et al.*, 1991). In another stud c-*yes*-1 protooncogene was amplified in the DN derived from canine lymphoid leukemia cells (Mina *al.*, 1994). The canine c-*yes* proto-oncogene has bee cloned and sequenced (Zhao *et al.*, 1995). Expression c c-Ha-*ras*, c-Ki-*ras*, and c-N-*ras* was discerned in norm and neoplastic tissues from the dog and cow (Mad well *et al.*, 1989). The nucleotide sequences of the clin cally relevant regions of the c-Ki-*ras* and c-N-*ras* gen were subsequently reported (Saunders *et al.*, 199 Kraegel *et al.*, 1992), as well as preliminary data o the activation of c-Ki-*ras* in canine spontaneous lun tumors (Kraegel *et al.*, 1992). Some data are also no emerging regarding the canine, feline, and equine tu mor suppressor genes p53. Genetic sequences of th canine p53 gene, encompassing regions of exons 3– were reported (Kraegel *et al.*, 1995). A 284th codo mutation was described in a canine papilloma (Ma *et al.*, 1994b) and in several thyroid carcinomas (Devil *et al.*, 1994). Mutated p53 species have also been d scribed in feline hematopoietic tumors and a felir mammary carcinoma (Okuda *et al.*, 1993, 1994; Ma *et al.*, 1993b; Mayr *et al.*, 1995b). Wild-type equine p5 cDNA sequences between exons 2 and 9 have bee described, and two mutations were detected in equir cutaneous squamous-cell carcinomas at sites of know

activation by ultraviolet light in human cutaneous carcinomas (Pazzi *et al.*, 1995).

CHAPTER

27

Cerebrospinal Fluid

CLETA SUE BAILEY AND WILLIAM VERNAU

The analysis of cerebrospinal fluid (CSF) has been described as the central nervous system equivalent of the complete blood count (Jamison and Lumsden, 1988), and the analogy is a good one. A CSF analysis provides a general index of neurologic health and often provides evidence of the presence of disease. Similar to a complete blood count, CSF analysis has reasonable sensitivity but low specificity. The possible alterations of CSF are relatively limited compared to the varieties of neurologic diseases that exist (particularly if the analysis is restricted to total cell counts and total protein determination). Additionally, the type and degree of CSF abnormality seems to be related as much to the location of disease as to the cause or the severity of

the lesion; meningeal and paraventricular diseases generally produce greater abnormalities than deep parenchymal diseases. Previous therapy may affect the type, degree, and duration of CSF abnormalities as well. The CSF abnormalities identified upon analysis are also dependent on the CSF collection site with respect to lesion location (Thomson *et al.*, 1990, 1989). Lastly, the CSF of animals with neurological disease is not always abnormal (Tipold, 1995). Only occasionally does CSF analysis provide a specific diagnosis (Kjeldsberg and Knight, 1993)—for example, if infectious agents (bacteria or fungi) or neoplastic cells are observed. In most situations, the chief utility of CSF analysis is to assist in the diagnostic process by excluding the likelihood of certain disease processes being present. As is the case with all tests of relatively low specificity, examination of CSF is most useful when the results are correlated with the history, clinical findings, imaging studies, and ancillary laboratory studies. As stated by Fankhauser (1962), "It is futile to make a diagnosis based solely on the CSF findings and particularly on single alterations of it. Only the entire picture of all findings linked with the other clinical symptoms is of value in reaching a diagnosis."

I. FUNCTIONS OF CEREBROSPINAL FLUID

Cerebrospinal fluid has four major functions: (1) physical support of neural structures, (2) excretion and "sink" action, (3) intracerebral transport, and (4) control of the chemical environment of the central nervous system. Cerebrospinal fluid provides a "water jacket" physical support and buoyancy. When suspended in CSF, a 1500-g brain weighs only about 50 g. The CSF is also protective because its volume changes reciprocally with changes in the volume of intracranial contents, particularly blood. Thus, the CSF protects the brain from changes in arterial and central venous pressure associated with posture, respiration, and exertion. Acute or chronic pathological changes in intracranial contents can also be accommodated, to a point, by changes in the CSF volume (Fishman, 1992; Rosenberg, 1990; Milhorat, 1987).

Excretory function is provided by the direct transfer of brain metabolites into the CSF. This capacity is particularly important because the brain lacks a lymphatic system. The lymphatic function of the CSF is also manifested in the removal of large proteins, and even cells such as bacteria or blood cells, by bulk CSF absorption (see Section II.D, CSF Absorption). The "sink" action of the CSF arises from the restricted access of water-soluble substances to the CSF and the low concentration of these solutes in the CSF. Therefore, solutes entering the brain, as well as those synthesized by the brain, diffuse freely from the brain interstitial fluid into the CSF. Removal may then occur by bulk CSF absorption or, in some cases, by transport across the choroid plexus into the capillaries (Fishman, 1992; Rosenberg, 1990; Milhorat, 1987; Davson and Segal, 1996)

Because CSF bathes and irrigates the brain, including those regions known to participate in endocrine functions, CSF may serve as a vehicle for intracerebral transport of biologically active substances. For example, hormone-releasing factors, formed in the hypothalamus and discharged into the CSF of the third ventricle, may be carried in the CSF to their effective sites in the median eminence. The CSF may also be the vehicle for intracerebral transport of opiates and other neuroactive substances (Fishman, 1992; Milhorat, 1987).

An essential function of CSF is the provision and maintenance of an appropriate chemical environment for neural tissue. Anatomically, the interstitial fluid of the central nervous system and the CSF are in continuity (see Section II.A, Anatomy of Brain–Fluid Interfaces); therefore, the chemical composition of the CSF reflects and affects the cellular environment. The composition of the CSF (and the interstitial fluid) is controlled by cells forming the interfaces, or barriers, between the "body" and the neural tissue. These semipermeable interfaces, the blood–brain barrier, the blood–CSF barrier, and the CSF–brain barrier, control the production and absorption of CSF and provide a fluid environment that is relatively stable despite changes in the composition of blood (Fishman, 1992; Milhorat, 1987; Davson and Segal, 1996).

II. CSF FORMATION, CIRCULATION, AND ABSORPTION

The brain (and the spinal cord) as an organ is isolated in many ways from the body and the systemic circulation. This isolation is accomplished anatomically by several interfaces between brain tissue and systemic fluids (Table 27.1). At these interfaces, select

TABLE 27.1 Composition of the Brain–Fluid Interfaces[a]

Interface	Cell type	Junction type
Blood–brain	Brain capillary endothelium	Tight junction
Blood–CSF		
Blood–CSF	Choroid plexus epithelium	Apical tight junctio
CSF–blood	Arachnoid cells	Tight junction
	Arachnoid villi	Valve
CSF–brain	Ependyma	Gap junction
	Pia mater	Gap junction

[a] Modified from Rosenberg (1990).

tive carriers and ion pumps transport electrolytes and essential nutrients and thereby control the brain's microenvironment. A substantial portion of this control is achieved through the formation, circulation, and absorption of CSF at these brain–fluid interfaces (Rosenberg, 1990; Davson and Segal, 1996).

A. Anatomy of Brain–Fluid Interfaces

1. The Blood–Brain Barrier

The important blood–brain (and blood–spinal cord) interface is formed by the endothelial cells of the intraparenchymal capillaries. In most areas of the brain and spinal cord, the capillary endothelium differs from that of other body tissues in the following ways: (1) the absence of fenestrae, (2) the presence of tight junctions between adjacent cells, (3) a lower number of pinocytotic pits and vesicles, (4) a higher number of mitochondria, and (5) closely applied, perivascular, astrocytic foot processes. These features result in the capillary endothelium being a selective barrier—the blood–brain barrier—that regulates the entry, and probably the exit, of biologically important substances and aids in the maintenance of a precise, stable environment for the neural tissues (Rosenberg, 1990; Milhorat, 1987; Davson and Segal, 1996).

2. The Blood–CSF Barrier

One part of the blood–CSF interface is formed by the epithelial cells of the circumventricular organs. The circumventricular organs, which include the four choroid plexuses, the median eminence, the neural lobe of the hypophysis, and other specialized areas, border the brain ventricles and are involved with specific secretory activities that appear to require a direct contact with plasma. The capillaries within these organs are fenestrated, similar to capillaries in other organs of the body. Overlying each of the organs are specialized epithelial cells joined by intercellular tight junctions at their apical (ventricular) borders. These epithelial cells also are characterized by an abundance of intracellular organelles and lysosomes. These organelles are probably an important aspect of the barrier and secretory functions of these cells (Rosenberg, 1990; Milhorat, 1987). The choroid plexuses are the major source of CSF. They are formed by evaginations of the ependyma and the pial blood vessels into the ventricles, and they consist of a single row of cuboidal, specialized epithelial cells thrown into villi around a core of blood vessels and connective tissue. The apical (ventricular) surface of the epithelial cells has a brush border of microvilli with occasional cilia. The basal and lateral cell surfaces have numerous infoldings. Overall, the structure of these cells resembles that of other epithelia specialized for fluid transport, such as proximal renal tubular epithelium (Rosenberg, 1990; Milhorat, 198 Davson and Segal, 1996). Autonomic nerve termina have also been identified in the choroid plexus, b their function is unclear (Fishman, 1992; Nilsson *al.*, 1992).

The second part of the blood–CSF interface formed by the arachnoid membrane at the arachno villi. These villi are microscopic evaginations of t arachnoid membrane into the lumen of the dural s nuses. The barrier function of these arachnoid cells demonstrated by their tight junctions. Their transpo function is indicated by giant intracellular vacuole some of which have both basal and apical opening and pinocytotic vesicles. The sinus surface of a villu is covered by sinus endothelium (Rosenberg, 199 Milhorat, 1987). Endothelium-lined channels may lin directly with the subarachnoid space (Davson an Segal, 1996; Bell, 1995). Arachnoid villi are not limite to intracranial venous sinuses, but also are present a the spinal nerve roots penetrating into the spinal veir (Milhorat, 1987; Bell, 1995).

3. The CSF–Brain Interface

The extensive CSF–brain (and spinal cord) interfac consists of the ependyma within the cavities of th central nervous system and the pia mater coverin the central nervous system. These two layers are eac composed of a single layer of cells joined by gap junc tions. The ependyma and the pia mater are not impor ant permeability barriers; the CSF (ventricular and sub arachnoid) and the brain interstitial fluid are directl continuous (Milhorat, 1987; Davson and Segal, 1996)

B. CSF Formation

1. Choroidal and Extrachoroidal Formation

Cerebrospinal fluid is formed principally by the cho roid plexus, with a smaller amount being formed extra choroidally (Milhorat, 1987; Davson and Segal, 1996) Choroidal formation involves two processes that occu in series: first, filtration across the choroidal capillary wall, and second, secretion by the choroidal epithe lium. Within the choroid plexus, hydrostatic pressur of the choroidal capillaries initiates the transfer of wa ter and ions to the interstitial fluid and then to th choroidal epithelium. Water and ions are then trans ferred into the ventricles by either (1) intracellula movement across the epithelial membranes or (2) inter cellular movement across the apical tight junction between epithelial cells. Both of these processes ar probably dependent upon ion pumps. Secretion of CSF results from the active transport of sodium which is dependent on the membrane-bound, sodium-

potassium activated ATPase present at the apical (ventricular) surface of the choroidal epithelium (Rosenberg, 1990; Davson and Segal, 1996). The presence of autonomic nerve terminals in the choroid plexus suggests a neural control of CSF secretion. However, the functional role of this innervation in normal and pathologic conditions is unknown (Fishman, 1992; Nilsson *et al.*, 1992).

Spurred primarily by clinical evidence that excision of the choroid plexus did not benefit human patients with hydrocephalus, experimental evidence now supports the existence of an extrachoroidal source of CSF. The diffusion of brain interstitial fluid across the ependyma or pia mater is the apparent source of this extrachoroidal CSF component. Formation of the interstitial fluid is thought to occur by active transport processes (secretion) at the cerebral capillaries, but an alternative theory proposes passive permeability of the capillary endothelium and active transport by the surrounding astrocytes (Rosenberg, 1990; Milhorat, 1987). The relative contributions of choroidal and extrachoroidal sources to CSF in normal and pathologic conditions are not certain. Some investigators report the choroid plexus to be the major if not the sole source of CSF, whereas others conclude that at least one-third of newly formed CSF is extrachoroidal (Milhorat, 1987; Davson and Segal, 1996).

2. *Rate of CSF Formation*

Regardless of the amount of extrachoroidal formation, the rate of CSF formation is closely correlated to the weight of the choroid plexus and varies among species (Table 27.2) (Cserr, 1971; Welch, 1975). Increases and decreases in formation rate have been achieved experimentally, but the general tendency is for the formation rate to remain relatively constant. The formation rate directly parallels the rate of sodium exchange, which is linked to the bicarbonate ion. The enzyme carbonic anhydrase plays an important role because it provides the bicarbonate. Inhibition of carbonic anhydrase slows (but does not abolish) sodium, bicarbonate, and chloride flow, resulting in a reduction of CSF secretion (Maren, 1992). Several drugs and conditions inhibit CSF production (Table 27.3), but their clinical utility is limited either by their time frame of action or by their toxicity (Rosenberg, 1990; Pollay 1992; Davson and Segal, 1996).

Moderate variations in intracranial pressure probably do not affect CSF formation. However, studies of chronically hydrocephalic animals have shown a reduction of CSF formation with increasing intraventricular pressure. The secretion process may also be affected by chronically increased intracranial pressure (Fishman, 1992).

TABLE 27.2 Rate of CSF Formation in Various Species[a]

Species	Rate (μl/min)
Mouse	0.325
Rat	2.1–5.4
Guinea pig	3.5
Rabbit	10
Cat	20–22
Dog	47–66
Sheep	118
Goat	164
Calf[b]	290
Monkey	28.6–41
Human	350–370

[a] Estimated by ventriculo-cisternal perfusion. Modified from Davson and Segal (1996).
[b] Calhoun *et al.* (1967).

C. CSF Circulation

Cerebrospinal fluid flows in bulk from sites of production to sites of absorption. Fluid formed in the lateral ventricles flows through the paired interventricular foramina (foramina of Monro) into the third ventricle, then through the mesencephalic aqueduc

TABLE 27.3 Factors Influencing CSF Formation[a]

Effect	Substance or condition	Site of action
Increase	Cholera toxin	cAMP
	Phenylephrine[b]	Cholinergic pathways
Decrease	Acetazolamide, furosemide	Carbonic anhydrase
	Atrial natriuretic hormone	cGMP
	Diazepam analog[c]	Choroidal benzodiazepine receptor
	Dopamine D_1 receptor agonist	Choroidal dopamine receptor
	Hyperosmolarity	Choroidal capillaries

	Noradrenaline[b]	cAMP/Choroidal Na^+–K^+-ATPase
	Omeprazole[c]	H^+–K^+-ATPase?
	Ouabain	Na^+–K^+-ATPase
	Serotonin receptor agonist	Choroidal serotonin recept
	Steroids[c]	Choroidal Na^+–K^+-ATPase
	Vasopressin	Choroidal vasopressin (V_1) receptor

[a] Modified from Fishman (1992).
[b] Nilsson *et al.* (1992).
[c] Davson and Segal (1996).

(aqueduct of Sylvius) into the fourth ventricle. The majority of CSF exits from the fourth ventricle into the subarachnoid space; a small amount may enter the central canal of the spinal cord. In people, CSF enters the subarachnoid space through the lateral apertures (foramina of Luschka) and the median aperture (foramen of Magendie) of the fourth ventricle. Animals below the anthropoid apes do not have a median aperture (Fletcher, 1993; Fankhauser, 1962). Cerebrospinal fluid has also been shown to flow from the spinal subarachnoid space into the spinal perivascular spaces, across the interstitial space, then into the central canal (Stoodley *et al.*, 1996). Mechanisms for propelling the CSF along its route probably include (1) the continuous outpouring of newly formed ventricular fluid, (2) the ciliary action of the ventricular ependyma, (3) respiratory and vascular pulsations, and (4) the pressure gradient across the arachnoid villi (Milhorat, 1987).

D. CSF Absorption

Absorption of CSF occurs by bulk absorption of the fluid and by absorption or exchange of individual constituents of the fluid, that is, ions, proteins, and drugs. Bulk absorption occurs directly into the venous system and depends primarily upon the CSF hydrostatic pressure; as the pressure rises, the absorption rate increases (Davson and Segal, 1996). If intracranial pressure falls below a critical point, bulk absorption decreases, a homeostatic response to stabilize the intracranial pressure and the CSF volume. The primary site of bulk absorption, at least in people, is the arachnoid villi that project into the dural sinuses. Two other routes are through lymphatic channels in the dura and through the perineural sheaths of cranial nerves (particularly the olfactory nerve) and spinal nerves. Perineural absorption may be through arachnoid villi projecting into perineural veins, lymphatics, or connective tissue (Milhorat, 1987; Davson and Segal, 1996). The importance of these various absorption routes varies with the species (Bell, 1995).

Absorption through the arachnoid villi occurs transcellularly through micropinocytotic vesicles and giant intracellular vesicles, but may also occur through endothelium-lined, intercellular clefts. The mechanisms appear to vary among species (Bell, 1995). Absorption is unidirectional from the CSF into the venous blood—the villi act like one-way valves. The basis for the valve-like mechanism appears to be transport by the giant vesicles (see Section II.A.2). Particles ranging in size from colloidal gold (0.2 μm) to erythrocytes (7.5 μm) can be transported across the villi. In disease conditions, accumulations of larger particles (e.g., protein molecules, erythrocytes, leukocytes) within the villi may impair absorption, leading to hydrocephalus (Fishman, 1992; Milhorat, 1987). The choroid plexus also has an absorptive function, acting on specific substances in the CSF rather than by bulk fluid absorption. A variety of compounds are actively transported from the CSF, in a fashion reminiscent of the proximal renal tubule. Solutes may also be cleared from the CSF by diffusion into adjacent brain cells or capillaries (Fishman, 1992; Milhorat, 1987).

III. CELLULAR COMPOSITION OF NORMAL CSF

A. Total Erythrocyte and Nucleated Cell Count

Cerebrospinal fluid normally does not contain erythrocytes (Chrisman, 1992; Rand *et al.*, 1990b; Cook and DeNicola, 1988; Wilson and Stevens, 1977). Most commonly, the presence of erythrocytes in a CSF sample is iatrogenic, due to inadvertant trauma associated with the needle placement. However, CSF erythrocytes may also originate from pathologic hemorrhage. The normal nucleated-cell counts of CSF in domestic animals are given in Table 27.4. The most widely accepted reference ranges for the numbers of leukocytes in the CSF of dogs and cats are 0–5 cells/μl (deLahunta, 1983; Oliver and Lorenz, 1993) to 0–8 cells/μl (Duncan *et al.*, 1994). However, these ranges are a little too broad in our experience and the most comprehensive series in the literature confirm this. Jamison and Lumsden

TABLE 27.4 Total White Blood Cell Count of Normal CSF in Domestic Animals

Species	Collection site[a]	N[b]	Cells/μl[c]	Reference
Dog	C	50	0–2	Jamison (1988)
Dog	C, L	31	0–4	Bailey (1985)
Cat	C	33	0–2	Rand (1990)
Horse	Pooled C and L	44	0–6	Mayhew (1977)
Horse	C	14	0–5	Furr (1994)
Cow	L	16	0.85–3.52[d]	Welles (1992)
Llama	L	17	0–3	Welles (1994)
Sheep	L	NS[e]	0–5	Fankhauser (1962)
Goat	NS	NS	0–4	Brewer (1983)
Pig	NS	NS	0–7	Fankhauser (1962)

[a] C = cerebellomedullary cistern. L = lumbar subarachnoid space.
[b] *N* = number of animals.
[c] Range.
[d] 95% confidence interval.
[e] NS, not stated.

(1988) examined 50 clinically and histopathologically normal dogs and derived cerebellomedullary CSF reference limits of 0–2 cells/μl. In fact, all except one of these dogs had counts of 0–1 cells/μl (personal communication). Bailey and Higgins (1985) examined 31 dogs that were clinically and histopathologically normal. For cerebellomedullary CSF, the mean was 1.45 cells/μl, with the 95% confidence intervals being 1.04–1.86 and the observed range being 0–4 cells/μl. Of 31 dogs, 26 had counts between 0 and 2 cells/μl. They also found that lumbar CSF had significantly lower counts with a mean of 0.55 cells/μl, a 95% confidence interval of 0.22–0.88 and an observed range of 0–4 cells/μl, although 30/31 dogs had counts of 0–2 cells/μl. We currently feel that a normal count for cerebellomedullary CSF in dogs is 0–2 cells/μl, with 3 cells/μl being in the gray zone and 4 cells/μL being abnormal. Rand *et al.* (1990b), derived reference limits for cerebellomedullary CSF from 33 cats that were clinically and histopathologically normal. The samples did not have blood contamination. The mean ± 1 SD for the white blood cell count was 0.1 ± 0.4 with an observed range of 0–2 cells/μl. Of 33 cats, 30 had counts of 0 cells/μl. Three cells or more per microliter is therefore considered abnormal in cerebellomedullary fluid of cats.

B. Differential Cell Count

1. Leukocytes

Excellent morphologic descriptions of the cell types normally found in the CSF of domestic animals can be found elsewhere (Rand *et al.*, 1990b; Cook and DeNicola, 1988; Jamison and Lumsden, 1988). Normal CSF consists of varying proportions of small lymphocytes and monocytes. The proportions are species and age dependent (Kjeldsberg and Knight, 1993). In dogs, monocytic type cells predominate (Jamison and Lumsden, 1988), although there is significant individual variation. In cats (Rand *et al.*, 1990b), monocytoid cells also predominate, with a mean of 87%, whereas small lymphocytes have a mean of 9%. This same trend is observed in horses, with 73.6% monocytes and 26.2% lymphocytes (Furr and Bender, 1994). However, small lymphocytes predominate in cattle (Welles *et al.*, 1992) and llamas (Welles *et al.*, 1994). In the human literature prior to 1975, any neutrophils present at all in the CSF were thought to be indicative of disease (Kjeldsberg and Knight, 1993). However, with the advent of techniques for concentrating CSF specimens, such as the cytocentrifuge, it became clear that a very small number of neutrophils may be found in normal human CSF (Fishman, 1992; Kjeldsberg and Knight, 1993). Similar observations have been made in many veterinary spe cies, and rare neutrophils are a common and norma finding in the CSF of all domestic species. Eosinophil are not present in normal CSF, although a single ce is occasionally seen on cytocentrifuge slides of fluid with normal total cell counts. Large foamy activate macrophages or phagocytes are not seen in norma CSF (Fishman, 1992; Christopher *et al.*, 1988) and the presence is nonspecific evidence of an inflammator disorder. Plasma cells are not seen in normal CSF (Fish man, 1992; Pelc *et al.*, 1981; Kjeldsberg and Knigh 1993) . Their presence is indicative of underlying in flammatory disease. In people, plasma cells are see particularly in acute viral disease and various chron inflammatory conditions, including tuberculous men ingitis, syphilis, multiple sclerosis, and the Guillain Barré syndrome (Pelc *et al.*, 1981; Kjeldsberg an Knight, 1993). In animals, plasma cells have been ob served in various conditions, including distempe (Vandevelde and Spano, 1977), other viral meningit (Vandevelde and Spano, 1977), rabies (Green *et a* 1992), granulomatous meningoencephalomyelitis (Ba ley and Higgins, 1986a; Vandevelde and Spano, 1977 neoplasia, and abscessation (personal observations Therefore, although they are abnormal, no specificit is associated with their presence in CSF. Similarly, rea tive lymphocytes are not found in normal CSF, bu their presence has no specificity. They can be seen i active or resolving infectious disease, immun mediated diseases, and neoplasia (Cook and D Nicola, 1988).

2. Other Cells

Cells other than leukocytes can be seen in both no mal and abnormal CSF. Cells lining the leptomeninge choroid plexus cells, and ependymal cells can be see as single cells, or, more often, as small papillary cluste or sheets. Cytologically, choroid plexus cells and epen dymal cells are indistinguishable (Cook and DeNicol 1988; Kjeldsberg and Knight, 1993). The majority lining cells seen in normal CSF are thought to be ch roid plexus cells (Kjeldsberg and Knight, 1993). Exce lent descriptions and photographs of these cell typ can be found elsewhere (Rand *et al.*, 1990b; Cook ar DeNicola, 1988; Kjeldsberg and Knight, 1993). Cho drocytes are occasionally seen in CSF sampled by lum bar puncture, likely due to the spinal needle nickin the intervertebral disc (Bigner and Johnston, 1981 Squamous cells can be observed in CSF and may be du to skin contamination or an underlying pathologic process such as epidermoid cysts (Kornegay and Go gacz, 1982) or metastatic carcinomas. Bone-marro cells (immature hematopoietic precursors) have bee

described in the CSF of people (Kjeldsberg and Knight, 1993) and dogs (Christopher, 1992). In people, bone-marrow cells in the CSF are usually associated with lumbar puncture, usually in infants or in patients with vertebral bone abnormalities that create difficulties during the sampling process. The cells are present because of sampling from the vertebral body or articular process. Christopher (1992) observed hematopoietic cells in the lumbar CSF of two dogs and speculated that it was due either to marrow penetration or to dural extramedullary hematopoiesis (Christopher, 1992). Extramedullary hematopoiesis has been observed in the choroid plexus of five dogs that did not have underlying hematologic abnormalities or the presence of extramedullary hematopoiesis elsewhere (Bienzle *et al.*, 1995). Although the CSF was normal in these dogs and hematopoietic cells were not observed, this site could provide another potential source for the presence of these cells in CSF. Metastatic myeloid leukemia could conceivably produce similar findings, but peripheral blood and marrow examination would clarify the origin of the cells in question. Neurons, astrocytes, glial cells, and neutral tissue have been observed in the CSF of people (Bigner and Johnston, 1981) and also in cerebellomedullary cisternal samples associated with traumatic taps in animals (personal observation).

IV. BIOCHEMICAL CONSTITUENTS OF NORMAL CSF

Because CSF is a product of plasma filtration and membrane secretion, its composition is different from that of plasma. In general, CSF is a clear, colorless, nearly acellular, low-protein fluid. Various ions, enzymes, and other substances are also found in normal CSF. In health, the CSF composition is maintained relatively constant by the various membrane interfaces, although some fluctuations occur with fluctuations in plasma composition. The chemical composition of the CSF of various animal species is summarized in Tables 27.5 through 27.8. These values should serve only as a guide; normal values must be established for individual laboratories.

A. Ontogeny of CSF

In people and animals, differences in CSF appearance and composition exist between neonates and adults. Human neonatal CSF is usually xanthochromic, probably because of a greater protein and bilirubin content than adult CSF. Glucose content is also increased, more closely approximating the blood glucose level. Many of these differences, such as protein content, are attributed to immaturity of the blood–brain barrier. Immaturity of the blood–brain barrier may be due to an increased number of fenestrae in the brain capillaries or inadequate closure of their endothelial tight junctions. Other factors that may contribute to age differences in CSF composition are the integrity of the blood–CSF barrier, the rate of CSF secretion and efficiency of absorption, the volume of the extracellular space of the brain, and the lipid solubility of the substances (Fishman, 1992; Davson and Segal, 1996). Protein also decreases with age in foals and puppies (Furr and Bender, 1994; Rossdale *et al.*, 1982; Meeks *et al.* 1994). In contrast, two studies of calves found that CSF protein increased with age (St. Jean *et al.*, 1995 Binkhorst, 1982). Foals also had xanthochromia and a higher CSF glucose and creatine kinase levels than adults (Furr and Bender, 1994; Rossdale *et al.*, 1982) The WBC count decreased with age in puppies and calves (Meeks *et al.*, 1994; Binkhorst, 1982).

Studies done in prenatal, neonatal, and adult laboratory animals (including rats, rabbits, pigs, sheep, cats dogs, and monkeys) and people have shown that, in general, the CSF/plasma concentration ratios (R_{CSF}) of Na^+, Mg^{2+}, and Cl^- increase with age. The R_{CSF} of K^+ HCO_3^-, and urea decrease. In some instances, however (e.g., Cl^- and K^+), changing plasma levels of these substances contribute to the change in the R_{CSF}. The R_{CSF} of total protein, as well as those of the individual proteins, decreases with age. The decreasing concentration of proteins in the CSF compared to plasma protein is an indication of the maturation of the blood–brain and blood–CSF barriers. In rats, the R_{CSF} of amino acids also falls quickly with age, although large individual variations exist. Taurine, for example, has a higher level in the adult than the newborn. This fact, as well as the species-specific transport of some proteins (e.g., albumin) into the CSF indicates a special mechanism of transport based on factors other than molecular weight (Davson and Segal, 1996).

B. Proteins in the CSF

Proteins identified in the CSF are given in Tables 27.9 and 27.10. In general, the concentration of a CSF protein is inversely related to its molecular weight. If the blood–brain barrier is normal, serum proteins with a molecular weight greater than 160,000 Da are largely excluded. However, Felgenhauer (1974) reported CSF : serum protein distribution ratios to be better correlated with the hydrodynamic radii than with the molecular weight of the proteins. Almost all the proteins normally present in CSF are derived from the serum. The exceptions are transthyretin (prealbumin)

and transferrin, which are also synthesized by the choroid plexus, and beta and gamma trace proteins, tau protein (tau fraction, modified transferrin), glial fibrillary acidic protein, and myelin basic protein, which appear to be synthesized intrathecally (Thompson, 1988).

1. Albumin

With electrophoretic techniques, protein in the CSF can be separated into prealbumin, albumin, and alpha, beta, and gamma globulins. The major protein in CSF is albumin, which is synthesized only in the liver. The limited entry of albumin into the CSF is dependent upon the blood–brain/CSF barrier to macromolecules. When total CSF protein is increased, the albumin concentration is increased disproportionately. This phenomenon illustrates the role of molecular size in determining the distribution of serum proteins into the CSF (Felgenhauer, 1974).

2. Alpha and Beta Globulins

Immunoelectrophoresis can separate the alpha and beta globulins into several proteins (Table 27.9). The origin of tau protein ($beta_2$ transferrin) is uncertain. This protein may be modified serum transferrin (beta transferrin) or it may be a unique protein, "tau protein," in the CSF (Fishman, 1992). In veterinary and human medicine, no correlation has been made be

tween changes in the concentrations of these globulins and specific neurologic disease (Fishman, 1992; Sorjonen *et al.*, 1991). Thus, their measurement has limited clinical use at this time.

3. *Gamma Globulins*

Because of the changes found in association with multiple sclerosis and other inflammatory diseases, the gamma globulins have received a great deal of attention. Electrophoretic techniques define the gamma globulins as a heterogeneous group of proteins with migrations at similar rates (see Table 27.9). The gamma globulin fraction contains immunoglobulins. Immunologic assays identify three major immunoglobulins in normal CSF—IgG, IgA, and IgM. Minute amounts of other immunoglobulins have also been detected in normal CSF (Fishman, 1992; Kjeldsberg and Knight, 1993).

a. IgG

The major immunoglobulin in normal CSF is IgG, which normally originates from the serum. An increased level of CSF gamma globulin has been reported in a number of inflammatory central nervous system disorders. In disease conditions, gamma globulin may enter the CSF through dysfunctional blood–brain/CSF barriers, or may be synthesized intrathecally by cells that have migrated into the brain or CSF and are participating in the disease process (Fishman, 1992; Kjeldsberg and Knight, 1993).

b. IgM and IgA

Cerebrospinal fluid IgM and IgA also originate normally from the serum. However, in certain diseases, particularly inflammatory diseases, these immunoglobulins are produced within the central nervous system as well (Fishman, 1992; Kjeldsberg and Knight, 1993). IgM is ontogenetically and phylogenetically the most primitive immunoglobulin and is therefore detected at an earlier stage of the general immune response of the body. IgM is also the first immunoglobulin to return to normal when the offending antigen disappears. The characteristics of IgM and IgA participation in the intrathecal immune response still need to be resolved, however (Tipold *et al.*, 1994; Felgenhauer, 1982).

4. *Other Proteins*

Many other proteins have been identified in CSF, including myelin basic protein, S-100 protein, C-reactive protein, interferon, embryonic proteins, fibronectin, and glial fibrillary acidic protein. In general, the CSF concentrations of these proteins may be altered by a number of neurologic disease processes. The utility of assay of these proteins in clinical veterinary or human medicine has yet to be established (Fishman, 1992; Kjeldsberg and Knight, 1993).

C. Glucose

The CSF glucose is derived solely from the plasma by facilitated diffusion. The concentration of CSF glucose depends upon the blood glucose concentration, the rate of glucose transport into the CSF, and the metabolic rate of the central nervous system. The normal CSF glucose level is about 60–80% of the blood glucose concentration, reflecting at least in part the high metabolic rate of the central nervous system. Equilibration with plasma glucose requires about 1 to 2 hours; thus, ideally, plasma glucose should be determined about 1 hour prior to CSF aspiration and analysis. In people, a glucose gradient exists along the neuraxis; the concentration decreases from ventricular to lumbar fluid (Fishman, 1992; Kjeldsberg and Knight, 1993).

D. Enzymes

Numerous enzymes have been assayed in the CSF of animals(see Tables 27.5 through 27.8) (Rand et al., 1990a; Wilson, 1977; Jackson *et al.*, 1996) and people (Banik and Hogan, 1983). These enzymes have three possible sources: (1) blood, (2) neural tissue or neural tumors, or (3) cells within the CSF (Fishman, 1992; Kjeldsberg and Knight, 1993). In probably every instance, the blood enzyme levels are higher than the CSF levels. Unfortunately, many studies of CSF levels in disease fail to report the concurrent blood level and a measure of blood–brain/CSF barrier integrity. However, studies of CSF creatine kinase (CK) in dogs and horses did not find a relationship between WBC counts, serum CK, or CSF total protein and CSF CK (Furr and Tyler, 1990; Jackson *et al.*, 1996). Regarding correlation of CSF RBC with CSF CK, one study reported a significant correlation (Indrieri *et al.*, 1980), whereas another study did not find a statistical association between the two parameters (Jackson *et al.*, 1996). To date, none of the enzyme assays has been shown to be sufficiently sensitive or specific to warrant its routine use in clinical practice (Rand *et al.*, 1994b; Fishman, 1992; Kjeldsberg and Knight, 1993; Jackson *et al.*, 1996; Indrieri *et al.*, 1980).

E. Neurotransmitters

Because they are produced by neurons, neurotransmitters and their metabolites have been extensively studied in people for their potential use as markers

of neuronal activity and neurologic and psychiatric disease (Davis, 1990). The concentrations of several neurotransmitters (e.g., γ-aminobutyric acid, dopamine) and their metabolites (e.g., 5-hydroxyindolacetic acid, homovanillic acid, and dihydroxyphenylacetic acid) have been measured in the CSF from various sites in dogs, sheep, goats, cattle, and horses (Vaughn *et al.*, 1989b, 1988a; Sisk *et al.*, 1990; Loscher and Schwartz Porsche, 1986; Ruckebusch and Costes, 1988; Bardo and Ruckebusch, 1984; Ruckebusch and Sutra, 198 Faull *et al.*, 1982). Some metabolite concentrations hav a gradient along the neuraxis (Vaughn and Smyth

1989; Vaughn *et al.*, 1988b; Ruckebusch and Costes, 1988; Ruckebusch and Sutra, 1984), and some are age-related (Smyth *et al.*, 1994; Vaughn *et al.*, 1989b; Ruckebusch and Costes, 1988). Despite intense interest, more research is needed to verify the clinical utility of assay of these substances in the CSF (Fishman, 1992; Kjeldsberg and Knight, 1993).

F. Other CSF Constituents

Many other substances have been measured in CSF in experimental and clinical situations. These include electrolytes, gases, organic and amino acids, ammonia, urea, creatinine, prostaglandins, cytokines, and hormones. Assay of these substances is not particularly helpful in the diagnosis of neurologic disease in people because the substances are not generally associated with specific disease (Fishman, 1992; Kjeldsberg and Knight, 1993). Their usefulness in veterinary medicine has yet to be established.

G. Concentration Gradient along the Neuraxis

In cats (Hochwald *et al.*, 1969), dogs (Bailey and Higgins, 1985; Vaughn *et al.*, 1988b), horses (Andrews *et al.*, 1990a; Vaughn and Smyth, 1989), rhesus macaques (Smith and Lackner, 1993) and people (Fishman, 1992; Davson and Segal, 1996), the total protein concentration increases along the neuraxis from rostral to caudal. For example, in people the total protein concentration of ventricular, cerebellomedullary cistern, and lumbar subarachnoid fluid is about 26, 32, and 42 mg/dl, respectively (Weisner and Bernhardt, 1978). (Total protein, albumin, and globulin contents of cerebellomedullary cistern and lumbar subarachnoid

TABLE 27.10 Protein Content of Cerebellomedullary Cisternal CSF of Healthy Dogs, Cats, and Horses as Identified by Electrophoresis[a]

Protein fraction	Dog (Sorjonen, 1987)	Cat (Rand *et al.*, 1990a)	Horse (Kristensen and Firth, 1977)
Prealbumin			2.0 ± 0.9
Albumin	37 ± 4.29 (31–44)	11 ± 15 (1–53)	43.4 ± 6.8
Alpha globulin	28 ± 5.27 (24–31)	21 ± 11 (0–48)	
$Alpha_1$			5.3 ± 1.3
$Alpha_{2a}$			3.3 ± 0.8
$Alpha_{2bc}$			6.4 ± 1.8
Beta globulin	25 ± 5.31 (19–30)	57 ± 15 (37–91)	
$Beta_1$			17.0 ± 3.2
$Beta_2$			7.8 ± 2.3
Gamma globulin	7.75 ± 1.84 (6–9)	12 ± 7 (0–29)	14.8 ± 3.3

[a] Mean ± SD percentage of total CSF protein; range in parentheses.

CSF for dogs, cats, and horses are given in Tables 27.5, 27.6, and 27.7, respectively.) The concentration of the albumin and globulin fractions also increases from ventricular to lumbar fluid. The increased protein content may be the result of a greater permeability of the spinal blood–CSF barrier than the ventricular barrier to albumin (Fishman, 1992), additions of protein from adjacent nervous tissue (e.g., IgG from lymphocytes located in or near the CSF pathway (Weisner and Bernhardt, 1978)), progressive equilibration of CSF with plasma through the capillary walls (Weisner and Bernhardt, 1978), and low flow rates of lumbar CSF (Davson and Segal, 1996).

A study of healthy dogs also identified a small but significant gradient for the CSF WBCs; lumbar fluid contained significantly fewer cells than cerebellomedullary fluid (Bailey and Higgins, 1985). Another study did not find a difference in WBC counts between fluids from the two sites (Vaughn *et al.*, 1988b). However, 4 of the 10 dogs in this study had CSF total WBC counts $>3/\mu$l, and none of the dogs were necropsied to verify their health. Therefore, some of these dogs may have had subclinical neurologic disease, disguising a small cellular gradient. The small number of WBCs in normal fluid may make a cellular gradient more of a theoretical issue than a practical issue, however. If a cellular gradient exists, it may be due to fewer cells entering the lumbar CSF than the cerebellomedullary CSF, a greater rate of cell lysis in the lumbar CSF, a greater migration rate of WBCs from lumbar CSF back into the blood, or loss of WBCs that entered the CSF rostrally and lysed as CSF circulated to the caudal subarachnoid space.

A gradient has also been reported for CSF neurotransmitter metabolites in the dog (Vaughn *et al.*, 1988b) and the horse (Vaughn and Smyth, 1989). In each species, the neurotransmitter metabolite content of cerebellomedullary CSF was greater than that of lumbar subarachnoid CSF. This gradient probably reflects the major source of the neurotransmitter (brain) and transport of the metabolite from the CSF into the blood along the spinal axis (Vaughn *et al.*, 1988b).

V. CSF COLLECTION AND ANALYTICAL TECHNIQUES

A. Collection

1. *General Techniques*

Specific details for the collection of CSF from the various species are covered in many excellent articles and textbooks (Holbrook and White, 1992; Mayhew, 1989; deLahunta, 1983; Kornegay, 1981; Brewer, 1983; Fowler, 1989; Brewer, 1987; Boogerd and Peters, 1986) and will not be covered here except for the authors' preferred technique of collection from the cerebellomedullary cistern of dogs and cats (see later discussion). Considerations that apply regardless of species are sterility, use of a spinal needle, and collection from animals with increased intracranial pressure. In order to prevent iatrogenic central nervous system infection sterility during the collection procedure is vital. A generous area around the puncture site should be clipped and surgically prepared. Preparation of too small an area can lead to contamination if any difficulty in palpating landmarks or entering the subarachnoid site is encountered. Additionally, the use of a fenestrated drape is highly recommended. Spinal puncture is contraindicated in an area of severe pyoderma/furunculosis, cellulitis, or epidural abscess. A needle with a stylet (spinal needle) should be used to prevent implantation of a plug of epidermis in the subarachnoid space which not only could lead to infection but could also seed an epidermoid tumor. Replacement of the stylet upon withdrawal is controversial, either preventing or causing entrapment and severance or dislocation of nerve root filaments (Fishman, 1992). Aspiration of CSF from animals with increased intracranial pressure may result in brain herniation. Appropriate anesthetic agents, hyperventilation, and mannitol may decrease the probability of herniation. Use of the smallest gauge needle possible may also help prevent herniation by decreasing CSF leakage through the puncture hole in the meninges. Only the minimal amount of CSF necessary to perform the desired tests should be withdrawn. Brain herniation can occur following lumbar taps as well as cerebellomedullary cistern taps.

2. *Collection Site*

The choice of collection site is influenced by the species and breed of animal, the location of the neurologic lesion, and anesthetic considerations. The size of some animals may make lumbar subarachnoid puncture difficult if not impossible. However, cerebellomedullary puncture usually can be accomplished even in very large or obese animals. Because of differences in anatomy, the type or breed influences the exact site for lumbar puncture in the dog; L3–4 or L4–5 is recommended for large-breed, nonchondrodystrophic dogs (e.g., German shepherd dogs), whereas L4–5 or L5–6 is recommended for small, chondrodystrophic dogs (e.g., dachshunds) (Morgan *et al.*, 1987). The puncture site chosen should be as close to the lesion as possible without penetrating the lesion, or the site should be caudal to the lesion. In animals with spinal disease, cerebellomedullary fluid is abnormal more frequently with cervical disease than it is with thoracic

lumbar disease, but overall lumbar fluid is abnormal more often than cerebellomedullary fluid. With intracranial disease, CSF from both sites is usually abnormal, perhaps because both sites are caudal to the lesion (Thomson *et al.*, 1990; Scott, 1992; Thomson *et al.*, 1989). Occasionally, CSF is collected from both sites. Although the order of collection, cerebellomedullary or lumbar CSF collected first, appears not to influence the analytical results significantly (Bailey and Higgins, 1985), aspiration from the relatively small lumbar subarachnoid space is easier if the CSF pressure has not just been lowered by cerebellomedullary CSF collection. Cerebellomedullary puncture should be done under general anesthesia. In most instances, lumbar puncture can be done with sedation and local anesthesia. Therefore, if general anesthesia is contraindicated, a lumbar puncture should be done.

3. CSF Collection from the Cerebellomedullary Cistern

The authors' preferred technique for CSF collection from the cerebellomedullary cistern is to utilize the palpable bony landmarks that are the closest to the puncture site. These structures are the vertebral arch of C1 and the external occipital protuberance. After anesthetic induction and intubation, the animal is placed in lateral recumbancy and padding is placed under the neck to align the dorsal cervical and cranial midline parallel to the tabletop. The assistant is instructed to "tuck in the animal's chin" and push the external occipital protuberance toward the operator. This procedure flexes the atlanto-occipital joint and maximizes the space between the occipital bone and C1. Asking the assistant to simply flex the neck seems to produce flexion of the midcervical area more than the atlanto-occipital area. The external occipital protuberance, the C2 spinous process, and the C1 vertebral arch are palpated. The last structure is located by rolling a fingertip off the cranial edge of the C2 spinous process and palpating firmly, feeling for a transverse bony ridge (the C1 vertebral arch). The C1 vertebral arch can usually be palpated, and if so, the puncture is made on the midline just in front of the fingertip palpating the vertebral arch. If C1 is not palpable, the distance between the cranial edge of the C2 spinous process and the occipital protuberance is noted, and the puncture is made on the midline about one-third of that distance cranial to the cranial edge of the C2 spinous process. In rare cases, neither C1 nor C2 can be palpated. In this situation, the lateral edge of each C1 transverse process is palpated and a triangle from each edge to the occipital protuberance is constructed visually. The puncture is made on the midline in the center of that triangle.

B. Physical Examination: Clarity, Color, and Viscosity

After collection, the CSF is examined visually and the clarity, color, and viscosity are recorded. Normal CSF is clear and colorless and has essentially the same viscosity as water. For accurate assessment, the CSF can be compared to the same amount of distilled water in the same type of container. The containers can be held against a white, typewritten page to judge color and clarity, and gently shaken to assess viscosity. If the CSF appears abnormal, the color and clarity of the supernatant after centrifugation should be noted.

C. Cytological Analysis

1. General Techniques

Collection of CSF in a plastic or silicon-coated glass tube is preferred because monocytes will adhere to glass and can activate in the process (Fishman, 1992). This can result in erroneous cell counts and also alter morphology. In practical terms, this is of little consequence in those specimens that are rapidly processed but becomes more significant as the delay between collection and processing increases. A complete cytologic examination includes both a total cell count and a differential, as well as thorough morphologic assessment. A differential and thorough morphologic assessment should be performed routinely, even on those samples that have cell counts within normal limits. In our experience, very low cell counts alone cannot be used as an indicator of normality. In one study that utilized cytocentrifugation, nearly 25% of canine CSF samples with cell counts in the normal range had abnormalities in cell type or morphology (Christophe *et al.*, 1988). Abnormalities included the presence of phagocytic macrophages, increased percentage of neutrophils in the differential, and the presence of reactive lymphocytes and plasma cells. Malignant cells have been observed in samples with normal counts (Bichsel *et al.*, 1984b; Grevel and Machus, 1990). This certainly emphasizes the importance of cytologic assessment especially in specimens with normal cell counts. In general terms, CSF samples should be processed as soon as possible after collection, as cells degenerate relatively quickly in CSF (Chrisman, 1992; Fishman 1992; Steele *et al.*, 1986; Kjeldsberg and Knight, 1993). This is because of the marginal hypotonicity of the fluid and very low protein content (in nonpathologic specimens). Proteins and lipids tend to have

membrane-stabilizing effect (Steele *et al.*, 1986). A multitude of veterinary references state that processing must be performed within 30 minutes of collection (Thomson *et al.*, 1990; Oliver and Lorenz, 1993; Cook and DeNicola, 1988; Chrisman, 1983) and this necessitates analysis in the individual veterinary hospital or practice setting. However, there is a complete lack of controlled veterinary studies to confirm this assertion, although, as stated previously, the sooner the better, in general terms. There have been several human studies performed. Steele found that there were significant differences in rates of lysis that were dependent on cell type. At room temperature, neutrophil counts decreased most rapidly and were significantly reduced at 1 hour and 2 hours, 68 ± 10% (SEM) and 50 ± 12% of original values, respectively. Values were not significantly reduced at half an hour. Lymphocyte and monocyte numbers were not significantly altered until 3 hours (69 ± 7% and 66 ± 7%, respectively). However, refrigeration at 4°C markedly reduces the rate of lysis, with only 15% decrease in the total white blood cell numbers at 2 hours (Kjeldsberg and Knight, 1993). Another study (Stokes *et al.*, 1975) reported the following rates of disappearance for white blood cells at room temperature: 4 hours—10% lysis, 18 hours—70% lysis, 36 hours—100%. Because there is differential sensitivity of cell types, both cell counts and the differential are altered with time. The authors have observed this phenomenon. When differential counts are compared between slides made immediately and those made via cytocentrifugation 3–6 hours later, there is a marked decrease in the percentage of neutrophils (personal observation). This would tend to confirm the preceding data. Therefore, the recommendation that analysis be performed within 30 minutes is reasonable, but it is predicated on the conditions that the sample is exposed to. Refrigeration obviously slows lysis, likely long enough for transport to reference laboratories in some instances. Addition of protein to the sample helps preserve cells and also expedites transport of samples to more remote facilities. There was excellent correlation between the total numbers of cells on the slides and the differential between sediment slides processed immediately and those preserved with fetal bovine serum (200 μl of CSF and 200 μl of fetal bovine serum) and cytocentrifuged 2–4 hours later (Rand *et al.*, 1990b). We have observed excellent morphology on slides made from CSF as long as 12 hours postcollection, when the sample was immediately mixed with approximately 20% by volume of autologous, well-centrifuged serum and transported on an ice pack. However, the effects on cell count and differential are unknown under these conditions. This is perhaps an option for practitioners in remote locations without the capability or expertise to process CSF. The duration c cell preservation under different conditions require further study.

2. *Total Leukocyte and Erythrocyte Counts*

Electronic cell or particle counters are not sensitiv enough to be used for enumeration of cells in CSI The level of background counts with these counters frequently in excess of the counts present in the majo ity of CSF samples that are analyzed. Therefore, coun are performed with the use of a standard hemacytome ter chamber with a Neubauer ruling (Cook and DeN cola, 1988; Jamison and Lumsden, 1988; Brobst an Bryan, 1989). The chamber is charged with undilute fluid. Ideally, the cells should be allowed to settle fo 10 minutes in a humidified environment. This allow all the cells to be visible in the same plane of focu The cells in the 9 largest squares on both sides of th chamber are counted (18 squares in total) and the resu multiplied by 0.55 to obtain the number of cells pe microliter. Numerous references recommend countin the cells in 9 large squares and multiplying by 1.1 t determine the count per microliter. To the untraine observer, unstained leukocytes and erythrocytes ma be difficult to differentiate. Leukocytes are larger an the presence of nuclei gives them a more granula appearance than erythrocytes. With experience, nu clear morphology can often be appreciated (Cook an DeNicola, 1988). The cytoplasmic border is usuall slightly irregular. In contrast, erythrocytes are usuall smaller, smooth, and refractile, although they may be come crenated upon standing (Jamison and Lumsde 1988). A number of techniques have been develope to lyse erythrocytes and stain leukocytes in an effo to expedite counting. Technical details can be found i numerous sources (Chrisman, 1992; Cook, 1985; Brob and Bryan, 1989), but there are several major disadva tages associated with these methods (Jamison an Lumsden, 1988), and we do not recommend them.

3. *Cytologic Examination*

A wide variety of methods to facilitate cytolog examination of CSF have been reported and compare (Grevel, 1991; Roszel, 1972; Kölmel, 1977; Sörnäs, 196 Barrett and King, 1976; Steinberg and Vandeveld 1974; Ducos *et al.*, 1979; Hansen *et al.*, 1974; Woodrul 1973; Jamison and Lumsden, 1988). There is contr versy as to which method is optimal, and all have the strengths and weaknesses. Methods include simp centrifugation, sedimentation and variations therec membrane filtration, and cytocentrifugation (Jamisc and Lumsden, 1988). The reader is referred to the references for specific methodological details. In th

great majority of cases, simple centrifugation produces slides that are completely unsatisfactory for cytologic examination. Membrane filtration techniques have the chief advantage of excellent cellular recovery with yields approaching 90–100% (Barrett and King, 1976). However, the methodology is laborious and time consuming, the morphology relatively poor, many cells are partly hidden in the filter substance, which itself stains variably, and the technique requires specialized, nonroutine staining techniques that the great majority of veterinary cytologists have no experience or expertise in interpreting. For these reasons, they are not recommended. Cytocentrifugation (Hansen *et al.*, 1974; Woodruff, 1973) has become the method of choice in both human (Fishman, 1992; Kjeldsberg and Knight, 1993) and veterinary medicine (Christopher *et al.*, 1988; Jamison and Lumsden, 1988). The technique is rapid and simple and provides slides with good cytologic detail. The technique is enhanced by the addition of protein to the CSF sample prior to centrifugation. This helps preserve cell morphology. Conditions of cytocentrifugation vary from laboratory to laboratory. We personally prefer the method described by Rand (Rand *et al.*, 1990b). The disadvantages of cytocentrifugation include the expense of the instrument and the relatively low cell yield. In one comparative study (Barrett and King, 1976), the following cell yields were determined: Millipore filtration 81 ± 3 % (SEM), Nucleopore filtration 69 ± 3%, and cytocentrifugation 11 ± 1%. The Sornas method of centrifugation results in a cell yield, after staining, of approximately 20% (Sörnäs, 1967). The sedimentation technique of Sayk, modified by Kölmel (Grevel, 1991; Grevel and Machus, 1990; Kölmel, 1977) results in a yield of approximately 30% (Kölmel, 1977), although this can be increased to almost 90% if a membrane filter is substituted for direct sedimentation onto a slide. We have some experience with the Kölmel apparatus and technique and have found the cell morphology to be at least as good as that in cytocentrifugation, with an apparently superior cell yield, although this would need to be confirmed with controlled comparative studies. Therefore, most studies would suggest that sedimentation techniques result in greater cell yields than cytocentrifugation, although there is a least one study that found the yield of cytocentrifugation to be marginally higher than that of sedimentation (Ducos *et al.*, 1979). Standard Romanowsky stains are recommended for staining of slides. They provide good cellular detail on air-dried CSF preparations and are familiar to most observers. These stains include the Wright's and Wright–Giemsa staining methods, as well as a variety of rapid staining methods including Diff-quik and Camco-quik (Jamison and Lumsden, 1988).

4. Immunocytochemistry

There are very few reports in the veterinary literature documenting the use of immunocytochemistry for the assessment of CSF. In people, the value of cytologic diagnosis of CSF can be improved if morphologic studies are appropriately supplemented by immunocytochemistry (Kjeldsberg and Knight, 1993). Immunophenotypic studies of cytocentrifuge slides are useful in the differential diagnosis of leukemia, maligant lymphoma, primary brain tumors, and metastatic tumors (Bigner and Johnston, 1981; Bigner, 1992; Kjeldsberg and Knight, 1993). Panels of monoclonal antibodies are often used, with the greatest limitation being the volume and the cellularity of the specimen that is available for the marker studies. Undifferentiated tumor panels frequently include leukocyte common antigen and cytokeratin antibodies. These can be very helpful in distinguishing single carcinoma cells from lymphocytes or monocytes (Bigner and Johnston, 1981; Bigner, 1992; Kjeldsberg and Knight, 1993). Glial fibrillary acidic protein has proven to be helpful in distinguishing a glial origin, but there are currently no specific markers to distinguish primary brain tumors. Immunocytochemistry can be used also to characterize the lymphocyte subpopulations present in CSF. Of the lymphocytes found in normal human CSF, 75–95% are T cells, with a mean of approximately 85% (Kjeldsberg and Knight, 1993). Within the population of T cells, T helper cells predominate and account for up to 88% of T cells. Alterations of these percentages have been shown to have significant associations with disease in people (Kjeldsberg and Knight, 1993). Similar studies are lacking in domestic animals but would potentially be quite useful. In people, most cental nervous system lymphomas are B cell in origin, and immunocytochemistry can be used to document monoclonality (Bigner and Johnston, 1981; Bigner, 1992). This is strong evidence (but not definitive proof) of malignancy. The B-cell origin can also be confirmed. For patients with T-cell lymphomas, marker studies can be more difficult to interpret as T cells predominate in normal and inflammatory CSF (Kjeldsberg and Knight, 1993). If there is systemic involvement, then comparison with the peripheral phenotype is useful to confirm presence in the CSF. Immunocytochemistry has also been utilized to detect infectious agents such as cytomegalovirus in human patients (Kjeldsberg and Knight, 1993).

5. Polymerase Chain Reaction

Polymerase chain reaction (PCR) technology represents a powerful adjunct to routine cytologic assessment and has the potential to revolutionize CSF analysis by dramatically increasing both the sensitivity and

specificity of diagnosis. Because PCR exponentially increases *in vitro* the number of original DNA copies to a final number dependent on the number of cycles programmed, it is uniquely suited to the low volumes and small cell numbers frequently found in CSF samples. In people, one of the most powerful and useful applications of PCR methodology has been its use to confirm malignancy and detect minimal residual disease in lymphomatous meningitis (Rhodes *et al.*, 1996). This is accomplished via detection of clonal immunoglobulin or T-cell receptor gene rearrangements and the detection of clone-specific rearrangements, respectively. However, the exquisite sensitivity may result in false positive results due either to contamination or to very low initial numbers of cells producing an artifactual clonal band. Other applications include detection of a wide variety of infectious agents, including toxoplasma, borrelia, TB, and herpes simplex (Christen *et al.*, 1995; Lin *et al.*, 1995; Novati *et al.*, 1994; Guffond *et al.*, 1994). In the great majority of these studies, PCR has resulted in a more rapid diagnosis with superior sensitivity and specificity when compared to those of standard culture and serologic diagnostic techniques. In veterinary medicine, PCR has been used to detect several infectious agents in CSF samples, including sarcocystis neurona, toxoplasma, and listeria (Fenger, 1994; Peters *et al.*, 1995; Stiles *et al.*, 1996). The same advantages appear to apply in these instances, although some agents such as listeria may not gain access to the meningoventricular system, resulting in negative results when applied to CSF of confirmed positive cases (Peters *et al.*, 1995). Further developmental work in conjunction with prospective studies will be required before the true utility of PCR-based CSF diagnostics can be accurately assessed in domestic animals.

D. Protein Analysis

1. *Measurement of CSF Total Protein*

An increase in the concentration of CSF total protein was recognized as an indicator of neurologic disease soon after the introduction of lumbar puncture in human medicine. A number of tests were developed to assess qualitative changes in CSF protein, such as Lange's colloidal gold test, the Nonne–Appelt test, the Pandy test, and others. These qualitative tests largely have been replaced by quantitative methods. Several techniques have been developed for the quantitative measurement of CSF total protein, including turbidometric methods, biuret procedures, and Lowry's method. The accuracy of these methods in many clinical laboratories is no better than ±5% (Fishman, 1992). Total CSF protein values are reported in numerous articles and vary noticeably with the technique and the laboratory performing the assay. Therefore, clinicians must learn the normal values for their own laboratories.

2. *CSF Protein Fractionation*

A number of techniques for fractionation of CSF proteins have been developed. These include electrophoresis using paper or cellulose acetate, agar, agarose polyacrylamide, and starch gels. Immunoelectrophoresis, electroimmunodiffusion, radioimmunoassay, and isoelectric focusing are more recent techniques (Fishman, 1992; Kjeldsberg and Knight, 1993). Because of the normally low protein content, most of these methods require concentration of the CSF, which can create technical artifacts in the measured protein content. Techniques that do not require CSF concentration, such as electroimmunodiffusion, are therefore advantageous (Fishman, 1992).

3. *Albumin and the CSF/Serum Albumin Index*

Because albumin is synthesized only extrathecally increased CSF albumin indicates damage to the blood-brain/CSF barriers, intrathecal hemorrhage, or a traumatic CSF tap. In these conditions, albumin will leak into the CSF in general proportion to its serum concentration. Therefore, in the absence of intrathecal hemorrhage (pathologic or iatrogenic), the ratio of CSF albumin to serum albumin can be used as an indicator of barrier dysfunction (Tibbling *et al.*, 1977; Link and Tibbling, 1977). This ratio is called the albumin index (also known as albumin quota or albumin quotient) and is calculated as follows (Kjeldsberg and Knight, 1993):

$$\text{Albumin index} = \frac{\text{CSF albumin (mg/dl)}}{\text{serum albumin (g/dl)}}$$

Values above the normal range indicate increased barrier permeability. The use of this index is potentially limited, however, because the large variability of CSF albumin in normal animals (at least in dogs and horses Andrews *et al.*, 1994, 1990a; Bichsel *et al.*, 1984b; Krakowka *et al.*, 1981) yields a large variability in the values for this index (Davson and Segal, 1996). In people the albumin index is age dependent, being highest in newborns and adults over 40 years of age (Kjeldsberg and Knight, 1993).

4. *Quantitative Measurement of Immunoglobulins*

a. IgG and the IgG/Albumin Index

The identification of intrathecal production of immunoglobulin is helpful in the diagnosis of neurologic disease. Immunoglobulin G is the dominant CSF ir

munoglobulin. However, the IgG content of CSF is not a particularly useful measurement by itself, because the IgG present in CSF may be of serum origin (via a dysfunctional blood–brain/CSF barrier, intrathecal hemorrhage, or traumatic puncture) or intrathecally produced (as in various neural diseases). Varied opinions exist regarding the best way to calculate the contribution of IgG from each source (Trotter and Rust, 1989; Thompson, 1988). To determine the probable origin of CSF IgG, it can be related mathematically to a protein of purely extrathecal origin. Because albumin is synthesized entirely extrathecally, it is the preferred comparison protein and is the most widely used (Fishman, 1992). Transferrin and alpha$_2$ macroglobulin have also been recommended because of their extrathecal origin (Schliep and Felgenhauer, 1974).

The simplest formula for correction of the CSF IgG level for extrathecal "contamination" and thereby demonstration of intrathecal IgG synthesis is the IgG/albumin index (Tibbling *et al.*, 1977; Link and Tibbling, 1977). This index is calculated using the CSF and serum concentrations of albumin and IgG as follows (Kjeldsberg and Knight, 1993):

$$\text{IgG index} = \frac{\dfrac{\text{CSF IgG (mg/dl)}}{\text{serum IgG (g/dl)}}}{\dfrac{\text{CSF albumin (mg/dl)}}{\text{serum albumin (g/dl)}}}.$$

The denominator of this index (CSF albumin/serum albumin) is the albumin index . Because albumin is synthesized only extrathecally, the albumin index assesses the amount of albumin crossing the blood–brain/CSF barriers, and therefore is a measure of barrier integrity. Blood contamination of the CSF with as little as 0.2% serum (equivalent to about 5000–10000 RBC/μl) by a traumatic puncture falsely elevates the IgG index in people (Peter and Tourtellotte, 1986). Also, the IgG index loses reliability when CSF protein levels are less than 25 mg/dl or greater than 150 mg/dl (Boerman *et al.*, 1991).

An additional problem with the IgG index is its basic premise that the selectivity of the protein transfer at the blood–CSF barrier is independent of the actual permeability condition. This concept has been shown to be incorrect, and the IgG index, as well as the IgA and IgM indices, vary in a nonlinear fashion with progressive impairment of the barrier (Reiber and Felgenhauer, 1987). Therefore, Reiber and Felgenhauer (1987) developed a formula to calculate the intrathecally synthesized fractions of IgG, IgM, and IgA in the CSF.

b. IgM and IgA Indices

As with IgG, CSF IgM and IgA may be of serum origin or intrathecally produced. Indices for IgM and IgA can be calculated in the same fashion as those for IgG (Fryden *et al.*, 1978). However, because of high variability in normal IgM and IgA levels and the biological variation of these large molecules, the application of the same formula for IgM and IgA indices as used for the IgG index may only provide rough estimates (Tipold *et al.*, 1994; Reiber and Felgenhauer, 1987).

5. Qualitative Immunoglobulin Assays

Qualitative assays of CSF immunoglobulins include agarose-gel electrophoresis, acrylamide immunoelectrophoresis, isoelectric focusing, and immunofixation. These tests separate the proteins into "bands" and provide information regarding the CSF protein composition. Although abnormal band patterns are not specific for a particular disease, they do indicate pathology and may indicate a type of disease. Abnormal band patterns may be detected even in patients with a normal IgG index. Thus, both quantitative and qualitative immunoglobulin assays are useful in the assessment of central nervous system disorders, particularly immunologic or inflammatory diseases (Fishman, 1992; Kjeldsberg and Knight, 1993).

E. Antibody/Antigen Tests

A variety of CSF antibody and antigen tests are now available for viruses, fungi, rickettsia, protozoa, and other organisms (Greene, 1990). For antibody titers, two samples taken 2 weeks apart should be assayed. Because of interrun variability, the samples should be assayed at the same time in the same analytical run. Interpretation of CSF antibody titers must take into account the possibility of transudation of serum antibodies through a defective blood–brain/CSF barrier. Serum antibodies could be present because of disease, previous exposure to antigen, or vaccination. Ideally, the CSF/serum albumin index and IgG index are also determined (see Sections V.D.3 and 4) to identify blood–CSF barrier dysfunction and intrathecal production of immunoglobulin. Intrathecal production of antigen-specific antibody (specific Ig) can be determined with an antibody index in the same way as intrathecal IgG production is detected with the IgG index. The formula is (Reiber and Lange, 1991)

$$\text{Antibody index} = \frac{\dfrac{\text{CSF specific Ig}}{\text{serum specific Ig}}}{\dfrac{\text{CSF total Ig}}{\text{serum total Ig}}}.$$

A modification of this formula accounting for large local synthesis of polyclonal IgG in the central nervous system may be necessary (Reiber and Lange, 1991). An

antibody index > 1 suggests intrathecal production of the specific antibody (Reiber and Lange, 1991; Munana *et al.*, 1995). Antibody indices have been calculated in human patients with a variety of diseases (Reiber and Lange, 1991). The diagnostic reliability of these indices and application to clinical veterinary medicine needs further study.

Antigen detection tests include immunoelectrophoretic techniques, agglutination tests, and ELISA for bacterial antigens and latex agglutination for cryptococcal antigens. The recently developed PCR procedures detect specific antigen DNA in CSF and are highly sensitive, specific, and rapid (see Section V.C.5). The ELISA and PCR procedures have much promise for the diagnosis of neural infections (Kjeldsberg and Knight, 1993).

F. Microbial Tests

The Gram stain, the Ziehl–Neelson acid-fast stain, and both aerobic and anaerobic cultures of CSF are time-honored methods for diagnosis of bacterial central nervous system infections. Bacteriological tests must be performed as soon as possible after CSF acquisition because some bacteria undergo rapid autolysis in the test tube. Additional tests such as the acridine orange stain for bacteria and tests for microbial antigens by counterimmunoelectrophoresis or agglutination techniques may also be useful (Fishman, 1992).

G. Blood Contamination

Erythrocytes may be present in CSF samples because of subarachnoid hemorrhage or, more commonly, because of traumatic puncture. Blood contamination due to traumatic puncture is a common problem during CSF collection and, depending on its degree, can interfere with cytologic interpretation. Blood contamination is more likely to occur with lumbar puncture as opposed to cerebellomedullary cisternal puncture (Thomson *et al.*, 1990; Bailey and Higgins, 1985; Oliver and Lorenz, 1993). Blood contamination is a source of leukocytes and hence can affect both the count and the differential. In one study of CSF in cats (Rand *et al.*, 1990b), the total leukocyte count, the neutrophil percentage, and the eosinophil percentage were positively correlated with the CSF erythrocyte count once this count exceeded 500 erythrocytes per microliter. However, there was no significant increase in total white blood cell count or alteration in the differential percentages with up to 500 RBC/μl of CSF. Numerous correction factors have been used to correct leukocyte counts for the effect of blood contamination and include the following: In people, 1 white blood cell per 700 red blood cells is subtracted from the total whi blood cell count (Fishman, 1992); in dogs, 1 white bloo cell per 500 red blood cells is subtracted from the tot count (Bailey and Higgins, 1985), and in cats, a max mum of 1 white blood cell per 100 red blood cells subtracted (Rand *et al.*, 1990b). A more accurate fo mula takes into account the actual white blood ce and red blood cells counts of the patient and hen compensates for any significant alterations in the counts (Fishman, 1992),

$$W = WBC_F - \frac{WBC_B \times RBC_F}{RBC_B},$$

where W is the white blood cell count of the flui before blood was added, that is, the corrected coun WBC_F is the total white blood cell count in the blood fluid; WBC_B is the white blood cell count in the peripl eral blood per microliter; and RBC_F and RBC_B are th numbers of red blood cells per microliter in the CS and blood, respectively. Despite all of these elabora corrections, our own experience is that many thou sands of red blood cells in contaminated samples CSF will frequently be observed without any accomp nying white blood cells, suggesting that these corre tion factors may not be valid. This empirical observ tion has been made by others (deLahunta, 1983). Th lack of validity has been proven by several studi (Wilson and Stevens, 1977; Novak, 1984). Wilson an Stevens (1977) concluded that blood contamination a peared to have little effect on white blood cell numbe and that the preceding correction formula was unreli ble. They found 91 samples from both normal an diseased animals where there were numerous re blood cells but no white blood cells. Some of the re blood cell counts exceeded 15,000 RBC/μl, but whi blood cells were still absent. Novak (1984) conclude that the standard computations frequently overcorre white blood cell counts in blood-contaminated CS and the magnitude of the overcorrection may obscu disease in some instances—in eight infants with si nificant blood contamination but proven bacteri meningitis, correction computations normalized overcorrected the white blood cell counts. The mech nism of this overcorrection could not be defined, b it is clear that that the presence of low numbers neutrophils should not be immediately discount when red cells are concurrently found (Christopher *al.*, 1988).

A study of feline CSF (Rand *et al.*, 1990a) also four that values for CSF total protein, lactate dehydrog nase, creatine kinase, IgG ratio, and γ-globulin percen age were affected by blood contamination. The CS total protein value of blood-contaminated CSF ma be corrected using the formula for white blood ce

correction given earlier but substituting the total protein levels of the bloody CSF and the serum for the corresponding white blood cell counts (Kjeldsberg and Knight, 1993). In people, bloody contamination of CSF with as little as 0.2% serum (equivalent to about 5000–10000 RBC/ml) elevates the IgG index (Fishman, 1992).

VI. GENERAL CHARACTERISTICS OF CSF IN DISEASE

A. Physical Characteristics: Clarity, Color, and Viscosity

Normal CSF is clear and colorless and has the consistency of water. In pathological conditions the clarity, color, and/or consistency may change.

1. Clarity

Cloudy or turbid CSF is usually due to pleocytosis; about 200 WBC/μl or 400 RBC/μl will produce a visible change. With these low levels of cellularity the CSF may appear opalescent or slightly hazy. Microorganisms, epidural fat, or myelographic contrast agent may also produce hazy or turbid CSF.

2. Color

Although the term xanthochromia means yellow color, it has often been used to describe pink CSF as well. The color of CSF is most usefully described as (1) pink or orange, (2) yellow, or (3) brown. These colors correspond to the major pigments derived from red cells: oxyhemoglobin, bilirubin, and methemoglobin. Oxyhemoglobin is red in color, but after dilution in the CSF it appears pink or orange. Oxyhemoglobin is released from lysed red cells and may be detected in the CSF supernatant about 2 hours after red cells enter the CSF. The level of oxyhemoglobin reaches its peak about 36 hours later and disappears over the next 4–10 days. Bilirubin is yellow in color. Bilirubin is the derivative of hemoglobin and is considered to formed by macrophages and other leptomeningeal cells that degrade the hemoglobin from lysed red cells. Bilirubin is detected about 10 hours after red cells enter the CSF, reaches a maximum at about 48 hours, and may persist for 2 to 4 weeks. Bilirubin is also the major pigment responsible for the abnormal color of CSF with a high protein content. Methemoglobin in CSF is dark yellow-brown. Methemoglobin is an oxidation product of hemoglobin characteristically found in encapsulated subdural hematomas and in old, loculated intracerebral hemorrhages (Fishman, 1992; Kjeldsberg and Knight, 1993). Occasionally blackish CSF is encountered in animals with melanin-producing tumors in the nervous system.

Causes of a CSF color change other than red-cell contamination include icterus due to liver disease or hemolytic disease, markedly increased CSF total protein level, and drug effects. Both free and conjugated bilirubin may be present in the CSF, although the amount of bilirubin in the CSF does not correlate well with the degree of hyperbilirubinemia. If the CSF protein level is increased, the color change will be greater because of increased amounts of the albumin-bound bilirubin. High CSF protein content alone can impart a yellow color to the CSF (Fishman, 1992; Kjeldsberg and Knight, 1993). The drug rifampin is well know to impart an orange-red color to body fluids. Rifampin is 90% bound to protein, and hypoproteinemia may result in the staining of CSF (Fishman, 1992).

3. Viscosity

Increased viscosity is usually due to a very high CSF protein content, particularly fibrinogen. If pleocytosis is present, a surface pellicle or a clot may form. In this situation, collection of the CSF in a heparinized or EDTA tube may be necessary to obtain an accurate cell count. Cryptococcosis may increase CSF viscosity because of the polysaccharide capsule of the yeast. Epidural fat or nucleus pulposus in the CSF may also increase viscosity, or it may result in globules within the fluid (Fishman, 1992; Kjeldsberg and Knight, 1993).

B. Cytology

An increase in the cellularity of CSF is termed pleocytosis. In general terms, the degree of pleocytosis is dependent upon several factors, including the nature of the inciting cause and the severity and location of the lesion with respect to the subarachnoid space or ventricular system (Cook and DeNicola, 1988). It should also be emphasized that normal CSF analysis does not exclude the presence of disease (Fishman, 1992; Kjeldsberg and Knight, 1993). This is especially true with deep parenchymal lesions that do not communicate with the leptomeninges, and hence the subarachnoid space or the ependymal surfaces. In these cases, despite the presence of neurologic disease that is often severe, the lesion may not affect the CSF cellularity (Cook and DeNicola, 1988). Abnormal CSF findings always indicate the presence of pathologic abnormality.

1. Neutrophilia

A marked pleocytosis with neutrophil predominance generally suggests either bacterial meningitis (Kornegay *et al.*, 1996; Kjeldsberg and Knight, 1993)

or suppurative, nonseptic (corticosteroid-responsive) meningitis (Tipold and Jaggy, 1994; Meric, 1988, 1992a). Total leukocyte counts in excess of 2000 cells per microliter are frequently encountered in these diseases and may even exceed 10,000 cells per microliter (Meric, 1992a). Observation of bacteria or a positive culture confirms septic meningitis. In our experience, bacteria are more commonly observed in the CSF of large animals afflicted with septic meningitis than in dogs or cats with septic meningitis. Neutrophil nuclear morphology is often used as a criterion for determining the likelihood of sepsis, with nuclear degenerative changes or karyolysis being interpreted as evidence of bacterial disease. However, the neutrophils in confirmed cases of septic meningitis in dogs and cats are frequently well preserved, especially if there has been prior therapy. Therefore, absence of bacteria or degenerative nuclear changes in neutrophils cannot be used to exclude unequivocally a diagnosis of septic meningitis, although it does make it less likely. In people, acute viral meningoencephalitis can initially produce a neutrophilic pleocytosis (Fishman, 1992; Converse *et al.*, 1973; Kjeldsberg and Knight, 1993) that may persist from a few hours to several days prior to the development of the more typical mononuclear reaction. A similar phenomenon has been documented in animals (Green, 1993). Occasionally, distemper virus infection can cause massive encephalomalacia (Vandevelde and Spano, 1977), resulting in a neutrophilic pleocytosis in contrast to the moderate mononuclear pleocytosis that is more typical. Central nervous system neoplasia may result in a neutrophil predominance in the CSF, especially if there is significant necrosis and inflammation associated with the tumor. Moderate to marked pleocytosis with neutrophil predominance is a common finding in canine meningioma (Bailey and Higgins, 1986b). Canine intervertebral disc disease is predominantly characterized by a mild mononuclear pleocytosis (Thomson *et al.*, 1989). However, acute severe disease may result in counts greater than 50 cells per microliter with more than 50% neutrophils (Thomson *et al.*, 1989). This finding is a reflection of acute inflammation that may be exacerbated by myelomalacia in some instances. The authors have seen a similar phenomenon associated with fibrocartilaginous thromboembolism in dogs. A neutrophilic pleocytosis of varying severity often occurs following myelography with iodinated contrast agents (Widmer *et al.*, 1992; Johnson *et al.*, 1985; Carakostas *et al.*, 1983). These changes usually peak at 24 hours post myelogram (see Section VII for further details). Similarly, a neutrophilic pleocytosis has been observed postictally in people. We have occasionally observed similar findings in dogs (see Section VII).

2. *Lymphocytosis*

Alterations in both numbers and morphology of lymphocytes (see Section III.B) in the CSF occur in a variety of diseases. Central nervous system viral infections often result in a predominantly lymphocytic pleocytosis, which has been documented in dogs (Vandevelde and Spano, 1977), cats (Rand *et al.*, 1994a; Dow *et al.*, 1990), horses (Green *et al.*, 1992; Hamir *et al.*, 1992), sheep and goats (Brewer, 1983) and numerous other species. In people, CSF lymphocytosis has been observed in bacterial meningitis following antibiotic therapy (Fishman, 1992; Cargill, 1975; Converse *et al.* 1973; Kjeldsberg and Knight, 1993). This is a good example of how therapy and chronicity can alter the CSF findings. A similar finding has been reported in the dog (Tipold and Jaggy, 1994; Sarfaty *et al.*, 1986) and the calf (Green and Smith, 1992).

3. *Eosinophilia*

Eosinophils are not present in normal, uncontaminated (by blood) CSF, although single eosinophils are occasionally seen on cytocentrifuge slides from animals with CSF that has normal nucleated counts and protein content. Although the presence of eosinophils in CSF is abnormal and is evidence of underlying disease, no diagnostic specificity is associated with their presence, as they can be found in a variety of disease (Bosch and Oehmichen, 1978). Additionally, CSF eosinophilia and peripheral blood eosinophilia do not necessarily occur together, and if they do, no positive correlation exists between the magnitude of peripheral blood eosinophilia and the severity of the CSF eosinophilia (Smith-Maxie *et al.*, 1989; Bosch and Oehmichen 1978). In one case series of eight dogs with eosinophilic meningoencephalitis, five of eight had concurrent peripheral eosinophilia, but no correlation was present between the peripheral and CSF eosinophil counts. The two dogs with the highest CSF eosinophil counts had peripheral eosinophil counts within normal reference limits. In people, central nervous system invasion by parasites, especially *Angiostrongylus cantonensis*, is the most frequent cause of eosinophilic pleocytosis, and in many of these cases eosinophils predominate in the differential cell count (Bosch and Oehmichen, 197 Kuberski, 1979). CSF eosinophilia can also occur in association with bacterial, fungal, and viral infection and hence can be seen concurrently with suppurative granulomatous, and lymphocytic inflammatory processes of the central nervous system (Smith-Maxie *al.*, 1989; Jamison and Lumsden, 1988). However, many of these cases, eosinophils represent less than 5% of the total cell count in CSF (Smith-Maxie *et a* 1989; Bosch and Oehmichen, 1978). Other documente

causes in people include neurosyphilis, tuberculosis, rickettsial disease, foreign-body reactions to shunt tubes, intrathecal penicillin or contrast agents, hypereosinophilic syndrome, multiple sclerosis, lymphoma, Hodgkin's disease, leukemia, melanoma, disseminated glioblastoma, idiopathic disorders, and systemic allergic reactions (Fishman, 1992; Smith-Maxie *et al.*, 1989; Kuberski, 1979; Kjeldsberg and Knight, 1993). In animals, CSF pleocytosis that consists predominantly or almost exclusively of eosinophils is rare. We have personally seen CSF eosinophilia in association with idiopathic or steroid responsive eosinophilic meningoencephalitis (Smith-Maxie *et al.*, 1989) and canine neural angiostrongylosis (Mason, 1989). Pleocytosis with eosinophil predominance has also been described in central nervous system cryptococcosis (Vandevelde and Spano, 1977), although this finding is not common in our experience. Other documented causes of CSF eosinophilia (though not predominance) in animals include bacterial encephalitis, distemper, rabies, toxoplasmosis, neosporosis, cuterebral encephalitis, central nervous system nematodiasis, protothecosis, granulomatous meningoencephalomyelitis, lymphoma, astrocytoma, and cerebral infarction (Chrisman, 1992; Lester, 1992; Darien *et al.*, 1988; Vandevelde and Spano, 1977; Jamison and Lumsden, 1988).

4. *Neoplastic Cells*

The observation of neoplastic cells in CSF samples from animals with central nervous system neoplasia is rare in our experience. Very few veterinary studies have investigated the incidence of positive CSF cytology in confirmed cases of central nervous system neoplasia. In one study involving 77 histopathologically confirmed cases of primary central nervous system neoplasia in dogs, neoplastic cells were not observed in a single case (Bailey and Higgins, 1986b). However, in this study, cytologic assessment was performed only on those cases with an elevated cell count and these only accounted for 41.3% of cases. As stated previously, cases have been reported in the veterinary literature in which tumor cells were observed in the CSF but the CSF cell counts were within normal limits (Grevel *et al.*, 1992; Bichsel *et al.*, 1984b; Grevel and Machus, 1990). Additionally, in the study assessing primary brain tumors in 77 dogs (Bailey and Higgins, 1986b), CSF differentials and cytology were performed on cytospin slides. The cell yield with cytospin smears is very low, approximating 10% (Barrett and King, 1976) in some studies, and this may partly explain the failure to observe neoplastic cells in this study. Other veterinary studies utilizing different techniques report a higher incidence of neoplastic cell observation in the CSF from confirmed cases of central nervous system neoplasia In two studies utilizing a Kölmel sedimentation appa ratus, tumor cells were seen in the CSF of five of eigh cases (Grevel and Machus, 1990) and four of nine case (Grevel *et al.*, 1992). In the former study, two of th five cytologically positive cases had normal cell counts In another study utilizing a membrane filter techniqu (Bichsel *et al.*, 1984b), three of nine cases of dogs witl central nervous system neoplasia had CSF samples i which neoplastic cells were observed. Both of the tech niques utilized in these studies result in a higher cel yield than cytocentrifugation, which may be partly re sponsible for the increased incidence of neoplastic cel observation in the CSF in these studies.

A much larger number of studies assess the inci dence of CSF neoplastic cells in people with centra nervous system neoplasia. Overall sensitivities that ar frequently quoted are 70% for central nervous syster leukemia, 20–60% for metastatic meningeal carcinoma and approximately 30% for primary central nervou system tumors (Kjeldsberg and Knight, 1993), regard less of the technique utilized. The detection rate o malignant cells in the CSF is significantly improvec by the collection of multiple samples (Olson *et al.*, 1974) These figures are supported by one study utilizin cytocentrifugation in 117 cases of histopathologicall confirmed central nervous system neoplasia (Glass *e al.*, 1979). Overall, 26% (31/117) were positive. How ever, if only those cases with leptomeningeal involve ment were considered, the incidence increased to 59% Conversely, of 66 cases in which the tumor did no reach the leptomeninges, only a single case was posi tive. In another study, only 13.9% of all gliomas hac a positive CSF cytology (Balhuizen *et al.*, 1978). Thi low incidence is likely due to the fact that the grea majority of gliomas do not extend into the subarach noid space (Balhuizen *et al.*, 1978). As a result of thes studies, the following generalizations are frequentl made in human medicine: (1) A positive CSF cytolog is a reliable indicator of central nervous system malig nancy and almost always reflects a leptomeningea tumor (or one involving the ventricular system), anc (2) a negative cytology does not exclude the presenc of an intracerebral tumor, particularly a deep paren chymal mass that does not breach the pia or the ventric ular system. Controlled studies are required in veteri nary medicine to determine the incidence of positiv CSF cytology in confirmed cases of the different type of central nervous system neoplasia and also to com pare the sensitivities of different preparative methods These studies may be hampered by the general lac of experience at identifying cells derived from centra nervous system neoplasms. Tumor cells can be erro neously identified as normal ependymal or choroic

plexus cells. Solitary tumor cells from metastatic carcinomas can be mistaken for lymphocytes or monocytes (Kjeldsberg and Knight, 1993). The need for the preceding types of studies has been somewhat decreased by the advent of routine access to advanced imaging techniques.

C. Protein

1. *Changes in CSF Total Protein Content*

An increase in the total protein content of CSF is the single most useful alteration in the chemical composition of the fluid (Fishman, 1992). However, this alteration accompanies many diseases and is therefore nonspecific. Increased total protein may be caused by (1) increased permeability of the blood–brain/spinal cord/CSF barriers allowing passage of serum proteins into the CSF, (2) intrathecal globulin production, and (3) interruption of CSF flow and/or absorption. Particular emphasis has been put on CSF flow rate as a major factor in CSF protein content (Reiber, 1994). In many diseases, two or all three of these mechanisms are at work. In complete spinal subarachnoid space blockage (e.g., by a compressive lesion or arachnoiditis), CSF withdrawn caudal to the block may clot when aspirated. This phenomenon is called Froin's syndrome and results from very high CSF protein levels caused by the defective flow and absorption and blood–spinal cord barrier breakdown (Fishman, 1992; Kjeldsberg and Knight, 1993).

Decreased total protein is much less common. Theoretically, low levels of CSF protein could result from decreased entry of protein into the CSF or increased removal. No evidence exists to support the first mechanism. Increased removal can occur, however, if intracranial pressure is increased while the barriers to serum protein remain normal. In this situation, bulk flow absorption of CSF is increased, while entrance of protein into the CSF remains normal. Protein content of fluid collected from the lumbosacral site could be decreased if large volumes are removed, or if ongoing leakage of CSF from the lumbar area is occurring. In these situations, lumbosacral CSF is replaced more quickly than normal by ventricular CSF, which has a lower protein content than lumbosacral CSF (Fishman, 1992; Kjeldsberg and Knight, 1993). Low CSF protein has also occurred in people with hyperthyroidism, leukemia, or water intoxication (Fishman, 1992; Kjeldsberg and Knight, 1993).

2. *Albuminocytologic Dissociation*

In many disease processes, the CSF cell count and CSF total protein increase in rough parallel. In some disorders, though, the cell count remains normal, or nearly so, whereas the total protein is notably increased, a phenomenon termed albuminocytologic dissociation. Some degenerative disorders, ischemia/infarction, immune-mediated diseases (e.g., polyradiculoneuritis), tumors, and neural compression produce albuminocytologic dissociation (Laterre, 1996).

3. *Increased CSF Albumin and Albumin Index*

Elevation of CSF albumin (which originates in the serum), and consequently an increased albumin index, is indicative of dysfunction of the blood–brain/spinal cord/CSF barriers or contamination of the CSF by blood (from intrathecal hemorrhage or traumatic spinal tap). Barrier damage occurs in most types of neurologic disorders, including inflammatory diseases, neoplasia, trauma, compression, and occasionally metabolic diseases (Sorjonen, 1987; Bichsel *et al.*, 1984b, Sorjonen *et al.*,1991; Krakowka *et al.*, 1981).

4. *Increased CSF IgG and IgG Index*

The CSF IgG can be increased by transudation of protein across damaged blood–brain/CSF barriers, by intrathecal hemorrhage (pathologic or iatrogenic), or by intrathecal IgG synthesis. An elevated CSF IgG content and increased IgG index, indicating intrathecal IgG synthesis, is typical for infectious inflammatory diseases (Tipold *et al.*, 1994, 1993b). In contrast, animals with noninflammatory diseases usually have normal IgG indices (Tipold *et al.*, 1993b). In a few animals with noninfectious disorders, mild intrathecal IgG synthesis occurs, reflecting the presence of inflammatory infiltrates around the lesion (Tipold *et al.*, 1993b). Therefore the IgG index is often useful for distinguishing between inflammatory and noninflammatory lesions which is not always possible on the basis of CSF cell counts alone (Bichsel *et al.*, 1984b). In one study (Tipold *et al.*, 1993b), 7 of 66 dogs with noninflammatory lesions had no pleocytosis but had an elevated IgG index; in contrast, 17 of 32 dogs with noninflammatory disease had pleocytotic CSF and a normal IgG index. The authors of this study consider an IgG index ≥ 2.8 as proof of intrathecal synthesis allowing a diagnosis of meningoencephalomyelitis, and an IgG index between 1.3 and 2.8 as suggestive of inflammatory disease. In a few dogs with intense inflammatory lesions and intrathecal IgG production, the IgG index may not be elevated because of marked IgG transudation against which the local IgG synthesis is undetectable (Bichsel *et al.* 1984b). Traumatic puncture and red blood cell contamination of the CSF can artifactually increase the IgG index. Additionally, the normal IgG index of cerebellomedullary fluid and that of lumbar fluid are likely

to be different because of the different protein concentrations of these fluids.

5. *Classification of Disease Based on Albumin Index and IgG Index*

Alterations of the albumin index and the IgG index can be grouped into three pathogenetic categories: (1) blood–brain/CSF barrier disturbance (increased albumin index), (2) intrathecal IgG synthesis (increased IgG index), and (3) barrier disturbance combined with intrathecal IgG production (both indices increased). These categories correlate somewhat with certain types of disease. Barrier disturbance may be seen in degenerative, inflammatory, metabolic, space-occupying, vascular, and traumatic conditions (Sorjonen, 1987; Bichsel *et al.*, 1984b; Sorjonen *et al.*, 1991). Intrathecal IgG synthesis is typical of inflammatory conditions (Tipold *et al.*, 1994), but also occurs in noninfectious disorders that have secondary inflammation, such as some tumors (Tipold *et al.*, 1993b; Bichsel *et al.*, 1984b). Barrier disturbance coupled with intrathecal IgG production is typical of infectious–inflammatory diseases (Bichsel *et al.*, 1984b).

6. *Increased CSF IgM, IgA, and IgM and IgA Indices*

The immunoglobulins IgM and IgA may be increased in the CSF of animals with inflammatory neurologic disease. A study of 69 dogs with inflammatory disease detected IgM elevations in 16 dogs and IgA elevations in 40 (Tipold *et al.*, 1994). An increased CSF IgM index is considered by some investigators to be a good indication of recent or persistent immunological stimulation in people (Sharief and Thompson, 1989). In contrast, Felgenhauer (1982) reported IgM was present through all stages of human herpes and bacterial meningitis, and increased and decreased with IgG. Perhaps a transition from IgM to IgG production does not occur in the central nervous system (Tipold *et al.*, 1994); or perhaps, in the presence of a normal or near-normal blood-CSF barrier, IgM accumulates in the CSF (Felgenhauer, 1982). In people with *Borrelia* infection, CSF IgM is persistently produced and the IgM index is a better indicator of this disease than is the IgG index (Fishman, 1992). Further studies need to be done in animals to determine the specificity of the various immunoglobulin alterations.

7. *Electrophoretic Patterns of CSF Protein in Disease*

Abnormalities in the CSF electrophoretic pattern can suggest categories of disease (Sorjonen, 1987; Sorjonen *et al.*, 1991). In one study, dogs with inflammatory diseases had one of three patterns: (1) little or no blood–brain barrier disturbance (as determined by CSF albumin concentration and the albumin quota) with decreased gamma globulin, (2) mild blood-brain barrier disturbance with markedly increased gamma globulin, and (3) moderate or marked blood–brain barrier disturbance with increased gamma globulin. Dogs with intervertebral disc protrusion or cervical spondylomyelopathy had a pattern of normal barrier function or severe barrier disturbance with decreased alpha globulin. Dogs with brain neoplasia had marked barrier disturbance and normal or mildly increased alpha and beta globulins (Sorjonen *et al.*, 1991).

In the gamma globulin region, three patterns of protein bands can occur—monoclonal, oligoclonal, and polyclonal. Oligoclonal bands are associated with disease and are seen in a high percentage of people with multiple sclerosis or encephalitis. These bands, readily identifiable against the low background of normal polyclonal IgG in the CSF, are thought to represent the products of a limited number of plasma-cell clones. Oligoclonal bands unique to CSF (i.e., not present in serum) indicate intrathecal synthesis of immunoglobulin and may be more sensitive than the IgG index in detecting this synthesis. People with multiple sclerosis may have a normal IgG index yet have CSF oligoclonal banding; thus, the demonstration of these bands is considered by some to be the single most useful test in the diagnosis of multiple sclerosis (Kjeldsberg and Knight, 1993). Oligoclonal bands are also seen in patients with inflammatory diseases and in some patients with neoplasia (Fishman, 1992). Occasionally, a single (monoclonal) band is identified in the CSF electrophoretic pattern of people. Monoclonal bands have been seen in neurologically normal people as well as patients with neurologic disease (Kjeldsberg and Knight, 1993).

8. *Other CSF Proteins*

Numerous attempts have been made to correlate specific CSF proteins, particularly "brain-specific" proteins, with specific diseases. Proteins such as C-reactive protein, interferon, myelin basic protein, and S-100 are increased in the CSF associated with neurologic disease, but these increases are found in many heterogeneous conditions. This nonspecificity limits the clinical usefulness of these protein assays. However, the measurement of some of these proteins is thought to be useful as a screening procedure for neurologic disease or as an indication of prognosis (Fishman, 1992; Kjeldsberg and Knight, 1993; Lowenthal *et al.*, 1984). The clinical usefulness of these assays needs further investigation.

9. Plasma Proteins in the CSF

Alterations in plasma proteins may be reflected in the CSF. For example, the serum protein monoclonal gammopathy of multiple myeloma may be evident in the CSF. Bence–Jones proteins are also readily seen in the CSF. The high-molecular-weight paraproteins do not cross the normal blood–brain barrier, however. Serum protein electrophoresis is indicated in patients with elevated CSF globulins to clarify the source of the globulins (Fishman, 1992).

D. Antibody Titers

The CSF antibody titer can be measured for a number of diseases (Green *et al.*, 1993; Greene, 1990). Interpretation of the results is confounded by the need to differentiate among titers caused by vaccination, exposure to the antigen without development of the disease, and actual disease. Interpretation of CSF antibody titers could be aided by an accurate vaccination history, comparison of CSF and serum titers, assessment of blood–brain/CSF barrier function and intrathecal immunoglobulin production by determination of albumin and immunoglobulin indices, determination of CSF IgM levels, and analysis of acute and convalescent samples (Chrisman, 1992; Green *et al.*, 1993).

E. Glucose

Increased CSF glucose usually reflects hyperglycemia. Decreased CSF glucose occurs with several disorders of the nervous system, particularly acute, bacterial, fungal, amebic, or tuberculous meningitis. In people, low CSF glucose is also characteristic of diffuse carcinomatous meningitis, meningeal cysticercosis or trichinosis, and syphilitic meningitis. The major factors responsible for low CSF glucose levels are inhibition of the entry of glucose due to alteration of membrane glucose transport and increased anaerobic glycolysis by neural tissue. As noted earlier, hyperglycemia elevates the CSF glucose, which may mask a decreased CSF level. Therefore, calculation of a CSF/serum glucose ratio has been recommended to identify pathologically low CSF glucose level (Kjeldsberg and Knight, 1993). A low CSF glucose level in the absence of hypoglycemia indicates a diffuse, meningeal disorder, rather than focal disease (Fishman, 1992). Decreased CSF glucose classically has been associated with bacterial meningitis, but many human patients with bacterial meningitis have normal CSF glucose levels. Therefore, the recommendation has been made that CSF glucose need be measured only if the opening CSF pressure, cell count, cytospin differential, and protein are inconclusive (Hayward *et al.*, 1987).

F. Enzymes

Numerous enzymes have been assayed in the CSF of animals (Rand *et al.*, 1994b; Furr and Tyler, 1990; Wilson, 1977; Jackson *et al.*, 1996). Of these, creatine kinase has received the most attention and opinions of its usefulness are somewhat conflicting. Although Furr and Tyler (1990) confirmed previous observations that CSF creatine kinase activity was elevated in several neurologic diseases, they concluded that the greater frequency of elevation in the CSF of horses with protozoal myelitis vs horses with cervical compressive myelopathy indicated this enzyme assay was useful in differentiating these two diseases. This conclusion was disputed by Jackson *et al.* (1996), who did not find the sensitivity or specificity of creatine kinase measurement sufficient for diagnosis of a specific disease. Jackson *et al.* (1996) also concluded that contamination of the CSF sample with epidural fat or dura mater may contribute to previously unexplained elevations in CSF creatine kinase activity. Their conclusion regarding this enzyme's lack of sensitivity and specificity reflects the current situation with all of the enzymes in CSF studied to date—none have sufficient specificity to warrant their routine use as diagnostic tests (Rand *et al.*, 1994b; Fishman, 1992; Kjeldsberg and Knight, 1993; Jackson *et al.*, 1996; Indrieri *et al.*, 1980). The site of CSF collection with respect to the location of the lesion may be responsible for some of the lack of diagnostic significance in CSF enzyme analysis. Cerebellomedullary fluid may be less affected than lumbar fluid in animals with spinal disease (Indrieri *et al.*, 1980). Measurement of enzyme isomers may increase the specificity (Kjeldsberg and Knight, 1993).

G. Other Constituents

1. Interferon

Interferon is increased in the CSF in a large percentage of people with viral encephalitis–meningitis. This finding is not specific, however, as increases are also found in patients with bacterial meningitis (Glimaker *et al.*, 1994) or multiple sclerosis, and occasionally in patients with noninflammatory neurologic diseases (Brooks *et al.*, 1983). In an experimental study of canine distemper, interferon appeared to be a valid marker for persistence of the virus in the central nervous system (Tsai *et al.*, 1982). Studies on the clinical application of CSF interferon assay would be interesting.

2. Neurotransmitters

γ-Aminobutyric acid (GABA) is a major inhibitory neurotransmitter, whose dysfunction has been suggested to play a role in experimental (Griffi

et al., 1991) and clinical seizure disorders. A study of epileptic dogs found the average CSF concentration of GABA to be significantly reduced, a situation similar to that in people (Loscher and Schwartz-Porsche, 1986). Increased CSF levels of the biogenic amine neurotransmitter metabolites homovanillic acid and 5-hydroxyindoleacetic acid were found in 2 of 10 collies experimentally given invermectin (Vaughn *et al.*, 1989a). Both of these collies had severe neurologic deficits. Neurotransmitter metabolite concentrations were also elevated in the CSF of goats demonstrating neurologic abnormalities after experimental boron toxicosis (Sisk *et al.*, 1990). Significant differences in neurotransmitter concentrations were also found between the CSF of normal dogs and that of narcoleptic dogs (Faull *et al.*, 1982). The use of neurotransmitter assays in clinical diagnosis needs more investigation.

3. Quinolinic Acid

Quinolinic acid is a neuroexcitotoxic metabolite of L-tryptophan and an agonist of *N*-methyl-D-aspartate receptors. Increased levels have been found in people with a varitey of neurological diseases, including AIDS (Heyes *et al.*, 1992), and in macaques infected with simian immunodeficiency virus (Smith, 1995). Quinolinic acid levels may be elevated in CSF of animals with inflammatory nervous system disease. Therefore, it may be useful as a marker of inflammation and perhaps also as an indicator of prognosis (Smith, 1995).

4. Lactic Acid

In human medicine, the measurement of CSF lactic acid has been advocated in differentiating bacterial from viral meningitis. The concentration of CSF lactic acid is elevated in conditions causing severe or global brain ischemia and anaerobic glycolysis. Therefore, many diseases may elevate CSF lactic acid, and the overlapping CSF lactate levels limit the value of CSF lactate assay (Fishman, 1992; Kjeldsberg and Knight, 1993). A study of CSF lactic acid levels in horses with neurologic disease found elevated lactate levels in several types of central nervous system diseases (Green and Green, 1990). Therefore, as with people, increased CSF lactic acid in the horse appears to be a nonspecific indicator of central nervous system disease. Interestingly, in the horses studied, elevated lactic acid was the only CSF abnormality associated with brain abscess (Green and Green, 1990).

5. 3-OH Butyrate

The measurement of serum 3-OH butyrate concentration is useful in the feeding management of pregnant ewes and in the diagnosis of pregnancy toxemia. Following death, however, rapid autolytic change renders serum biochemical analysis useless. Scott *et al.* (1995) compared the 3-OH butyrate concentrations of serum collected antemortem and aqueous humor and CSF collected within 6 hours of death. Their results indicated that either fluid was suitable for postmortem determination of 3-OH butyrate levels, and that such data could be extrapolated to indicate antemortem serum 3-OH butyrate concentration and the possibility that pregnancy toxemia contributed to the death of the animal.

VII. CHARACTERISTICS OF CSF ASSOCIATED WITH SPECIFIC DISEASES

A. Degenerative Disorders

This group of disorders includes a variety of diseases such as the inherited, breed-specific polyradiculoneuropathies, myelopathies, and encephalopathies; motor neuron diseases; and cerebellar abiotrophies. The storage diseases can also be included in this group. The inclusion of canine degenerative myelopathy is arguable, awaiting further clarification of its pathogenesis. The CSF in animals with degenerative disorders is characteristically normal, reflecting the lack of inflammation in the disease process (Braund, 1994; Oliver and Lorenz, 1993). A mild to moderate increase of CSF total protein may occur in several of these disorders, however. Increased total protein is also found in people with motor neuron disease, Parkinson's disease, and various hereditary neuropathies and myelopathies. The mechanism of the protein increase is unknown. Electrophoretic studies of CSF associated with some human neurodegenerative disorders have shown a transudative pattern. Intrathecal immunoglobulin production has also been found in people with motor neuron disease (Fishman, 1992). In storage diseases such as globoid-cell leukodystrophy, accumulations of metabolic material may be seen in CSF cells (Roszel, 1972).

1. Canine Degenerative Myelopathy

Although the CSF of dogs with degenerative myelopathy may be normal, a mild elevation of the white blood cell count is present occasionally (Bichsel *et al.*, 1984b). More common is a normal cell count coupled with a mild to moderate elevation of total protein (approximately 40–70 mg/dl). This albuminocytologic dissociation may support the theory that this disorder is an immune-mediated disease (Waxman *et al.*, 1980). However, the common existence of concurrent chronic, spinal cord compression by Type II disc pro

trusion in these dogs complicates the situation, because chronic cord compression may also produce an increase in total protein. The elevated total protein in canine degenerative myelopathy is probably due to increased CSF albumin (Bichsel *et al.*, 1984b). The CSF IgG index is usually normal (Tipold *et al.*, 1993b; Bichsel *et al.*, 1984b), indicating a lack of intrathecal IgG production.

2. *Degenerative Myeloencephalopathy of Llamas*

A degenerative myeloencephalopathy has been identified in two adult llamas. Lesions consist of bilateral white-matter degeneration in all spinal-cord segments, and degenerate neurons in the brain-stem nuclei or degeneration of brain-stem white-matter tracts. Inflammation is not evident. Lumbosacral CSF from both animals was normal (Morin *et al.*, 1994).

3. *Equine Motor Neuron Disease*

The CSF of horses with this disorder is either normal or has albuminocytologic dissociation (Divers *et al.*, 1994; Cummings *et al.*, 1990). In a study of 28 cases (Divers *et al.*, 1994), 9 of 26 horses had elevated CSF protein. The albumin quotient was abnormal in only 2 of 19 horses. The IgG index was increased in 8 of 16 horses. The abnormalities in total protein and IgG index did not appear to be associated with the duration or severity of clinical signs. The increased protein and IgG index in these horses suggest that intrathecal production occurs. Blood–brain barrier damage and intrathecal IgG production also occur in people with motor neuron disease (Apostolski *et al.*, 1991).

B. Idiopathic Disorders

1. *Granulomatous Meningoencephalomyelitis*

The CSF associated with granulomatous meningoencephalomyelitis (GME) is usually abnormal. The fluid may be clear or hazy and is generally colorless. The total white blood cell count is moderately to markedly elevated, as is the total protein. The white blood cell differential is variable, but typically lymphocytes predominate, with monocytes/macrophages and neutrophils making up the remainder in about equal percentages (Bailey and Higgins, 1986a; Braund, 1994; Tipold, 1995; Thomas and Eger, 1989; Sarfaty *et al.*, 1986). A 15–30% neutrophilic component is suggestive of GME, but the white blood cell differential can range from 95% neutrophils (Sorjonen, 1990) to 100% mononuclear cells. Plasma cells, cells undergoing mitosis, and large, mononuclear cells with abundant foamy cytoplasm are occasionally present (Bailey and Higgins, 1986a; Braund, 1994). Lumbar fluid is also abnormal, although it generally has fewer cells and less protein than cerebellomedullary fluid (Bailey and Higgins, 1986a). Electrophoresis of CSF suggests that blood–brain barrier dysfunction is present in the acute stage of disease; intrathecal IgG production with resolution of the barrier dysfunction occurs in chronic disease (Sorjonen, 1990). The albumin quota is elevated (Sorjonen, 1987), and the IgG index is usually elevated (Tipold *et al.*, 1994, 1993b; Bichsel *et al.*, 1984b). If barrier dysfunction is severe, with marked transudation of protein, the IgG index may be normal because the amount of intrathecally produced IgG is small in comparison to the amount of transudated serum IgG (Fishman, 1992; Bichsel *et al.*, 1984b).

2. *Necrotizing Encephalitis of Pug Dogs, Maltese Dogs, and Yorkshire Terriers*

A necrotizing encephalitis of unknown cause has been identified in Pug Dogs (deLahunta, 1983; Cordy and Holliday, 1989), Maltese dogs (Stalis *et al.*, 1995), and Yorkshire terriers (Tipold *et al.*, 1993a). The lesions are similar in each breed, although the distribution of lesions in the Pug and Maltese dogs (large, diffuse, cerebral) is different than in the Yorkshire terriers (well-defined multifocal, brain stem). The CSF associated with the Pug and Maltese-dog diseases has a moderate to marked, predominantly lymphocytic white blood cell count (although one Maltese had 62% neutrophils) and moderate to marked elevation in total protein (Stalis *et al.*, 1995; deLahunta, 1983; Cordy and Holliday, 1989; Bradley, 1991). The CSF of the Yorkshire terriers has mild to moderate increases of white blood cell and protein, with a predominantly mononuclear differential count (Tipold, 1995; Tipold *et al.*, 1993a). Seizures are a consistent clinical sign for the Pugs and the Maltese dogs, but not the Yorkshire terriers. The relationship of the seizures to the more severe CSF abnormalities of the Pug and Maltese dogs compared to those of the Yorkshire terriers is interesting to consider.

C. Immune-Mediated Diseases

1. *Acute Idiopathic Polyradiculoneuritis/ Coonhound Paralysis*

Acute idiopathic polyradiculoneuritis is one of the most common canine polyneuropathies, and coonhound paralysis is the most common form. The disorder resembles Guillain–Barré syndrome of people. In affected dogs, the classical CSF abnormality is albuminocytologic dissociation without pleocytosis. The abnormality is more obvious in lumbosacral CSF than

in cerebellomedullary CSF (Cuddon, 1990; Cummings *et al.*, 1982). The CSF IgG level and IgG index may also be increased, indicating intrathecal immunoglobulin production (Tipold *et al.*, 1993b; Cuddon, 1990).

2. *Equine Cauda Equina Neuritis*

This disease is thought to be an autoimmune polyneuritis. The CSF of affected horses may be xanthochromic and typically has a prominent, usually lymphocytic pleocytosis (at least in the chronic stage) and moderately elevated protein. The CSF can also be normal (Mayhew, 1989; Yvorchuk, 1992).

3. *Steroid-Responsive Meningitis/Arteritis*

Steroid-responsive meningitis/arteritis is a common, suppurative meningitis of dogs. The CSF has a marked, often extreme, neutrophilic pleocytosis and moderately to markedly increased protein. Occasionally, a single sample collected early in the disease is normal (deLahunta, 1983; Tipold, 1995; Meric, 1988). The IgG index is typically elevated (Tipold *et al.*, 1994, 1993b), and IgM and IgA levels are often elevated as well (Tipold *et al.*, 1995, 1994). Microbial cultures are negative. In protracted or inadequately treated cases, the pleocytosis is mild to moderate with a mixed population or even a mononuclear cell predominance; the protein level may be normal or slightly elevated. The CSF may even be normal (Tipold and Jaggy, 1994). A polyarteritis/vasculitis reported in beagles, Bernese mountain dogs, German short-haired pointers, and sporadically in other breeds (Meric, 1988) has similar CSF abnormalities and pathologic changes and may be the same disease as steroid-responsive meningitis/arteritis (Tipold and Jaggy, 1994).

D. Infectious Diseases

The variety of CSF abnormalities associated with infectious disease reflects the variety of infectious diseases affecting the central nervous system. If the infection causes inflammation, the total white blood cell count and protein usually will be elevated, but the degree and type of abnormality depend on the infectious agent, the immune status of the animal, the location of the infectious process (e.g., surface-related vs parenchymal), the duration of the infection, and previous treatment. The general rules of inflammation due to infection apply, that is, bacterial infections result in suppurative inflammation, whereas viral infections result in nonsuppurative inflammation. Several important exceptions exist, however.

1. *Bacterial Diseases*

The CSF associated with aerobic or anaerobic bacterial infections of the central nervous system may be clear, hazy or turbid (depending on the cell count), and colorless or amber with moderate to marked elevations of total white blood cell count and total protein. Because of the elevated protein, the CSF may clot or foam when shaken. The white blood cell differential count has a characteristically high percentage of neutrophils (>75%), which may be degenerate (Rand *et al.*, 1994a; Green and Smith, 1992; Scott, 1995; Foreman and Santschi, 1989; Santschi and Foreman, 1989; Dow *et al.*, 1988; Tipold, 1995; Kornegay, 1981; Meric, 1988; Baum, 1994). The protein is composed of albumin that has crossed the diseased blood–brain/CSF barrier and immunoglobulin produced intrathecally; therefore, the IgG index is usually elevated (Tipold *et al.*, 1994, 1993b). The IgM and IgA levels may be normal or increased (Tipold *et al.*, 1994). The CSF of animals with chronic or treated bacterial infections may be nonsuppurative with mild to moderate elevations of total white blood cell count and total protein (Green and Smith, 1992). Occasionally, extracellular or intracellular bacteria may be seen on a Gram stain (Green and Smith, 1992; Foreman and Santschi, 1989; Kornegay, 1981). Because some bacteria undergo rapid autolysis in the test tube, bacterial culture of these infections is often unrewarding. Nonetheless, culture should be attempted. Polymerase chain reaction techniques may be used to detect the presence of bacterial DNA (Peters *et al.*, 1995).

a. Listeriosis

The CSF of cattle with meningoencephalitis caused by *Listeria monocytogenes* typically has mild to moderate elevations in total white blood cell count and total protein, with the white cells being mostly mononuclear cells, in spite of the fact that it is a bacterial infection (Rebhun and deLahunta, 1982). These mild changes probably reflect the characteristic lesions of this disease, which are mononuclear vascular cuffing and parenchymal microabscesses. The disease in sheep may produce a CSF similar to that of infected cattle (Scarratt, 1987). However, two studies reported ovine CSF to have moderate to marked elevations in white blood cell count and protein, with a neutrophilic pleocytosis (53 to 100% neutrophils) (Scott, 1993, 1992). Perhaps the mononuclear CSF reported in cattle reflects a more chronic stage or resolution of the disease (Green and Smith, 1992; Kjeldsberg and Knight, 1993). A study of bacterial culture and polymerase chain reaction (PCR) for the detection of *L. monocytogenes* in the CSF of 14 infected ruminants yielded no positive cultures and

only one positive PCR. The authors concluded that *L. monocytogenes* only occasionally gains access to the meningoventricular system in the course of the disease, and that reliable, *in vivo* diagnosis of listeric encephalitis generally cannot be based on the detection of the organism in the CSF (Peters *et al.*, 1995).

b. Neuroborreliosis (Lyme Disease)

Although neuroborreliosis caused by the Lyme disease spirochete, *Borrelia burgdorferi*, has been suspected in dogs (Mandel *et al.*, 1993; Feder *et al.*, 1991) and horses (Hahn *et al.*, 1996; Burgess and Mattison, 1987), the actual incidence in animals is unknown, largely because of diagnostic difficulties. These difficulties arise from a delay or repression of seroconversion after infection; the high number of seropositive, clinically normal animals; the persistence of infection and seropositivity despite resolution of clinical disease; antibody cross reactivity; and difficulty in culturing the organism from tissue or fluid samples (Appel *et al.*, 1993; Madigan, 1993; Parker and White, 1992; Levy *et al.*, 1993). The CSF associated with neuroborreliosis in animals has not been characterized. In people, CSF abnormalities are related to the stage of the disease. When present, typical abnormalities are a mononuclear pleocytosis (T lymphocytes, plasma cells, and IgM-positive B cells (Sindern and Malin, 1995)) with a moderately elevated total protein and normal or decreased CSF glucose (Fishman, 1992). Persistent CSF oligoclonal bands and intrathecal synthesis of IgG, IgM, and IgA occur (Henriksson *et al.*, 1986). Diagnosis is enhanced by the determination of intrathecal synthesis of specific *B. burgdorferi* antibodies (Kaiser and Lucking, 1993), but cross reactivity is a problem (Fishman, 1992). *Borrelia burgdorferi* antibodies have also been detected in the CSF of dogs (Mandel *et al.*, 1993; Feder *et al.*, 1991). PCR techniques for CSF have been recently developed, but the diagnostic success rate is variable (Lebech, 1994). The CSF of a horse was reported PCR positive for *B. burgdorferi* (Hahn *et al.*, 1996).

c. Rickettsial Diseases

Rickettsial diseases such as ehrlichiosis, usually caused by *Ehrlichia canis*, and rocky mountain spotted fever, caused by *Rickettsia rickettsii*, sporadically involve the central nervous system of animals. In dogs with neural ehrlichiosis, the CSF resembles that of viral diseases, that is, the white blood cell count and protein may be normal or slightly to moderately elevated with a predominantly mononuclear pleocytosis (Maretzki *et al.*,1994; Greene *et al.*, 1985; Buoro *et al.*, 1990; Meinkoth *et al.*, 1989; Firneisz *et al.*, 1990). The albumin quotient is reported to be elevated (Sorjonen *et al.*, 1991). Occasionally, *Ehrlichia* morulae may be observed in CSF mononuclear cells or neutrophils (Maretzki *et al.*, 1994). The few reports of CSF associated with Rocky Mountain spotted fever suggest a difference from ehrlichiosis in that the CSF pleocytosis of Rocky Mountain spotted fever may be predominantly neutrophilic, particularly early in the disease (Breitschwerdt, 1995; Breitschwerdt *et al.*, 1985; Greene *et al.*, 1985; Rutgers *et al.*, 1985). A predominantly neutrophilic pleocytosis has also been reported in dogs experimentally infected with *R. rickettsii* (Breitschwerdt *et al.*, 1990). In this same study, IgG or IgM antibodies were not detected in the CSF of experimentally infected dogs, but were detected in the CSF of one naturally infected dog that also had a high serum titer (Breitschwerdt *et al.*, 1990).

d. Thromboembolic Meningoencephalitis

In cattle, *Hemophilus somnus* causes bacteremia and thromboembolism, with some preference for neural tissue. The vascular lesion results in multifocal hemorrhages. Consequently, the CSF is characteristically yellow with a high red blood cell count (not iatrogenic in origin), and moderately to markedly increased white blood cell count (predominantly neutrophils) and protein (George, 1996; Mayhew, 1989; Ames, 1987; Littl and Sorensen, 1969). The bacterium can be cultured only occasionally from CSF, and more easily from septicemic animals (Little, 1986; Nayer *et al.*, 1977).

2. *Viral Diseases*

The CSF associated with viral diseases is characterized by nonsuppurative inflammatory changes. The total white blood cell count and total protein are generally mildly to moderately elevated. The white cell population may be mixed with a majority of mononuclear cells or may be entirely mononuclear cells. Occasionally, neutrophils predominate, particularly in the early stages of disease or in certain diseases (see later discussion). The IgG index is commonly elevated (Tipold *al.*, 1993b; Bichsel *et al.*, 1984b). The IgA and IgM leve may also be elevated. The CSF of viral infections ma also be normal, particularly if the meninges or ependyma are not involved (Rand *et al.*, 1994a; Tipold *et a* 1994; Fishman, 1992; Fankhauser, 1962; Tipold, 199

a. Canine Distemper

The CSF abnormalities associated with canine distemper vary strikingly with the stage of the disease Dogs with acute, demyelinating, noninflammatory distemper encephalitis may have normal or near-norm CSF (mild elevations of total cell count and total protein) (Tipold, 1995; Johnson *et al.*, 1988). Protein elevation is most likely due to blood–brain barrier dysfunction (Bichsel *et al.*, 1984b). The IgG index may also

normal or occasionally mildly elevated, which correlates with the histological findings of multifocal demyelination with very little or no infiltration of inflammatory cells (Tipold *et al.*, 1994, 1993b; Bichsel *et al.*, 1984b; Vandevelde *et al.*, 1986; Johnson *et al.*, 1988). The acute form of nervous canine distemper is an exception to the usual association of an elevated IgG index with infectious neurologic diseases because infiltration with inflammatory cells occurs only in the chronic stage of distemper encephalitis (Vandevelde *et al.*, 1986). The CSF IgM and IgA content is also usually normal (Tipold *et al.*, 1994; Johnson *et al.*, 1988). The CSF of subacute/chronic, inflammatory distemper usually has a moderately elevated total white blood cell count, primarily mononuclear, and moderately elevated protein (Bichsel *et al.*, 1984b; Tipold, 1995). The IgG index is typically elevated (Bichsel *et al.*, 1984b; Vandevelde *et al.*, 1986) and IgA levels are commonly increased. Interestingly, IgM levels are increased more often in the chronic stage than in the dogs with acute, noninflammatory distemper (Tipold *et al.*,1994, 1993b). The IgM and IgA are presumably of intrathecal origin (Tipold *et al.*, 1994), although blood–brain barrier dysfunction is also present in some dogs and therefore protein could be of serum origin (Sorjonen, 1987; Bichsel *et al.*, 1984b; Sorjonen *et al.*, 1991). Occasionally the CSF is normal or has only mild changes in cell count or total protein content (Tipold et al., 1994, 1993b; Bichsel *et al.*, 1984b; Sorjonen *et al.*, 1991; Tipold, 1995; Vandevelde *et al.*,1986). Antimyelin antibody and antiviral antibody have also been identified in the CSF of inflammatory distemper (Vandevelde *et al.*, 1986). Canine distemper virus antibody is normally absent from CSF; when present it is diagnostic of infection. False-positive results can occur, however, if the CSF is contaminated by serum distemper virus antibody by either iatrogenic or pathologic blood–brain barrier disturbance. The CSF of delayed-onset canine distemper (also known as old-dog encephalitis) has an elevated protein and nonsuppurative, inflammatory cytology. The IgG index is elevated, and much of the CSF IgG is virus specific, suggesting an intrathecal anti-viral immune response. The IgM and IgA concentrations are normal (Johnson *et al.*,1988).

b. Equine Herpesvirus Myeloencephalitis

With its predilection for endothelial cells, the equid herpesvirus 1 (EHV-1) may cause vasculitis and perivascular hemorrhage in the brain and spinal cord. As a result, the CSF is often xanthochromic. The total white blood cell count may be normal while the total protein level is moderately to markedly elevated (albuminocytologic dissociation). The CSF/serum albumin ratio is increased (Klingeborn *et al.*, 1983). In some cases the total protein is normal, perhaps because the CSF is analyzed very early in the course of the disease before the protein level has risen, or late in the disease after the level has subsided (Kohn and Fenner, 1987). Antibodies to the virus may be identified in the CSF (Blythe *et al.*, 1985; Klingeborn *et al.*, 1983; Jackson *et al.*, 1977) Antiviral CSF antibodies are not present routinely in neurologically normal horses, horses vaccinated with modified live EHV-1, or horses with other neurologic diseases (Blythe *et al.*, 1985). However, because of destruction of the blood–brain barrier, serum antiviral antibodies may pass into the CSF and confound the interpretation of the CSF titers (Blythe *et al.*, 1985 Klingeborn *et al.*, 1983; Kohn and Fenner, 1987; Jackson *et al.*, 1977). Determining the CSF IgG index may help to assess the relevance of a positive CSF EHV-1 titer.

c. Feline Infectious Peritonitis

The feline infectious peritonitis (FIP) coronavirus may cause a multifocal, pyogranulomatous meningitis choroid plexitis, and ependymitis characterized by perivascular granulomas around small blood vessels The CSF associated with these lesions consistently has a moderate to marked elevation of white blood cells and protein. In one study, the CSF of cats with FIP was distinctive compared to that of cats with other inflammatory central nervous system diseases in having greater than 200 mg/dl total protein (Rand *et al.* 1994a). Despite the viral nature of the disease, the white cell population is dominated by neutrophils, commonly greater than 70% (Rand *et al.*, 1994a; Kline *et al.*, 1994; Baroni and Heinold, 1995). Prolonged glucocorticosteroid therapy may result in a normal CSF in rare instances; the authors have observed this on at least one occasion.

d. Feline Immunodeficiency Virus

The CSF associated with feline immunodeficiency virus (FIV) neurologic disease typically has a mild, primarily lymphocytic, pleocytosis (Dow *et al.*, 1990, Phillips *et al.*, 1994). In experimentally infected cats, the pleocytosis appears related to the duration, and perhaps route, of infection, as well as to the age of the cat. In one study, pleocytosis appeared within 2–8 weeks of inoculation of adult cats, then disappeared by 20 weeks (Dow *et al.*, 1990). In a study of kittens, the total and differential cell counts were normal at 3 and 12–16 months postinoculation (Podell *et al.*, 1993) The total protein content is typically normal, although the albumin quotient and IgG index may be elevated (Dow *et al.*, 1990; Podell *et al.*, 1993). Antibodies to the virus may be detected in the CSF, and their presence in CSF that has not been contaminated by peripheral blood is presumptive evidence of FIV neural infection

(Dow *et al.*, 1990; Phillips *et al.*, 1994). In experimentally inoculated cats, FIV antibodies developed in the CSF 4–8 weeks after the appearance of CSF pleocytosis (Dow *et al.*, 1990). The virus can be recovered from the CSF of most cats that have intrathecal antibodies (Dow *et al.*, 1990; Phillips *et al.*, 1994). In the immunodeficient, chronic stage of FIV infection, the effect of possible opportunistic neural infections on CSF must be considered.

e. Rabies

Because rabies is an overwhelmingly fatal, zoonotic disease, there is a paucity of information regarding its CSF abnormalities. In people, the total white blood cell count is normal or has a mild, lymphocytic pleocytosis, and total protein is mildly increased. Occasionally, the pleocytosis is marked (Fishman, 1992). The CSF of animals with rabies may be normal or abnormal. Typical abnormalities include a mild to moderate mononuclear pleocytosis and mild to moderate elevations in total protein. The white cells may be predominantly lymphocytes, with macrophages, neutrophils, and occasionally plasma cells and eosinophils (Braund, 1994; Green *et al.*, 1992; Hanlon *et al.*, 1989; Coles, 1980; Hamir *et al.*, 1992). A neutrophilic pleocytosis reported for one horse was thought to reflect an early stage of the disease (Green, 1993). Xanthochromia was detected in the CSF of 3 of 5 horses in one study (Green *et al.*, 1992), perhaps due to antemortem head trauma. The CSF IgM titer increases in 2–3 weeks or more after the onset of clinical rabies (Murphy *et al.*, 1980). Because of this delay, a negative titer result does not eliminate rabies infection as a possibility (Greene and Dreesen, 1990). Infective virus may be isolated from the CSF before clinical signs of the disease appear, and neutralizing antibodies in the CSF may not be identified until after clinical signs develop (Fekadu and Shaddock, 1984). Because of the human health hazard, CSF collection should be avoided if rabies is suspected.

3. *Fungal Diseases*

Fungal infection of nervous tissue is relatively uncommon, although *Cryptococcus neoformans* has a predilection for the central nervous system. The CSF associated with neural cryptococcosis is quite variable. The total white blood cell count can be near normal or markedly increased. The white blood cell differential count is typically mixed with a majority of neutrophils (Berthelin *et al.*, 1994; Steckel *et al.*, 1982). However, mononuclear CSF has been reported (deLahunta, 1983; Berthelin *et al.*, 1994), as has eosinophilic fluid (deLahunta, 1983; Vandevelde and Spano, 1977). The total protein is typically elevated, although sometimes only marginally so. The albumin quotient and IgG index are mildly to markedly elevated (Sorjonen *et al.*, 1991). Cryptococcal organisms are commonly seen in the CSF (93% in one report/review) (Berthelin *et al.*, 1994) and cultures are often, but not invariably, positive. Latex agglutination for cryptococcal antigen in the CSF may also be positive, but experience with this test with CSF is limited (Berthelin *et al.*, 1994).

The literature contains only a few reports of the CSF abnormalities associated with neural aspergillosis, blastomycosis, coccidioidomycosis, or histoplasmosis. Again, the CSF abnormalities are variable; a mixed pleocytosis and elevated protein is typical (Vandevelde and Spano, 1977; Mullaney *et al.*, 1983; Coates, 1995; Gelatt *et al.*, 1991; Nafe *et al.*, 1983; Schaer *et al.*, 1983; Kornegay, 1981). In a reported case of aspergillosis of the brain of a dog, the CSF had a normal total nucleated cell count (differential count was not done) and a normal protein (Parker and Cunningham, 1971).

4. *Prion Disorders*

The transmissible spongiform encephalopathies are a group of neurodegenerative diseases of people and animals caused by prions (proteinaceous infectious particles). The diseases in this group include kuru and Creutzfeldt–Jakob disease of people, bovine spongiform encephalopathy, scrapie of sheep and goats, transmissible mink encephalopathy, and spongiform encephalopathies in deer, captive ungulates, and domestic cats (Schreuder, 1994a,b). The CSF associated with the spongiform encephalopathies in animals has normal cytology, protein content, and electrophoretic pattern. Thus, these diseases, although apparently infectious, do not appear to damage the blood–brain barrier or elicit an immune response in the central nervous system (Scott et al., 1990; Lowenthal and Karcher, 1994; Millson *et al.*, 1960; Strain *et al.*, 1984).

E. Ischemic Disorders

In general, neural ischemia causes blood–brain/CSF barrier dysfunction resulting in increased CSF protein. If infarction occurs, the tissue destruction and cellular response may result in CSF pleocytosis. With extensive, particularly acute, infarction the pleocytosis may be substantially neutrophilic (Fishman, 1992). In animals, CSF abnormalities have been reported for fibrocartilaginous embolism and cerebral ischemia/infarction.

1. *Fibrocartilaginous Embolism*

The characteristics of CSF associated with fibrocartilaginous embolism have been reported for dogs and horses. About one-third of the reported canine cases have normal CSF, about one-third have pleocytosis usually mononuclear, and increased protein, and abou

one-third have albuminocytologic dissociation (Cauzinille and Kornegay, 1996; Bichsel *et al.*, 1984a). Similar findings have been reported for two horses (Jackson *et al.*, 1995; Taylor *et al.*, 1977). The type of pleocytosis, neutrophilic or mononuclear, probably depends on the size, location, and age of the infarct. The CSF albumin is reported to be normal, and the IgG index either normal or slightly elevated, the latter reflecting the inflammation around the lesion (Tipold *et al.*, 1993b; Bichsel *et al.*, 1984b). Normal CSF may be associated with a better prognosis for recovery (Cauzinille and Kornegay, 1996).

2. *Cerebral Ischemia/Infarction*

Cerebral infarction (ischemic encephalopathy) has been reported primarily in cats, but also in a few dogs. In cats within the first week of onset, the white blood cell count is normal or mildly elevated with a mixed, predominantly mononuclear, pleocytosis, and protein is mildly to markedly elevated (Rand *et al.*, 1994b; deLahunta, 1983). Dogs with cerebral infarction have similar CSF characteristics (Bichsel *et al.*, 1984b; deLahunta, 1983; Vandevelde and Spano, 1977; Joseph *et al.*, 1988), although two dogs in one report had a mixed, but predominantly neutrophilic, pleocytosis and normal protein (Vandevelde and Spano, 1977). The neutrophilic pleocytosis reflected the acute encephalomalacia noted on histopathologic examination (Vandevelde and Spano, 1977). In one dog of another report, the CSF albumin and IgG index were normal (Bichsel *et al.*, 1984b). Another dog with a deep, parenchymal, hemorrhagic infarct in the basal nuclear region had normal CSF (Norton, 1992).

F. Malformations of Neural Structures

Although reports with CSF analysis are relatively few, the CSF of animals with neural malformations is generally normal (Rand *et al.*, 1994b; Vandevelde and Spano, 1977; Milner *et al.*, 1996; Meric, 1992b; Shell *et al.*, 1988; Greene *et al.*, 1976; Wilson *et al.*, 1979). However, if the malformation interferes with CSF circulation or absorption, abnormalities in protein and even cell count may be present. The CSF may also be altered by secondary or additional unrelated processes (Rishniw *et al.*, 1994). For example, intraventricular hemorrhage can occur in hydrocephalic animals, producing xanthochromic CSF with an increased white blood cell count and protein content.

1. *Intracranial Intra-arachnoid Cysts*

Intracranial intra-arachnoid cysts have been identified in six dogs: two Lhasa apsos, two pugs, one shih tzu, and one German short-haired pointer (Vernau *et al.*, 1996). Analysis of cerebellomedullary CSF was performed in three of the dogs. In two, the CSF was normal (clear, colorless, <2 WBC/μl, <25 mg/dl total protein). The CSF of the third dog had a moderate, lymphocytic pleocytosis and moderately increased total protein, suggesting a nonsuppurative, inflammatory process. Necropsy of this dog identified a nonsuppurative, necrotizing meningoencephalitis unrelated to its cyst (Vernau *et al.*, 1996).

G. Metabolic/Nutritional Disorders

Cerebrospinal fluid analysis is not done commonly in animals with metabolic or nutritional neurologic disorders because most of these disorders are diagnosed from historical and physical findings and laboratory tests of blood and urine. When other procedures are nondiagnostic, or when therapy does not eliminate, or perhaps worsens, the neurologic dysfunction, CSF analysis is indicated to investigate other causes of the neurologic signs. In most cases, routine analysis of CSF associated with metabolic or nutritional disorders does not detect abnormalities (Fishman, 1992; Scott, 1995; Bichsel *et al.*, 1984b; Vandevelde and Spano, 1977). Although brain edema is relatively common with some of these disorders (e.g., hypoxia, hyponatremia, or the osmotic dysequilibrium syndromes of hemodialysis or diabetic ketoacidosis), the edema is usually cytotoxic rather than vasogenic. Therefore, the blood–brain/CSF barrier is usually intact and CSF protein is normal. If edema is severe enough to result in brain ischemia, infarction, or herniation, the blood–brain/CSF barrier becomes dysfunctional, vasogenic edema occurs, and CSF protein rises. If neural necrosis ensues, the white blood cell count may also increase. Even in the (apparent) absence of vasogenic edema, blood–brain barrier leakage may occur, perhaps because of the biochemical effects of the disorder on the barrier cells. Animals and people with uremic or hepatic encephalopathies or hypothyroidism may have increased total protein with a normal IgG index (Fishman, 1992; Bichsel *et al.*, 1984b, 1988). People with diabetic neuropathy may also have increased CSF protein (Fishman, 1992). Animals with severe metabolic encephalopathies often have seizures, and the effect of seizures on the CSF must also be considered (see Section VII.H.2). Disorders in which neural necrosis is a primary feature, such as the polioencephalomalacia of thiamine deficiency, typically have a pleocytosis and increased total protein (Bichsel *et al.*, 1984b; George, 1996; deLahunta, 1983). Specific biochemical analysis of CSF may show abnormalities, such as abnormalities in osmolality or electrolyte content with salt or water intoxication (Mayhew, 1989; Kopcha, 1987), abnormalities in amino acid levels (such as glutamine) with hepatic encephalopathy (Schaeffer

et al., 1991; Grabner *et al.*, 1991), and elevated citrulline in bovine citrullinemia (Healy *et al.*, 1990).

H. Miscellaneous Conditions

1. Alterations in CSF Following Myelography

Changes in the composition of CSF following myelography have been reported in people (Fishman, 1992) and animals (Widmer and Blevins, 1991; Burbidge *et al.*, 1989). Most contrast agents are low-grade leptomeningeal irritants, resulting in leptomeningeal inflammation that is reflected in the CSF. By 90 minutes after myelography, the total white blood cell count and total protein can be elevated and the white blood cell differential count altered. The pleocytosis is typically a mixed mononuclear/neutrophilic response, with the proportion of mononuclear cells to neutrophils varying with the contrast agent used and the time interval after myelography. The pleocytosis may resolve within 10 days (Johnson *et al.*, 1985), although individual animals may have a slightly increased total white blood cell count up to 14 days following contrast injection (Spencer *et al.*, 1982; Wood *et al.*, 1985). In contrast, one study of the contrast agents iohexol and iotrolan did not detect any alteration of total white blood cell count in CSF taken between 1 and 14 days following myelography (van Bree *et al.*, 1991). The CSF specific gravity and Pandy test score can also be elevated, presumably partly because of the presence of the contrast media (Widmer *et al.*, 1992). Increased CSF albumin and immunoglobulin levels may be due predominantly to blood–brain/CSF barrier leakage, and may return to normal levels within 5 days (Johnson *et al.*, 1985). In summary, any alteration of CSF within the first week or two following myelography must be assessed cautiously.

2. Seizures: Interictal and Postictal CSF Characteristics

Patients with seizures due to progressive intracranial or some extracranial disorders typically have CSF changes reflecting the disorder. In contrast, the interictal CSF of patients with nonprogressive, intracranial disease should be normal. Postictal CSF is often abnormal, however. Pleocytosis of postictal CSF has been well documented in people (Fishman, 1992; Rider *et al.*, 1995; Barry and Hauser, 1994). The white blood cell counts may be up to 80/μl with a neutrophilic component from 5 to 92%. The cell counts are highest at about 24 hours after the seizure. The mechanism of the pleocytosis is obscure (Fishman, 1992). Convulsive seizures, regardless of cause, may also induce a reversible increase in blood–brain/CSF barrier permeability, resulting in a transient elevation of CSF protein. Brain metabolism is also stimulated during the seizure, resulting in an increase in brain lactate production and a decrease in brain pH (Fishman, 1992). However, differentiating the effects of the local (brain) phenomena from the effects of systemic phenomena that occur during seizures (hypertension, acidosis, hypoxia, etc.) is difficult. For example, severe, experimental hyperthermia in dogs (core body temperature >41.2°C) results in increased CSF enzymes, calcium, and chloride, probably due to increased blood–brain/CSF barrier permeability (Deswal and Chohan, 1981). Interpretation of postictal CSF must be done cautiously because of the potential confusion of a postictal, "idiopathic epileptic" condition with a progressive disease that alters the CSF primarily. For children with seizures, the recommendation has been made that CSF with >20 white blood cell/μl or >10 polymorphonuclear cells/μl no be attributed to the seizures (Rider *et al.*, 1995).

I. Neoplasia

The CSF associated with neoplastic conditions affecting the central nervous is quite variable, reflecting the variety of tumors, locations, and tissue reactions to the disease. The CSF is usually clear and colorless although xanthochromia may be present if hemorrhage has occurred. The total white blood cell count is often normal, but pleocytosis may occur, particularly with meningiomas and choroid plexus tumors (and occasionally other tumors) (Bailey and Higgins, 1986b; Carrillo *et al.*, 1986). Pleocytosis is usually mononuclear although meningiomas may have >50% neutrophil (Bailey and Higgins, 1986b). Neural lymphosarcoma often has a lymphocytic/lymphoblastic pleocytosis (Lane *et al.*, 1994; Williams *et al.*, 1992; Couto *et al.* 1984), except in cattle, in which the tumor is usually extradural (Sherman, 1987). One report indicates that pleocytotic CSF is associated with a significantly shorter survival time than is normal or albuminocytologic CSF (Heidner *et al.*, 1991). The commonest CSF abnormality is increased total protein, with choroid plexus tumors producing the most marked elevation (Rand et al., 1994b; Bailey and Higgins, 1986b; Moore *et al.*, 1994; Sarfaty *et al.*, 1988; Mayhew, 1989; Brehm *et al.*, 1992; Waters and Hayden, 1990; Roeder *et al.* 1990; Kornegay, 1991). Dogs with neural neoplasia, particularly of the meninges or choroid plexus, commonly have blood–brain/spinal cord barrier disturbance and subsequently an increased albumin quotient (Sorjonen, 1987; Bichsel *et al.*, 1984b; Sorjonen *et al.* 1991; Moore *et al.*, 1994). In one study, this abnormality was most common with choroid plexus tumors and least common with astrocytomas (Moore *et al.*, 1994

Alpha and beta globulin levels are usually normal; gamma globulins are normal or mildly increased (Sorjonen, 1987; Sorjonen *et al.*, 1991; Moore *et al.*, 1994). The IgG index may be elevated, reflecting the presence of inflammatory infiltrates around the lesion (Tipold *et al.*, 1993b; Bichsel *et al.*, 1984b).

The CSF associated with spinal neoplasia is reported to be normal more often than is the CSF of brain tumors (Fingeroth *et al.*, 1987; Luttgen *et al.*, 1980; Schott *et al.*, 1990). This finding may reflect the fact that most spinal neoplasia is extradural or that most spinal tumors are relatively small at the time of diagnosis. It may also reflect the site of CSF collection—that most of the samples are cerebellomedullary rather than lumbar, although many reports do not state the puncture site. Cerebrospinal fluid collected caudal to the lesion is abnormal more often than is CSF collected cranial to the lesion (Thomson *et al.*, 1990).

J. Parasitic Diseases

1. Equine Protozoal Encephalomyelitis

Equine protozoal encephalomyelitis (EPM), caused by *Sarcocystis neurona* (*S. falcatula* (Dame *et al.*, 1995)), is characterized by multifocal areas of mononuclear, perivascular inflammation and necrosis; severe lesions may be hemorrhagic and have neutrophilic infiltration (Mayhew and deLahunta, 1978; Madigan and Higgins, 1987). The CSF may be normal or have mild to moderate mononuclear pleocytosis and increase in total protein (Mayhew, 1989; Reed *et al.*, 1994). Xanthochromia is occasionally present, as well as neutrophils and eosinophils (Mayhew, 1989). The CSF albumin concentration and albumin quotient are reported to be normal and the IgG index elevated, indicating intrathecal IgG production (Andrews and Provenza, 1995). Antibodies to *S. neurona* can be identified in the CSF by immunoblot analysis (Granstrom, 1993). The test is very sensitive and specific for the diagnosis of EPM; however, its accuracy depends on an intact blood–brain/CSF barrier because many horses have serum antibodies to *S. neurona* but do not have clinical disease (Andrews and Provenza, 1995; Fenger, 1995). Detection of *S. neurona* in the CSF by polymerase chain reaction provides definitive evidence of the presence of the parasite in the central nervous system. The results of polymerase chain reaction assay are independent of serum leakage across the blood–brain/CSF barrier (Fenger, 1994).

2. Neosporosis, Toxoplasmosis

Both *Neospora* and *Toxoplasma* can invade the central nervous system, causing necrosis, vasculitis and a multifocal, granulomatous meningoencephalomyelitis. *Neospora* seems to have more of a predilection fo the central nervous system than *Toxoplasma,* particu larly in young dogs (Dubey *et al.*, 1989, 1988). The CSI associated with neural protozoal infections generall has a mild to moderate increase in white blood cel count and total protein. Typically, the white blood cel differential count shows a mixed pleocytosis witl monocytes, lymphocytes, neutrophils, and eosinophil in order of decreasing percentage (Rand *et al.*, 1994a Cuddon *et al.*, 1992; Tipold, 1995; Vandevelde anc Spano, 1977; Kornegay, 1981; Dubey *et al.*, 1990; Averil and deLahunta, 1971; Hass *et al.*, 1989). Occasionally the white blood cell count and protein are normal (Tipold, 1995; Parish *et al.*, 1987). The CSF IgG index wa elevated in three of three dogs studied; in two of twc dogs, the IgM was normal and the IgA was elevatec (Tipold *et al.*, 1994, 1993b). In a study of experimentall infected cats, *T. gondii*-specific IgG was intrathecall produced, but *T. gondii*-specific IgM was not detected (Munana *et al.*, 1995). Antiprotozoal antibodies in the CSF may be detected by a variety of methods (Ruehlmann *et al.*, 1995; Cole *et al.*, 1993; Patton *et al.*, 1991) However, the presence of antibodies does not necessarily indicate clinical disease (Munana *et al.*, 1995; Dubey and Lindsay, 1993). Recently, polymerase chain reaction techniques have been developed to identify the protozoa in tissue and fluids, including CSF (Stiles *et al.*, 1996; Parmley *et al.*, 1992; Novati *et al.*, 1994). Occasionally the organisms themselves may be seen in CSF cells (Dubey, 1990; McGlennon *et al.*, 1990).

In considering the CSF abnormalities of toxoplasmosis and neosporosis, two issues must be kept in mind. First, reports of toxoplasmosis prior to 1988 (when *Neospora* was identified) must be carefully scrutinized because many of these cases were actually neosporosis. Second, because *T. gondii* is not a primary pathogen, clinical toxoplasmosis is relatively rare and is seen mostly in conjunction with a second disease, particularly canine distemper, which may itself alter the CSF (Dubey *et al.*, 1989).

3. Migratory Parasites

Neural invasion by migratory parasites is relatively common in large and exotic animals, yet rare in dogs and cats. The CSF may reflect the physical trauma and consequent inflammatory response, and in some cases an immune reaction to the parasite tissue. The CSF abnormalities are variable and probably depend to some degree on the specific parasite, as well as on its location and the type of incited response. For example, *H. bovis* larvae in the cow normally lodge in the lumbar epidural space and their effect on the spinal cord may be primarily compression. The CSF in such a case could

be normal or have only mildly to moderately elevated protein. Parasites that actually invade neural tissue may leave the CSF unchanged or produce CSF with mild to marked pleocytosis and protein elevation, as well as xanthochromia. An eosinophilic pleocytosis is suggestive of parasitism, and typical of some parasites such *Parelaphostrongylus* (Mason, 1989; George, 1996; Pugh *et al.*, 1995; Baum, 1994). However, eosinophilic pleocytosis is not pathognomonic for parasitism, nor does a lack of eosinophils in the CSF rule out neural parasitism (Lester, 1992; Braund, 1994; George, 1996; deLahunta, 1983). The development of an ELISA technique using *Parelaphostrongylus*-specific immunoglobulin to detect parasite antigen in the CSF might be of diagnostic value (Dew *et al.*, 1992).

K. Toxicity

Even though neurologic signs may occur, the CSF associated with toxicity is usually normal (e.g., cows with lead poisoning, tetanus, or botulism) (Fankhauser, 1962; Feldman, 1989). Mild elevations of the white blood cell count and protein may occur if the toxin causes breakdown of blood-brain/CSF barrier or neural degeneration or necrosis, such as in some cases of lead poisoning (Fankhauser, 1962; Swarup and Maiti, 1991; Dorman *et al.*, 1990; Dow *et al.*, 1989; George, 1996; Mayhew, 1989; Little and Sorensen, 1969). Lead has been shown to poison capillary endothelial cells selectively (Goldstein *et al.*, 1977), as well as to cause cerebral cortical necrosis (Christian and Tryphonas, 1970). If necrosis is severe, the white blood cell count and the total protein can be markedly increased with a predominance of neutrophils, as with leukoencephalomalacia caused by moldy corn poisoning in horses. Xanthochromia is also a characteristic of moldy corn poisoning, reflecting the perivascular hemorrhages in the central nervous system (McCue, 1989; Masri *et al.*, 1987). With toxicities, biochemical alterations of the CSF may occur more commonly than alterations of CSF cell counts or protein. At the onset of fatal signs of lead poisoning, CSF glucose, urea, creatinine, and creatine kinase levels are increased (Swarup and Maiti, 1991). Neurostimulatory toxins may result in elevated monoamine metabolites in the CSF (Sisk *et al.*, 1990). Ivermectin toxicity producing recumbency in dogs elevates the CSF concentrations of homovanillic acid and 5-hydroxyindoleacetic acid (Vaughn *et al.*, 1989a). Interestingly, copper poisoning in sheep does not produce significant increases in CSF copper, zinc, or iron levels (Gooneratne and Howell, 1979).

L. Trauma/Compression of Neural Tissue

The CSF abnormalities associated with trauma and/or compression are variable depending on the rate at which the neural insult developed, the degree of neural damage, the location of the lesion (particularly wit respect to the CSF collection site), the elapsed tim since the onset of the neural insult, and the mainte nance or progression of the insult. With acute traum the CSF may be pink and hazy or turbid, or actuall bloody. After centrifugation, the supernatant can b clear. If hemorrhage occurred more than 48 hours prio to CSF collection, the supernatant may be yellow be cause of bilirubin. The total red blood cell count ma be markedly elevated. The white blood cell count ma be mildly to moderately elevated, reflecting eithe hemorrhage into the subarachnoid space or inflamm tion instigated by the trauma. Erythrophagocytosi may be present. The pleocytosis is usually a mixed ce population, and a substantial proportion of neutrophil (40–50%) is possible. Total protein may be moderatel to markedly elevated because of disruption of bloo vessels, interruption of CSF flow and absorption, an necrosis (Thomson *et al.*, 1989; Green *et al.*, 1993). Thu the CSF of acute trauma may have a distinct, inflam matory character. With spinal cord trauma/compre sion, lumbar CSF is more consistently abnormal tha cerebellomedullary CSF (Thomson *et al.*, 1990). Th CSF abnormalities of chronic trauma or sustained com pression tend to be milder than the abnormalities c acute damage. The white blood cell count may be no mal or mildly elevated with generally a mixed or m nonuclear pleocytosis. The cerebellomedullary CSF c horses with cervical stenotic myelopathy is reporte to be hypocellular with a reduced number of lymph cytes (Grant *et al.*, 1993). The CSF protein associate with chronic trauma or sustained neural compressio may be normal to moderately elevated (Thomson *al.*, 1989; Mayhew, 1989). The albumin content an the albumin quotient of CSF associated with trauma compression may be normal or increased, the latt reflecting the vascular damage and edema (Sorjone 1987; Sorjonen *et al.*, 1991; Bichsel *et al.*, 1984b; Andrew and Provenza, 1995). The gamma globulin percentag and the IgG index are usually normal. Occasional el vations probably reflect the presence of inflammato cells in the lesion (Tipold *et al.*, 1993b; Bichsel *et a* 1984b; Andrews and Provenza, 1995).

CHAPTER

28

Clinical Biochemistry in Toxicology

JAMES R. TURK AND STAN W. CASTEEL

The availability of accurate historical information, including a list of the animal species affected, clinical signs, toxins suspected, potential route of exposure, vehicle, relative amount, and timing of exposure, is often a limiting factor in the diagnosis of toxic disease. This information permits the diagnostician to make a rational selection of samples and tests to be performed by considering the known target organs of the toxins suspected. Unfortunately, this information is often unavailable during the initial stages of an intoxication. In the absence of such detailed history, the identification of target organs using clinical biochemistry may be helpful in the retrospective creation of a list of potential toxins.

There are species differences in the most useful biochemical markers of organ-specific cellular injury and in the susceptibility to various toxins (Kramer, 1989). For this reason, the following discussion is organized on an organ system and species basis. Neither bacterial toxins nor hereditary disease predisposing to intoxication will be discussed.

I. HEPATOTOXICITY

Many toxins induce hepatic injury (Table 28.1). The susceptibility of the liver to toxic insult is in part a consequence of its location between the digestive tract and the rest of the body and the central role it plays in biotransformation and disposition of xenobiotics (Miyai, 1991; Snyder, 1979). Extrahepatic metabolism of toxins by mixed-function oxidases may affect the target organ and potential hepatotoxicity of a given xenobiotic (Gram *et al.*, 1986). A variety of factors, including the induction of these enzyme systems by drugs (Snyder, 1979) and suppression of enzyme activity by infectious agents and cytokines (Monshouwer *et al.*, 1995), may modify the response to a given toxin. Lipophilic compounds tend to be more hepatotoxic than hydrophilic ones because of elimination of the latter by the kidney (Kelly, 1993). Many toxins are hepatotoxic and nephrotoxic, however, and most toxins have multiple target organs.

The cytosolic enzyme alanine aminotransferase (ALT) is nearly specific for hepatocellular injury in the dog and cat. The plasma half-life of this enzyme in these species is approximately 60 hours. Increased serum levels parallel the magnitude of hepatocellular

TABLE 28.1 Hepatotoxins[a]

Hepatotoxin	Disease onset	Geography	Species affected
Aflatoxin B_1 (*Aspergillus flavus*)	Acute to chronic	Worldwide	All
Agave lecheguilla	Acute	US, MEX	Cp, O
Blue-green algae (cyanobacteria)	Acute	Worldwide	All
Chlorinated hydrocarbons	Acute to chronic	Worldwide	All
Copper	Acute to chronic	Worldwide	O, All
Compositae	Acute	AFR, AUS	B, O, P
Corticosteroids	Chronic	Worldwide	Cn
Cresols (pitch)	Acute	Worldwide	P
Cycadales	Acute to chronic	AUS, FL, PR, DOM REP	B, O
Cylcopiazonic acid (*Penicillium cyclopium*)	Acute to chronic	UK	B, E, O
Dimethylnitrosamine	Acute to chronic	Worldwide	B, Cn, F, O
Ethanol	Acute to chronic	Worldwide	All
Fumonisin (*Fusarium moniliforme*)	Chronic	Worldwide	B, E, O, P
Gossypol (cottonseed)	Acute to chronic	Worldwide	B, Cp, E, O, P
Hymenoyxs odorata (bitterweed)	Acute to chronic	US	O
Indospicine (*Indigofera* spp.)	Acute to chronic	AUS	B, Cn, E
Iron	Acute	Worldwide	P, E
Karwinskia humboldtiana (coyotillo)	Acute to chronic	MEX, TX	B, Cp, O
Kochia scoparia (fireweed)	Chronic	US	B
Lantana camara	Chronic	AUS, AFR, MEX, US	B, O, E
Mebendazole	Acute	Worldwide	Cn
Moldy hay	Chronic	US	B
Myoporaceae	Acute to chronic	AUS, NZ	B, O
Nolina texana (sacahuiste)	Chronic	US	B, Cp, O
Petroleum	Acute	Worldwide	All
Phalloidin (*Amanita*)	Acute	Worldwide	All
Phomopsin (mycotoxin on lupines)	Acute to chronic	AUS, US	B, O
Phenytoin/primidone	Chronic	Worldwide	Cn
Phosphorus	Acute	Worldwide	All
Pyrrolizidine alkaloids	Chronic	Worldwide	B, Cp, E, O, P
Ricinus communis (Castor bean)	Acute	Worldwide	All
Rubratoxins (*Penicillium rubrum*)	Acute to chronic	Worldwide	B, CN, E, F
Sawfly larvae	Acute	AUS, DENMARK	B, Cp, O
Solanaceae	Acute	AFR, AUS, S AM, US	B, Cp, O
Sporodesmin (*Pithomyces chartarum*)	Chronic	AUS, AFR, NZ	B, O
Tannic acid (*Quercus* spp., oaks)	Acute	Worldwide	B, Cp, E, O
Terminalia oblonga[a] (yellow-wood)	Acute to chronic	AUS	B, O
Tetradymia spp. (rabbit/horsebrush)	Chronic	US	B, Cp, O
Trema aspera (poison peach)	Acute	AUS	B
Trifolium hybridum (Alsike clover)	Chronic	Worldwide	B, E, O
Xanthium strumarium (Cocklebur)	Acute	US	B, P

[a] B, bovine; Cn, canine; Cp, caprine; E, equine; F, feline; O, ovine; P, porcine.

injury in acute disease. Several days following injury, ALT levels may be spuriously low. Therefore, ALT is not helpful in evaluating chronic liver disease. ALT levels also may be elevated by corticosteroid treatment ALT is not useful in evaluating hepatic disease in the horse, cow, sheep, goat, or pig.

Aspartate aminotransferase (AST) occurs in most cells; however, it is useful in evaluating hepatocellular and muscular injury because of its high activity in these tissues. Elevation of AST is more specific than that of ALT in evaluation of hepatocellular insult in large animals.

Alkaline phosphatase (AP) isoenzymes occur in liver, bone, intestine, kidney, placenta, and leukocytes. Serum AP is of mainly hepatic origin in the dog, cat, and horse. Hepatic isoenzymes have a longer half-life (days) than intestinal, renal, or placental (minutes) isoenzymes. Cholestasis induces hepatic AP. Intrahepatic cholestasis tends to cause progressive increase, whereas extrahepatic obstruction may produce an increase that subsequently plateaus. Increase in serum AP precedes hyperbilirubinemia. Corticosteroids, phenobarbital, chlorinated hydrocarbons, and other compounds may induce hepatic AP. Increased osteoblastic activity in hyperparathyroidism, bone healing, or osteosarcoma may elevate AP. Alkaline phosphatase is insensitive for the detection of cholestasis in ruminants because of the wide variation in the normal activity of this enzyme.

Gamma glutamyltransferase (GGT) is found in many cells; however, the renal convoluted tubular epithelium, canalicular surfaces of hepatocytes, and bile-duct epithelium contain the highest activity. In renal disease GGT is excreted in the urine. Serum GGT is generally of hepatic origin and is elevated during cholestasis. GGT is more sensitive than AP for the detection of cholestatic disease in horses, cattle, sheep, and pigs. Increased serum GGT activity proved to be a sensitive and long-lived indicator of liver insult in cattle exposed to moldy hay (Casteel *et al.*, 1995). Like alkaline phosphatase, GGT appears in serum as a result of increased synthesis, rather than as a result of leakage from cells (Pearson, 1990).

In acute hepatic injury ALT and AST are generally elevated and AP may be normal. In chronic disease with cholestasis AP and GGT often are elevated and ALT and AST may be normal or only slightly elevated (Cornelius, 1989).

High activity of sorbitol dehydrogenase (SDH) is found in hepatocellular cytoplasm. The plasma half-life of this enzyme is very short and serum activities may return to normal within 5 days of hepatocellular insult.

Lactate dehydrogenase (LDH) is a tetrameric enzyme with five isoenzymes that catalyze the reversible conversion of L-lactate to pyruvate in all tissues. All LDH isoenzymes are found in varying concentrations in all tissues. LDH_1 is the principal isoenzyme in cardiac muscle and kidney of most species. It is also found in the liver of cattle and sheep. Unlike the other isoenzymes, it is heat stable at 65°C for 30 minutes. LDH is the principal isoenzyme in skeletal muscle and erythrocytes. Serum LDH activity is tissue nonspecific; however, necrosis of muscle, liver, and hemolysis are the major causes of elevations.

Bilirubin is derived from destruction of damaged or senescent erythrocytes by macrophages of the spleen liver, and bone marrow. It is noteworthy that bilirubin at physiologic levels is an antioxidant (Stocker *et al.* 1987). Bilirubin is transported in plasma bound to proteins (albumin, globulin). Hepatic uptake and glucuronide conjugation renders it water soluble. Conjugated bilirubin is secreted into bile canaliculi and transported to the intestine, where the majority is transformed into urobilinogen by intestinal flora and excreted. Direct diazo assay for bilirubin detects conjugated bilirubin. Total bilirubin is measured after addition of alcohol, which allows additional color development. Unconjugated bilirubin is determined by the difference in direct and total bilirubin. Cholestasis results in conjugated hyperbilirubinemia. Bilirubinuria may occur because of "regurgitation" of conjugated bilirubin. Increased AP or GGT precedes hyperbilirubinemia in most species. Hemolysis may result in unconjugated hyperbilirubinemia and elevations of LDH_5.

Sulfobromophthalein (BSP) injected intravenously is removed rapidly from the blood, conjugated by hepatocytes, and excreted in bile. The rate of hepatic blood flow, functional hepatic mass, and patency of the biliary system affect hepatic clearance of this compound. Altered blood flow secondary to cardiotoxicity discussed later may increase BSP retention.

Acute toxic hepatic necrosis increases serum bile acids (cholic and chenodeoxycholic) in the dog, horse sheep, and cow.

Ammonia is generated by microbial activity within the intestinal tract. It is absorbed from the intestine and transported to the liver by the portal venous system, where it is converted to urea by the healthy liver Elevations of plasma ammonia during fasting or following ammonia challenge suggests reduction in functional hepatic mass.

Severe hepatic insufficiency may result in hypoproteinemia (Kaneko, 1989a) with reduction of plasma oncotic pressure that promotes tissue edema and effusions which mimic the effects of cardiotoxins.

The clinical signs of acute submassive or massive hepatic necrosis may include anorexia, vomiting, icterus, hepatic encephalopathy, disseminated intravascular coagulopathy, edema, and effusions. Surprisingly, there may be few or no clinical signs in some cases. The activity of ALT and SDH with short half-lives may be elevated, but often fall rapidly. Inducible enzymes such as AP and GGT may increase gradually

All enzymes may return to normal in the presence of chronic severe liver disease. Hyperbilirubinemia may follow if lesions progress to chronicity and fibrosis.

Chronic hepatotoxicity has sequelae for most organ systems, but especially the nervous (hepatic encephalopathy), integumentary (secondary photosensitization in herbivores), and cardiovascular systems. Cardiotoxins and pneumotoxins may produce enzyme elevations suggestive of hepatic or renal disease due to ischemia/hypoxia.

Ingestion of toxic plants (Table 28.1) tends to be more common in herbivores than carnivores; however, nonherbivorous species are often susceptible if they are willing to ingest them. In addition to hepatotoxins, the blue-green algae (actually classified as cyanobacteria) that contaminate water (Carmichael, 1994) possess neurotoxins that may induce sudden death before any alterations in clinical biochemistry or morphologic changes.

Hepatotoxic plants of the order Compositae include *Asaemia axillaris, Athanasia trifurcata, Helichrysum blandowskianum, Lasiospermum bipinatum,* and *Xanthium* spp. The toxin in these plants has been identified as carboxyatractyloside.

Cycadales contain methylazoxymethanol, which is converted by hepatic microsomal activity to potent alkylating agents.

Hepatotoxic plants of the order Myoporaceae include *Myosporum deserti, M. acuminatum, M. insulare, M. tetramdum,* and *M. laetum.* These plants contain furanosesquiterpenoid oils, the best characterized of which is ngaione.

Chronic intoxication of swine with fumonisins, mycotoxins produced by *Fusarium moniliforme,* is associated with elevations of serum total bilirubin, AP, AST, GGT, and cholesterol (Casteel *et al.,* 1994b). In addition, fumonisins inhibit *N*-acetyl transferase, resulting in loss of complex sphingolipids and accumulation of sphinganine and sphingosine in tissues and serum (Riley *et al.,* 1993).

Iron toxicity from nutritional supplements may produce hepatic necrosis in foals (Acland *et al.,* 1984) and pigs (Kelly, 1993).

Hepatotoxic pyrrolizidine alkaloids are found in the plant species *Amsinckia intermedia, Crotolaria* spp., *Cynoglossum officinale, Echium plantagineum, Heliotropium europeaum, Senecio jacobea, S. vulgaris,* and *S. longilobus.*

Hepatotoxic Solanaceae include *Cestrum parqui, C. laevigatum,* and *C. aurantiacum.* The toxin in these plants has been identified as atractyloside.

Sawfly larvae (*Lophyrotoma interruptus* and *Arge pullata*) infesting eucalyptus and birch trees in Australia and Denmark, respectively, have been reported to induce hepatic necrosis in cattle, sheep, and goats browsing foliage.

Terminalia oblongata, the yellow-wood tree of Australia, contains hepatotoxic tannins and pucicalagin, which induces acute hepatic necrosis (Kelly, 1993).

II. NEPHROTOXICITY

Acute nephrotoxicity (Table 28.2) may initially induce polyuria that is followed by oliguria or anuria. Nephrotoxins affecting approximately 66% of the nephrons will result in inability to concentrate urine to a specific gravity greater than 1.030 in the dog, 1.035 in the cat, and 1.025 in the horse and cow. Chronic toxicity may result in isosthenuria (constant urine osmolality in the range of glomerular filtrate, 1.008–1.012).

The majority of urea is synthesized in the liver from ammonia formed by protein catabolism or intestinal absorption. Urea enters the vascular system and is distributed throughout the total body water compartment by passive diffusion. The urea concentrations of blood and glomerular filtrate are approximately equal. Urea passively diffuses from the tubular lumen back to the blood. Urine flow rate is inversely related to urea reabsorption. Gastrointestinal secretion is inconsequential in monogastrics; however, in ruminants up to 90% of urea in glomerular filtrate may be reabsorbed and enter the rumen via saliva for utilization in amino acid synthesis.

Azotemia, elevation in blood urea nitrogen (BUN) may occur as prerenal, renal, or postrenal. Prerenal azotemia may result from increased protein catabolism (e.g., hepatotoxins, myotoxins, other necrosis) or decreased renal perfusion (e.g., cardiotoxins). Renal azotemia occurs only after approximately 75% of the nephrons have lost function.

Renal disease also results in elevation of serum creatinine. The majority of serum creatinine originates from the endogenous conversion of phosphocreatine in muscle, which occurs at a relatively constant rate. Creatinine is not reutilized. The creatinine pool is modified by muscle mass, conditioning, and muscle disease. Creatinine also is distributed throughout the compartment of total body water. It diffuses more slowly than urea, however, and is not reabsorbed within the tubules after leaving as glomerular filtrate. Creatinine concentration is not affected significantly by diet, protein catabolism, or urinary flow. Reduced renal perfusion affects BUN and creatinine similarly (Finco, 1989). Elevations of BUN and creatinine are not proportional in renal disease of ruminants because of reutilization of urea by the rumen.

TABLE 28.2 Nephrotoxins[a]

Nephrotoxin	Disease onset	Geography	Species affected
Amaranthus retroflexus (pigweed)	Subacute	US	B, P
Antibiotics	Acute to chronic	Worldwide	All
Cantharidin (blister beetle)	Acute	US	B, Cp, E, O
Chlorinated hydrocarbons	Acute	Worldwide	All
Ethylene glycol	Acute	Worldwide	B, Cn, F, P
Fumonisin (*Fusarium moniliforme*)	Acute to chronic	Worldwide	E, O, P
Gossypol (cottonseed)	Chronic	Worldwide	B
Hemoglobin	Acute		All
Hypercalcemia	Chronic	Worldwide	All
Isotropis spp.	Acute	AUS	B, O
Lantana camara	Chronic	US, MEX, AUS, AFR	B, E, O
Menadione	Acute	Worldwide	E
Metals (Cd, Hg, Pb, Tl)	Acute to chronic	Worldwide	All
Myoglobin	Acute		All
Ochratoxin (*Penicillium ochraceus*)	Chronic	Worldwide	P
Oxalates	Acute to chronic	Worldwide	B, Cp, O, P
Paraquat/diquat	Acute	Worldwide	All
Petroleum	Acute	Worldwide	All
Phenothiazine	Acute	Worldwide	E
Phenylbutazone	Acute	Worldwide	E
Phosphorus	Acute	Worldwide	All
Pyrrolizidine alkaloids	Chronic	Worldwide	B, Cp, E, O, P
Tannins (*Quercus* spp., oaks)	Acute	Worldwide	B, Cp, E, O
Terminalia oblongata (yellow-wood)	Acute to chronic	AUS	B, O

[a] B, bovine; Cn, canine; Cp, caprine; E, equine; F, feline; O, ovine; P, porcine.

The heat stable LDH_1 isoenzyme discussed earlier may be elevated in renal disease.

Hyperkalemia may occur in renal failure with oliguria or anuria and acidosis. Hypercalcemia is common in equine renal disease, whereas hypocalcemia and hypochloridemia are common in bovine renal disease.

Proteinuria in the absence of occult blood and cellular sediment is suggestive of renal disease. Glomerular lesions typically result in high protein levels in which albumin is the major constituent. Tubular disease, typical of many nephrotoxins, generally results in lower protein levels containing high levels of globulins. Hypoproteinemia secondary to chronic urinary loss (Kaneko, 1989a) promotes tissue edema and effusions that may mimic cardiotoxicity and hepatotoxicity, as discussed previously.

Bilirubin is considered to be mildly nephrotoxic. Bilirubinuria may occur due to "regurgitation" of conjugated bilirubin resulting from cholestatic hepatotoxins. Myoglobin is also nephrotoxic. Myoglobinuria may occur with toxic necrosis of skeletal and cardiac muscle. Hemoglobin appears to be nephrotoxic in the presence of concurrent dehydration or hypovolemia. Hemoglobinuria may occur with hemolytic toxins.

Dehydration exacerbates the nephrotoxicity of many agents, especially antibiotics in all species and nonsteroidal anti-inflammatory drugs (phenylbutazone) in the horse. Nephrotoxic antibiotics include the aminoglycosides (amikacin, gentamicin, kanamycin, neomycin, streptomycin, and tobramycin), amphotericin B, cephalosporins, polymixins, sulfonamides, and tetracyclines (Maxie, 1993). Elevation of GGT in urine is a sensitive indicator of aminoglycoside toxicity (Gossett *et al.*, 1987).

Hypercalcemia and hyperphosphatemia may result in nephrocalcinosis following iatrogenic hypervitaminosis D or ingestion of cholecalciferol rodenticide (Fooshee and Forrester, 1990) by any species. Ingestion of the toxic plants containing vitamin D-like analogs, including *Cestrum diurnum*, *Dactylis glomerata*, some *Solanum* species, and *Trisetum flavescens*, by herbivores

also may produce hypercalcemia with calcification of soft tissues, including the kidney.

Nephrotoxic metals include arsenic, bismuth, cadmium, lead, mercury, and thallium (Maxie, 1993).

Plants containing toxic concentrations of soluble oxalates include the species *Amaranthus retroflexus* (pigweed), *Halogeton glomeratus*, *Oxalis* spp., *Rheum rhaponticum* (rhubarb), and *Sarcobatus vermiculatus* (greasewood). Intoxication with ethylene glycol from antifreeze is one of the more common accidental or malicious poisonings encountered in dogs and cats. Birefringent hippurate and oxalate crystals may be observed in urine sediments (Kramer *et al.*, 1984).

Nephrotoxic pyrrolizidine alkaloids include the plant species listed in Section I on hepatotoxicity.

Trees of the genus *Quercus* (oaks) and *Terminalia oblongata* (yellow-wood tree) contain tannins that induce acute tubular necrosis when leaves, buds, or acorns are ingested. *Amaranthus retroflexus* (pigweed), via an unidentified toxic principle, also induces similar renal disease in cattle (Casteel *et al.*, 1994a) and pigs (Osweiler *et al.*, 1969) in the absence of oxalate nephrosis. At postmortem examination, there were consistent elevations of urea and creatinine concentrations in ocular fluid and serum.

III. TOXINS AFFECTING SKELETAL AND CARDIAC MUSCLE

The clinical signs of weakness, dysmetria, and incoordination suggest not only the possibility of neurologic disease, but also skeletal muscular or cardiovascular disease. Acute toxicity of skeletal or cardiac muscle (Table 28.3) can be detected by elevations in serum creatine (phospho)kinase [C(P)K] (Cardinet, 1989). This dimeric enzyme catalyzes the reversible reaction phosphocreatine + ADP ⇆ creatine + ATP and has three isoenzyme types, CK_1, CK_2, and CK_3. CK_1 is found in brain, peripheral nerves, cerebrospinal fluid, and viscera, but is not found in serum during neurologic disease. CK_2 is found in cardiac muscle and in minute amounts in skeletal muscle. CK_3 is found in cardiac and skeletal muscle. CK plasma half-life is short and is considered to be specific for muscle when hemolysis, elevated bilirubin, muscle fluid contamination during venipuncture, and dilution of CK inhibitors during sample processing can be excluded. When injury is not progressive CK elevations maximize within 6–12 hours and return to normal within 24–48 hours. Continuing necrosis results in persistent elevation.

As discussed previously, LDH_5 is the principal isoenzyme in skeletal muscle and erythrocytes. LDH activity is tissue nonspecific, but muscle and liver necrosis and hemolysis are the major sources for elevations of serum activity. In muscle necrosis elevation of serum LDH activity is of lower magnitude, parallels CK elevation, and peaks with 48–72 hours. Elevation of serum AST occurs more slowly than that of CK or LDH and may persist for several days after cessation of muscle injury.

Necrosis of skeletal muscle may result in release of myoglobin and potassium, resulting in myoglobinemia and hyperkalemia. Myoglobinuria, detectable by urinalysis, may induce secondary nephrotoxicity.

Cardiac glycosides disrupt cardiac ion channels producing sudden dysrhythmias and often death (Cheville, 1988). Plants containing cardiac glycosides include *Bryophyllum tubiflorum*, *Digitalis* spp. (foxglove) *Homeria* spp. (cape tulip), *Nerium oleander* (oleander) *Thevetia peruviana* (yellow oleander), and *Tylecodon* spp. (Robinson and Maxie, 1993). Most intoxications occur in herbivores. Amphibians producing cardiac glycosides include *Bufo alvarius*, *B. marinus*, and *Dendrobates* spp. (poison dart frog). Most intoxications occur in cats and dogs that become curious about these animals.

Fluoroacetate containing plants include *Acacia georginae*, *Dichapetalum cymosum*, *Gastrolobium* spp., and *Oxylobium* spp. Fluoroacetate (compound 1080) also has been utilized as a rodenticide. It is not directly toxic, but combines with oxaloacetic acid to form fluorocitrate, which inhibits *cis*-aconitase and succinic dehydrogenase of the citric acid cycle, thus reducing ATP generation.

Glycosides and fluoroacetate may produce sudden death that precedes alterations of clinical chemistry or morphologic changes.

Hypercalcemia may induced cardiac calcinosis and nephrotoxicity, as discussed earlier.

Hyperkalemia from myotoxicity (especially gossypol)(Albrecht *et al.*, 1969), nephrotoxicity, or adrenal necrosis (hypoaldosteronism) may exert a dysrhythmogenic (Q–T prolongation and high-amplitude T waves) effect upon the heart. Potassium chloride injection also has been used for lethal poisoning by individuals attempting to circumvent detection by insurance adjusters (Casteel *et al.*, 1989).

Cardiotoxic metals include lithium, cadmium, nickel, barium, lanthanum, manganese, vanadium, lead, and cobalt (Van Vleet and Ferrans, 1986). Iron dextran toxicity in pigs may produce necrosis of skeletal muscle and hyperkalemia, sparing the myocardium (Kelly, 1993).

Quinolizidine alkaloids in *Lupinus* spp., *Laburnum anagyroides*, and *Thermopsis montana* have been shown to produce skeletal muscle necrosis in cattle with elevations of serum CK and AST in the absence of myoglob

TABLE 28.3 Toxins Affecting Cardiac and Skeletal Muscle[a]

Toxins	Disease onset	Geography	Species affected
Cardiac glycosides	Acute	Worldwide	All
Cassia occidentalis (coffee senna)	Acute	Worldwide	B, Cp, O, P

nuria (Keeler and Baker, 1990). Quinolizidine alkaloids are also teratogenic.

The numerous chemotherapeutic agents that have been associated with cardiotoxicity have been reviewed elsewhere (Van Vleet and Ferrans, 1986).

Cardiotoxins may produce serum enzyme elevations suggestive of hepatic or renal disease secondary to ischemia/hypoxia.

IV. TOXINS AFFECTING THE LUNG AND RESPIRATORY TRACT

Disease affecting the respiratory tract is often clinically apparent on the basis of dyspnea. Dyspnea in veterinary medicine is more often the result of pneumonia rather than intoxication. However, when body temperature is normal, the possibility of pulmonary edema induced by toxins affecting the lung and respiratory tract (Table 28.4) or cardiovascular system should be considered. Since, with the exception of the horse, domestic mammals remove excess heat by panting, reduced respiratory capacity secondary to intoxication also may result in elevated body temperature.

Angiotensin-converting enzyme (ACE) is concentrated on the luminal surface of pulmonary endothelial cells. Most circulating ACE originates from the lung; however, many tissues including tubular epithelial and endocrine cells contain this enzyme (Erdos, 1987). Serum ACE activity is altered in chronic and acute pulmonary disease (Hollinger, 1983). Unfortunately, assays for this enzyme are not readily available in most veterinary clinical biochemistry laboratories, and ACE remains primarily a research tool.

Acute pulmonary edema is the typical lesion resulting from toxins affecting the epithelial–endothelial interface of the alveolus. Because CO_2 is approximately 20 times more diffusible than O_2, early pulmonary edema typically results in decreased p_aO_2, while p_aCO_2 remains normal or may decrease with hyperventilation, producing respiratory alkalosis. Severe pulmonary edema may result in elevated p_aCO_2 (hypercapnia and respiratory acidosis) (Carlson, 1989).

Chronic insult to the alveolar epithelial–endothelial interface may progress to pulmonary fibrosis (e.g.,

TABLE 28.4 Toxins Affecting the Lung and Respiratory Tract[a]

Toxins	Disease onset	Geography	Species affected
Eupatorium adenophorum	Chronic	AUS	E
Fumonisin (*Fusarium moniliforme*)	Acute to chronic	Worldwide	P

Pyrrolizidine alkaloids	Chronic	Worldwide	B, Cp, E, O, P

[a] B, bovine; Cn, canine; Cp, caprine; E, equine; F, feline; O, ovine; P, porcine.

paraquat intoxication) and be associated with low p_aO_2 and elevated p_aCO_2. Pulmonary fibrosis impinging upon the pulmonary vasculature may induce pulmonary hypertension and cor pulmonale associated with enzymologic alterations suggestive of hepatoxicity due to passive hepatic congestion.

Cattle are susceptible to several toxins that induce acute pulmonary edema, including ingestion of perilla ketone in *Perilla frutescens*, 4-ipomeanol in sweet potatoes (*Ipomoea batatas*) infected with *Fusarium solani* (Doster *et al.*, 1978), and the generation of 3-methylindole by ruminal *Lactobacillus skatoli* from tryptophan in lush pasture grasses (Breeze and Carlson, 1982).

Some of the pyrrolizidine alkaloids, notably monocrotaline from *Crotolaria spectabilis*, may induce chronic pulmonary arteriopathy resulting in pulmonary hypertension that progresses to right heart failure and elevation of enzymes suggestive of cardiotoxicity or hepatotoxicity. Similar pulmonary arteriopathy occurs in pigs with chronic fumonisin intoxication (Casteel *et al.*, 1994b).

Organochlorines and organobromines include chlorinated naphthalenes, polychlorinated biphenyls (PCBs), polybrominated biphenyls (PBBs), and dibenzofurans. These industrial toxins are cumulative and result in hypovitaminosis A that is associated with squamous metaplasia of columnar epithelium of the respiratory tract and hyperkeratosis, as discussed under integumentary toxins.

The numerous chemotherapeutic agents that have been associated with pulmonary toxicity or hypersensitivity have been reviewed elsewhere (Myers, 1993).

V. TOXINS AFFECTING THE GASTROINTESTINAL TRACT

Disease affecting the gastrointestinal tract is ofte clinically apparent on the basis of vomiting or diarrhe In veterinary medicine these are more often the resu of infectious disease rather than intoxication. Howeve the possibility of gastrointestinal toxins (Table 28.! should be considered, especially in acute outbreal affecting several animals sharing the same env ronment.

Vomiting and diarrhea may produce dehydratic that results in mild to moderate elevations of BU plasma protein, packed cell volume (PCV), and urir specific gravity. BUN elevations are usually of less magnitude than those encountered in nephrotoxicit

Metabolic alkalosis (increased pH, normal or i creased pCO_2, increased HCO_3^- and HCO_3^-/H_2CO_3) an hypochloridemia may result from chloride loss assoc ated with vomiting (Tennant and Hornbuckle, 1989

Metabolic acidosis (decreased pH, normal or d creased pCO_2, decreased HCO_3^- and HCO_3^-/H_2CO may result from secretory loss of bicarbonate in d arrhea.

In the absence of evidence of malnutrition, hepati or renal disease, chronic gastrointestinal malabsor tion or protein loss should be considered as a potenti cause of hypoproteinemia (Kaneko, 1989a).

Peracute intestinal toxicity, such as inorganic arsen ingestion, may result in transient elevations of s rum AP.

Ingestion of strong acids or alkalis may induce in mediate and severe damage to the gastrointestin mucosa.

TABLE 28.5 Toxins Affecting the Gastrointestinal Tract[a]

Toxins	Disease onset	Geography	Species affected
Acids/alkalis	Acute	Worldwide	All
Aleurites fordi (Tung oil tree)	Acute	AUS, US	B

Tannins (*Quercus* spp., oaks)	Acute	Worldwide	B, Cp, O
Trichothecenes	Acute	Worldwide	All
Urginea maritima (sea onion)	Acute	Worldwide	Cn, F, P
Zearalenone (*Fusarium roseum*)	Chronic	Worldwide	P
Zinc	Acute	Worldwide	B, Cn, O

[a] B, bovine; Cn, canine; Cp, caprine; E, equine; F, feline; O, ovine; P, porcine.

The seleniferous plants that may be associated with acute gastroenteritis in herbivores are discussed under the integumentary system.

Trichothecenes, especially T-2, produced by *Fusarium* spp., and the macrocyclic trichothecene produced by *Stachybotrys alternans*, are highly irritant and produce acute ulceration and hemorrhage of the gastrointestinal tract. These mycotoxins also produce acute ulcerative and necrotizing lesions of the skin and chronic pancytopenia with hemorrhage.

The estrogenic mycotoxin zearalenone may induce rectal prolapse in pigs in addition to affecting reproductive performance.

VI. TOXINS AFFECTING ERYTHROCYTES AND THE HEMATOPOIETIC SYSTEM

Toxins inducing hemolysis (Table 28.6) may produce elevations of serum LDH, anemia, icterus, hemoglobinemia, hemoglobinuria with secondary nephrotoxicity, and unconjugated bilirubinemia.

Chronic, drug-induced, immune-mediated hemolysis has been associated with *para*-aminosalicylic acid, chlorpromazine, dipyrine, insecticides, penicillin, phenacetin, quinine, quinidine, and sulfonamides (Valli, 1993).

Mellitin is a hemolyzing component of hymenopterous toxins and comprises approximately 50% of bee venom (Cheville, 1988).

Chronic nephrotoxicosis leading to uremia may result in hemolysis due to retention of creatinine and guanidinosuccinic acid. This mechanism is usually insufficient to produce acute hemolytic crises, but may result in anemia due to increased erythrocyte destruction.

The anthelmintic phenothiazine may be acutely hemolytic in sheep and horses. It also may induce primary photosensitization as discussed under integumentary toxins.

The venom of various snakes, including the Crotalidae, Elapidae, Hydrophidae, and Viperidae, contains a mixture of toxins of which phospholipase A_2 (PLA_2) is an important component. PLA_2 is directly lytic for

TABLE 28.6 Toxins Inducing Hemolysis[a]

Toxins	Disease onset	Geography	Species affected
Allium spp. (onion)	Acute	Worldwide	B, Cn, E, O

Zinc	Acute to chronic	Worldwide	B, Cn, O, P

[a] B, bovine; Cn, canine; Cp, caprine; E, equine; F, feline; O, ovine; P, porcine.

erythrocytes and may induce hemolysis, and for platelets and may induce hemorrhage and coagulopathy (Cheville, 1988).

Additional toxins inducing hemorrhage (Table 28.7) include dicumarol derived from moldy sweet clover (*Melilotus* spp.) and the synthetic derivatives used as anticoagulant rodenticides, such as brodifacoum, bromadiolone, diphacinone, fumarin, pindone, and warfarin. These agents are vitamin K antagonists. Prothrombin (factor II), and factors VII, IX, and X require vitamin K for their production. The half-life of factor VII is approximately 4–6 hours, whereas half-lives of factors IX and X are approximately 14–18 hours, and that of prothrombin is 40 hours. Therefore, prolongation of the one-stage prothrombin time (PT) occurs earliest, followed by prolongation of the activated partial thromboplastin test (PTT). Vitamin K antagonists do not affect fibrinogen or platelet numbers initially, but may eventually result in exhaustion of their supplies. Excessive hemorrhage following slight trauma, epistaxis, melena, and hematuria may occur with these intoxications (Dodds, 1989).

Reduced synthesis of antithrombin III and antiplasmin in acute hepatotoxicity may promote thrombosis followed by unchecked fibrinolysis with generation of fibrin split products that interfere with platelet function.

Chronic hepatotoxicity in which hepatic mass is reduced by 70% or more may result in sufficiently inadequate synthesis of both clotting factors and their inhibitors to prolong PT and PTT. Chronic cholestasis with interruption of the enterohepatic circulation of bile salts also may result in malabsorption of fat-soluble vitamin K, producing a syndrome similar to anticoagulant intoxication.

Toxins inducing pancytopenia include estrogen, *Pteridium aquilinum* (bracken fern), and the trichothecene mycotoxins. Insufficient numbers of platelets

TABLE 28.7 Toxins Inducing Hemorrhage/Coagulopathy[a]

promote hemorrhage and consumption coagulopathy (Valli, 1993).

VII. TOXINS AFFECTING HEMOGLOBIN AND OXIDATIVE METABOLISM

Lead poisoning interrupts heme synthesis at the level of formation of protoporphyrin and causes accumulation of delta-aminolevulinic acid. Increased urinary excretion of this metabolite is an indication of lead intoxication.

Toxins inducing oxidation of ferrous iron in hemoglobin to ferric iron in methemoglobin (Harvey, 1989) include the herbicide sodium chlorate, the stalk parts of nitrate-accumulating plants such as corn and wheat, hay grown on heavily fertilized soils under drought conditions, fertilizer, or water contaminated by fertilizers or organic material. Ruminants are most susceptible to the nitrate-accumulating plants *Amaranthus* spp. (pigweed), *Avena sativa* (oats), *Chenopodium* spp. (lambsquarter), *Sorghum* spp., and *Triticum aestivum* (wheat) because of the ability of rumen microbes to reduce nitrate to the proximate toxicant, nitrite. Monogastrics and ruminants are equally susceptible to nitrite-based fertilizers (Osweiler *et al.*, 1985). Nitrate/nitrite intoxication produces a brown discoloration of the blood due to methemoglobinemia.

Carbon monoxide (CO) competes with oxygen binding to the heme moiety in hemoglobin and myoglobin. CO affinity for the hemoglobin binding site is approximately 200 times that of O_2, resulting in tightly bound carboxyhemoglobin and decreased blood oxygen transport. Because continuous delivery of O_2 is critical to the heart and brain, carbon monoxide may induce signs of cardiotoxicity or neurotoxicity. Anoxia of the liver, kidney, and muscle may produce elevations of serum enzymes referable to these systems.

CO, cyanide, and H_2S are potent inhibitors of cytochrome oxidase and may produce sudden death due to failure of oxidative metabolism that precedes alterations in clinical biochemistry or morphology.

There are numerous plants containing cyanogenic glycosides that may affect herbivores, especially ruminants. The most common cultivated species include *Cynodon* spp., *Sorghum* spp., and *Prunus* spp. (Jubb and Huxtable, 1993).

VIII. TOXINS AFFECTING THE ENDOCRINE SYSTEM

Carbadox/Mecadox is an antibacterial agent that, with prolonged exposure at levels greater than 25 ppm, induces degeneration of the zona glomerulosa of the adrenal gland associated with reduced plasma aldosterone, hyperkalemia, and hyponatremia (Capen, 1993).

The drug *ortho-,para'*-2,2-bis(2-chlorophenyl-4-chlorophenyl)-1,1-dichloroethane (*o,p'*DDD) is toxic to the zonae fasciculata and reticularis of the adrenal gland and is used as therapy for canine hyperadrenocorticism. This toxin reduces circulating cortisol levels.

Goitrogenic substances induce iodine deficiency or inhibit organification of iodine (Kaneko, 1989b). Thiocyanates, produced by ruminal digestion of cyanogenic glycosides from the toxic plants *Cynodon* spp. and *Trifolium repens*, and goitrin, derived from *Brassica* spp., are goitrogenic. Mimosine (discussed later under integumentary toxins) is metabolized in the rumen to a compound that inhibits organic binding of iodine by the thyroid gland. Thioamides (sulfonamides) inhibit thyroperoxidase. All of these substances may reduce serum T_4 and T_3. Iodine toxicity producing hyperplastic goiter in horses has been associated with feeding kelp.

Hepatic glucuronidation is the rate-limiting step for biliary excretion of T_4. Sulfation by phenol sulfotransferase is the rate-limiting step for excretion of T_3. Induction of hepatic microsomal enzymes may increase T_4/T_3 elimination and disrupt the hypothalamic–pituitary–thyroid axis, resulting in excessive thyroid-stimulating hormone (TSH). Xenobiotics that induce hepatic microsomal enzymes include benzodiazepines, calcium channel blockers, chlorinated hydrocarbons, phenobarbital, PCBs, PBBs, retinoids, and steroids (Capen, 1993).

Toxins inducing hypercalcemia are discussed in the section on nephrotoxicity. Certain species of the Solanaceous produce toxins that may induce chronic atrophy of parathyroid chief cells. Chronic nephrotoxicity, especially in the dog, may result in hypocalcemia and hyperphosphatemia, which stimulates excessive production of parathyroid hormone. Impaired intestinal absorption of calcium and increased mobilization from the skeleton also may occur secondary to insufficient renal production of 1,25-dihydroxycholecalciferol by the kidney (Capen, 1993).

Vicia villosa (hairy vetch) produces angiocentric eosinophilic granulomatous inflammation of the skin, myocardium, kidney, lymph nodes, thyroid, and adrenal glands. The mechanism is unknown. Biochemical alterations suggestive of cardiotoxicity, nephrotoxicity, and depression of serum thyroxine and cortisol levels may occur.

IX. TOXINS AFFECTING THE NERVOUS SYSTEM

Many acute and chronic neurotoxins (Table 28.8) produce illness or death without alterations detectable by routine clinical biochemistry performed on blood

TABLE 28.8 Toxins Affecting the Nervous System[a]

Toxins	Disease onset	Geography	Species affected
Asclepias spp. (milkweed)	Acute	N AM	All
Aspergillus clavatus	Acute	UK, S AFR	B, O
CO	Acute	Worldwide	All
Centaurea spp.	Chronic	US	E
Cyanide	Acute	Worldwide	All
Cycadales	Chronic	AUS, DOM REP, US	B
Eupatorium rugosum (white snakeroot)	Acute to chronic	US	B
Fluoroacetate	Acute	AUS, S AFR	B, Cn, Cp, F, O
Fumonisin (*Fusarium moniliforme*)	Chronic	Worldwide	E
Hepatic encephalopathy	Chronic		All
Hexachlorophene	Chronic	Worldwide	All
Halogenated salicylanilide	Chronic	Worldwide	Cp, O
Helichrysum spp.	Acute to chronic	AUS, S AFR	B, Cp, O
Karwinskia humboldtiana (coyotillo)	Chronic	US	All
Kochia scoparia (fireweed)	Chronic	US	B
Lead	Chronic	Worldwide	All
Lolium perenne (perennial ryegrass)	Acute	Worldwide	B, E, O
Nitrate/nitrite	Acute	Worldwide	B, Cp, O
Organophosphates	Acute to chronic	Worldwide	All
Phalaris	Chronic	AUS, NZ, S AFR, US	B, O
Renal encephalopathy	Chronic		All
Selenium	Acute to chronic	Worldwide	P
Solanum spp.	Chronic	Worldwide	B
Strychnine	Acute	Worldwide	All
Stypandrol	Acute to chronic	ASIA, AUS	B, Cp, O
Swainsonine	Chronic	AUS, N AM	B, Cp, E, O
Thiaminase	Chronic	Worldwide	B, Cn, E, F, O
Trachyandra spp.	Chronic	AUS, S AFR	Cp, E, O, P

[a] B, bovine; Cn, canine; Cp, caprine; E, equine; F, feline; O, ovine; P, porcine.

or serum. Protein, AST, LDH, and CK_1 may be elevated in cerebrospinal fluid samples (Feldman, 1989).

Accumulations of endogenous toxins secondary to hepatotoxicity and nephrotoxicity may produce neurologic dysfunction. Conversely alterations that mimic hepatotoxicity, nephrotoxicity, and muscle, respiratory, and gastrointestinal toxicity may occur secondary to ischemia/anoxia from depression of cardiopulmonary centers, or by affecting sympathetic/parasympathetic balance.

Increased urinary excretion of delta-aminolevulinic acid is a potential indicator of lead intoxication.

Organophosphates induce cholinesterase inhibition, which can be detected as reduction of plasma or whole blood cholinesterase activity.

Subacute selenium intoxication in pigs exposed to complete rations containing 9.7–27 ppm selenium for 45 days is manifested as a central nervous system disor der characterized initially by hindlimb ataxia progress ing to posterior paralysis. The clinical syndrome i associated with focal symmetrical poliomyelomalaci of the ventral horns of the cervical and lumbosacra intumescences (Casteel *et al.*, 1985). Hoof separation a the coronary band also occurs. The clinical pathologi alterations are consistent with dehydration from inabi ity to reach water sources. Iatrogenic disease in the do may result from parenteral administration of seleniur preparations (Turk, 1980).

Solanum kwebense, *S. dimidiatum*, and *S. fastigiatu* produce neuronal vacuolation resembling a lysosoma storage disease. The biochemical basis of this lesio is unknown.

Swainsonine is an indolizidine alkaloid produce by certain species of the plants genera *Astragalus*, *Oxy*

tropis, and *Swainsona*. This toxin inhibits lysosomal alpha-mannosidase, resulting in a lysosomal storage alteration that affects cells in many organs, but is often lethal because of its neurologic effect.

Thiaminases that may induce polioencephalomalacia in herbivores are present in *Equisetum arvense* and *Pteridium aquilinum*. Many uncooked fish species also contain thiaminase, which may produce encephalopathy affecting primarily carnivores. The coccidiostat amprolium is a thiamine antagonist that produces polioencephalomalacia in ruminants. Calves early in the course of polioencephalomalacia may have reduced blood transketolase (which requires thiamine pyrophosphate as a cofactor) and increased pyruvate (Jubb and Huxtable, 1993).

X. TOXINS AFFECTING THE INTEGUMENT

Most toxins affecting the skin (Table 28.9) will induce no or nonspecific alterations in clinical biochemistry. Fortunately, lesions are usually readily visible by physical examination.

Topical exposure to strong acids or alkalis may induce immediate and severe damage of the stratum corneum and epidermis.

Ergot and ergot-like syndromes are produced by the fungi *Claviceps purpurea* in infected rye and other cereal grains, and *Acremonium coenophilaum* in fescue and other pasture grasses. These fungi produce vasoconstrictive alkaloids that are derivatives of lysergic acid, including ergotamine, ergometrine, and ergotoxine (*C. purpurea*) and ergovaline (*A. coenophilaum*). Skin lesions are the result of ischemic necrosis that is usually most impressive in the distal extremities.

Dermatotoxic heavy metals include thallium and arsenic (Yager and Scott, 1993). Thallium is still used as a rodenticide in some countries, but is mainly of historical interest in many developed countries in which it has been banned. Thallium induces parakeratosis and alopecia. The mechanism is unknown, but is speculated to center around alteration of sulfhydryl groups in keratin. Arsenic toxicity exerts similar influences.

Mimosine is a toxic amino acid occurring in *Mimosa pudica* and *Leucaena leucocephala*. This toxin produces alopecia by mechanisms that are incompletely understood, but may involve metal chelation that inhibits metalloenzymes.

Organochlorines and organobromines include chlorinated naphthalenes, PCBs, polybrominated PBBs, and dibenzofurans. These industrial toxins are cumulative and result in alopecia, hyperkeratosis, and squamous metaplasia of columnar epithelium of the respiratory tract.

Molybdenum toxicosis results in a relative copper deficiency in cattle and sheep that produces depigmentation as a consequence of the decreased activity of tyrosinase.

Toxic photosensitization, enhanced susceptibility of the skin to actinic radiation, occurs primarily in lightly pigmented skin of herbivores and may be primary or secondary to chronic hepatotoxicity (Yager and Scott, 1993). Primary disease is due to exogenous photodynamic agents that include treatment with the anthelmintic phenothiazine and grazing of toxic plants such as *Ammi majus* (Bishop's weed, furocoumarin), *Cymopterus watsoni* (spring parsley, furocoumarin) *Fagopyrum* spp. (buckwheat, fagopyrin), *Hypericum perforatum* (St. John's wort, hypericin), and *Thamnosma texana* (Dutchmen's britches, furocoumarin).

TABLE 28.9 Toxins Affecting the Integumentary System[a]

Toxins	Disease onset	Geography	Species affected
Acids/alkalis	Acute	Worldwide	All
Ergotism	Acute to chronic	Worldwide	All
Kerosene	Chronic	Worldwide	B
Metals (As, Tl)	Chronic	Worldwide	All
Mimosine	Chronic	Worldwide	B, E, O, P
Organobromines/organochlorines	Chronic	Worldwide	All
Photosensitization, primary	Acute to chronic	Worldwide	All
Photosensitization, secondary	Acute to chronic	Worldwide	B, O
Selenium	Chronic	Worldwide	All
Trichothecenes	Acute	Worldwide	All
Vicia villosa (hairy vetch)	Chronic	Worldwide	B, E

[a] B, bovine; Cn, canine; Cp, caprine; E, equine; F, feline; O, ovine; P, porcine.

Secondary, or hepatogenous, photosensitization occurs in herbivores with diffuse liver damage that reduces the ability to excrete phylloerythrin. This photodynamic agent is formed from chlorophyll by gastrointestinal flora and is transported by the portal system to the liver where it is normally conjugated and excreted in the bile. When phylloerythrin escapes into the systemic circulation, it is poorly excreted by the kidneys and accumulates in tissues, including the skin.

Plants classified as seleniferous actively concentrate Se. Seleniferous plants can be subclassified as obligate (requiring Se) and facultative (Se not required). *Astragalus* spp. (locoweed), *Machaeranthera* spp., *Oonopsis* spp. (goldenweed), *Stanleya* spp., and *Xylorrhiza* spp. (wood aster) are obligate accumulators of selenium. These species are generally nonpalatable and are consumed only by herbivores with little other available forage. Several plants are facultative accumulators of selenium, including the genera *Aster, Atriplex, Catilleja, Gutierrezia,* and *Sideranthus,* which are more often linked with forage-associated selenium intoxication. In addition, various grasses and crops may accumulate from 1 to 25 ppm selenium when grown on seleniferous soils. The difference in selenium accumulation by these three groups is rather indistinct. Grasses are by far the most important group from the standpoint of sheer numbers of livestock affected.

Grazing of seleniferous plants may result in acute gastroenteritis, but also induces what has historically been called "alkali disease," which manifests as alopecia and dystrophic growth of the hooves, primarily in horses, cattle, and goats. There are conflicting reports regarding the hepatotoxicity, nephrotoxicity, and cardiotoxicity of selenium.

Vicia villosa (hairy vetch) produces angiocentric eosinophilic granulomatous inflammation of the skin, myocardium, kidney, lymph nodes, thyroid, and adrenal glands. The mechanism is unknown. The skin lesions are pruritic.

CHAPTER

29

Clinical Biochemistry of Laboratory Rodents and Rabbits

WALTER F. LOEB

I. INTRODUCTION

Vast numbers of clinical laboratory determinations are performed on sera and other body fluids from rodents and rabbits. The majority of these are performed in fulfillment of objectives of the research in which the animals are utilized, but others are to validate the animals' health status prior to research or occasionally as an aid in the diagnosis of spontaneous laboratory animal diseases.

To enable the results of the determinations to yield optimal and maximal information, several criteria must be met. First, the specimen, as analyzed in the laboratory, should represent the animal's status as validly as possible. Artifacts introduced by specimen collection, handling, and deterioration must be avoided. Second, the analyses performed must be appropriate to the species and the objectives of the determination. The appropriate analyte to determine may vary with the species. For example, in the guinea pig the principal glucocorticoid is cortisol, whereas in the rat and mouse it is corticosterone.

Analytes vary in turnover time with species and disease. The marked elevation of lactate dehydrogenase, isocitrate dehydrogenase, malate dehydrogenase, phosphohexose isomerase, and aspartate aminotransferase in mice infected with Riley's agent is due to impaired reticuloendothelial clearance rather than to increased release (Notkins, 1965). The structure of an analyte, particularly a protein or peptide, may vary from one species to another, which becomes a critical issue in the selection of immunoassay techniques (see Section X, Hormones).

Third, interpretation of the data must be performed with a comprehension of the physiological and pathological factors that influence the results of the analyses under consideration. Appropriate methods of quality control should be utilized to ensure the accuracy and precision of the determined values. Historical reference values appropriate to the species, breed or strain, sex, and age are particularly important when determinations are performed on individual animals for diagnostic purposes. In research studies, the principal decision-making criterion lies in the statistical significance of the difference of group means between treated and appropriate contemporary control animals, but historical reference ranges are useful as an overall quality control measure to evaluate the control animals as well as the analytic procedures (Weingand *et al.*, 1992).

This chapter covers the clinical biochemistry of the rat, mouse, hamster, gerbil, guinea pig, and rabbit and describes some unique features of each of these species. It is not intended to redundantly repeat features common to all or most mammalian species. Among laboratory rodents, rats have been most extensively investigated by the tools of clinical chemistry. Available serum volume may limit the clinical chemical determinations that can be performed on a mouse, particularly on a survival basis. This must be considered in experimental design. Lesser numbers of hamsters and rabbits are utilized in research, generally for selected applications. Guinea pigs represent such a divergence from classic phylogenic pathways that their utilization in research should be carefully evaluated (Wriston, 1984). Despite their convenient body size and pleasant temperament, they are difficult to bleed.

II. SPECIMEN COLLECTION

Blood volume in rodents and rabbits varies with species from 5 to 9% of body weight (Levine, 1995; Morton *et al.*, 1994; McLaughlin and Fish, 1994). Laboratory rats such as CD (cesarian-derived) rats of Sprague–Dawley origin are quite uniform and free from spontaneous disease. In adult rats, 1 ml of blood can be collected every 2 weeks without influencing subsequent results. Ten milliliters can be collected terminally. Mice share uniformity and quality as laboratory animals with rats; however, their small body size constitutes a distinct disadvantage to the investigator who requires repeated or multiple clinical laboratory determinations. Seventy-five microliters of blood may be collected weekly without affecting subsequent results, and approximately 1 ml may be collected terminally from a well-hydrated adult mouse by a skillful animal technician (Loeb, 1987).

Artifacts resulting from techniques of blood sampling must be avoided or minimized. Mice from which approximately 0.4 ml of blood is drawn rapidly develop a marked elevation of alanine aminotransferase, aspartate aminotransferase, and lactate dehydrogenase. This elevation persists for 48 hours. Additional serum samples drawn during this period reflect the effect produced by the prior blood collection, rather than the animal's pathophysiologic status (Goldsmith and Loeb, unpublished data, 1982).

Jugular puncture can be performed easily in rats and is particularly valuable in obtaining blood samples with minimal tissue trauma (Fig. 29.1). The rat is held on its back by an assistant, with the rat's forelegs spread on a bleeding board. The rat's head is covered with a perforated plastic hood, to prevent biting and to calm the animal, and turned to one side. The jugula vein is located in a triangle formed on the opposit side by the rat's neck and shoulder and can be ven punctured with a 23- gauge-$\frac{5}{8}$-inch needle. Three millil ters of blood can readily be collected from an adult ra without evidence of undue stress. Skilled teams of a animal technician and an assistant can bleed rats i this fashion at the rate of one every 30 seconds (Everet 1982, personal communication).

Other sites from which blood samples may be co lected, in some instances only on a terminal basis, in clude the retroorbital sinus (currently most widel used in the United States), tail vein, heart, aorta, c vena cava. A technique for collection of blood fro the tributaries of the dorsal metatarsal vein betwee the digits of the rat has been reported by Snitily *et a* (1991). In the United Kingdom, the collection of bloo from the retroorbital sinus or plexus is discourage and is only permitted terminally, under anesthesi (Morton *et al.*, 1994). The site of sampling and anesth tic agent used (or physical restraint without anesthesi may affect results. Specimens collected from the retr orbital sinus had higher creatine kinase values tha those collected from the heart or vena cava, and spec mens collected under carbon dioxide anesthesia ha higher leukocyte counts than those collected und methoxyflurane, pentobarbital, or ketamine–xylazir (Thompson, 1986; Everett and Harrison, 1983; Fried *et al.*, 1975; Suber and Kodell, 1985).

In the rabbit, blood samples are most often collecte from the ear vein. Though conveniently located, th vein is extremely small and it is difficult to obtain a adequate specimen. Jugular puncture of an anesth tized rabbit with a shaved neck may readily be pe formed, yielding a more satisfactory sample. In mic hamsters, and guinea pigs, the retroorbital sinus, hea aorta, or vena cava are most commonly used for bloo collection, the latter two only terminally. In the mous small samples may be collected by capillarity by a incision in the tail vein.

When repeated sampling over a short time perio is required, appropriate venous or arterial vascul catheters can be implanted and the catheterized anim restrained with an elastic tether. These catheters a kept full of heparinized saline between sampling an must be flushed with the animal's blood immediate prior to sampling (Bodziony and Schwille, 1985). Whe animals were caged in pairs and removed from th cage for bleeding, stress-affected analyte values suc as glucose and corticosteroids were shown to be high in the second animal bled than in the first (Dunn an Scheuing, 1971).

In collecting serum or plasma, it is essential to remo it from the erythrocytes as promptly as possible. Pr longed exposure of serum to erythrocytes results in

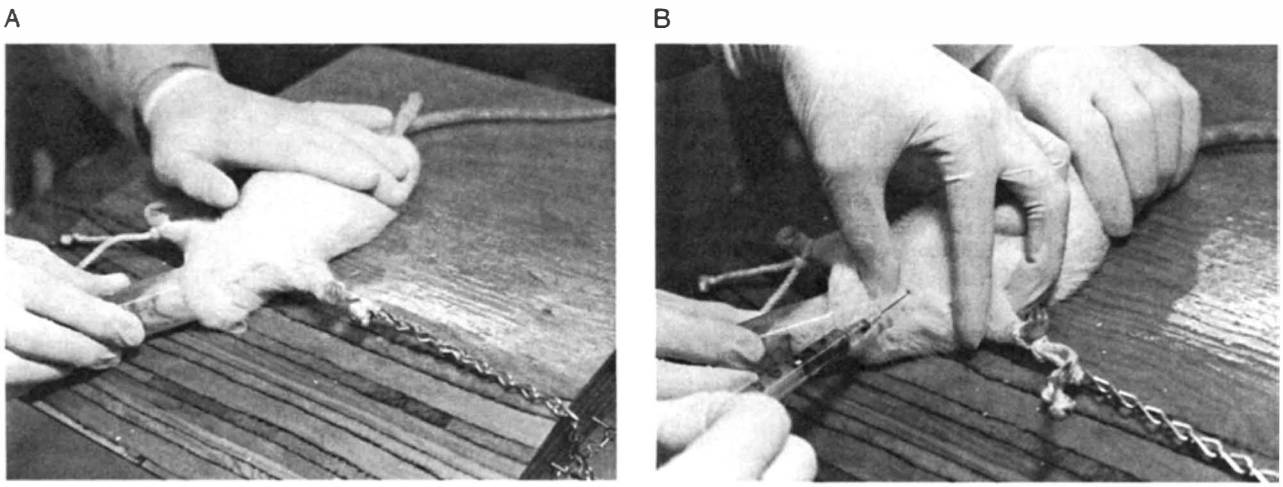

FIGURE 29.1 Technique for jugular venipuncture in the rat. (a) The rat is placed on its back on a rat board by an assistant. The forelegs are spread apart by cords hooked to pins in the sides of the board. The head is covered with a plastic hood made from the bottom of a centrifuge tube and is turned away from the technician. (b) Venipuncture is performed in the triangle formed by the rat's neck and shoulder, using a $\frac{5}{8}$-inch 23-gauge needle.

loss of glucose owing to glycolysis, elevation of lactate dehydrogenase, and, to a lesser degree, elevation of inorganic phosphorus and aspartate aminotransferase. In rodents, potassium-rich erythrocytes leak large quantities of potassium into the serum. Generally, serum should be removed from erythrocytes 20–30 minutes after blood collection. Although serum is generally used in the United States, plasma is more commonly used in Europe. This has advantages: the blood specimen may be centrifuged immediately, precluding leakage of the analytes discussed earlier and consumption of glucose, and the volume yield is better. Concentrations of analytes are generally comparable in serum or plasma, except for globulin and total protein, which are approximately 0.5 g/dl higher in plasma because of the presence of fibrinogen. The anticoagulant used must not interfere with the required analyses. Lithium heparin is generally appropriate. Slaughter and Moen (1991) recommend the use of aqueous solution of lithium heparin in preference to dry lithium heparin, particularly for blood collected from the orbital sinus.

Studies in rodents, particularly rats, have shown that 72 hours of fasting are required to achieve a nonabsorptive state similar to that achieved in dogs, rhesus monkeys, or humans in 12–24 hours (Thompson, 1986). Shorter fasts of 12, 24, or 48 hours do result in a progressive reduction in serum glucose. Overnight fasting in rats decreases the activity of alkaline phosphatase and the concentration of albumin and increases the concentration of free fatty acids, bilirubin, and bile acids. As rats, in particular, are night feeders, depriving rats of food overnight essentially eliminates food consumption for 24 hours. The decision whether or not to deprive rodents of food prior to blood sampling for clinical chemistry should be made on an individual basis depending on the objectives of the study, with the understanding that a nonabsorptive state is not achieved by overnight food deprivation. Valid comparisons can only be made if the protocol with respect to food deprivation is consistent throughout the study (Weingand *et al.*, 1992).

Knudtzon (1984) studied the effects of saline injection, feeding, fasting, transportation, immobilization, and noise on the serum glucose, insulin, glucagon, and free fatty acids of rabbits. Saline injection increased the serum glucose but did not affect the other analytes studied. Serum levels of glucose and fatty acids were elevated for 2 hours after the rabbits were transported. Bleeding the rabbits 44 ml increased all of the analytes. After 16 hours of fasting, plasma levels of glucose and insulin decreased while those of glucagon and fatty acids increased. Immobilization overnight inhibited the hypoglycemia induced by fasting. Impulse noise (96 decibels) did not affect the levels of the analytes.

III. CYCLIC BIORHYTHMS

Cyclic variations occur in the concentrations of many analytes, especially hormones, and must be taken into consideration in experimental design and the interpretation of results. Daily variation, termed circadian, is most often the result of the light–dark cycle. In rats and mice, levels of ACTH and corticoste-

rone are highest early in the dark period, falling rapidly to lowest values in the middle of the dark period (D'Agostino *et al.*, 1982; Ottenweller *et al.*, 1979). These cycles are not present at birth but develop early in life. Takahashi *et al.* (1982) have shown that either natural biological mother or foster mother rats entrain blinded rat pups with their own cycles of corticosterone, which in turn are a function of the light–dark cycle to which the mother rats have been exposed. Cycles less than a day in duration, such as the episodic secretion of growth hormone or luteinizing hormone, are termed ultradian.

In sexually mature female rats, levels of ACTH, corticosterone, and thyroxine vary with the estrous cycle and are highest during proestrus and lowest during diestrus (Buckingham *et al.*, 1978). Similar fluctuations of serum corticosterone were demonstrated in mice (Nichols and Chevins, 1981). In hamsters, both cortisol and corticosterone are present in significant concentrations. Peak levels of both hormones occur during the beginning of the dark period. Corticosterone levels are higher than cortisol in the early part of the light phase, but cortisol levels are higher than corticosterone when both hormones are increasing (Albers *et al.*, 1985; Otterweller *et al.*, 1985).

Other cyclic variations may be seasonal. In both wild and captive environments, rabbits in Tunisia were shown to have seasonal variations in testosterone and thyroxine. Testosterone peaked sharply in October and fell in November and December, with low values observed from January to September. Thyroxine peaked twice yearly, in October and again in spring (Ben Saad and Bayle, 1985).

IV. TRANSGENIC ANIMALS

The development of transgenic technology, incorporating the insertion or deletion of genes, has revolutionized animal research. In effect, each transgenic manipulation creates a new species. Transgenic animals differ from conventional ones with respect to clinical chemistry in that they may express a protein not normally found in that species, have an altered concentration of an analyte, have an aberrant regulatory mechanism, or, in the case of knockout animals, fail to express a protein normally present or lack a receptor. Immunochemical analytic methods utilizing monoclonal antibodies have special applicability in discriminating between the protein present in the conventional animal and that expressed as a result of transgenic manipulation (i.e., human growth hormone vs mouse growth hormone in a transgenic mouse). A comprehensive consideration of the unique aspects of transgenic animals is beyond the scope of this chapter. Rather, several studies in transgenic animals are reviewed to provid examples of differences from conventional animal with respect to clinical biochemistry.

Human renin reacts specifically with human angic tensinogen to release angiotensin I, converted b angiotensin-converting enzyme (ACE) to angiotensi II. Rat or mouse angiotensinogen is very resistant t the action of human renin. Transgenic mice have bee produced that express human renin, as well as other that express human angiotensinogen. These animal are normotensive. Cross breeding these mice result in mice that express both human renin and huma angiotensinogen. These so-called dual gene strain mic are hypertensive but respond to renin inhibitors, AC inhibitors, and angiotensin II receptor antagonists Similar studies have been performed in rats (Wagne *et al.*, 1993).

Transgenic mice that express human growth hor mone, ones that express bovine growth hormone, an ones that express rat growth hormone have been devel oped. Transgenic mice expressing both mouse growt hormone and human growth hormone are of norma size when born. At about 4 weeks of age, growth be comes accelerated because of the stimulation of insulir like growth factor 1 (somatomedin C) by growth hor mone. Adult transgenic mice expressing huma growth hormone weigh 50–100% more than their con ventional siblings. Males express approximately twic the concentration of human growth hormone as fe males. The transgenic mice age faster and have shorte lifespans than their conventional siblings. The trans genic females are sterile. Ovarian function and ovula tion appear to be normal, but human growth hormone unlike mouse growth hormone, fails to support th mating-induced prolactin release required for the acti vation and maintenance of luteal function. If femal transgenic mice, expressing human growth hormone breed and are supported by progesterone administra tion or prolactin-secreting pituitary implants, they be come pregnant and deliver live pups, but generally d not lactate adequately for the survival of the pups Male transgenic mice expressing human growth hor mone are fertile, but have a shortened reproductiv lifespan and decreased reproductive aggressivenes with age (Asa *et al.*, 1992; Bartke *et al.*, 1991; Stefaneani *et al.*, 1993).

Chorionic gonadotropin in the species in which i occurs, FSH, LH, and TSH are glycoprotein hormone having an α- and a β-subunit. The α-subunit is highly species specific and is similar among hormones of thi class within a given species of animal, that is, it confer the species specificity on the hormone. The β-subuni conveys the function on the molecule, and β-subunit for a given hormone are similar though not identica

among various species. Transgenic mice expressing human FSH-β have been developed. The human FSH-β gene is expressed exclusively in pituitary gonadotrophs, and the mice secrete an interspecies heterodimer consisting of mouse FSH-α and human FSH-β, as well as a much smaller amount of conventional mouse FSH. These mice have elevated pituitary and serum FSH when compared to conventional controls, but their responses to gonadectomy and sex steroid replacement are qualitatively similar to those of conventional animals.

Transgenic mice that express human insulin have been developed. These mice also express mouse insulin I and mouse insulin II in a normal ratio (see Section V, Glucose and Glucoregulatory Hormones). These mice have normal total serum insulin concentrations and normal serum glucose, and they respond normally to challenges to glucose metabolism. These findings document posttranscriptional controls in glucose/insulin regulation (Schnetzler *et al.*, 1993).

The enzyme creatine kinase consists of dimers of two monomers termed m (for muscle) and b (for brain). In the conventional mouse, as in other species, the enzyme in skeletal muscle is mm, that in cardiac muscle is predominantly mm and partially mb, and the enzyme in brain is bb. Because mb is present in significant activity only in cardiac muscle, the finding of this isoenzyme in serum generally characterizes myocardial injury. Transgenic mice microinjected with rat CK b gene overexpress CK b monomere. Their skeletal muscle averages 60% mm, 32% mb, and 8% bb (Brosnan *et al.*, 1993).

These few selected examples have been presented to document some of the unique features that have been reported with respect to clinical chemistry in transgenic animals.

V. GLUCOSE AND GLUCOREGULATORY HORMONES

In both rats and mice, serum glucose decreases with age (Loeb and Caracostas, 1990; Loeb *et al.*, 1996). In mice the rate of decrease is approximately 2 mg/dl/month. This is associated with improved response to glucose challenge and with increased size and insulin content of the islets of Langerhans (Leiter *et al.*, 1988). A similar age-related decrease in serum glucose was observed in spontaneously hypertensive rats (SHRs), though the islet size and insulin contents did not differ between young and aged SHRs (Iwase *et al.*, 1994).

Although serum glucose is affected by numerous factors, it is most extensively studied in the numerous animal models of diabetes mellitus that include both rodent and nonrodent species. In humans, diabetes may be subdivided into Type I, or the insulin-dependent type, also termed the severe, juvenile, or early-onset type, and Type II, or the non-insulin-dependent type, also termed the adult-onset type. The former generally represents an absolute deficiency of insulin, whereas the latter is characterized by hyperglycemia in the presence of hyperinsulinemia. An interesting model of insulin-dependent diabetes mellitus described in the guinea pig has been shown to result from an infectious agent affecting the pancreas. There is profound glycosuria and variable but mild hyperglycemia and ketonuria. There is fatty degeneration of the pancreas with impaired exocrine as well as endocrine function. Diabetic cataracts and diabetic renal glomerular disease in the guinea pig resemble those seen in man (Lang and Munger, 1976).

The C57Bl/6J *ob/ob* obese mouse is a widely studied model of non-insulin-dependent diabetes mellitus. The mouse is obese, hyperglycemic, and hyperinsulinemic, consistent with the corresponding disease in humans (Austin *et al.*, 1984). Using radiolabeled glucose, Wittmers and Haller (1983) have demonstrated that these mice clear glucose from the blood similarly to lean controls, and concluded that the characteristic hyperglycemia is due to accelerated glycogenolysis and gluconeogenesis. Surwitt *et al.* (1985) demonstrated that these obese mice were not consistently hyperglycemic, but were subject to stress hyperglycemia while lean controls were not. Adrenalectomy of these obese mice resulted in normalization of glucose tolerance curves.

The diurnal cycles of serum glucose and insulin as well as tissue enzymes participating in glucoregulation were studied in *db/db* mice, another model of non-insulin-dependent diabetes. Though insulin levels were consistently elevated, glucose levels varied widely, falling to levels approximating those of nondiabetic controls near the end of the light period. Little evidence of circadian rhythm was seen in the glucose or insulin of nondiabetic controls, or the insulin of diabetic mice (Roesler *et al.*, 1985).

The Zucker fatty rat (*fa/fa*) is characterized by obesity and hyperinsulinemia, though it is normoglycemic. Although not truly diabetic, it has some of the characteristics of non-insulin-dependent diabetes. Hyperinsulinemia has been demonstrated at 2 weeks of age, though total pancreatic insulin does not differ from lean (*Fa/Fa*) rats (Blonz *et al.*, 1985).

The LA/N corpulent rat resembles the Zucker *fa/fa* rat in the properties of obesity, hyperinsulinemia, normoglycemia, and hyperlipidemia, though hyperinsulinemia is more marked in the LA/N corpulent rat. Serum corticosterone levels are significantly higher in

LA/N corpulent rats (340 ng/ml) than in lean controls (255 ng/ml) (Elwood *et al.*, 1985).

The BB rat is a widely used model of insulin dependent diabetes mellitus (IDDM, Type I). The incidence of diabetes in this strain may be markedly reduced by treatment with an inhibitor of platelet-activating factor, a potent modulator of inflammation, anaphylaxis, hypersensitivity, and cellular immune responses (Jobe *et al.*, 1993).

Glycosylation of proteins is a nonenzymatic process occurring when specific proteins are exposed to carbohydrates. Glycosylated hemoglobin (in humans, principally hemoglobin A1c) forms continuously during the life of the erythrocyte in relationship to the concentration of serum glucose. Thus, it has proved to be a valuable long-term monitor of glucoregulation, particularly in diabetics. Conventional Sprague–Dawley rats had a glycosylated hemoglobin of 4.22 ± 2.18%, whereas Sprague–Dawley rats made diabetic by treatment with streptozotocin had values of 7.96 ± 3.40 (mean ± 2 SD). The rats made diabetic with streptozotocin also had significantly higher levels of erythrocyte 2,3-diphosphoglycerate (Alder *et al.*, 1992). In the healthy rabbit, Higgins *et al.* (1982) demonstrated a mean hemoglobin A1c of 1.4% and a total glycosylated hemoglobin of 2.3% (of total hemoglobin). In contrast, in humans these values were 4.9 and 6.9%, in the dog 3.3 and 3.3%, and in the pig 0 and 0.3%.

Insulin and glucagon, in common with other peptide hormones, vary in structure among species. Whether an immunoassay having antibody to and competitive hormone of one species will be valid in another species depends on the structural similarity of the molecule, in particular the portion of the molecule to which the antibody is raised. Rats, mice, and hamsters have two distinct nonallelic insulin molecules present in all members of the species. Neither of these is proinsulin or C-peptide. Mouse insulin II is identical to rat insulin II, and mouse insulin I differs from rat insulin I by a single amino acid. Rats have approximately equal quantities of insulin I and insulin II. The assay used to measure total insulin in rats, mice, and hamsters must recognize both molecules equally. The assay for rat insulin may be used to measure mouse insulin; for greatest accuracy, it should then be calibrated with mouse insulin (Markussen 1971; Smith, 1966). The insulin produced by the pancreatic islets of the guinea pig is immunologically quite different from the insulin of either man or rat and cannot be accurately measured by either assay. However, the guinea pig produces another insulin-like molecule from nonpancreatic sources. This molecule, which is not released into the plasma, does not appear to be involved in overall glucoregulation. It reacts with the immunoassay for human insulin. Therefore, using the immunoassay for human insulin on guinea pig serum fails to measure the principal glucoregulatory insulin (Jukes, 1979; Rosenzweig *et al.*, 1980)

Glucagon is a molecule that is generally similar among various animal species. Rat glucagon can be measured with the human immunoassay. The guinea pig, however, has a distinctly different molecule, not measurable by the human assay (Huang *et al.*, 1986).

VI. PROTEINS

Fetal mice have three unique fetal proteins. One of these, α-1-fetoprotein, has also been demonstrated in the sera of mice with transplantable hepatoma. Three specific pregnancy-dependent proteins have been described in the sera of pregnant mice (Quimby, 1988) One of these, pregnancy-associated murine protein-1 (PAMP-1), shows partial immunologic cross reactivity with human pregnancy zone protein. Its concentration varies with the estrus cycle of the mouse; its concentration is highest in diestrus. Its serum level remains low until the 7th day of gestation, when it rises rapidly peaking at the 11th day and then declining (Hau *et al.*, 1991).

In the Syrian hamster, synthesis of a unique pentraxin termed "female protein" is under the control of sex steroids. Concentrations in females (0.5–3 mg/dl are 100- to 1000-fold greater than in males. Levels may be experimentally modified by sex steroid treatment Female protein shares structural similarity with human C-reactive protein and serum amyloid P component and can be demonstrated to be present in hamster tissue amyloid. Although similar to acute-phase reactants of other species, female protein, in acute-phase reactions in the hamster, increases in concentration 5 to 10-fold in males and decreases by 50% in females (Coe and Ross, 1985; Dowton *et al.*, 1985).

In rabbits, experimental infection with the parasite *Setaria cervi* resulted in increases in total proteins and all electrophoretic globulin bands and a decrease in albumin. These changes began within the week after infection, peaked at 3 weeks, and almost returned to control values by 6 weeks. Two precipitin antibodies to the parasite were demonstrated immunoelectrophoretically during the peak hyperglobulinemia (Khatoon *et al.*, 1984).

VII. LIPIDS AND LIPOPROTEINS

Because of the role of the rat in biomedical research the lipids and lipoproteins of the rat, though differing markedly from those of humans, have been extensively

studied. Normal serum cholesterol values in rats fed conventional diets are typically about one-third those of humans. In contrast to humans, 60% of the cholesterol is transported as high-density lipoprotein (HDL) cholesterol. Serum cholesterol levels in the hooded Long–Evans rat are somewhat higher than in Wistar rats. Possibly because of the low level of serum cholesterol and proportionately high level of HDL cholesterol, the rat is quite resistant to the induction of hyperlipidemia and atherosclerosis. Hypothyroidism may result in mild hypercholesterolemia. The Zucker Fatty Rat (*fa/fa*), previously discussed in Section IV, is one of several hypercholesterolemic and hypertriglyceridemic genetic strains, having values approximately three time those of Wistar controls (Carroll and Feldman, 1988). In addition to the lipoproteins recognized in other species, a very high density lipoprotein (VHDL) having very rapid catabolism has been demonstrated in the rat. This lipoprotein has a density of 1.23 g/ml and consists of 85% protein and 15% lipid including cholesterol esters and free cholesterol (Därr *et al.*, 1985).

Sullivan *et al.* (1993) studied the response of gerbils, hamsters, and guinea pigs to the feeding of high-fat/high-cholesterol diets and concluded that among these rodents, the guinea pig is the best rodent model for man. Transgenic rodents expressing human lipoprotein apoproteins appear to be superior to conventional rodents for the study lipid disorders and atherosclerosis (Rubin and Schultz, 1993).

Although reference values for cholesterol in the rabbit resemble those of the rat, and, as in the rat, the principal component is HDL cholesterol, hypercholesterolemia is more readily induced by dietary manipulation. The Watanabe hereditable hyperlipemic rabbit (WHHL) is a model of familial hypercholesterolemia. Homozygotes have mean serum cholesterol levels of 500 mg/dl and may reach 1000 mg/dl. The principal fraction in these animals is low-density lipoprotein cholesterol with only small quantities of HDL. Affected animals develop atherosclerosis by 5 months of age (Tanzawa *et al.*, 1980).

VIII. ENZYMES

The sensitivity and organ specificity of the leakage enzymes in detecting cellular injury depend on several factors, including the comparative activities in various tissues, turnover time, and intracellular distribution. There are two isoenzymes of alanine aminotransferase, one located in the mitochondria, the other in the cytosol. The cytosol isoenzyme is lost when cell membrane permeability increases, whereas loss of the mitochondrial isoenzyme generally requires cell necrosis. Coupling the difference in intracellular distribution with the distribution among various tissues leads to the conclusion that in the rat and mouse, the measurement of alanine aminotransferase is quite sensitive and hepatospecific, whereas in the guinea pig it is insensitive and not hepatospecific. In the rat, the measurement of sorbitol dehydrogenase (L-iditol dehydrogenase) has been shown to be quite hepatospecific and more sensitive in the detection of hepatocellular injury than other enzymes, including alanine aminotransferase (Clampitt and Hart, 1978; Dooley, 1983; Teschke *et al.*, 1983). The article by Boyd (1983) is an excellent resource for the determination of sensitivity and organ specificity of the various enzymes.

The increase in serum lactate dehydrogenase and other enzymes in mice infected with Riley's agent (LDH virus) has been shown to be due to impaired clearance rather than increased release of the enzymes (Notkins, 1965). Serum levels of alkaline phosphatase of hepatobiliary origin are increased in cholestasis and in response to inducer drugs such as barbiturates that result in increased hepatocellular endoplasmic reticulum. Two isoenzymes of alkaline phosphatase are present in the sera of normal adult mice. The inoculation of mice with mouse hepatitis virus results in the appearance of a third isoenzyme of hepatic origin in the serum (Everett and Harrison, 1983). In guinea pigs, dietary deficiencies of zinc or manganese result in an elevation of serum alkaline phosphatase (Alberts *et al.*, 1977; Underwood, 1971).

γ-Glutamyltransferase activity in the sera of healthy rats may be insufficient to permit detection, but it is significantly increased in cholestasis (Ringler and Dabich, 1979).

IX. BILE ACIDS AND BILIRUBIN

Measurement of total serum bile-acid concentration has been shown to be a sensitive and specific indicator of hepatic injury and disease as well as of disorders of enterohepatic circulation in various species (Hardison *et al.*, 1985; Iga and Klaasen, 1982; Gopinath *et al.*, 1980). Thompson *et al.* (1987) have developed and validated a method for the separation and quantification of individual bile acids by high-performance liquid chromatography (HPLC) and demonstrated a greater number of individual bile acids in rat serum than in the sera of several other species studied. Using various chemical and physical methods to induce hepatic disease or enterohepatic circulatory disturbances, they demonstrated that each of these had a unique pattern of changes in the bile-acid profile. This approach shows great potential for the de-

tection and definition of hepatic disease in rodents; it appears to be more sensitive and specific than the measurement of individual analytes utilized for the assessment of hepatic status, and it does not require the extensive handling essential to liver function tests utilizing exogenous dyes.

Several hereditary models of aberrant bilirubin metabolism are available. Gunn rats lack bilirubin UDP-glucuronyltransferase comparable to Crigler–Najjar syndrome of humans. Jansen *et al.* (1985) have described a jaundiced mutant rat of Wistar derivation with conjugated hyperbilirubinemia in which serum bilirubin levels are 100 times those of unaffected controls. Over 90% of the bilirubin is conjugated, predominantly diconjugated. Transport of bromsulfophthalein is impaired. No morphologic lesions are associated with this defect. This may represent an appropriate model for some of the features of the Dubin–Johnson syndrome of humans. These rats have been designated TR− (transport minus) and may be a valuable model for the study of ATP-dependent hepatocanalicular anion transport (Jansen and Elferink, 1993). A hyperbilirubinemic mutant rat of Sprague–Dawley derivation, designated EHBR, or Eisai hyperbilirubinuria rat, has some of the features of human Dubin–Johnson syndrome, and some of Rotor's syndrome. This rat has normal hepatic uptake and storage, and impaired secretion into bile. Affected animals have mesangial granular deposition of IgG, IgM, IgA, and C3, suggestive of IgA nephropathy (Hosokawa *et al.*, 1992).

X. HORMONES

The release of growth hormone and of luteinizing hormone is pulsatile, and valid interpretation requires measurement over time. Single values may be misleading (Fox and Smith, 1984; Watts and Fink, 1984; Bullier-Picard *et al.*, 1986). The growth defect in the Brattleboro rat appears to be the result of decreased hepatic growth hormone receptors rather than a deficiency of growth hormone (Bullier-Picard *et al.*, 1986). The mean growth hormone levels in obese Zucker rats are significantly lower than in lean controls, and pulses tend to be lower and less frequent (Finkelstein *et al.*, 1986). The frequency of pulses of luteinizing hormone decreases with age in mice, though peak values do not change (vom Saal *et al.*, 1994).

Immunoassay procedures depend on the "recognition" of an antigen by an antibody. Species-specific differences in the amino acid sequence of a hormone may result in failure of an antibody raised against the same hormone from another species to recognize, causing a nonsense result, or in "incomplete recognition," underestimation of the concentration of the target hormone. In contrast to TSH, FSH, growth hormone, or prolactin, which are species specific, ACTH can be measured in all mammalian species by a single assay method using an antibody prepared against the first 24 amino acids of the molecule. More than 50 species, including all common laboratory and domestic species, share this same amino acid sequence. Information on cyclic periodicity of hormones of rodents and rabbits is found in Section III.

Thyroxine (T_4) and 3,3',5-triiodothyronine (T_3), its monodeiodinated, physiologically more active derivative, exist in serum partially free, but predominantly bound to transport proteins. Both the transport proteins and the overall binding affinity vary with species In the rat, approximately 0.05% of the T4 and 0.25% of the T_3 are free. In the rat and mouse, approximately 80% of thyroid hormones are bound to albumin, and 20% to thyroxine-binding prealbumin. Thyroxine-binding prealbumin is a transport protein that appears to exist in all species, though its electrophoretic migration may vary somewhat with species. Only the free hormone is believed to be physiologically active. The effect of the interaction of obesity and fasting on thyroid hormones was investigated in lean and obese Zucker rats by Young *et al.* (1985). In lean rats 4–7 days of fasting resulted in a marked decrease in total and free thyroxine (T_4) and total and free triiodothyronine (T_3). In obese Zucker rats 4–7 days of fasting produced no change in the serum levels of these hormone whereas more prolonged fasting resulted in elevation of total hormones from baseline without any change in the free hormones. These alterations were explained by an increase in serum thyroxine-binding globulin a protein present in low concentration in the rat. In hamsters and rats, serum levels of thyroxine and triiodothyronine decrease significantly as a function of age (Neve *et al.*, 1981; Rao-Rupanagudi *et al.*, 1992). In rat this is associated with a decrease in the height of follicular epithelial cells and a decreased number of follicles

The chronic administration of ethanol to mice significantly increases hepatic T_3 receptors, which may relate to alcohol-induced hypothyroidism. Experimental autoimmune thyroiditis in mice, a model for Hashimoto's thyroiditis of man, can be induced by the administration of mouse thyroglobulin with Freund's adjuvant. Its experimental production can be blocked by pretreatment with an infusion of thyroid stimulating hormone.

Calcitonin is produced by the parafollicular cell originating from the neural crest. Calcitonin is straight-chain polypeptide consisting of 32 amin

acids. Its amino acid sequence is highly species specific. Its synthesis is stimulated by calcium ion. The release of calcitonin is stimulated by glucagon, prolactin, TSH, thyroxine, gastrin, secretin, and pancreazymin. In rats serum calcitonin increases with age from undetectable values (less than 90 pg/ml) at 6 weeks of age, to over 14,000 pg/ml at 27 months. It varies with the estrus cycle, being lowest during proestrus. It is higher in feeding than in nonfeeding rats.

The adrenal glucocorticoid axis (consisting of hypothalamus, pituitary, and adrenal cortex, particularly the zona fasciculata), becomes functional in fetal rats between the 18th and 22nd day of gestation. In adult rats, serum corticosterone levels are significantly higher in females than in males. In mice, 18-day female fetuses have significantly higher corticosterone levels than male fetuses, though the corticosterone content of the adrenal is similar in fetuses of both sexes. Stress to or adrenalectomy of the mother eliminates this sex-dependent difference in the fetus (Montano *et al.*, 1993). In the rat and mouse, cleavage of pro-opiomelanocortin (the precursor of ACTH) yields a large ACTH molecule about twice as long, but containing the same 24-amino-acid sequence, as the 39-amino-acid ACTH molecule of man. This large ACTH molecule is reported not to induce the formation of 17α hydroxylase. This has been proposed to explain the secretion of corticosterone rather than cortisol in rats and mice (Woodman, 1990). The hamster, however, secretes both in ratios that vary with circadian rhythm (see Section III, this chapter). The rabbit also has significant levels of both cortisol and corticosterone. In the serum of the rat, corticosterone occurs 2–19% free, approximately 80% bound to transcortin, and 10% bound to albumin. Serum transcortin levels are reduced by the exogenous administration of ACTH (Amario *et al.*, 1994).

Stress, including very mild stress, elevates the blood level of glucocorticoids. Restraint doubles the corticosterone level of rats in 2 minutes and elevates it 12-fold in 20 minutes (Liu *et al.*, 1996). If rats are housed in pairs and are removed to be bled, the second animal generally has a higher corticosterone value than the first; removal of the cagemate is sufficient stress to elevate the corticosterone. If mice are housed in groups of 8, corticosterone levels are elevated for 2 weeks in comparison with mice housed in pairs or groups of 4. After 2 weeks, corticosterone levels decline to those seen in pairs or groups of 4.

Serum testosterone levels have been shown to be significantly higher in neonatal (1–5 days old) male mice and hamsters than in females of the same age. Pang and Tang (1984) believed this to play an important role in the neural sexual differentiation of rodents

XI. URINE AND URINARY TRACT EVALUATION

The measurement of serum urea nitrogen (BUN) or serum creatinine constitutes an extremely insensitive indicator of impaired renal function in rodent and rabbits. Serum creatinine is higher in young male rats than in young females, but this difference is abolished by 8 months of age. The use of the endogenous creatinine clearance test is a more sensitive and specific test of impaired glomerular filtration than the measurement of urea nitrogen or creatinine. It requires a timed urine specimen and a serum sample (Ringler and Dabich, 1979).

The validity of studies on the urine of rodents and rabbits may be compromised by artifacts resulting from urine collection. Timed urines must be protected from contamination and evaporation, and kept cold throughout the collection period. A technique of bladder catheterization and urine collection via the catheter passed through a tether has been described by Mandavilli *et al.* (1991).

The urine of the rat (*Rattus norwegicus*) and that of the golden hamster (*Mesocrecetus auratus*) was studied and compared to the urine of the mole rat (*Spalax ehrenbergi*), a subterranean rodent, by Haim *et al.* (1985). These workers showed a higher content of calcium and magnesium in the urine of mole rats and hamsters than in albino laboratory rats. Urine osmolality was highest in rats (388.2 $\pm$ 56.7 mOsm/kg), lower in hamsters (330.9 $\pm$ 23.6 mOsm/kg), and lowest in mole rats (301.6 $\pm$ 27.9 Mosm/kg), and urea and phosphate were significantly lower in mole rats than in hamsters or rats. Haim *et al.* (1985) speculated that these characteristics may adapt the mole rat to subterranian existence and the hamster to burrow dwelling.

Flatt and Carpenter (1971) studied crystals in the normally cloudy urine of the rabbit. They determined that normal rabbit urine contains calcium carbonate monohydrate, anhydrous calcium carbonate, and magnesium ammonium phosphate. A detailed compilation of the urinary analytes of the Sprague–Dawley rat has been reported by Shevock *et al.* (1993).

Proteinuria is commonly present in aged male mice of many strains and less frequently in females. The protein is of lower molecular weight than albumin and is of renal origin (Everett and Harrison, 1983).

A modified water-concentration test may readily be applied to laboratory rodents and appears to be more

sensitive than other simple methods of detecting renal disease or impaired renal function. Water is withheld for 12 hours, after which a urine sample is collected for the measurement of specific gravity (Ragan, 1988). The urine concentrating ability of mice in response to water deprivation declines with age (Harrison and Archer, 1983).

Hypertension-prone Sabra rats challenged by acute sodium loading secreted significantly less urine than normotensive controls, including rats of the parent strain. Although this urine contained a higher concentration than that of normal controls, the sodium excretion (per unit time) was significantly lower in the hypertensive rats, demonstrating the role of impaired renal sodium excretion in hypertension (Fregly and Rowland, 1985; Meckler *et al.*, 1985).

The measurement of urinary enzymes constitutes a sensitive assessment of renal injury. Enzymes may be expressed in terms of activity per 24 hours or in a ratio to urine creatinine. Although many enzymes have been studied, the diagnostic utility of *N*-acetyl-β-glucosaminidase (NAG) and of γ-glutamyltransferase (GGT) has been best validated in the rat and mouse. The excretion of NAG, a lysosomal enzyme, is elevated in renal papillary damage. The brush border of the proximal convoluted tubules is very rich in GGT. In the rat, GGT activity in the kidney is 200–300 times as high in the kidney as it is in the liver, though the kidney does not contribute appreciably to the GGT activity of the serum. Factors other than renal injury, such as diuresis, may elevate the urinary excretion of renal enzymes, in particular that of NAG (Stonard *et al.*, 1987; Bomhard *et al.*, 1991, 1994).

CHAPTER

30

Avian Clinical Biochemistry

J. T. LUMEIJ

I. INTRODUCTION

Avian medicine and surgery has been recogni as a distinct specialty in veterinary medicine on t continents (Europe, Australia, and North Ameri This has occurred because of the increasing demanc veterinary care for individual birds that have attain high sentimental and/or economic value. The f approach that had been practiced for decades in p try medicine had only limited applicability for indi ual pet birds, and alternative diagnostic and therap

tic techniques were developed. Clinical signs in birds are often nonspecific and the information gained by physical examination is limited. Earlier demands for large blood sample volumes and limited veterinary involvement in pet bird disease were major obstacles to the diagnostic application of clinical biochemistry in avian medicine. The introduction of micromethods in clinical laboratories and the public demand for veterinary care for individual birds has removed these obstacles. The scientific and clinical work of the past decade in avian clinical biochemistry has led to its development as an indispensable tool in avian medicine.

II. COLLECTION OF BLOOD SAMPLES

A. Size of Blood Samples

An important consideration when taking blood samples from small birds is response to blood loss. Kovách *et al.* (1969) studied the mortality of various avian and mammalian species following blood loss and showed that birds can better tolerate severe blood loss than mammals (Fig. 30.1). This is due to their much greater capacity for extravascular fluid mobilization (Djojosugito *et al.*, 1968; Wyse and Nickerson, 1971). Kovách *et al.* (1969) found that in healthy birds, the amount of blood that can be removed without deleterious effects is 3% of body weight in ducks and pigeons, 2% in chickens, and 1% in crows and pheasants (Fig. 30.1). In patients a maximum of 1% is a safe limit for the amount of blood that can be collected for diagnostic purposes.

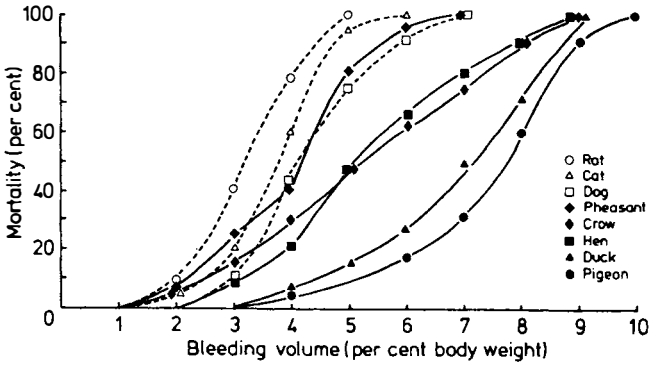

FIGURE 30.1 Mortality after identical blood losses in various avian and mammalian species (abscissa). Every hour 1% of body weight blood was withdrawn from every animal (ordinate). The percentage of animals lost during the hour following bleeding has been recorded and plotted. (After Kovách *et al.*, 1969. Reprinted with permission from Lumeij, 1987a.)

B. Handling of Blood Samples

Nearly all routine hematological and biochemical investigations can be performed when lithium heparin is used. The use of one single sample limits unnecessary blood spillage, which is an important consideration when dealing with small birds. When plasma is used, more plasma can be harvested than serum from the collecting tube.

In mammals, EDTA is regarded as the best anticoagulant for preservation of cellular morphology and good staining characteristics (Schmidt *et al.*, 1963), but this is not necessarily true in avian hematology. There are many avian species where EDTA causes disruption of the red blood cells. Fourie (1977) found heparin to be the most suitable anticoagulant for hematology in pigeons. Hawkey *et al.* (1983) found that EDTA produced progressive hemolysis in blood samples from crowned cranes. Dein (1986) reported a similar reaction in crows, jays, brush turkey, and hornbills. Similar reactions to EDTA are see in blood from crows and magpies (Lumeij, unpublished). Blood smears should be made immediately after collection of the sample to prevent changes in blood cell morphology.

The normal time lag of up to 60 minutes between collection of a blood sample and separation of plasma from cells that is common in human medicine (Laessig *et al.*, 1976) is not acceptable in avian clinical biochemistry. Immediately after collection, plasma and cells should be separated by centrifuging. In pigeon blood at room temperature, a rapid decline (10% in 10 minutes 30% in 30 minutes, up to 65% in 2 hours) of potassium concentrations occurs because of a shift of potassium ions from the plasma into the red blood cells. In chickens, decreases were smaller overall, with a 29% decrease being noted after 2 hours (Lumeij, 1985a). Many reports on blood chemistry in birds are based on serum instead of plasma or on plasma from blood samples that were not centrifuged immediately. Therefore, reported plasma potassium concentrations are often too low.

C. Sampling Procedures

In most species, the right jugular vein is the preferred site for blood sampling. This thick-walled vein is less prone to hematoma formation (Law, 1960; McClure and Cedeno, 1955; Stevens and Ridgeway, 1966). The medial metatarsal vein is especially useful for multiple sampling of small blood volumes in larger birds such as pigeons. Blood can be collected using a needle and syringe or a blood lancet. In the pigeon, the jugular vein is not readily accessible.

The wing vein or ulnar vein is the vein that is traditionally used in poultry. After being swabbed with alcohol, the vein is punctured with a blood lancet (Gratzl and Koehler, 1968). These authors warn against the use of the comb for blood collection in poultry because the risk of exsanguination is high, especially during cold weather. In pet birds, the use of a blood lancet for blood collection from the ulnar vein cannot be recommended because this site is very prone to hematoma formation, often even when a needle is used. The advantage of the cutaneous ulnar vein is that it can be located in all avian species.

In ostriches, it is safer to avoid the clearly visible jugular vein and take blood from the ulnar vein using a sideways approach to the standing animal after it has been hooded and the wing has been lifted upwards by two assistants.

In ducks and geese, the venous occipital sinus is the preferred site for blood sampling (Vuillaume, 1983). It is located at the junction of the base of the skull and the first cervical vertebra.

Cardiac puncture carries the risk of cardiac tamponade, so this technique is not recommended for use in avian clinical practice. Some clip a toenail to obtain a blood sample. Disadvantages of this method are that it is painful to the bird, the sample may become contaminated with tissue fluids, it may cause damage to the nail bed, and the amount of blood that can be obtained is limited. When a toenail is clipped to obtain a blood sample, contamination of the sample with urates from the droppings may give falsely high readings (Rosskopf *et al.*, 1982; Ekstrom and Degernes, 1989). Therefore, the nail should be thoroughly cleaned before clipping. Different bleeding sites (e.g., venous blood vs cardiac blood) may cause variation in hematological or biochemical values (Kern and De Graw, 1978).

A vacuum system greatly facilitates blood sampling from the jugular and cutaneous ulnar veins and from the venous occipital sinus. A 3-ml vacuum tube is sufficient for most cases (Venoject, Omnilabo, Breda, The Netherlands).

III. STARVATION AND POSTPRANDIAL EFFECTS—CIRCADIAN AND CIRCANNUAL RHYTHMS

Some plasma chemical constituents are influenced by starvation or food consumption. Up to 4 days of starvation in pigeons did not result in hypoglycemia, but rather a starvation hyperglycemia occurred after 3 days (Lumeij, 1987b). Constituents that have markedly increased values postprandially are uric acid and total bile acid concentrations (Lumeij, 1991; Lumeij and Remple, 1991, 1992). Furthermore, daily or yearly fluctuations have also been reported for some chemical constituents. In fasted pigeons maintained on a natural daily 17-hour photoperiod, a circadian rhythm was found in plasma glucose concentrations (Lumeij *et al.*, 1987a) with high values early during the photophase (Fig. 30.2). Basal plasma thyroxine concentrations in racing pigeons were significantly higher in July than in September and December (Lumeij and Westerhof, 1988a). Age, sex, altitude, nutritional status and egg laying may also cause variation (Driver, 1981; Kocan and Pits, 1976; McGrath, 1971; Mori and George, 1978; Simkiss, 1967).

IV. PLASMA PROTEINS

A. Introduction

Plasma proteins are important complementary constituents in the diagnosis of gastrointestinal, hepatic, renal, and/or infectious diseases. Determination of plasma proteins seldom leads to a specific diagnosis (e.g., monoclonal gammopathies), but will help the clinician to evaluate the nature, severity, and progress of a disease.

B. Plasma vs Serum

In pigeons, the concentration of total protein (TP) in plasma is about 1.5 g/liter higher than in serum because the former contains fibrinogen: TP_{serum} =

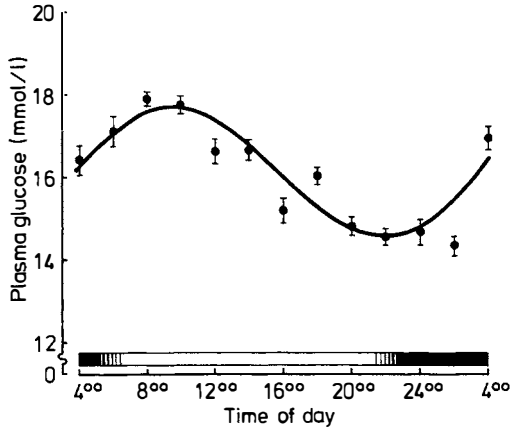

FIGURE 30.2 Mean (± SEM) plasma glucose concentration as a function of time in fasted racing pigeons. A cosines function $y(t)$ is fitted to the data: $y(t) = 16.26 + 1.55 \cdot \cos(0.2618t - 2.4646)$. The relevance of the fit as judged by means of the multiple correlation coefficient was significant ($R = 0.892$, $P < .01$). Reprinted with permission from Lumeij *et al.* (1987a).

$-1.7 + 1.01\ TP_{plasma}$ (Fig. 30.3). The correlation is highly significant ($P < .000001$; $R = 0.99$; $n = 50$) (Lumeij and Maclean, 1996).

C. Physiological Variation in Female Birds

In female birds, a considerable increase in plasma TP concentration occurs just prior to egg laying because of an estrogen-induced increase in the globulin fraction (Griminger, 1976). The proteins are the yolk precursors (e.g., vitellogenin and lipoproteins) that are synthesized in the liver and transported to the ovary, where they are incorporated into the oocyte (Griffin *et al.*, 1984).

D. Refractometry vs the Biuret Method

Lumeij and De Bruijne (1985b) demonstrated that the refractometric method is unreliable for use in avian blood and that this method should not be used in avian practice. The refractometric method consistently yields higher results than TP as determined by the biuret method, and the correlation coefficient between these two methods is low. Even though it has been demonstrated that the refractometric method is unreliable in avian blood, this method is still being used (Clubb *et al.*, 1990). One study suggested that only temperature-compensated refractometers are reliable (Andreasen *et al.*, 1989). In another study in our laboratory (Lumeij and Maclean, 1996) using plasma and serum of 58 pigeons, two types of refractometers were compared with the biuret method. Neither instrument proved to give an accurate measurement of plasma total protein. Both refractometers gave considerably higher values than the biuret method, with the temperature-compensated instrument being consistently higher in readings than the non-temperature-compensated one (Fig. 30.4). It was concluded that a species- and refractometric-specific conversion factor must be applied before refractometric results can be used, and then only as a rough estimate of the TP. Another important consideration is that TP determinations without information on plasma protein electrophoresis have limited value (see later discussion). For avian clinical practice it is advised to establish TP values using the biuret method.

E. Effect of Protein Standards

Most commercial laboratories use a human standard for TP and albumin (Alb) determinations without validating the method for the species from which the blood sample was obtained. There are significant differences between TP concentrations when different standards are used, such as human, bovine, pigeon and chicken standards, although there is a high correlation between the results obtained with the various standards (Spano *et al.*, 1988; Lumeij *et al.*, 1990). When

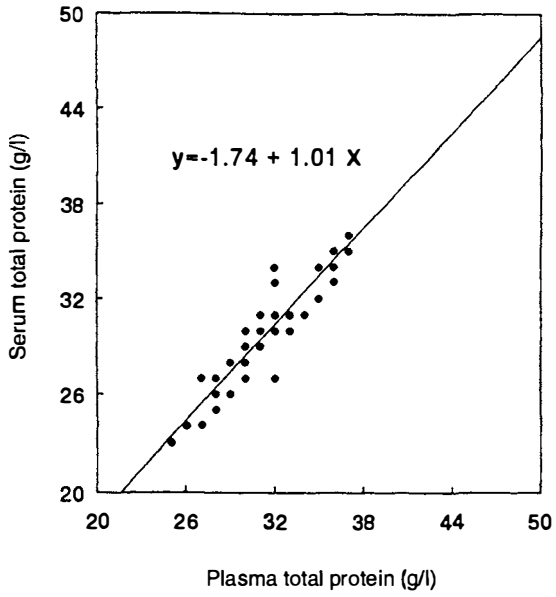

FIGURE 30.3 Relation between plasma and serum total protein by biuret method in racing pigeons (n = 50; g/liter). (From Lumeij and Maclean, 1996).

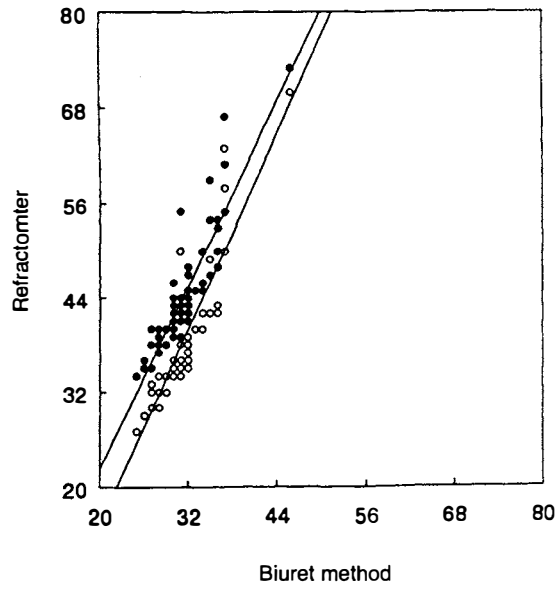

FIGURE 30.4 Relation between plasma total protein concentration by biuret method and two types of refractometers in pigeon (g/liter; $n = 58$). ● = temperature-compensated refractometer ($y = -16.38 + 1.93\,x$; $r = 0.89$); ○ = non-temperature-compensated refractometer ($y = -25.88 + 2.06\,x$; $r = 0.89$). (From Lumeij and Maclean, 1996).

a pigeon standard was used to determine serum TP concentration (TP_p) with the biuret method, values found were significantly higher than values found with the biuret method using the human standard (TP_h), but there was a high correlation (Lumeij *et al.*, 1990):

$$TP_h = 2.94 + 0.83\ TP_p\ (P < .0001;\ r = 0.93).$$

Spano *et al.* (1988) found consistently lower TP values in chicken serum with the use of a chicken standard than with a bovine standard. Because the use of a species-specific standard for all avian species is unrealistic and because a high correlation exists between the results obtained with the various standards, it is recommended that reference values for the various avian species be established using the most commonly used standard, namely the human standard.

F. Plasma Protein Electrophoresis—Albumin/Globulin Ratio

Plasma protein electrophoresis (PPE) on cellulose acetate membranes is used routinely in avian patients in our clinic (Lumeij and De Bruijne, 1985a) and the protein fractions are called albumin and α-, β- and τ-globulin. Often a prealbumin fraction can also be observed (Fig. 30.5). In healthy birds the albumin fraction is the largest protein fraction. In acute or chronic inflammatory conditions a rise in total protein caused by elevated globulin fractions may occur. Often albumin concentrations are decreased in these situations. The combined effect of these changes is a decrease in the albumin/globulin (A/G) ratio. Often the TP concentration is within the reference range, while the A/G ratio is decreased; therefore the A/G ratio is often of greater clinical significance than the TP. Examples of diseases with a decrease in the A/G ratio are egg-related peritonitis, and chronic infectious diseases such as aspergillosis, psittacosis, and tuberculosis. Protein electrophoresis can also be used to monitor response to treatment. In liver failure, extremely low plasma TP can occur in combination with a decreased A/G ratio. Gastrointestinal and renal diseases can also lead to severe hypoproteinemia. In birds, protein malnutrition may lead to hypoproteinemia (Leveille and Sauberlich, 1961). Increased TP with a normal A/G ratio can be expected in dehydrated birds if the primary disease did not cause hypoproteinemia. To calculate the A/G ratio, prealbumin and Alb as determined by plasma protein electrophoresis are combined as A and all globulin fractions as G (Figs. 30.6 through 30.9; Lumeij, 1987e).

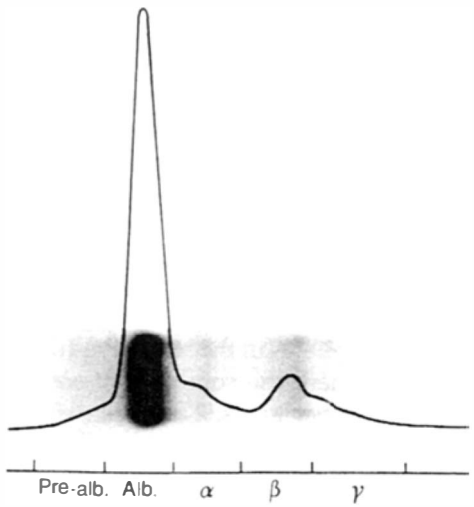

FIGURE 30.5 Densitometer scan and electrophoretic pattern from a representative pigeon serum. Prealbumin, albumin, and α-, β-, and τ-globulin. Reprinted with permission from Lumeij and De Bruijne (1985a).

G. Albumin Methodology

The labor-intensive PPE is not available in every laboratory, and Alb is commonly determined chemically by the bromcresol green (BCG) dye-binding method. Furthermore, most commercial laboratories will use a human standard for TP and Alb determinations, without validation for the species in question, although various standards can be used. The BCG method is unreliable in avian blood. Discrepancies between values obtained by dye-binding techniques and those obtained by electrophoresis have been demonstrated for chicken, duck, turkey, and pigeon (Spano *et al.*, 1988; Lumeij *et al.*, 1990).

Albumin determinations performed with dry methods (e.g., Kodak Ektachem) have not been validated for use in birds.

V. RENAL FUNCTION

A. End Products of Protein Metabolism—Hyperuricemia and Gout

Uric acid (UA) is the major end product of nitrogen (N) metabolism in birds. It constitutes approximately 60 to 80% of the total excreted N in avian urine (Skadhauge, 1983). Uricotelism permits excretion or storage of N waste in a small volume of water. Uric acid is relatively nontoxic when compared to ammonia (NH_3) and is essential for the development of the embryo in the egg of reptiles and birds. Uric acid is synthesized in the liver, and 90% is excreted via tubular secretion, largely independent of the urine flow rate (Skadhauge, 1981). The clearance of UA exceeds the glomerular

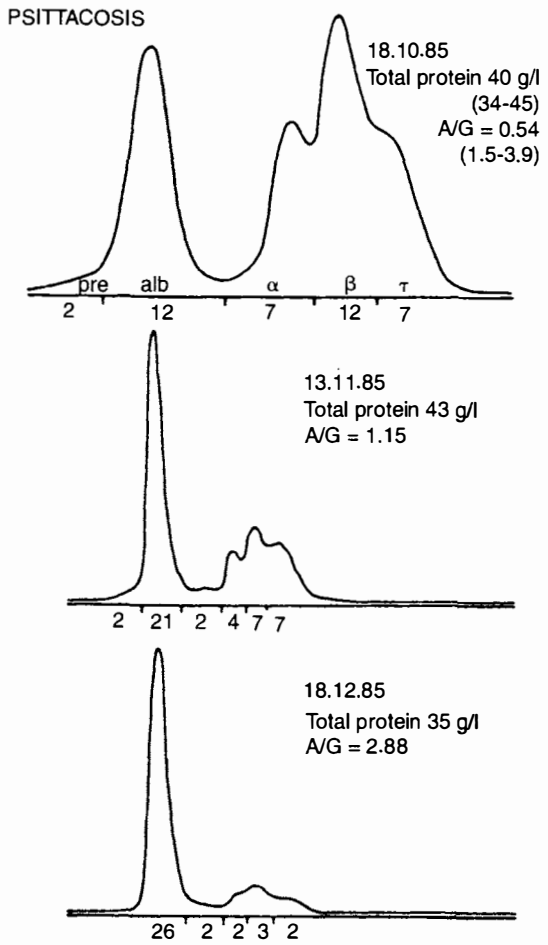

FIGURE 30.6 Plasma protein electrophoresis and the albumin : globulin ratio (A/G) in an African grey parrot (*Psittacus erithacus erithacus*) with psittacosis, before, during, and after treatment with doxycycline. FIGURE 30.7 Plasma protein electrophoresis in an Amazon par rot (*Amazona* sp.) with aspergillosis. At 4 1/2 months after a diagnosi was made and despite treatment with ketoconazole and 5 fluorocytosine, the globulin fraction was still elevated, causing th A/G ration to be decreased (reference values in parentheses). Re printed with permission from Lumeij (1987e).

filtration rate by a factor of 8–16. The rate of secretion is largely independent of the state of hydration of the bird. Very high concentrations of UA can be found in ureteral urine in dehydrated birds. Renal function disorders can eventually lead to increased plasma UA concentrations. Nonprotein nitrogen (NPN) substances in plasma such as UA, creatinine (Cr), and urea (UR) are increased only when renal function is below 30% of its original capacity.

B. Articular and Visceral Gout

Hyperuricemia can result in the precipitation of monosodium urate monohydrate crystals in joints (articular gout) and on visceral surfaces (visceral gout). The exact mechanism of deposition or the predilection for certain sites is unknown, although lower temperatures at predilection sites have been suggested. Gout should not be regarded as a disease entity, but rathe as a sign of a severe renal-function disorder.

When birds are given dietary protein in excess o their requirements, the excess protein is catabolizec and the N released is converted to uric acid. The tota amount of uric acid formed may surpass the clearin capacity of this substance from the body, and hyperuri cemia and articular or visceral gout may result. Th use of high-protein poultry pellets as the bulk food i psittacines may result in an increased incidence o gout.

There is no consensus on the different etiologie of articular and visceral gout in birds. The followin hypothesis, however, seems to explain all known fact about avian gout. A plasma urate concentration tha is slightly above the solubility of sodium urate wil lead to urate precipitates in the body. Predilection site are those areas where the solubility of sodium urat is lower than in other areas. The joints and synovia sheaths may be predilection sites because of a compara tively low temperature, which may reduce urate solu bility. Articular gout is a sign of chronic moderat hyperuricemia. Uric acid deposits grow with time an form the typical tophi of articular gout.

If urate crystals precipitate in the tubules or collec ing ducts of the kidney or the ureters (e.g., sever

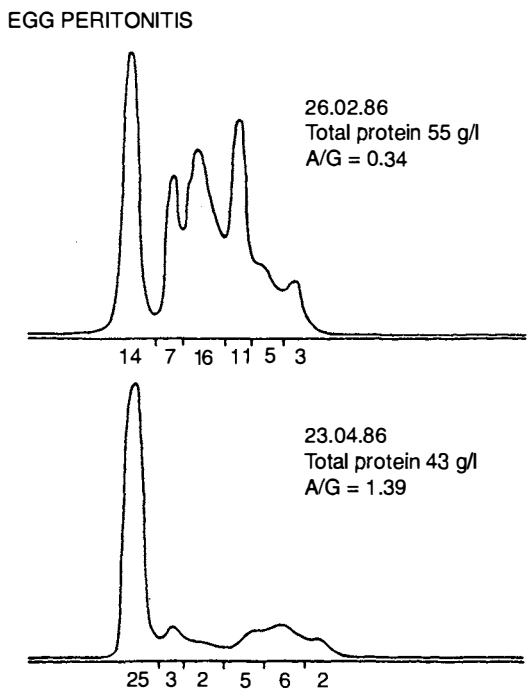

FIGURE 30.8 Serum protein electrophoresis and albumin : globulin (A/G) ratio in an emu (*Dromiceius novaehollandiae*) with an egg-related peritonitis. Two months after surgical treatment and remission of clinical signs a marked increase in the albumin fraction and decrease of the globulin fraction was observed. Reprinted with permission from Lumeij (1987e).

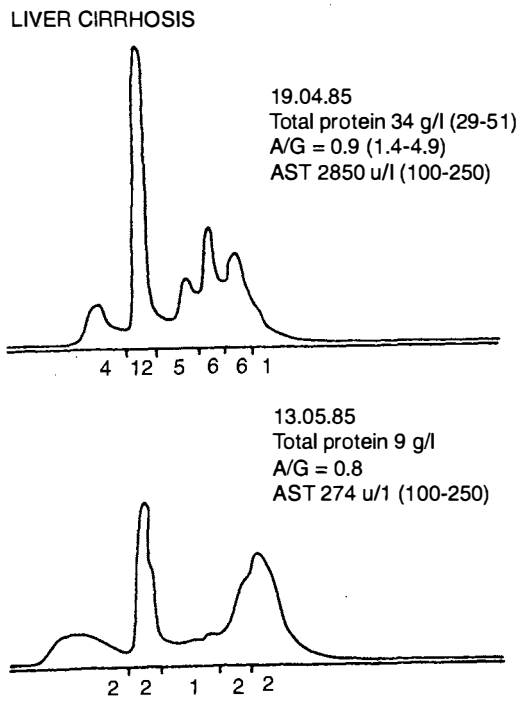

FIGURE 30.9 Total protein concentration, plasma protein electrophoresis, albumin : globulin ratio (A/G), and plasma aspartate aminotransferase (AST) activity in an Amazon parrot (*Amazona* sp.). At the first examination there was a marked elevation of AST and a decreased A/G. Liver cirrhosis was diagnosed by means of histological examination of a liver biopsy. The second protein electrophoresis was made from a plasma sample collected just before the bird was euthanized 1 month later. Reference values in parentheses. Reprinted with permission from Lumeij (1987e).

dehydration of long duration, vitamin A deficiency), this will lead to an acute obstructive uropathy (postrenal obstruction). Anuria or gross oliguria occurs, and tubular secretion of UA is severely compromised. This leads to a rapid and severe increase in plasma UA with precipitation of urates on many visceral surfaces and those predilection sites for articular gout. This condition of visceral gout will rapidly lead to death of the affected animal. This hypothesis is based on the fact that no inflammation or tophi are seen in typical predilection sites for articular gout because the condition has a rapidly fatal course. In this situation, the kidney tubules, collecting ducts, and ureters may contain uric acid deposits. An alternative situation could occur in acute tubular failure. In this condition, visceral gout could develop without urate deposits in the tubules, collecting ducts, and ureters.

C. Acute vs Chronic Renal Failure

Renal function disorders may result either from any progressive destructive condition affecting both kidneys (chronic renal failure) or under conditions where the function of the kidneys is rapidly and severely, but often reversibly compromised (acute renal failure). In acute renal failure, oliguria is common, whereas in chronic renal failure, polyuria is more common. It is important to exclude reversible conditions that can mimic irreversible chronic renal failure, such as prerenal renal failure caused by dehydration, shock, urolithiasis (postrenal renal failure), and renal causes. Appropriate and timely treatment of these conditions can often prevent further damage and in some cases result in improved function. Extrarenal factors such as infection, gastrointestinal hemorrhage, and hypovolemia can disturb an otherwise stable, well-compensated asymptomatic chronic renal patient and precipitate a desperately dangerous condition.

D. Prerenal Azotemia

Prerenal azotemia can be defined as the clinical condition associated with reduced renal arterial tension leading to oliguria and retention of nitrogenous wastes in the blood. It is often seen during shock or severe dehydration. No increased plasma UA concentrations were observed in 4-day dehydrated racing pigeons, whereas plasma urea concentration had a significant 6.5–15.3-fold increase. Plasma urea appeared to be the single most useful variable for early detection of prere-

nal causes of renal failure (Lumeij, 1987c). This is because urea is excreted by glomerular filtration, whereas tubular reabsorption is dependent on urine flow, which in turn depends on the state of hydration. During hydration almost all of the filtered urea is excreted and during dehydration nearly all of the filtered urea is reabsorbed. The tubular reabsorption of urea in conditions of renal failure accompanied by a low urine flow (e.g., dehydration) in combination with a nearly unchanged excretion of UA causes a disproportionate increase in plasma urea concentration, resulting in an increased urea/uric acid ratio. Urea is normally present in low concentration in avian plasma, and therefore plasma urea concentration has traditionally been considered as an inappropriate variable to evaluate renal function in birds.

When the state of dehydration continues and gets more severe, this may eventually lead to hyperuricemia. This might be caused by reduced tubular blood supply, which leads to reduced urate secretion. Urates may also precipitate in the tubuli when there is active tubular secretion of UA in the absence of urine flow. The latter condition looks very much like the one that is called acute uric acid nephropathy in humans (Watts, 1978).

E. Postprandial Effects

In raptors a significant postprandial increase in plasma UA and urea concentration occurs (Lumeij and Remple, 1991; Lumeij and Redig, 1992). Postprandial UA was similar to those in birds with hyperuricemia and gout and was well above the theoretical limit of solubility of urate in plasma. It is not clear why under physiological conditions, no urate deposits occur in raptors, which have hyperuricemia for at least 12 hours after ingesting a natural meal (Fig. 30.10). To avoid physiological food-induced increases in UA and urea that can complicate interpretation of plasma chemistry results in birds, blood samples should be collected after a 24-hour fasting period.

F. Other Changes Associated with Renal Failure

Hyperkalemia is a particular problem in acute renal failure that may lead to severe electrocardiographic changes and eventually to cardiac arrest. Hypocalcemia and hyperphosphatemia are usual in humans with renal failure. The former may lead to hypocalcemic tetany, especially with rapid correction of acidosis. In birds, special attention should be paid to these constituents of renal disease because these changes may have therapeutic implications. Anemia has been documented in birds with chronic renal failure.

G. Murexide Test

Macroscopically, the aspirated urates from articular gout look like toothpaste. The presence of urate can be confirmed by performing the murexide test or by microscopic examination of aspirates of tophi or joint accumulations. The test is performed by mixing a drop of nitric acid with a small amount of the suspected material on a slide. The material is evaporated to dryness over a Bunsen flame and allowed to cool. Then one drop of concentrated ammonia is added. If urates are present, a mauve color will develop. Microscopically sharp needle-shaped crystals can be seen in smears. A polarizing microscope is helpful in identifying the typical crystals.

VI. HEPATOBILIARY DISEASE

A. Clinical Enzymology

Clinical enzymology is described more fully in a separate chapter in this book and only a brief synopsis will be given here. Enzymes occur normally in the cytoplasm (e.g., aspartate aminotransferase [AST], alanine aminotransferase [ALT], lactic dehydrogenase [LDH]), mitochondria (glutamate dehydrogenase [GLDH] and AST), nucleus, or membranes (alkaline phosphatase [AP], gamma glutamyl transferase

[GGT]) of body cells, where they catalyze specific reactions. The distribution of various enzymes is markedly different among various organs and various animal species, which explains the variations in organ and tissue specificities among the various animal species. Generally, increased enzyme concentrations are a measure of recent organ damage rather than decreased organ function. Increased enzyme production has been reported in cholestatic liver disease in mammals (AP and GGT). Sometimes a decreased activity is of diagnostic value (e.g., decreased cholinesterase activity in organophosphate toxicity). Baseline activity of an enzyme in plasma is generally a reflection of the amount and turnover of the tissue that contains this enzyme. For example, the creatine kinase (CK) activity in plasma increases in direct proportion to the increase of skeletal muscle mass as a result of training. Increases in CK may also be seen simply as a result of the excitement of handling. Conversely, in chronic liver disease with fibrosis and a reduction in the number of functional hepatocytes, plasma activities of liver enzymes may be within normal limits despite the presence of severe liver fibrosis. The increase of a particular enzyme also depends on factors such as its rate of release, rate of production, and rate of clearance from plasma. Cytoplasmic enzymes will be released early in cell degeneration, whereas mitochondrial enzymes will be released after advanced cell damage. Enzymes with high tissue concentrations but with short half-lives are of limited value in clinical enzymology because of their rapid disappearance from plasma.

Generally, EDTA samples are not appropriate for enzyme assays because this anticoagulant may chelate metal ions that are required for maximal enzyme activity. Plasma and cells should be separated immediately after sampling to prevent leakage of intracellular enzymes into the plasma. Even if the cellular elements are separated from the plasma, freezing/thawing and refrigeration of plasma samples for several days may severely decrease enzyme activity and therefore should be avoided unless the effects of the storage procedure used are known.

B. Enzyme Activities in Avian Tissues

Enzyme profiles of the various organs have been studied in chickens, mallard ducks, turkeys, racing pigeons, budgerigars, and African grey parrots (Lumeij, 1994f; Figs. 30.11 through 30.13).

C. Clearance of Enzymes from Plasma

The half-life of an enzyme is defined as the time required for its concentration to be reduced by half. When an enzyme is injected into plasma, its clearance from the plasma generally follows a biphasic exponential decline. Initially, there is a very rapid decline which is the primary mixing or distribution phase followed by a slower secondary decline phase, which is the actual clearance of the enzyme from the plasma. During this secondary phase, a constant fraction of the enzyme is cleared per unit time; hence, the decline is linear on a semilogarithmic scale. The half-life ($t_{1/2}$) of the enzyme can be calculated from the regression function of the secondary linear phase of the semilogarithmic concentration–time curve and is independent of plasma enzyme activity.

Clearance half-lives of various enzymes considered to be of use for the differential diagnosis of liver and muscle disease in pigeons have been established by studying the disappearance rates of enzymes from plasma after IV injections of supernatants of homologous liver and muscle homogenates (Lumeij *et al.*, 1988a). For AST, ALT, and LDH, the half lives of the respective enzymes from liver and muscle were compared, whereas for GLDH and CK only liver and muscle were used, respectively (Table 30.1).

D. Experimentally Induced Liver and Muscle Damage

Plasma enzyme profiles after experimental or spontaneously occurring liver disease have been studied in a number of avian species. The results of studies in racing pigeons (Lumeij *et al.*, 1988a,b) with two different types of liver disease were compared to plasma chemistry changes after muscle injury. Liver disease was induced by ethylene glycol or D-galactosamine and muscle injury was induced by an intramuscular injection of doxycycline in three groups of six pigeons each. Plasma chemical changes were correlated with histological findings from organ samples taken just after the last blood collection (Fig. 30.14, Table 30.2).

Plasma AST activity and bile acid (BA) concentration were the most sensitive indicators of liver disease in the racing pigeon, followed by ALT, GGT, and LDH. Although all pigeons with histological proven ethylene glycol- or galactosamine-induced liver damage had increased AST activity and BA concentrations in their plasmas, these constituents were not raised at every sampling time. Increased plasma GLDH activities were associated with large necrotic areas in the liver. Moderate necrosis of liver cells resulted in slightly elevated GLDH activities. Degeneration of liver cells and hepatitis with single-cell necrosis did not give rise to elevated plasma GLDH activities. Plasma CK activity was never elevated because of liver damage, whereas GLDH, GGT, and BA were never elevated during muscle damage. Thus, these four constituents are useful for differ-

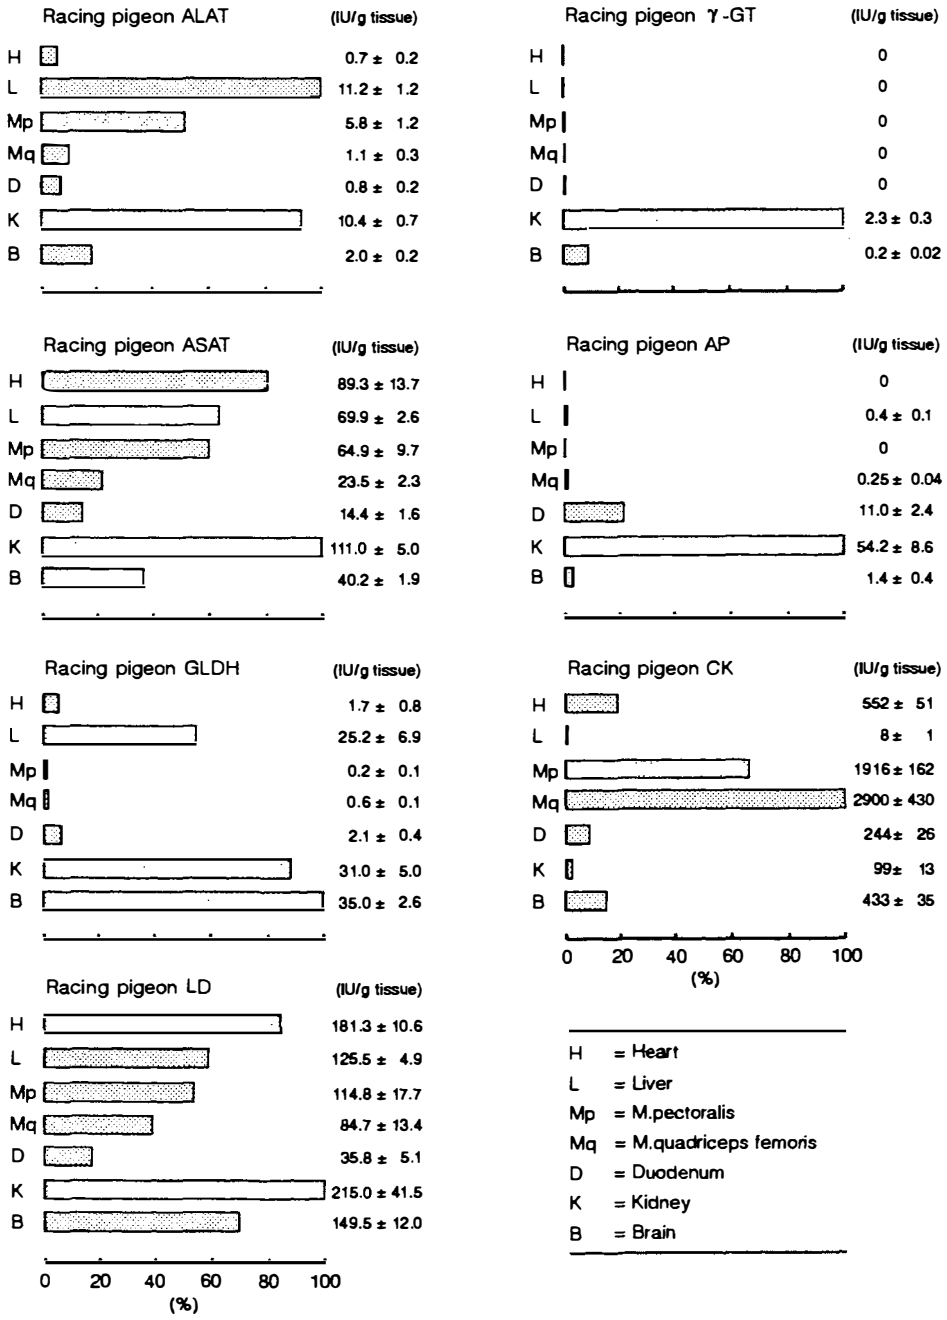

FIGURE 30.11 Relative distribution of various tissue enzymes in supernatants of pigeon tissue homogenates. Mean ± SEM, U/g wet tissue, $n = 6$. Reprinted with permission from Lumeij *et al.* (1988a).

entiating between liver and muscle disease. GLDH is the most liver-specific enzyme in the racing pigeon. Because GLDH is localized within the mitochondria of the liver cells, increased plasma GLDH activities, however, are only observed after liver cell necrosis.

The enzymes that are the most specific indicators of muscle and liver cell damage (CK and GLDH, respectively) have shorter half-lives than AST and ALT, which are not specific indicators of damage to either organ. Thus, after muscle or liver cell damage, AS and ALT activities in plasma can be increased eve though CK or GLDH activities have returned to bas line values. The fact that LDH has a shorter half-li than CK makes this enzyme valuable in the differenti diagnosis between muscle and liver disease in the p geon. When plasma LDH activity is increased in th absence of elevated CK activity, muscle damage is ur likely. Enzyme profiles can only serve as rough guide

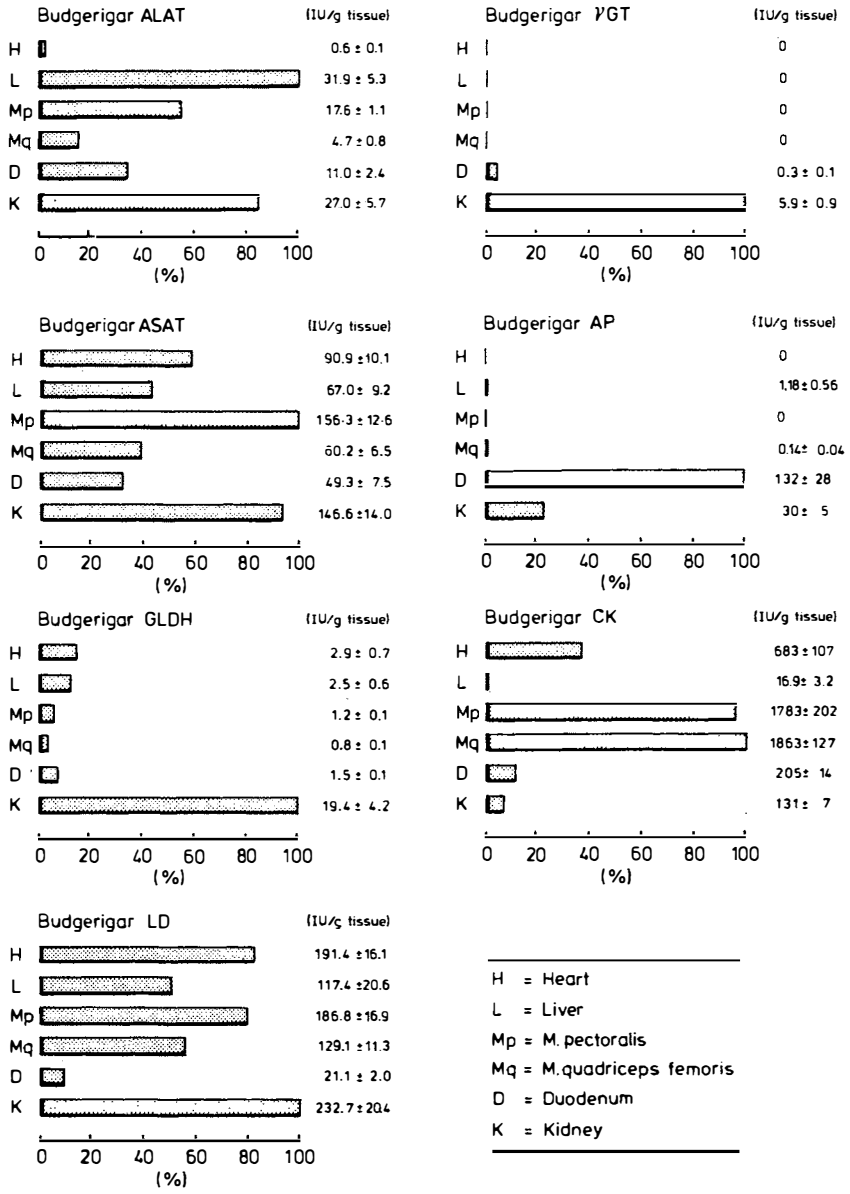

FIGURE 30.12 Relative distribution of various tissue enzymes in supernatants of tissue homogenates from the budgerigar, *Melopsittacus undulatus*. Mean ± SEM, n = 7, U/g wet tissue. Reprinted with permission from Lumeij and Wolfswinkel (1987).

to interpretation of increased plasma enzyme activity and are not characteristic for a particular organ. The most important reason is that the enzyme profile alters after enzymes have entered the circulation because of different removal rates for the various components.

Based on the tissue enzyme studies, it seemed that LDH would be the most sensitive indicator of liver cell damage, whereas ALT, because of its low activity in liver, would be of limited value. It also seemed that LD would be a more sensitive indicator of muscle cell damage than ALT. Experimentally induced liver and muscle damage, however, demonstrated that ALT activity in plasma is increased sooner than LDH activity. The relative increase of ALT was also larger than that of LDH, except in severe liver cell damage when accompanied by large areas of necrosis. Plasma ALT activities were increased for a longer period after organ damage compared to LDH. These findings can be explained by differences between their clearance half-lives. The clearance half-life of LDH is 15 to 30 times less than that of ALT.

Campbell (1986) reported increased AST and ALT activities in 75% of pigeons with aflatoxin B1-induced liver damage and increased LDH activities in 33%. In

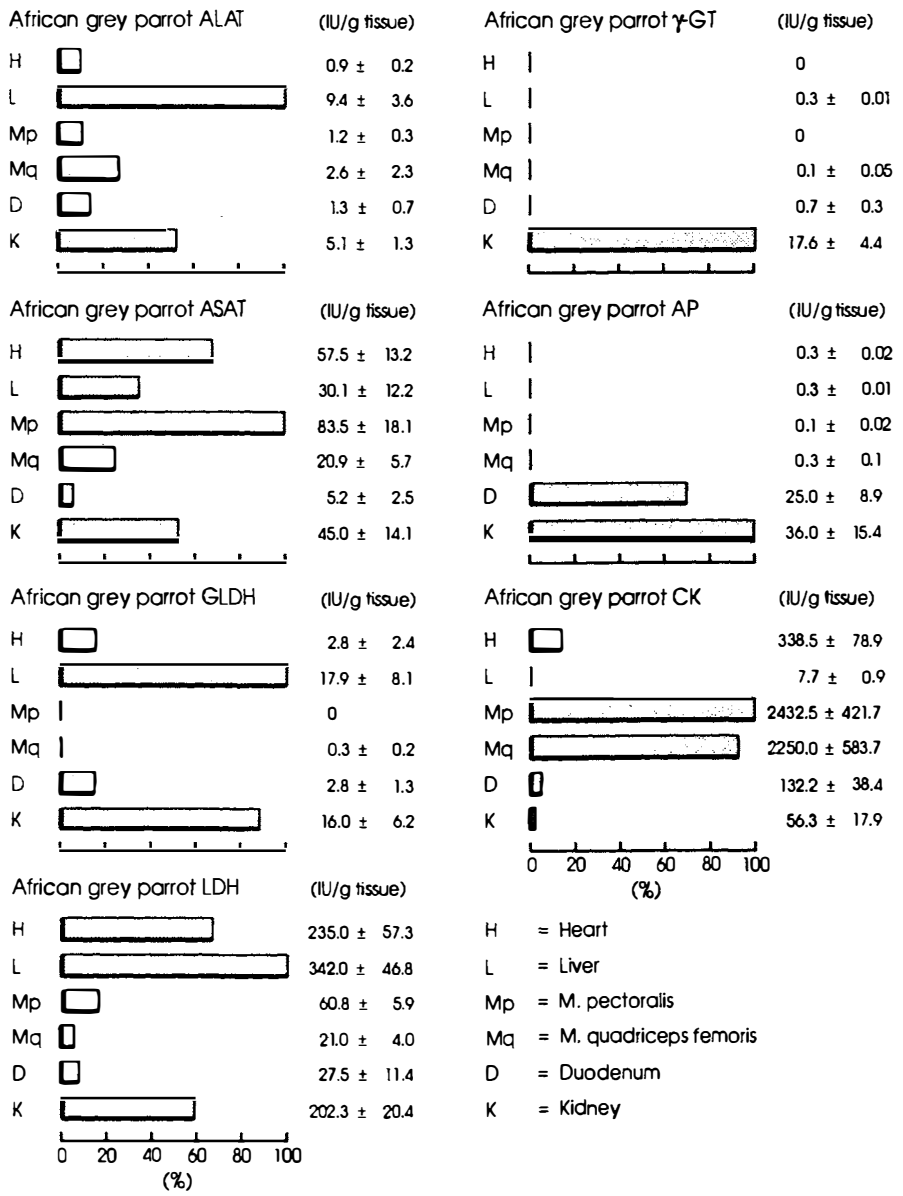

FIGURE 30.13 Relative distribution of various tissue enzymes in supernatants of tissue homogenates from the African grey parrot, *Psittacus erithacus*. Mean ± SEM, U/g wet tissue. Reprinted with permission from Lumeij (1994f).

addition, AP and GGT were not sensitive indicators of liver disease in pigeons, cockatiels, red-tailed hawks, and great horned owls. With the exception of GGT, these findings were confirmed by Lumeij *et al.* (1988a,b). The discrepancy might reflect the difference in the hepatotoxic agents used. In Lumeij *et al.* (1988a,b), GGT activities were increased in the majority of pigeons with experimentally induced liver disease, though no GGT could be detected in liver tissue homogenates. This might be explained by synthesis of GGT during (cholestatic) liver diseases, as has been reported in mammalian species (Kaplan and Righetti, 1969; Kryszewski *et al.*, 1973).

In birds, increased AP activities are predominantly associated with increased osteoblastic activity, such as skeletal growth, nutritional secondary hyperparathyroidism, rickets, and fracture repair osteomyelitis, as well as impending ovulation (Lumeij and Westerhof, 1987). Increased plasma AP associated with liver disease in birds is rare (Ahmed *et al.*, 1974). AP and CK were never elevated after liver cell damage and these enzymes in liver tissue were negligible. Increased ac-

tivities of liver enzymes in plasma may indicate recent damage to liver cells but do not give information on liver function. In end-stage liver disease (cirrhosis), it is possible to have normal activities of liver enzymes in the plasma, because active damage to liver cells has ceased (e.g., Fig. 30.9).

In psittacine birds, the use of a good anamnesis and the AST is sufficient to make a tentative diagnosis of liver disease. When birds are known to have been recently injected intramuscularly, increased AST and ALT should be interpreted with caution. Including a plasma constituent that specifically gives information on liver function, for example, total bile acids, has proven to be of great value. When liver disease is suspected, a biopsy is essential to establish a definite diagnosis.

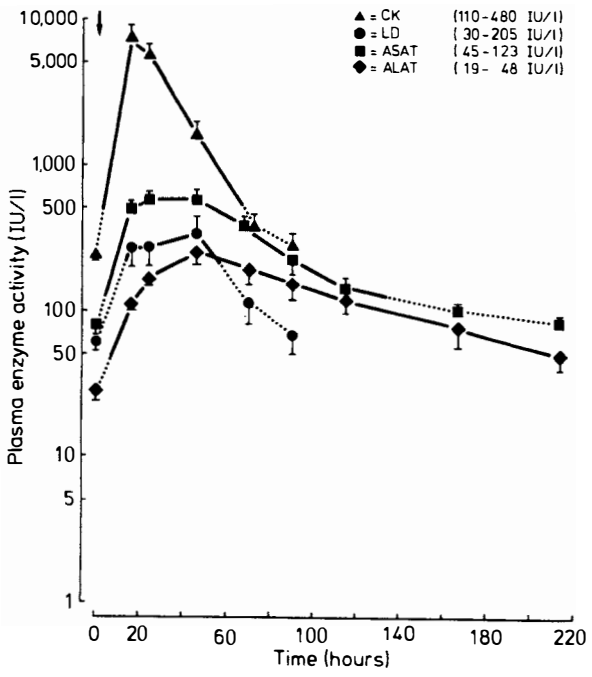

FIGURE 30.14 Mean (± SEM) plasma enzyme activities after intramuscular injection of 75 mg/kg doxycycline (Vibramycin—Pfizer, New York) in 6 racing pigeons. The parts of the curves that are above the reference range are indicated with continuous lines. Variables that did not show elevations above the reference range during the entire experiment (GLDH, AP, and bile acids) are not indicated. On histological examination at t = 215 hr degeneration and necrosis of muscle cells was seen. Reprinted with permission from Lumeij *et al.* (1988b).

E. Bile Pigments

The excretion of green urates is suggestive for liver disease in birds (Galvin, 1980; Lothrop *et al.*, 1986; Steiner and Davis, 1981). This discoloration is caused by biliverdin, which is the most important bile pigment

TABLE 30.2 Summary of Specificity and Sensitivity of Plasma Chemical Variables in Liver and Muscle Disease Based on Experimental Studies in Pigeons by Lumeij *et al.* (1988a,b)

	Liver disease		Muscle disease	
Variable	Specificity	Sensitivity	Specificity	Sensitivity
Bile acids	+++	+++	−	−
γ-GT	+++	+	−	−
AST	−	+++	−	+++
ALT	−	++	−	+++
AP	−	−	−	−
CK	−	−	+++	+++
LD	−	+	−	+
GLDH	+++	(+)[a]	−	−

[a] Elevated GLDH activity is a sign of extensive liver cell necrosis, since GLDH is a mitochondrial and not a cytoplasmatic enzyme. Liver cell degeneration will not cause elevated GLDH activities. In the budgerigar (*Melopsittacus undulatus*) GLDH activity in liver tissue is relatively low when compared to that of man and most of the domestic animals, including cockerel, duck, turkey, and pigeon (Lumeij and Wolfswinkel, 1987). However, in Amazon parrots with extensive liver necrosis due to Pacheco's disease, elevated GLDH activities were observed in plasma, which indicates that this variable is also useful in at least some of the psittacine species (Lumeij, unpublished observations).

in birds (biliverdinuria). Icterus or jaundice, which is caused by a hyperbilirubinemia, is seen infrequently in birds. When in chickens both bile ducts are ligated, the concentration of plasma bile pigments rises immediately but stabilizes after 2 weeks at about 85 μmol/liter, which is a much lower concentration than in mammals with total biliary obstruction. In sera of healthy ducks, low levels of bilirubin may be detected and significantly increased levels have been reported after experimental duck hepatitis virus infection. However, the observed levels of about 17 μmol/liter were well below the serum concentration of 34–51 μmol/liter, which has been mentioned as the level above which icterus becomes apparent in man. The infrequent occurrence of icterus in birds is explained by the absence of biliverdin reductase, which converts biliverdin to bilirubin (Lin *et al.*, 1974; Lind *et al.*, 1967; Tenhunen, 1971). It has been suggested that in birds, biliverdin may be converted to bilirubin by bacteria or nonspecific reducing enzymes (Lewandowski *et al.*, 1986). A yellow discoloration of avian plasma is often caused by the presence of carotenoids, which is often misinterpreted as being icteric.

F. Bile Acids as Indicators of Hepatobiliary Disease

Plasma bile acids and their salts are formed in the liver from cholesterol and are excreted in the intestine, where they assist in digestion of lipids. There is a continuous secretion of bile in birds both with and without a gall bladder. This is slightly increased postprandially because of the intrahepatic effects of intestinal hormones such as secretin, avian vasoactive intestinal peptide (VIP), and/or cholecystokinin (CCK). The sites of increased bile secretion and the regulatory mechanism are unknown (Lumeij, 1991). Via the enterohepatic recirculation, over 90% is reabsorbed in the jejunum and ileum (Hill, 1983). Plasma BA concentrations, including their salts and corresponding glycine and taurine conjugates (BA), are a reflection of the clearing capacity for bile acids of the liver. All liver functions, such as extraction, conjugation, and excretion, are involved in this process, and the BA provides information on the combined effects of these functions. It is now known that BA is a sensitive constituent for evaluating liver function, and it is widely used in man and domestic animals, including birds (De Bruijne and Rothuizen, 1988; Rutgers *et al.*, 1988; Hoffmann *et al.*, 1987; Lumeij, 1988). Reference values for BA have been established for the racing pigeon, the most common psittacine species (Lumeij and Overduin, 1990; Lumeij and Wolfswinkel, 1988), ostriches and peregrine falcons (Table 30.3). Lumeij (1987f) found that BA was the single mos useful plasma constituent for detecting liver functior disorders in the racing pigeon, where it is both specifi and sensitive. The main advantage over AST is tha the latter is not liver specific. In experimental live disease, a 5- to 10-fold increase of BA over the uppe limit of the reference range is common.

G. Effect of Feeding on Bile Acids

There is a significant postprandial increase in B/ in granivorous birds with and without a gallbladde (Lumeij, 1991) as well as in carnivorous birds (Fig 30.15; Lumeij and Remple, 1992). Although up to a 4.5 fold postprandial increase of BA was seen in individua birds, the concentrations were never increased mor than 1.65-fold over the upper limit of the referenc range, while in hepatobiliary disease five to ten-fol increases are common (Lumeij *et al.*, 1988a). Eve though postprandial increases might complicate inte pretation of BA, differentiation between postprandi increases and increases due to hepatobiliary disease i possible. Experimental findings suggest that value >70 μmol/l in fasted racing pigeons and value >100 μmol/l postprandially should be considered ir creased and suggestive for hepatobiliary disease.

H. Plasma Ammonia—Hepatoencephalopathy

A tentative diagnosis of hepatoencephalopathy often made when neurologic signs are seen in birc with liver disease. The syndrome, however, has n been well documented in birds. In mammals, hep toencephalopathy and hepatic coma are most ofte seen in portosystemic shunting in which portal bloo and its ammonia are shunted away from the live Hepatoencephalopathy is not a disease in itself, exce for the anatomic anomaly, but a medical conditic characterized by neurologic symptoms caused by i toxication of the brain by products of protein digestio namely NH_3. Most likely, degradation products fro protein act as false neurotransmitters. Protein-ri foods often trigger neurologic symptoms in these p tients. Fasting plasma NH_3 levels and plasma N levels 30 minutes after oral loading with NH_4Cl in t form of the NH_3 test (ATT) can be used to test t ability of the liver to convert NH_3 into urea. Fastir plasma NH_3 in healthy psittacines ranged from 36 274 μmol/liter, which is well above the fasting conce trations reported in dogs (Lumeij and Peccati, 199 Furthermore, some avian species will normally ha up to an eightfold increase of plasma NH_3 on the A using the canine protocol. Therefore, an abnormal A

is not diagnostic for portosystemic shunting in these species (Lumeij and Peccati, 1993).

VII. MUSCLE DISEASE

Muscle enzyme profiles, half-lives of these enzymes in plasma, and plasma chemistry changes after experimental muscle damage have been reported for racing pigeons (see Section VI.B). Enzyme profiles were studied for pectoral muscle, quadriceps muscle, and heart muscle in pigeons and parrots (Figs. 30.11 through 30.13). Creatine kinase was the most important enzyme in these three muscles, followed by LDH, AST, and ALT. Muscle damage was induced by injection of doxycycline in the pectoral muscle in pigeons (Fig. 30.14). Creatine kinase in plasma was markedly increased (about 20-fold) 16 hours after injection. However, within 66 hours plasma activities of CK had returned to the maximum value of the reference range. LD activities were only slightly elevated (about 2-fold) and only for about 40 hours. AST activities showed a marked increase (about 4-fold) for about 140 hours, whereas ALT showed a marked increase (about 5-fold) for about 214 hours. Despite that ALT activities in individual muscles are low, elevated plasma activities of this enzyme can be seen until 9 days after muscle damage. Plasma CK activities, on the other hand, return to within the reference range within 3 days after muscle damage, despite very high tissue activities. LD ap-

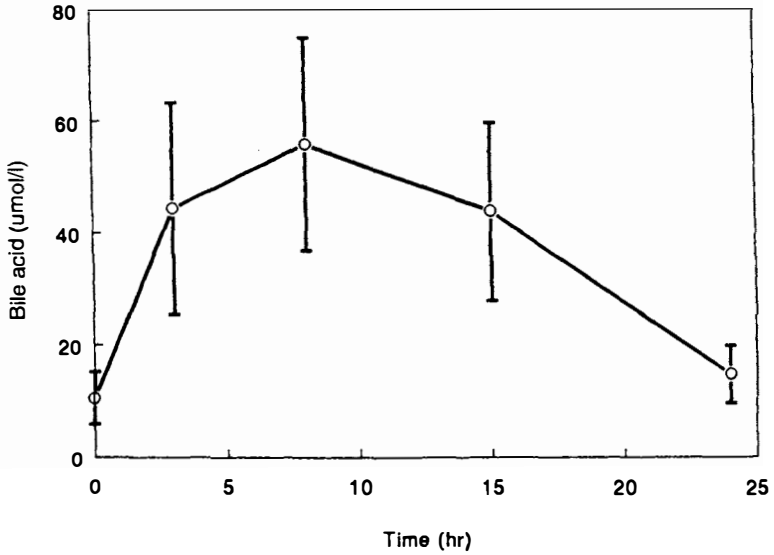

FIGURE 30.15 Plasma bile acid concentrations (mean ± SD) in peregrine falcons, *Falco peregrinus* (n = 6) after a 42-hr fasting period and 3, 8, 15, and 24 hr after birds were fed a complete skinned quail, *Coturnix coturnix* at 0 hr. Values at 3, 8, and 15 hr are significantly different from values at 0 and 24 hr ($P < .05$). Reprinted with permission from Lumeij and Remple (1992).

peared to be a relatively poor indicator of muscle cell damage, despite relatively high activity of this enzyme in muscle (Fig. 30.14). These findings can be explained by the differences in elimination half-lives of the respective enzymes (LD 50 minutes, CK 3 hours, AST 7 hours, ALT 12 hours) (Tables 30.1 and 30.2).

Not all elevated concentrations of muscle enzymes in plasma are an indication for muscle disease. Extreme muscular activity in the period preceding blood sampling is an important cause of elevated enzyme activities in plasma. In dogs plasma CK activities approximately double with exercise (Heffron *et al.*, 1976). Trained persons have plasma CK activities that are twice those of more sedentary people (Okinaka *et al.*, 1964). In humans, elevated activities of plasma CK can persist for about 1 week after exercise (Newham *et al.*, 1983). Chronic elevated plasma CK activities have been reported in certain occupational workers as a result of local muscular strain (Hagberg *et al.*, 1982; Brewster and De Visser, 1988). Plasma CK activity in healthy turkeys is extremely sensitive to physical exercise and stress. With controlled conditions of minimal exercise, stress, and time of handling, however, iatrogenic elevations of plasma CK activities can be prevented (Tripp and Schmitz, 1982). Elevated plasma CK activities can be expected in birds with large muscle mass after capture stress (e.g., ostrich). Intramuscular injections in birds are a well-known cause of elevated activities of plasma enzymes of muscle origin (Fig. 30.14). When physiological or iatrogenic causes of hyperCKemia can be ruled out, primary neuromuscular disease shoul be considered.

In birds several causes of degenerative myopath have been reported. In poultry furazolidone and iono phore coccidiostats are well-known causes of myocyt degeneration (Julian, 1991). Ingestion of the beans c coffee senna (*Cassia* spp.) has been suggested as a possi ble cause of acute myocyte degeneration in birds (Ra 1992). Two important causes of degenerative myopa thy in birds are exertional rhabdomyolysis (captur myopathy) and nutritional myopathy.

One of the signs of a deficiency of selenium and or vitamin E in birds is muscular degeneration. Som authors believe that exertional rhabdomyolysis is a acute manifestation of nutritional myopathy, althoug it has been recorded in species with apparently norm vitamin E levels (Spraker, 1980).

Capture myopathy has been reported in flamingc (Young, 1967; Fowler, 1978a,b), cranes (Brannian *al.*, 1982; Windingstad, 1983; Carpenter *et al.*, 1991 Canada geese (Chalmers and Barrett, 1982), turke (Spraker *et al.*, 1987), and ratites (Phalen *et al.*, 199 Dolensek and Bruning, 1978; Rae, 1992).

Nutrition-related myopathies have been reported i piscivorous birds that have been fed an unsuppl mented diet of previously frozen fish, primarily sme (Campbell and Montali, 1980; Carpenter *et al.*, 197 Nichols and Montali, 1987; Nichols *et al.*, 1986). Vitami E deficiency has also been associated with muscle l sions in raptors (Calle *et al.*, 1989; Dierenfeld *et a*

1989). Rae (1992) reported that a large percentage of young ratites submitted for necropsy exhibited evidence of degenerative myopathy, and she considered nutritional deficiency of vitamin E and possibly selenium as the most probable cause.

The muscular lesions produced by the various causes cannot be distinguished from each other, and the clinical history is important to establish a diagnosis (Rae, 1992). The use of serum or plasma vitamin E concentrations has been advocated to enable a clinical diagnosis of nutritional myopathy in birds (Rae, 1992). Mean (± SE) plasma concentrations of vitamin E (quantified as α-tocopherol) established in 274 captive cranes were 6.57 ± 0.82 μg/ml. Cranes species that evolved in temperate habitats had higher circulating levels of α-tocopherol than tropical or subtropical species: for example, black crowned crane (*Balearica pavonina*) (n = 10) 2.77 ± 0.23 μg/ml; Siberian crane (*Grus leucogeranus*) (n = 51) 9.41 ± 0.64 μg/ml (Dierenfeld *et al.*, 1993). In peregrine falcons (*Falco peregrinus*) circulating α-tocopherol concentrations <10 μg/ml were considered a reflection of a marginal vitamin E status, whereas plasma concentrations <5 μg/ml were considered deficient (Dierenfeld *et al.*, 1989). Only limited data are available on normal plasma concentrations of α-tocopherol in ratites. In apparently healthy rheas, circulating α-tocopherol concentrations ranged between 9.0 and 14.5 μg/ml, while two rheas, with muscular problems exhibited mean plasma concentrations of 1.34 μg/ml (Dierenfeld, 1989).

For the diagnosis of diseases of the cardiac muscle in birds, plasma chemistry has also been used. Enzymes that have been used include AST, LDH, and CPK. CPK activity in plasma from cardiac muscle origin (CPK-MB isoenzyme) was significantly higher in ducklings with furazolidone-induced cardiotoxicosis than in controls (Webb *et al.*, 1991).

VIII. CALCIUM AND PHOSPHORUS—METABOLIC BONE DISEASE

A. Relation between Total Calcium and Protein in Avian Plasma

About one-third of plasma calcium is protein bound and is biologically inactive. Total calcium concentration is influenced by plasma protein concentrations. The ionized fraction is important with regard to deposition of calcium salts and excitability of nervous tissues. In most laboratories, for technical reasons, only total calcium is measured. Hence, when total plasma calcium is measured it is also important to measure plasma protein concentrations and to make allowance for any deviations from the normal in the latter. A significant linear correlation was found between total calcium and albumin concentration in the plasma of 70 healthy African grey parrots (r = 0.37; P < .05) and a correction formula was derived on the basis of the concentration of albumin: Adjusted calcium (mmol/liter) = calcium (mmol/liter) −0.015 albumin (g/liter) + 0.4. Approximately 14% of the variability of calcium was attributable to the change in the concentration of plasma albumin (R^2 = 0.137) (Lumeij 1990).

A significant correlation was also found between total calcium and total protein concentration in 124 plasma samples of peregrine falcons (r = 0.65; P < .01). About 42% of the variability in calcium was attributable to the change in the plasma total protein concentration (R^2 = 0.417). The correlation between calcium and albumin was significant (r = 0.33; P < .01), but significantly smaller than the correlation between calcium and total protein (P < .01). Only 11% of the plasma calcium concentration was attributable to difference in concentration of albumin (R^2 = 0.108). An adjustment formula for plasma calcium concentration in the peregrine falcon was derived on the basis of the total protein concentration: Adj. Ca (mmol/liter) = Ca(mmol/liter) −0.02 total protein (g/liter) + 0.67 (Fig. 30.16; Lumeij *et al.*, 1993a). Application of a correction formula in African grey parrots and peregrine falcons is indicated when extremely low or extremely high plasma protein concentrations are found. The correction formulas just mentioned are based on total protein and albumin determinations with the methods outlined before (Section IV).

B. Estrogen-Induced Hypercalcemia

About 4 days before female pigeons are due to ovulate, the blood calcium concentration rises from a normal value of about 2.2 mmol/liter to a value of over 5.0 mmol/liter at the time of ovulation. This rise in calcium is caused by an increase in the protein-bound calcium due to the estrogen-induced transport of yolk proteins to the ovary as calcium complexes, whereby the concentration of ionized calcium remains constant (Simkiss, 1967). Since the total calcium concentration is the sum of biologically active ionized calcium, protein-bound calcium, and calcium chelated to anions, a total calcium concentration should always be interpreted in conjunction with plasma proteins (see Section VIII.A).

C. Physiological Marrow Ossification

Physiological marrow ossification is induced by the *combined* effects of estrogens *and androgens* and can be observed at about the same time as the estrogen-

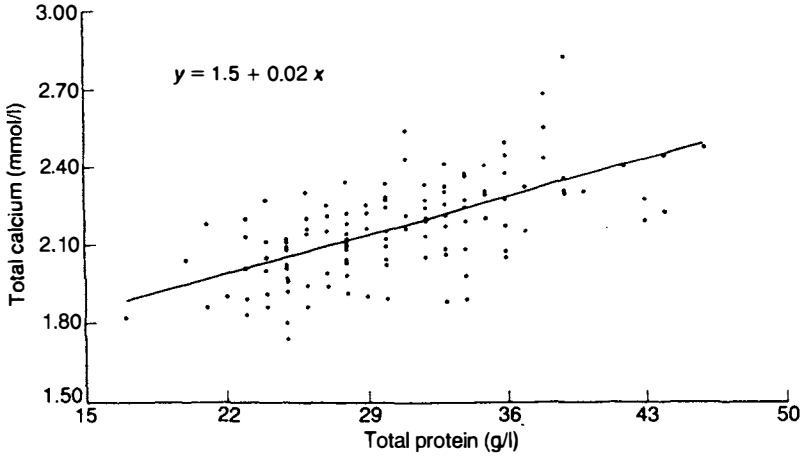

FIGURE 30.16 Significant relationship ($r = 0.65$; $P < 0.01$) between total protein and calcium in plasma of 124 peregrine falcons (*Falco peregrinus*). The least-square regression line is indicated. As the concentration of total protein decreases, there is a concurrent decrease in plasma total calcium. About 42% of the variability in calcium was attributable to the changes in the plasma total protein concentration ($R^2 = 0.417$). Reprinted with permission from Lumeij *et al.* (1993a).

induced hypercalcemia in female birds (Simkiss, 1967). There is a large increase in the quantities of calcium and phosphorus that are retained from the diet and laid down as medullary bone. This medullary bone may completely fill the marrow spaces of the long bones. It is most clearly seen in the limb bones, but occurs in most parts of the skeleton. This period of bone deposition coincides with increased osteoblastic activity. When the bird starts to secrete the eggshell, the medullary bone is resorbed by osteoclastic activity. Calcium is deposited in the eggshell as calcium carbonate and the phosphorus is excreted from the body. Medullary bone might be mistaken for a pathological condition when radiographs are being evaluated.

D. Hypocalcemia Syndrome in African Grey Parrots

A hypocalcemia syndrome known in birds of prey and African grey parrots is characterized by hypocalcemic seizures. A striking feature of this syndrome in African grey parrots which is not known in other birds is that demineralization of the skeleton is not obvious at the moment the seizures occur. The hypocalcemia syndrome is an important differential diagnosis in an African grey parrot that repeatedly falls off its perch. Reference values for plasma calcium concentrations in African grey parrots range from 2.0 to 3.25 mmol/liter (Rosskopf *et al.*, 1982). Lumeij (1990) studying a population of 72 African grey parrots found reference values of 2.1–2.6 mmol (inner limits of the percentiles $P_{2.5}$–$P_{97.5}$, with a probability of 90%) and a range from 2.0 to 3.4 mmol/liter. Hochleithner (1989b) studying 68 African grey parrots and using a dry chemistry system (Kodak Ektachem) reported reference values for Ca of 1.75–2.38 mmol/l (inner limits of the percentiles $P_{2.5}$–$P_{97.5}$). Hochleithner (1989a) reported five cases of hypocalcemia in African grey parrots with plasma calcium concentrations ranging from 0.75 to 1.5 mmol/liter. Rosskopf *et al.* (1985) state that the one consistent finding of the hypocalcemia syndrome is a blood calcium level below 1.5 mmol/liter. Values as low as 0.6 mmol/liter have been reported (Rosskopf *et al.* 1985). When borderline calcium concentrations are found, the correction formula reported in Section VIII.A should be used. When timely treatment with parenteral calcium and vitamin D_3 preparations is started and sufficient dietary uptake of calcium is taken care of, clinical signs will regress in a short time. It is therefore likely that the disease is caused by calcium and vitamin D_3 deficiency. The higher incidence of the hypocalcemia syndrome in African grey parrots might be associated with lower plasma concentrations of free calcium in this species (Lumeij, 1990).

E. Alkaline Phosphatase in Bone Disease

Alkaline phosphatases (APs) form a group of membrane-bound glycoproteins that hydrolyze monophosphate esters at alkaline pH. Three different isoenzymes have been identified. Although there is a significant activity of AP in various tissues, the physiological role is unclear, except for AP in bone tissue. AP activity in bone reflects the activity of osteo

blasts, and this enzyme is involved in the formation and mineralization of the bone matrix. In humans increased AP activity is observed during growth and in osteoproliferative disorders (Savova and Kirev, 1992). Different techniques have been used for identification of fractions responsible for increased plasma activities. The heat inactivation test has been developed to distinguish AP activity of bone origin from that of liver origin (Johnson *et al.*, 1972; Posen *et al.*, 1965). In humans, after heat inactivation at 56°C, residual activities higher than 35% indicate hepatic disease, whereas residual values lower than 25% indicate bone disease with increased osteoblastic activity (Fennely *et al.*, 1969; Fitzgerald *et al.*, 1969; Stolbach, 1969). Using a guinea fowl model with bone tumors induced by osteopetrosis virus, Savova and Kirev (1992) were able to confirm these findings also for an avian species. By comparing the findings with the more sensitive wheat germ lectin method (Rosalki and Foo, 1984; Brixen *et al.*, 1989), they showed that for guinea fowl the AP activity of bone origin can be inactivated at 58°C rather then 56°C. Savova and Kirev (1992) found that AP activity of bone origin in 15-week-old guinea fowl was twice as high as that of 1-year-old birds. They also confirmed the positive correlation between the intensity of virus-induced excessive bone growth and serum AP activity reported previously (Sanger *et al.*,1966; Barnes and Smith, 1977). The presumed high proportion of AP of bone origin was supported by the low values of residual activity after heat inactivation at 58°C (14.7 ± 3.7%) and after precipitation with wheat germ lectin (13 ± 1.2) during the period of active bone tumor formation (Savova and Kirev, 1992).

IX. IRON STORAGE DISEASE

Hemochromatosis is a disease of excessive storage of hemosiderin (hemosiderosis) in various body tissues. Hemosiderin is an iron-containing pigment derived from hemoglobin. The principal site of Fe accumulation is the liver, and many other body tissues are also affected. Hemochromatosis is especially well known in Ramphastidae, Sturnidae, mynahs, quetzals (Worell, 1994), and Psittaciformes (Rosskopf *et al.*, 1992). The etiology is at present unknown, but a high dietary Fe has been suggested. Cardiac complications are often seen in mynahs due to cardiac muscle hemosiderosis. Ramphastidae are generally clinically normal prior to death, but occasionally affected birds are listless 24 hours prior to death. In mynahs, general weakness, dyspnea, and ascites are commonly seen. Radiography may reveal hepatomegaly, cardiomegaly, or ascites. Blood chemistry is indicative of a liver function disorder. A specific diagnosis can be made by histological examination of a liver biopsy after specific staining for Fe (Turnbull blue). Total serum/plasma Fe and total iron binding capacity (TIBC) may be helpful in evaluating the iron status of the animal, although only limited work has been done on the clinical pathology associated with avian hemochromatosis. To measure the Fe status of an individual, three main compartments should be considered: storage Fe, transport Fe, and erythrocyte Fe. A semiquantitative method of establishing the amount of storage Fe is by examining histological sections for stainable Fe in liver biopsies. In humans with hemochromatosis, the urinary Fe excretion at 6 hours following the injection of the iron chelating agent deferoxamine or diethylenetriaminepentaacetic acid (DTPA) is significantly higher than in normal individuals. The concentration of the Fe storage protein ferritin (Ftn) in the serum is directly related to the available storage iron in the liver and is clinically the most useful method for assessing iron stores (Jacobs, 1978).

Transport iron is evaluated by measuring the serum Fe, the total iron binding capacity, and the unbound iron binding capacity (UIBC). The UIBC is calculated as the difference between the serum Fe and the TIBC. The TIBC represents the total amount of the Fe transport protein transferrin (Tf) in the serum, and the UIBC represents the amount of the Tf that is not bound to Fe and is available for Fe binding. Reference values for serum or plasma Fe concentration and TIBC in humans are 10–34 μmol/liter and 45–72 μmol/liter; respectively (Scott, 1978). In pigeons these values were 11–33 μmol/liter and 30–45 μmol/liter, respectively (Lumeij and De Bruijne, 1985a). In normal toucans (Ramphastidae) total serum Fe was below 63 μmol/liter, whereas TIBC was below 100 μmol/liter (Worell, 1991). Clinically normal toucans with bile acids, plasma chemistry, and hematological values within the normal reference limits had histological evidence of hemochromatosis and liver iron levels in excess of the normal 100–300 ppm (Worell, 1993). Currently, antemortem diagnosis of hemochromatosis in clinically normal toucans relies on a hepatic biopsy to determine characteristic histopathologic changes with or without serum Fe (Worell, 1994). Total serum Fe in a mynah bird (*Gracula religiosa*) with hemochromatosis exceeded 160 μmol/liter, whereas two control birds had values < 36 μmol/liter (Morris *et al.*, 1989). In another Balih mynah (*Leucopsar rothschildi*) with hemochromatosis, serum Fe at the time of diagnosis was 88 μmol/liter.

After combined treatment by phlebotomy and deferoxamine mesylate medication, a liver biopsy had minimal stainable Fe and the corresponding serum Fe was 21 μmol/liter (Loomis and Wright, 1993). During

treatment of hemochromatosis by repeated phlebotomies, establishment of the various red cell parameters is essential to detect excessive Fe depletion. Erythrocyte Fe is evaluated by red blood cell (RBC) morphology and the various RBC parameters such as the packed cell volume (PCV), hemoglobin (Hb), mean cell volume (MCV), mean cell Hb (MCH), and mean cell Hb concentration (MCHC).

X. DIABETES MELLITUS AND PLASMA GLUCOSE

The fundamental regulation of glucose metabolism in birds is identical to that in mammals, but there is a quantitative difference. Reference ranges for plasma glucose in birds are between 11 and 25 mmol/liter (Rosskopf *et al.*, 1982; Lumeij and Overduin, 1990). Physiological values up to 33 mmol/liter have been observed postprandially in pigeons (Lumeij, 1987b). Under stress, plasma glucose concentrations up to 33 mmol/liter may also be observed (Jenkins, 1994). The insulin content of the pancreas of granivorous birds is about one-sixth that of mammalian pancreata, while the glucagon content is about two to five times greater. Plasma glucagon (1 to 4 ng/ml) is about 10 to 50 times higher in birds than in mammals. Insulin is synthesized in the β cells of the pancreas, while glucagon is synthesized in the A cells.

Spontaneous diabetes mellitus, as characterized by polyuria/polydipsia (PU/PD), glucosuria, persistent hyperglycemia, and loss of weight despite good appetite, has been reported in a number of avian species, including budgerigars, cockatiels, an Amazon parrot, an African grey parrot, toco toucans, a red-tailed hawk, and the pigeon (Altman and Kirmayer, 1976; Candeletta *et al.*, 1993; Lothrop *et al.*, 1986; Lumeij, 1994d; Murphey, 1992; Schlumberger, 1956; Spira, 1981; Wallner-Pendleton *et al.*, 1993; Wiesner, 1971; Woerpel *et al.*, 1987). The species in which diabetes is most commonly encountered are budgerigars, cockatiels, and toco toucans. A tentative diagnosis can be made by finding glucose in urine, and a definitive diagnosis can be made by finding an increased plasma glucose concentration. A PU/PD with glucosuria does not always indicate diabetes mellitus.

In mammals, Fanconi's syndrome is characterized by renal glucosuria, hyperaminoaciduria, and hyperphosphaturia as well as renal loss of potassium, bicarbonate, water, and other substances conserved by the proximal tubule. Fanconi's syndrome should be considered as the final result of any one of many possible primary insults to proximal tubular function. The patient's symptoms reflect the disturbance of tubular function in addition to the primary cause of the syndrome. The syndrome may be inherited or acquired

There are some striking differences between birds and mammals with regard to pancreatic effects on carbohydrate metabolism. In mammals, pancreatectomy results in diabetes mellitus, whereas effects of pancreatectomy in birds are controversial. In granivorous birds, surgical extirpation or destruction of the pancreas with cytotoxic agents leads to hypoglycemic crisis and death, whereas pancreatectomies in carnivorous birds lead to diabetes mellitus. It is generally accepted that glucagon is more effective in granivorous birds that have a marked insulin insensitivity. The limited data available on spontaneous diabetes mellitus in granivorous birds suggest that in these species, diabetes mellitus is not caused by an insulin deficiency. Birds of prey may be more insulin dependent than granivorous birds (Wallner-Pendleton *et al.*, 1993).

Spontaneous diabetes mellitus in birds has been reported to be successfully treated with daily injections of insulin in dosages comparable to dosages used in dogs. These successful treatments of diabetic birds (disappearance of clinical signs) are surprising considering the relative insulin insensitivity that has been reported to occur in a variety of avian species.

Plasma insulin and glucagon concentrations have been established in three birds with hyperglycemia (Lothrop *et al.*, 1986). In all cases, insulin concentrations were similar to those of controls while glucagon concentrations were extremely high or extremely low. In another case of diabetes in an African grey parrot, Candeletta *et al.* (1993) reported extremely low insulin concentrations. The findings suggest that different etiologies are likely to be involved in the development of avian diabetes. Possible etiologies of diabetes mellitus in birds have been discussed (Lumeij,1994d).

XI. EXOCRINE PANCREATIC DISEASE

Exocrine pancreatic hormones present in the duodenum of birds include amylase, lipase, trypsin, and chymotrypsin. They facilitate degradation of carbohydrates, fats, and proteins, respectively. The inactive precursors of trypsin and chymotrypsin, trypsinogen and chymotrypsinogen, enter the duodenum, where they are activated by intestinal enterokinase. This mechanism prevents autodigestion of pancreatic tissue (Duke, 1986).

There are two basic manifestations of exocrine pancreatic hormone disorders: (1) acute pancreatitis or acute pancreatic necrosis, and (2) chronic pancreatitis resulting in pancreatic fibrosis and pancreatic exocrine insufficiency.

The pathogenesis of acute pancreatitis involves the activation of pancreatic enzymes in and around the pancreas and bloodstream, resulting in coagulation necrosis of the pancreas and necrosis and hemorrhage of peripancreatic and peritoneal adipose tissue. Increased amylase and lipase activities in plasma have been reported in birds with active pancreatitis. Reference values for plasma lipase and amylase have been measured in a population of 87 African grey parrots (Van der Horst and Lumeij, unpublished observations). α-Amylase activity in plasma was determined by a kinetic *p*-nitrophenylmaltoheptaoside method (Sopachem α-Amylase kit # 003-0311-00, Sopar-biochem, 1080 Brussels) at 30°C. Values ranged from 571 to 1987 U/liter (inner limits of $P_{2.5}$–$P_{97.5}$ with a probability of 90%).

Lipase activity was measured at 30°C using a test based on the conversion of triolein by lipase to monoglyceride and oleic acid. The associated decreased turbidity is measured in the UV range (Boehringer Mannheim kit # MPR 3-1442651). Reference values ranged from 268 to 1161 U/liter.

Hochleithner (1989b) reported reference values for plasma amylase in four different psittacine species using a dry chemistry system (Kodak Ektachem, Amylopectin, 25°C; Kodak, 1986). The values were considerably lower than the ones just discussed: budgerigar (n = 50) 187–585 U/liter; African grey parrot (n = 68) 211–519 U/liter; Amazon parrot (n = 30) 106–524 U/liter; macaw 276–594 U/liter.

Chronic pancreatitis results in fibrosis and decreased production of pancreatic hormones. When insufficient pancreatic enzymes are available in the duodenum, maldigestion and a passing of feces with excessive amylum and fat will occur. Affected animals have voluminous, pale or tan greasy feces. Fat can be demonstrated by Sudan staining.

Fecal amylase and proteolytic activity were determined in a population of 87 African grey parrots by Van der Horst and Lumeij (unpublished observations), using radial enzyme diffusion as reported by Westermarck and Sandholm (1980). Reference values (inner limits of $P_{2.5}$–$P_{97.5}$ with a probability of 90%) for fecal amylase were 6 to 18 mm and for fecal trypsin 14–19 mm.

XII. TOXICOLOGY

A. Lead

Lead poisoning is common in birds (Lumeij, 1985b; Dumonceaux and Harrison, 1994). A clinical diagnosis is made by demonstrating increased lead in whole blood or by demonstrating secondary effects of lead on various enzymes involved in heme synthesis. Blood Pb in clinically normal birds and in birds with signs of lead poisoning can be much higher than in mammals (Lumeij, 1985b). Blood Pb in birds without clinical signs and without known exposure to lead ranged between 2.5 and 180 μg/dl. Birds that had been exposed to Pb but had no clinical signs had Pb between 40 and 2000 μg/dl, whereas birds with clinical signs had blood Pb from 52 to 5840 μg/dl. Dieter (1979) proposed that a blood Pb of 20 μg/dl was physiologically detrimental in canvasback ducks, *Aythya valisaneria*, because a significant decrease in δ-aminolevulinic acid activity was observed at these Pb levels. The U.S. Fish and Wildlife Service presumes that blood Pb concentrations >20 μg/dl in 5% of hunter-killed or live-trapped waterfowl is indicative of some type of Pb assimilation in tissues (U.S. Federal Register 29673, 20 August 1986). Draury *et al.* (1993) uses the terms "detrimental" and "deleterious" in association with blood Pb of 20 μg/dl. Although a blood Pb of 20 μg/dl indicates increased exposure to Pb, these levels are not considered harmful to animals. The current clinical view is that blood Pb <50 μg/dl is generally not associated with clinical signs and has a good prognosis even without treatment. Lead between 50 and 100 μg/dl is associated with mild clinical signs and carries a good prognosis for recovery with treatment. Clinical signs and prognosis worsen when blood Pb exceeds 100 μg/dl, and when Pb exceeds 200 μg/dl the prognosis is guarded to poor (Degernes, 1995). When clinical signs are present, blood Pb >35 μg/dl is suggestive of Pb toxicosis (Klein and Galey, 1989). In psittacines blood Pb levels as low as 20 μg/dl are considered suggestive for Pb exposure (Dumonceaux and Harrison, 1994).

Most of the Pb in blood is associated with the red blood cells (Buggiani and Rindi, 1980). The nuclear inclusions that have been observed by electron microscopy in nucleated erythrocytes of pigeons with high blood Pb have led to the assumption that these could serve as storage sites, like the Pb inclusion bodies described in kidneys of Pb-poisoned rats. The capacity of birds to survive high blood Pb without overt toxicosis might be associated with these erythrocytic inclusion bodies (Barthalmus *et al.*, 1977).

Lead interferes with two enzymes in the hemoglobin biosynthetic pathway: δ-aminolevulinic acid dehydratase (ALA-D) and heme synthetase (Fig. 30.17). In humans ALA-D is inhibited even at normal blood Pb levels (McIntire *et al.*, 1973). When there is an increase in Pb, ALA-D is uniformly low. A level >600 IU/dl excludes Pb poisoning (Beeson *et al.*, 1979). A significant negative correlation exists between blood Pb and ALA-D in pigeons, urban-dwelling humans, urban

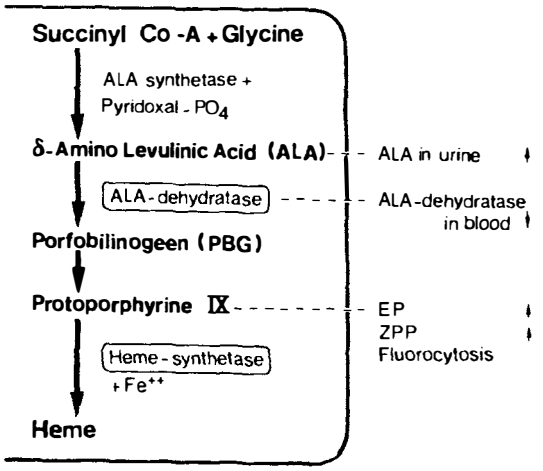

FIGURE 30.17 Schematic representation of heme synthesis. Lead interferes with the enzyme δ-aminolevulinic acid dehydratase (ALA-D), resulting in a lower activity of ALA-D in blood and a higher concentration of δ-aminolevulinic acid in the urine. Interference with the enzyme heme synthetase leads to an accumulation of protoporphyrin IX in the erythrocytes, which can be measured as FEPP or ZPP and leads to fluorocytosis. Modified with permission from Lumeij (1985b).

rats, and Pb-dosed wildfowl as long as the blood Pb is only moderately elevated. If the blood Pb increases above a moderate level, ALA-D does not decrease further. This phenomenon has been observed in pigeons and humans (Hutton, 1980). The inhibition of ALA-D in Pb poisoning leads to accumulation of ALA, and excess ALA is excreted in the urine.

Because Pb inhibits heme synthetase, protoporphyrin IX also accumulates in the erythrocytes. In human Pb poisoning, free erythrocyte protoporphyrin (FEPP) is in the range of 300–3000 μg/dl (reference range 15–60 μg/dl). If a fresh wet film of blood of a patient is examined under UV light (400 nm), 75–100% of the erythrocytes have a red fluorescence, fluorocytes. The accumulated FEPP imparts the red fluorescence to the fluorocytes (Beeson *et al.*, 1979). The fluorocyte test has also been used successfully for the diagnosis of Pb poisoning in rabbits (Roscoe *et al.*, 1975) and waterfowl (Barret and Karstad, 1971).

In humans, FEPP binds to zinc to form the fluorescent compound zinc protoporphyrin (ZPP), which can be measured fluorometrically in a single drop of whole blood (Roscoe *et al.*, 1979). Roscoe *et al.* (1979) found that the blood fluorescence spectra of Pb-poisoned mallard ducks were characteristic of metal-free protoporphyrin IX. They suggested that the reason for chelation of Zn by FEPP in human erythrocytes and not in duck erythrocytes might be due in part to the fact that duck erythrocytes contained only about one-third as much Zn as the human erythrocytes. By changing the factory-installed emission filter in a commercially available fluorometer used to screen humans for Pb intoxication by measurement of ZPP, they made the instrument suitable for measuring FEPP. They found that FEPP levels were at their highest 8 days after Pb-shot ingestion in mallard ducks. The highest value they recorded was 2284 μg/dl. FEPP was rarely elevated (>40 μg/dl) in freshly drawn blood from Pb-poisoned ducks. However, when the same blood was oxygenated and refrigerated prior to testing, FEPP concentrations increased because *in vitro* synthesis that terminated within 2 days. No such increase was manifested by controls. They found that FEPP was directly related to the clinical signs of Pb poisoning in mallard ducks, and those with Pb higher than 500 μg/dl began to show impaired motor function that could seriously affect their survival (Table 30.4).

In raptors, birds showing clinical signs of Pb toxicosis had consistently higher ZPP levels than other Pb-dosed birds with similar blood Pb values (Reiser and Temple, 1981). False-positive FEPP and ZPP elevations occur in humans suffering from iron deficiency anemia or erythrocytic protoporphyria (Wijngaarden and Smith, 1982).

B. Zinc

Zinc poisoning has been reported in birds after they ingest pennies (United States) minted after 198[illegible] (98% Zn) or metal fence clips (96% Zn). Galvanized wire is another well-known source of Zn poisoning in aviary birds (new-wire disease). Clinical signs includ

TABLE 30.4 Blood Protoporphyrin IX Concentrations Measured on the Hematofluorometer and Corresponding Clinical Signs of Lead Poisoning in Mallard Ducks[a]

Blood protoporphyrin IX	Clinical signs
> 801 μg/dl > 14.4 μmol/liter	Death Inability to stand, walk, fly Loss of voice Green watery diarrhea
501–800 μg/dl 9.0–14.4 μmol/liter	Muscular weakness Easily fatigued Unsteady gait Slight tail drop Green watery diarrhea
201–500 μg/dl 3.6–9.0 μmol/liter	Hyperexcitability Green watery diarrhea
40–200 μg/dl 0.7–3.6 μmol/liter	Green watery diarrhea
0–39 μg/dl 0–0.7 μmol/liter	No evidence of lead poisoning

[a] From Roscoe *et al.* (1979).

weight loss, depression, anorexia, gastrointestinal signs, and posterior paresis. Pathological lesions are especially seen in the pancreas and include acinar atrophy and proliferation of pancreatic ductules (Howard, 1992; LaBonde, 1995; Lloyd, 1992; Morris, 1985; Reece, 1986; Zdziarski *et al.*, 1994; Wight *et al.*, 1986).

Serum Zn can be used to establish a diagnosis, but extreme care must be taken to exclude contamination by Zn-containing grommets in plastic syringes or rubber stoppers in collecting tubes (Minnick *et al.*, 1982). Serum Zn levels in an affected group of ducks were 1260–1660 μg/dl as compared to a reference group ranging between 184 and 465 μg/dl. In a group of normal cockatiels, the mean serum Zn was 163 μg/dl. In general, blood Zn >1000 μg/dl is considered diagnostic and >200 μg/dl suggestive for Zn poisoning in psittacine birds (LaBonde, 1995).

C. Organophosphate and Carbamate

Organophosphates (OPs) and carbamates (CBMs) are the most common causes of avian insecticide poisoning. Poisoning occurs through inhalation or ingestion. The fundamental mechanism of OP and CBM poisoning is the inhibition of acetylcholinesterase (AChE). The LD-50 of this group of poisons is 10–20 times higher in birds than in mammals. The binding of CBM to AChE is reversible, in contrast to that of OP. Clinical signs include acute anorexia, crop stasis, ptyalism, ataxia, wing twitching, stargazing, weakness, diarrhea, prolapsed nictitans, and muscular tremors or stiffness. Dyspnea and bradycardia may be observed as the toxicity progresses. In severe cases, the birds may be recumbent with varying degrees of paralysis or seizures. An OP ester-induced delayed neuropathy has been reported in mammals and birds. The onset occurs 1 to 3 weeks after exposure and is not associated with AChE inhibition. With aging, metabolites of some OP compounds can affect peripheral axons and myelin sheaths, resulting in sensory and motor neuropathy. Associated clinical signs include weakness, ataxia, and decreased proprioception in the limbs progressing to paralysis (Porter, 1993; LaBonde, 1992, 1995; Lumeij *et al.*, 1993b).

Diagnosis of OP or CBM poisoning can be established by the AChE activity in blood, plasma, or serum. There are a number of different test procedures, but their results are not interchangeable. Besides AChE, another enzyme, pseudocholinesterase (PsChE) or butyrylcholinesterase (BChE, E.C. 3.1.1.8.), is found in sera. Although its physiological role is not defined, it is a useful indicator of exposure to OP and CBM compounds (Sherman *et al.*, 1964; Ludke *et al.*, 1975). Because plasma BChE activity increases with age in nestling passerines, this might partially account for it decreasing sensitivity in older birds to OP and CBM poisoning. Plasma BChE usually is inhibited more rapidly and to a larger degree than brain AChE and may be scavenging the active oxon forms of OP compounds that otherwise might inhibit brain AChE activity. Because of the lack of OP hydrolyzing enzymes in the plasma in many bird species or the low affinity of this class of enzymes for OP compounds in birds, the role of BChE in protecting individuals is important (Garc and Hooper, 1993).

It is important that results of AChE, PsChE, or BChE determinations be compared with those of nonexposed animals of the same species and age. Age-dependent changes in plasma AChE activities have been reported for many avian species. Furthermore, development patterns of plasma AChE differ between altricial and precocial species. In contrast to plasma BChE activities in nestlings of altricial species, plasma AChE and BChE activity decreased significantly with age in precocial species (Bennet and Bennet, 1991; Gard and Hooper, 1993).

Cases of suspected CBM toxicity may have normal AChE activities because of rapid regeneration, and therefore these samples should be run as soon as possible to be accurate. Because CBMs, unlike OP compounds, are reversible AChE inhibitors, AChE inhibition followed by thermal reactivation has been employed to discriminate between these poisonings (Hunt and Hooper 1993; Hunt *et al.*, 1993, 1995; Stansley, 1993).

Acknowledgments

The author is grateful to the publishers of the journals *Avian Diseases, Avian Pathology, Seminars in Avian and Exotic Pet Medicine,* and *The Veterinary Quarterly* for permission to use illustrations that were published previously in these journals, and to Wingers Publishing, Inc. APPENDIX I. SI UNITS

The Systéme Internationale d'Unites (SI), or the International System of Units, was recommended for use in the health professions by the World Health Assembly (WHA 30.39) in May 1977. The SI is the culmination of more than a century of effort to develop a universally acceptable system of units of measure. In the past decade, the use of SI has been rapidly gaining acceptance, with many nations now mandating its use and many others strongly recommending its use. Furthermore, many scientific journals now require that units be expressed in SI along with the conventional units if used. The following tables in this appendix briefly describe the basis of SI and provide factors for the conversion of conventional units to SI.

TABLE A SI Base Units

Quantity	Name of unit	Symbol
Length	meter (metre)	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Luminous intensity	candela	cd
Amount of substance	mole	mol

TABLE B SI Derived Units

Quantity	Name of unit	Symbol
Area	square meter	m^2
Volume	cubic meter	m^3
Speed, velocity	meter per second	m/s
Acceleration	meter per second squared	m/s^2
Substance concentration	mole per cubic meter	mol/m^3
Pressure	pascal	Pa
Work, energy	joule	J
Celsius temperature	degree Celsius	°C

TABLE C SI Prefixes

Factor	Prefix	Symbol	Factor	Prefix	Symbol
10^{18}	exa	E	10^{-1}	deci	d
10^{15}	peta	P	10^{-2}	centi	c
10^{12}	tera	T	10^{-3}	milli	m
10^{9}	giga	G	10^{-6}	micro	μ
10^{6}	mega	M	10^{-9}	nano	n
10^{3}	kilo	k	10^{-12}	pico	p
10^{2}	hecto	h	10^{-15}	femto	f
10^{1}	deca	da	10^{-18}	atto	a

TABLE D Non-SI Units Still in General Use

Quantity	Unit	Symbol	Value in SI
Time	minute	m	60 s
	hour	h	3600 s
	day	d	86,400 s
Volume	liter (litre)	l[a]	10^{-3} m^3
Mass	tonne	l	1000 kg
Length	angstrom	Å	10^{-10} m (0.1 nm)
Pressure	bar	bar	10^5 Pa
	atmosphere	atm	101,325 Pa
	mmHg	mm Hg	1.333×10^{-4} Pa
Radioactivity	curie	Ci	3.7×10^{10} Bequerel (Bq)
	roentgen	R	2.58×10^{-4} Ci/kg
	rad	rad	10^{-2} gray (Gy)
	rem	rem	10^{-2} sievert (Sv)

[a] Liter is often spelled out or symbolized by L to avoid confusion.

TABLE E SI Conversion Factors

Chemical constituent	Conventional "old unit"	× Factor =	New SI unit
Acetoacetate	mg/dl	0.098	mmol/l
Acetone	mg/dl	0.172	mmol/l
Albumin	g/dl	10.0	g/l
Ammonia	μg/dl	0.5872	μmol/l
Bicarbonate	mEq/l	1.0	mmol/l
Bilirubin	mg/dl	17.10	μmol/l
Bromosulfonphthalein	mg/dl	11.93	μmol/l
Calcium	mg/dl	0.2495	mmol/l
Carotenes	μg/dl	0.01863	μmol/l
Chloride	mEq/l	1.0	mmol/
Cholesterol	mg/dl	0.02586	mmol/l
Cobalt	μg/dl	0.1697	μmol/l
Coproporphyrin	μg/dl	15.0	nmol/l
Cortisol	μg/dl	27.59	nmol/l
CO_2, total	mEq/l	1.0	mmol/l
CO_2 pressure, pCO_2	mmHg	0.1333	kPa
Copper	μg/dl	0.1574	μmol/l
Creatinine	mg/dl	88.40	μmol/l
Fibrinogen	mg/dl	0.01	g/l
Fructose	mg/dl	55.51	μmol/l
Glucose	mg/dl	0.05551	mmol/l
Haptoglobin	mg/dl	0.01	g/l
Hemoglobin	g/dl	10.0	g/l
β-Hydroxybutyrate	mg/dl	0.096	mmol/l
Iodine	μg/dl	78.8	nmol/l
Insulin	μU/ml	7.175	pmol/l
Iron	μg/dl	0.1791	μmol/l
Lactate	mg/dl	0.1110	mmol/l
Lead	μg/dl	0.04826	μmol/l
Magnesium	mg/dl	0.4114	μmol/l
Manganese	μg/dl	0.1820	μmol/l
Mercury	μg/l	4.985	nmol/l
Methemoglobin	g/dl	10.0	g/l
Molybdenum	μg/dl	0.1042	μmol/l
Myoglobin	mg/dl	0.5848	μmol/l
Nitrogen	mg/dl	0.7138	mmol/l
O_2 pressure, pO_2	mmHg	0.1333	kPa
Phosphorus	g/dl	0.3229	mmol/l
Porphobilinogen	mg/dl	44.20	μmol/l
Potassium	mEq/l	1	mmol/l
Protein	g/dl	10	g/l
Protoporphyrin	μg/dl	0.0178	μmol/l
Pyruvate	mg/dl	113.6	μmol/l
Selenium	μg/dl	0.1266	μmol/l
Sodium	mEq/l	1	mmol/l
Thyroxine	μg/dl	12.87	nmol/l
Transferrin	mg/dl	0.01	g/l
Triglycerides (trioleate)	mg/dl	0.01129	mmol/l
Triiodothyronine	ng/dl	0.01536	nmol/l
Urate	mg/dl	59.48	μmol/l
Urea Nitrogen	mg/dl	0.7140	mmol/l
Urea Nitrogen	mg/dl	0.3570	mmol Urea
Urea	mg/dl	0.1665	mmol/l
Urobilinogen	mg/dl	16.90	μmol/l
Uroporphyrin	μg/dl	12.00	nmol/l
Vitamin A	μg/dl	0.03491	μmol/l

(continu

TABLE E (*Continued*)

Chemical constituent	Conventional "old unit"	×	Factor	=	New SI unit
Xylose	mg/dl		0.06660		mmol/l
Zinc	μg/dl		0.1530		μmol/l
Enzymes[a]	U/l		16.67		nkat/l

[a] There is yet no general agreement or recommendation for the use of the katal (1 kat = 1 mol/s) in place of the widely used international unit (1 U = 1 μmol/m). The U/l should continue to be used for all enzyme activities.

APPENDIX III. TEMPERATURE CORRECTION FACTORS (Tf) FOR SOME COMMON ENZYMES[a]

Assay temperature (°C)	AlP	CK	LDH	SDH	ALT/AST
20	2.61	2.05	2.10	1.48	2.29
21	2.37	1.82	1.96	1.42	1.85
22	2.15	1.70	1.80	1.37	1.71
23	1.95	1.59	1.67	1.32	1.59
24	1.77	1.49	1.55	1.27	1.45

[a] Abbreviations: AlP, alkaline phosphatase; CK, creatine kinase; LDH, lactate dehydrogenase; SDH, sorbitol (iditol) dehydrogenase; ALT, alanine aminotransferase; AST, aspartate aminotransferase.

APPENDIX II. CONVERSION FACTORS OF SOME NON-SI SERUM ENZYME UNITS TO SI INTERNATIONAL ENZYME UNITS[a]

Serum enzyme	Non-SI unit	×	Factor	=	SI
Aldolase (ALD)	Sibley–Lehninger unit (SLU) (Mg DNP/hour/ml)		0.75		U/liter
Amylase (AMYL)	Somogyi unit (SU) (mg G/30 minutes)		1.85		U/liter
Glutamic-oxalacetic transaminase (SGOT, AST)	Sigma–Frankel unit (SFU) Karmen unit (KU) Wroblewski–LaDue unit (WLU) Reitman–Frankel unit (RFU) (0.001 OD/m/ml)		0.48		U/liter
Glutamic pyruvic transaminase (SGPT, ALT)	Sigma–Frankel unit (SFU) Karmen unit (KU) Wroblewski–LaDue unit (WLU) Reitman–Frankel unit (RFU) (0.001 OD/m/ml)		0.48		U/liter
Isocitric dehydrogenase (ICD)	Wolfson–Williams–Ashman unit (WWAU) (nmol/h/ml)		0.0167		U/liter
Lipase	Roe–Byler unit (RBU) (μmol/h/ml)		16.7		U/liter
	Cherry–Crandall unit (CCU) (50 μmol/3h/ml)		2.77		U/liter
Phosphatase, acid	King–Armstrong unit (KAU) (mg phenol P/30 minutes)		1.85		U/liter
Phosphatase, alkaline (AlP)	King–Armstrong unit (KAU) (mg Phenyl P/30 m) Bodansky unit (BU) (mg P/hour)		7.10 5.4		U/liter U/liter
Sorbitol (iditol) dehydrogenase (SDH, IDH)	Sigma–Frankel unit (SFU) (nmol/hour/ml)		0.0167		U/liter

[a] U = 1 international unit = 1 μmol/minute = 16.67 nmol/second = 16.67 nkatal/second = 0.01667 μkatal/second.

Examples of Use

A. To correct an enzyme activity to a standard temperature of 30°C, multiply the assay value at any temperature by the Tf of that temperature: AlP activity at 27°C = 48 U/l; correct it to 30°C

$$48 \times 1.33 = 63.8 \text{ U/l}.$$

B. To correct an enzyme activity at any one temperature to another temperature, multiply the assay value at the first temperature by the ratio of the Tf of the first temperature to the Tf of the second temperature: AlP activity at 22°C = 38 U/l; correct it to 37°C:

$$38 \text{ U/l} \times 2.15/0.48 = 170.2 \text{ U/l at } 37°\text{C}.$$

APPENDIX IV. STABILITY OF SERUM ENZYMES UNDER VARIOUS STORAGE CONDITIONS[a]

Enzyme	25°C	4°C	−25°C
Acid phosphatase	4 hr[b]	3 days[c]	3 days[c]
Alkaline phosphatase	2–3 days[d]	2–3 days	1 month
Aldolase	2 days	2 days	Unstable[e]
Amylase	1 month	7 months	2 months
Cholinesterase	1 week	1 week	1 week
Creatine kinase	2 days	1 week	1 month
Glutamyl transferase	2 days	1 week	1 month
Glutamate dehydrogenase	1 day	2 days	1 day
Aspartate aminotransferase	3 days	1 week	1 month
Alanine aminotransferase	2 days	1 week	Unstable[e]
Hydroxybutyrate dehydrogenase	Unstable	3 days	Unstable[e]
Isocitrate dehydrogenase	5 hr	3 days	3 weeks
Leucine aminopeptidase	1 week	1 week	1 week
Lactate dehydrogenase	1 week	1–3 days[f]	1–3 days[f]
Malate dehydrogenase	Unstable	3 days	3 days
Sorbitol (iditol)dehydrogenase	Unstable	1 day	2 days

[a] No more than 10% of the original activity lost during the specified time.
[b] At pH 5–6.
[c] With added citrate or acetate.
[d] Activity may increase.
[e] Enzyme does not tolerate thawing well.
[f] Depends on the isoenzyme profile.

APPENDIX V. TEMPERATURE CONVERSIONS BETWEEN DEGREES CELSIUS AND DEGREES FAHRENHEIT[a]

°C	°F	°C	°F	°C	°F	°C	°F
−40	−40.0	−4	24.8	32	89.6	68	154.4
−39	−38.2	−3	26.6	33	91.4	69	156.0

−5	23.0	31	87.8	67	152.6	103	217.4

[a] °C = 5/9 × (°F − 32); °F = ($\frac{9}{5}$ × °C) + 32.

APPENDIX VI. NOMOGRAM FOR COMPUTING RELATIVE CENTRIFUGAL FORCES (RCF)

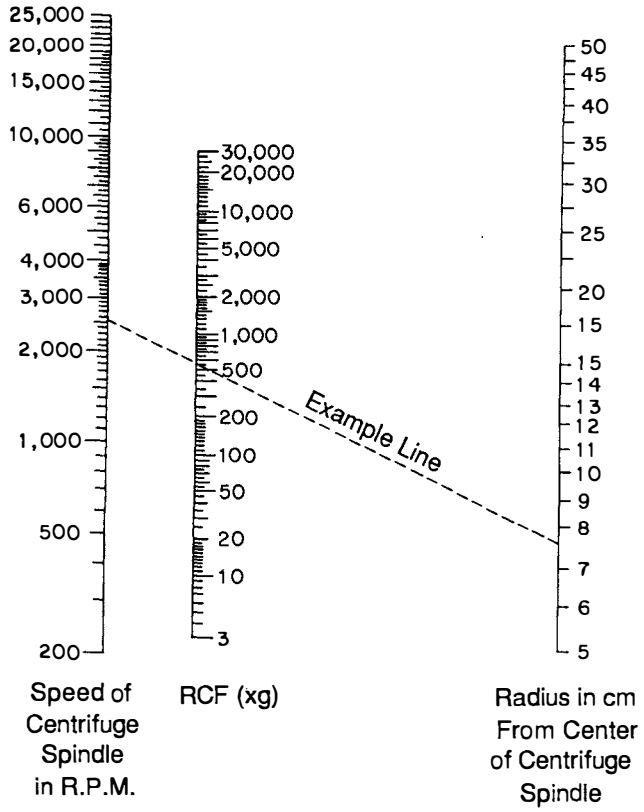

FIGURE VI.1 To calculate the RCF value at any point along the tube, measure the radius in cm from the center of the centrifuge spindle to the point. Draw a line from this radius value on the right hand column to the centrifuge speed on the left hand column. The RCF value is the point where the line intersects the center column.

APPENDIX VII. CONVERSIONS OF BODY WEIGHT TO SQUARE METERS OF BODY SURFACE AREA FOR DOGS AND CATS[a]

kg	m^2	kg	m^2
0.5	0.06		
1.0	0.10	26	0.89
2.0	0.16	27	0.91
3.0	0.21	28	0.93
4.0	0.26	29	0.95
5.0	0.30	30	0.98
6.0	0.33	31	1.00
7.0	0.37	32	1.02
8.0	0.40	33	1.04
9.0	0.44	34	1.06
10.0	0.47	35	1.08
11.0	0.50	36	1.10
12.0	0.53	37	1.12
13.0	0.56	38	1.14
14.0	0.59	39	1.16
15.0	0.62	40	1.18
16.0	0.64	41	1.20
17.0	0.67	42	1.22
18.0	0.69	43	1.24
19.0	0.72	44	1.26
20.0	0.74	45	1.28
21.0	0.77	46	1.30
22.0	0.79	47	1.32
23.0	0.82	48	1.33
24.0	0.84	49	1.35
25.0	0.86	50	1.37

[a] Calculated from

$$A = kW^{0.667} \times 10^{-4},$$

where A = body surface area in square meters (m^2); k = constant 10.1 for dogs; W = body weight in grams. For cats, the constant k is 10.0, so the conversion to body surface area closely approximates that for the dog and may be used interchangeably.

APPENDIX VIII. BLOOD ANALYTE REFERENCE VALUES IN LARGE ANIMALS[a]

Analyte[b]	Unit	Horse	Cow	Sheep	Goat	Llama	Pig
Acetylcholinesterase (AcChE): R	U/liter	450–790	1270–2430	640	270		930
Alanine aminotransferase (ALT, GPT): S, HP	U/liter	3–23	11–40		6–19	6–14	31–58

Uric acid	mg/kg/day	1–2	1–4	2–4	1–2			2–5
Urine volume	ml/kg/day	3–18	17–45	10–40	5–30	17–45	10–20	10–40
Uroporphyrin	mg/dl		1.5–7.0	3.8	5.0			

APPENDIX XIII. CEREBROSPINAL FLUID (CSF) ANALYTE REFERENCE VALUES IN LARGE ANIMALS

Analyte	Units	Horse	Cow	Sheep	Goat	Llama	Pig
Rate of formation	μl/m		290	118	164		
Alkaline phosphatase (AIP)	U/liter	0–8 (0.8 ± 0.9)					
Aspartate aminotransferase (AST)	U/liter	15–50 (30.7 ± 6.3)					
Calcium	mg/dl	2.5–6.0 (4.2 ± 0.9)	5.1–6.3	5.1–5.5	4.6		
Chloride	mmol/liter	95–123 (109.2 ± 6.9)	111–123	128–148	116–130	(116–143)	(134 ± 6.5
Cholesterol (Chol)	mg/dl	020.0 (4.8 ± 5.7)					
Creatine kinase (CK)	U/liter	0–8 (1.1 ± 3.1)					
Glucose	mg/dl	30–70 (48.0 ± 10.0)	37–51 (42.9 ± 1.0)	52–85	70	59–86 (69.3 ± 7.35)	45–87
γ-Glutamyltransferase (GGT)	U/liter	0.8–4.2 (2.6 ± 1.9)					
Hydrogen ion (pH)	units	7.13–7.36	7.22–7.26	7.3–7.4 (7.35)			
Lactate dehydrogenase (LD)	U/liter	12–34 (27.7 ± 8.0)	2–25 (13.94 ± 1.32)			7–24 (13 ± 5.6)	
Lactic acid (LAC)	mg/dl	(2.3 ± 0.2)					
Magnesium	mg/dl	1.1–3.0 (2.0)	1.8–2.1 (1.99 ± 0.03)	2.2–2.8	2.3		
Phosphorus	mg/dl	0.5–1.5 (0.8 ± 0.2)	0.9–2.5	1.2–2.0			
Potassium	mmol/liter	2.5–3.5 (3.0 ± 0.1)	2.7–3.2 (2.96 ± 0.03)	3.0–3.3	3.0	2.9–3.3 (3.19 ± 0.10)	
Pressure	mm H_2O	272–490					
Protein							
Total	mg/dl	40–170 (105 ± 38)	23.4–66.3 (39.1 ± 3.39)	29–42	12	31.2–66.8 (43.1 ± 9.0)	24–29
Albumin	mg/dl	22.6–67.9 (38.6)	8.21–28.71 (15.75 ± 1.53)			11.8–27.1 (17.9 ± 4.45)	17–24
Globulin:	mg/dl	3.4–18.4 (9.3)					5–10
γ-Globulin	mg/dl	3–10 (6.0 ± 2.1)	2.46–8.85			3.4–13.8	
Sodium	mmol/liter	140–150 (144.6 ± 1.9)	132–142 (140 ± 0.78)	145–157	131	134–160 (154 ± 5.8)	134–144
Specific gravity	unit	1.004–1.008	1.005–1.008				
Urea (UR)	mg/dl	0–43.2					
	mmol/liter	0–7.2					
Urea nitrogen (UN)	mg/dl	0–20 (11.8 ± 3.3)	8–11				
	mmol/liter	0–14.3 (0 ± 3.4)					
Viscosity	unit	1.00–1.05	1.019–1.029				
Cells (total WBC)	#/μl	0–6	0.85–3.52	0–5	0–4	0–3	0–7
Cells (total RBC)	#/μl	(195 ± 512)	5–1930			0–1360	

APPENDIX XIV. CEREBROSPINAL FLUID (CSF) ANALYTE REFERENCE VALUES IN SMALL AND SOME LABORATORY ANIMALS

Analyte	Units	Dog	Cat	Rat	Mouse	Rabbit	Monkey
Rate of formation	μl/m	47–66	20–22	2.1–5.4	0.325	10	28.6–41.0
Alaninine aminotransferase (ALT)	U/liter	0.96–15.36 (6.58 ± 0.65)					
Aspartate aminotransferase (AST)	U/liter	4.32–22.08 (9.65 ± 0.65)	0–34 (17 ± 7)				
Calcium	mg/dl	5.13–7.40 (6.56)	5.1–6.3 (6.0 ± 0.24)				
Chloride	mmol/liter	109–126 (130 ± 0.5)	111–123				
Creatine kinase (CK)	U/liter	(23.5 ± 0.19)	2–236 (47 ± 51)				
Glucose	mg/dl	48–57	18.2–130.9 (74.5 ± 23.6)				
Hydrogen ion (pH)	units	7.13–7.36	7.22–7.26				
Lactate dehydrogenase (LD)	U/liter		0–24 (12 ± 5)				
Magnesium	mg/dl	25.8–3.81	(3.24 ± 0.05)				
Phosphorus	mg/dl	2.82–3.47 (3.09)					
Potassium	mmol/liter	2.9–3.2 (3.3 ± 0.04)	(2.69 ± 0.09)				
Pressure	mm H_2O	24–172					
Protein							
Total	mg/dl	18–44 (28.68 ± 5.52)	0–30 (5 ± 9)				
Albumin	mg/dl	7.5–27.6 (17.1 ± 6.7)	19–25 (10.1 ± 12.9)				
Globulin:		14.0–21.1 (17.45 ± 0.83)					
IgA	μg/ml	0–0.2 (0.08)					
IgG	mg/dl	2.5–8.5 (4.68 ± 0.68)	0–5.3 (1.4 ± 0.27)				
IgM	μg/ml	0–5.8 (1.7)					
Sodium	mmol/liter	151.6–155 (153 ± 0.5)	158 (158 ± 4)				
Specific gravity	unit	1.003–1.012 (1.005)					
Urea	mg/dl	10–11	21.5–23.6				
	mmol/liter	1.7–1.8	3.6–3.9				
Urea nitrogen	mg/dl	4.7–5.1	10–11				
	mmol/liter	3.3–3.7	7.1–7.9				
Cells (total WBC)	#/μl	0–25	0–1				
Small mononuclear	%	15–95					
Large mononuclear	%	5–40					
Degenerate	%	0–40					
Cells (total RBC)	#/μl	<1500	<30
