Preface to the 5th Edition

The first edition of *Clinical Biochemistry of Domestic Animals* was published in 1963; now, 34 years later, this fifth edition is appearing. We can all appreciate that change is a constant in all human endeavor and that science in particular is changing at an ever more rapid pace. In recognition of this rapid progress, this fifth edition constitutes yet another major change from the previous edition. In recognition of the breadth, magnitude, and complexity of this change, two associate editors, Dr. John W. Harvey of the University of Florida at Gainesville and Dr. Michael L. Bruss of the University of California at Davis, joined a team to guide the preparation of this fifth edition. Many new contributors joined this effort, major revisions of previous contributions were undertaken, and four new chapters were added: Tumor Markers, Lysosomal Storage Diseases, Clinical Biochemistry in Toxicology, and Avian Clinical Biochemistry.

It is also fitting that this volume be dedicated to the memories of Dr. Charles E. Cornelius, co-editor of the first two editions and contributor to all previous editions, and of Dr. George H. Stabenfeldt, contributor to the third and fourth editions. Both were great personal friends and outstanding scientists, administrators, and teachers and are sorely missed.

The acceptance of the Système International d'Unités (SI units) continues to be resisted for many reasons, although its use is expanding, albeit slowly, throughout the world. The concept of the SI unit is retained in this fifth edition as it was in the fourth with the inclusion of both SI and conventional units throughout the text and the appendices. The appendices in this edition have also been expanded to include new analyte reference ranges for the variety of species with which this volume is concerned.

We take this opportunity to acknowledge our gratitude to the many contributors who through their conscientiousness have eased the incredibly formidable task of assembling a multiauthored volume of this magnitude. All contributors have been extremely enthusiastic and cooperative with us as well as with Academic Press in their efforts to move production of this volume forward in a timely fashion. From the outset, Academic Press, ably represented by editor Chuck Crumly and his staff, has been extremely diligent, providing constant encouragement, guidance, and assistance for which we are most appreciative.

This fifth edition represents a new departure with increased editorship and a host of new and emerging subject areas in the field of clinical biochemistry of domestic animals. It recognizes and welcomes the changing nature of the field as new knowledge is uncovered and, as a corollary, the need for the wider view that associate editors bring to this effort. All contributors can justly point with pride to this fifth edition.

Finally, we express our thanks to our families, who have given us incredible support in this undertaking and have persevered without complaint through our single-minded devotion to this effort.

CHAPTER

1

Concepts of Normality in Clinical Biochemistry

THOMAS B. FARVER

I. POPULATIONS AND THEIR DISTRIBUTIONS

A population is a collection of individuals or items having something in common. For example, one could say that the population of healthy dogs consists of all dogs that are free of disease. Whether a given dog belongs to the population of healthy dogs depends on someone's ability to determine if the dog is or is not free of disease. Populations may be finite or infinite in size.

A population can be described by quantifiable characteristics frequently called *observations* or *measures*. If it were possible to record an observation for all members in the population, one most likely would demonstrate that not all members of the population have the same value for the given observation. This reflects the inherent variability in populations. For a given measure, the list of possible values that can be assumed with the corresponding frequency with which each value appears in the population relative to the total number of elements in the population is referred to as the *distribution* of the measure or observation in the population. Distributions can be displayed in tabular or graphical form or summarized in mathematical expressions. Distributions are classified as discrete distributions or continuous distributions on the basis of values that the measure can assume. Measures with a continuous distribution can assume essentially an infinite number of values over some defined range of values, whereas those with a discrete distribution can assume only a relatively few values within a given range, such as only integer values.

Each population distribution can be described by quantities known as *parameters*. One set of parameters of a population distribution provides information on the center of the distribution or value(s) of the measure that seem to be assumed by a preponderance of the elements in the population. The mean, median, and

mode are three members of the class of parameters describing the center of the distribution. Another class of parameters provides information on the spread of the distribution. The spread of the distribution has to do with whether most of the values assumed in the population are close to the center of the distribution or whether a wider range of values is assumed. The standard deviation, variance, and range are examples of parameters that provide information on the spread of the distribution. The shape of the distribution is very important. Some distributions are symmetric about their center, whereas other distributions are asymmetric, being skewed (having a heavier tail) either to the right or to the left.

II. REFERENCE INTERVAL DETERMINATION AND USE

One task of clinicians is determining whether an animal that enters the clinic has blood and urine analyte values that are in the normal interval. The conventional method of establishing normalcy for a particular analyte is based on the assumption that the distribution of the analyte in the population of normal animals is the "normal" or Gaussian distribution. To avoid confusion resulting from the use of a single word having two different meanings, the "normal" distribution henceforth is referred to as the Gaussian distribution.

A. The Gaussian Distribution

Understanding the conventional method for establishing normalcy requires an understanding of the properties of the Gaussian distribution. Theoretically, a Gaussian distribution is defined by the equation:

$$y = \frac{1}{\sqrt{2\pi\sigma}} e^{-(x-\mu)^2/2\sigma^2},$$

where x is any value that a given measurement can assume, y is the relative frequency of x, μ is the center of the distribution, σ is the standard deviation of the distribution, π is the constant 3.1416, and e is the constant 2.7183.

Theoretically, x can take on any value from $-\infty$ to $+\infty$. Figure 1.1 gives an example of a Gaussian distribution and demonstrates that the distribution is symmetric around μ and is bell shaped. Figure 1.1 also shows that 68% of the distribution is accounted for by measurements of x that have a value within 1 standard deviation of the mean, and 95% of the distribution includes those values of x that are within 2 standard deviations of the mean. Nearly all of the distribution (97.75%) is contained by the bound of 3 standard deviations of the mean.

Most analytes cannot take on negative values and so, strictly speaking, cannot have Gaussian distributions. However, the distribution of many analyte values is approximated well by the Gaussian distribution because virtually all of the values that can be assumed by the analyte are within 4 standard deviations of the mean and, for this range of values, the frequency distribution is Gaussian. Figure 1.2 gives an example. The figure, adapted from the printout of BMDP2D (detailed data description including frequencies; Engleman, 1992), gives an example of the distribution of glucose values given in Table 1.1 for a sample of 168 dogs from a presumably healthy population. Though not perfectly Gaussian, the distribution is reasonably well approximated by the Gaussian distribution. Support for this claim is that the distribution has the characteristic bell shape and appears to be symmetric about the mean. Also, the mean [estimated to be 96.4 mg/dl (5.34 mmol/liter)] of this distribution is nearly equal to the median [estimated to be 95.0 mg/dl (5.27 mmol/liter)], which is characteristic of the Gaussian distribution. The estimates of the skewness and kurtosis coefficients are close to zero, also characteristic of a Gaussian distribution (Engleman, 1992; Remington and Schork, 1985; Snedecor and Cochran, 1989).

B. Evaluating Probabilities Using a Gaussian Distribution

All Gaussian distributions can be standardized to the reference Gaussian distribution, which is called the *standard Gaussian distribution.* Standardization in general is accomplished by subtracting the center of the distribution from a given element in the distribution and dividing the result by the standard deviation of the distribution. The distribution of a standardized Gaussian distribution, that is, a Gaussian distribution that has its elements standardized in this form, has its center at zero and has a variance of unity. The elements of the standard Gaussian distribution are traditionally designated by the letter z so that it can be said that z is $N(0,1)$. That all Gaussian distributions can be transformed to the standard Gaussian distribution is convenient in that just a single table is required to summarize the probability structure of the infinite number of Gaussian distributions. Table 1.2 provides an example of such a table and gives the percentiles of the standard Gaussian distribution.

Example 1 Suppose the underlying population of elements is $N(4,16)$ and one element from this population is selected. We want to find the probability that the selected element has a value less than 3.0 or greater than 6.1. In solving this problem, the relevant distribution is specified: x is $N(4,16)$. The probability of observ-

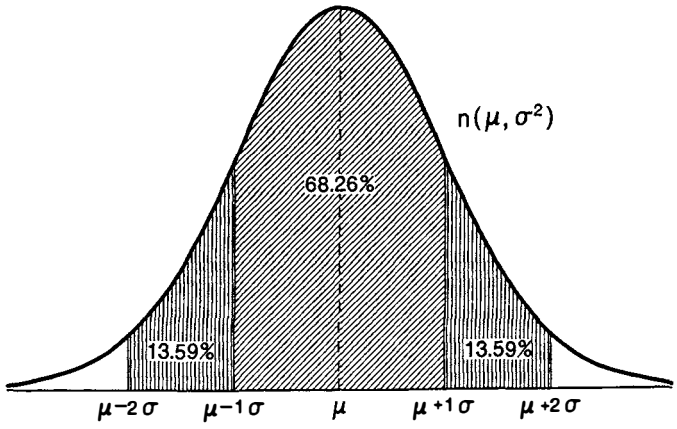

FIGURE 1.1 The Gaussian distribution.

ing $x < 3.0$ in the distribution of x is equivalent to the probability of observing $z < (3.0 - 4)/4 = -.25$ in the standard Gaussian distribution. Going to Table 1.2, $z = .25$ is approximately the 60th percentile of the standard Gaussian distribution and by symmetry $z = -.25$ is approximately the 40th percentile. Thus, the probability of observing a z value less than or equal to $-.25$ is approximately .40. The probability of observing $x > 6.1$ is equivalent to the probability of observing $z > (6.1 - 4)/(4) = +.525$. Table 1.2 gives the probability of observing a $z < .525$ as approximately .70, so the probability of observing a $z > .525$ approximately equals 1 − .70 or .30. The desired probability of observing a sample observation less than 3.0 or greater than 6.1 is the sum of .40 and .30, which is .7 or 7 chances in 10.

C. Conventional Method for Determining Reference Intervals

The first step in establishing a normal interval by the conventional method involves determining the mean and standard deviation of the distribution of the analyte. This can be accomplished by taking a representative sample (using a sampling design that

has a random component such as simple random sampling) from the population of normal animals and computing the mean and standard deviation of the sample.

Once these estimates of μ and σ are obtained, an animal coming into the clinic in the future is classified as being normal for a particular analyte if its value for the analyte is within the bound of some multiple of the standard deviation below the mean and some multiple of the standard deviation above the mean. The multiple is determined by the degree of certainty that is desired to be placed on the classification scheme. For example, if the multiple chosen is 2, which is the conventional choice, any animal entering the clinic with an analyte value within 2 standard deviations of the mean would be classified as normal, whereas all animals with a value of the analyte outside this boundary would be classified as abnormal. Because 95% of

TABLE 1.2 Percentiles of the Standard Gaussian (z) Distribution[a,b]

$z_{0.50} = 0$	$z_{0.90} = 1.282$	$z_{0.975} = 1.960$

$z_{0.60} = 0.253$	$z_{0.92} = 1.405$	$z_{0.99} = 2.326$
$z_{0.65} = 0.385$	$z_{0.93} = 1.476$	$z_{0.995} = 2.576$
$z_{0.70} = 0.524$	$z_{0.94} = 1.555$	$z_{0.999} = 3.090$
$z_{0.75} = 0.674$	$z_{0.95} = 1.645$	$z_{0.9999} = 3.719$
$z_{0.80} = 0.842$	$z_{0.96} = 1.751$	$z_{0.99999} = 4.265$
$z_{0.85} = 1.036$	$z_{0.97} = 1.881$	

[a] This table is adapted, with kind permission of the authors and publisher, from Dixon, W. J., and Massey, F. J. (1983). "Introduction to Statistical Analysis," 4th ed., Table A-4, p. 511. McGraw-Hill, New York.

[b] Example: The 75th percentile, or the z value below which is 75% of the Gaussian distribution, equals 0.674, $z_{0.75} = 0.674$. Percentiles smaller than the 50th percentile can be found by noting that the Gaussian distribution is symmetric about zero so that, for example, $z_{0.30} = -0.524$.

the Gaussian distribution is located within 1.96 or approximately 2 standard deviations of the mean, with this classification scheme, 2.5% of the normal animals would have a value of the analyte that would be below 2 standard deviations below the mean, and 2.5% of the animals would have an analyte value above 2 standard deviations above the mean. So with this classification scheme, there is a 5% chance that a true normal animal would be classified as being abnormal. Clinicians, by choosing 2 as the multiple, are willing to designate normal animals with extreme values of a particular analyte as being abnormal as the trade-off for not accepting too many abnormal animals as normals. With this methodology, no consideration is given to the distribution of abnormal animals because in fact there would be multiple distributions corresponding to the many types of abnormalities. The assumption is that for those cases where an analyte would be useful in identification of abnormal animals, the value of the analyte would be sufficiently above or below the center of the distribution of the analyte for normal animals. The reference interval for glucose based on the distribution from the sample of 168 normal dogs is 96.42857 mg/dl ± (1.96 × 14.61873 mg/dl) or 67.8 mg/dl (3.76 mmol/liter) to 125.1 mg/dl (6.94 mmol/liter).

Solberg (1994) gives $1/\alpha$ as the theoretical minimum sample size for estimation of the 100α and $100(1-\alpha)$ percentiles. Thus a minimum of 40 animals is required to estimate the 2.5th and 97.5th percentiles but many more than 40 is recommended.

D. Methods for Determining Reference Intervals for Analytes Not Having the Gaussian Distribution

The conventional procedure for assessing normalcy works quite well provided the distribution of the analyte is approximately Gaussian. Unfortunately, for many analytes a Gaussian distribution is not a good assumption. For example, Figure 1.3 describes the distribution of alanine aminotransferase (ALT) values given in Table 1.1 for the same sample of 168 normal dogs. This distribution is visibly asymmetric. The distribution has a longer tail to the right and is said to be skewed to the right or positively skewed. The skewness value (.91) exceeds the approximate 99th percentile of the distribution for this coefficient for random samples from a population having a Gaussian distribution. That the distribution is not symmetric and hence not Gaussian is also evidenced by the lack of agreement between the mean, median, and mode as shown in Fig. 1.3. Application of the conventional procedure for computing reference intervals [$\bar{x} \pm (1.96 \times SD)$] reveals a reference interval of 4.4 to 127.7 U/liter so that all the low values of the distribution fall above the value, which is 2 standard deviations below the mean of the distribution and more than 2.5% of the high values fall above the value, which is 2 standard deviations above the mean. The following sections gives two approaches that can be followed in such a situation to obtain reference intervals.

1. *Use of Transformations*

Frequently, some transformation (such as the logarithmic or square root transformation) of the analyte values will make the distribution more Gaussian (Kleinbaum *et al.*, 1988; Neter *et al.*, 1990; Zar, 1984). The boundaries for the reference values are two standard deviations above and below the mean for the distribution of the transformed analyte values. These boundaries then can be expressed in terms of the original analyte values by retransformation. Figure 1.4 describes the distribution of the ALT analyte values after transformation with natural logarithms. The reference boundaries in logarithmic units are equal to 4.08013 ± (1.96 × 0.47591) or (3.14734, 5.01292), which correspond to (23.3, 150.3 U/liter) in the original units of the analyte.

2. *Use of Percentiles*

The second approach that can be followed in the situation where an assumption of a Gaussian distribution is not tenable is to choose percentiles as boundaries (Feinstein, 1977; Herrera, 1958; Mainland, 1963; Mas-

sod, 1977; Reed *et al.*, 1971; Solberg, 1994). For example, if we wanted to misclassify only 5% of normal animals as being abnormal, the 2.5th and 97.5th percentiles could be chosen as the reference boundaries. Thus, animals would be classified as abnormal when having analyte values either below the value of the analyte below which are 2.5% of all normal analyte values or above the value of the analyte below which are 97.5%

of all normal analyte values. This method is attractive because percentiles are reflective of the distribution involved.

The 97.5th percentile is estimated as the value of the analyte corresponding to the $(n + 1) \times 0.975$th observation in an ascending array of the analyte values for a sample of n normal animals (Dunn, 1977; Ryan *et al.*, 1985; Snedecor and Cochran, 1989). For the ALT values from the sample of $n = 168$ animals, $(n + 1) \times 0.975 = 169 \times 0.975 = 164.775$. Since there is no 164.775th observation, the 97.5th percentile is found by interpolating between the ALT values corresponding to the 164th and 165th observation in the ascending array commonly referred to as the 164th and 165th order statistics (Ryan *et al.*, 1985; Snedecor and Cochran, 1989). The 164th order statistic is 138 U/liter and the 165th order statistic is 140 U/liter and the interpolation is $138 + .775(140 - 138) = 139.5$ U/liter. The 2.5th percentile is estimated similarly as the $(n + 1) \times 0.025$th order statistic, which is the 4.225th order statistic for the sample of ALT values. In this case, the 4th and 5th order statistics are the same, 24 U/liter, which is the estimate of the 2.5th percentile. Note that there is reasonable agreement between this reference interval and that obtained using the logarithmic transformation. This method of using percentiles as reference values can also be used for analytes having a Gaussian distribution. The 2.5th and 97.5th percentiles for the sample of glucose values are 65.4 mg/dl (3.63 mmol/liter) and 126.3 mg/dl (7.01 mmol/liter), respectively. This interval agrees very well with that calculated earlier using the conventional method.

E. Sensitivity and Specificity of a Decision Based on a Reference Interval

As alluded to earlier, in addition to the "normal" or healthy population, several diseased populations may be involved, each with its own distribution. Figure 1.5 depicts the distributions of one analyte for a single diseased population and for a normal healthy, nondiseased population. Note that there will be some overlap of these distributions. Little overlap may occur when the disease has a major impact on the level of the analyte, whereas extensive overlap could occur if the level of the analyte is unchanged by the disease.

Using a reference value based on values of the analyte for normal animals could lead to two types of mistakes in diagnosis of patients. First, normal patients with values beyond the normal interval would be classified incorrectly as diseased and would be the false positives. Second, diseased patients having values within the normal interval would be classified as non-

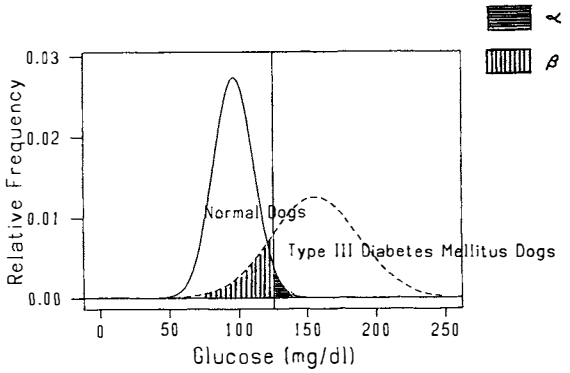

FIGURE 1.5 Overlapping Gaussian distributions of one analyte for a diseased dog population and a healthy, nondiseased dog population with upper limit of reference interval, α, and β error rates shown.

diseased, the false negatives. The two kinds of mistakes in classifying patients on the basis of analyte values are called the Type I error (saying a normal animal is diseased) and the Type II error (saying an animal is normal when in fact the animal is diseased). The probabilities of making these two errors, the error rates, are α and β, respectively. The size of these error rates is determined by the reference values, which are the decision points. We call $1 - \alpha$ the *sensitivity* of the diagnostic or decision process using reference values (the probability of deciding that a truly normal animal is normal on the basis of the given reference value) and $1 - \beta$ is the specificity of the decision process (the probability of deciding that a truly diseased animal is diseased). It is possible to change the reference values to reduce the size of α and in so doing increase the sensitivity of the test. However, such an action will also result in an increase in the size of β and therefore a reduction in the specificity of the test.

Example 2 Type III diabetic dogs have the chemical form of diabetes mellitus generally regarded as the first level of development of the disease offering the highest likelihood "for successful oral hypoglycemic therapy and/or dietary therapy" (Kaneko, 1977). Thus it would be useful to distinguish Type III diabetic dogs from normal dogs. Using the sample mean [155.6 mg/dl (8.63 mmol/liter)] and standard deviation [32.0 mg/dl (1.77 mmol/liter)] of the plasma glucose values given by Kaneko (1977) for five dogs with Type III diabetes mellitus as reasonable estimates of the corresponding parameters for the population of dogs with Type III diabetes mellitus, and assuming that this population distribution is approximately Gaussian, a comparison of this distribution of glucose values can be made with that for the population of

normal dogs described by the approximately Gaussian distribution with parameter estimates given in Fig. 1.2 [μ_x = 96.4 mg/dl (5.35 mmol/liter) and σ_x = 14.6 mg/dl (0.81 mmol/liter)]. These two distributions are shown in Fig. 1.5; they have reasonably good separation with moderate overlap. Based on this information, a diagnostic procedure is proposed whereby a dog entering the clinic with a glucose value above 125.1 mg/dl (6.94 mmol/liter), the upper limit of the normal reference interval, will be flagged as possibly having Type III diabetes mellitus, thereby indicating the need for more follow-up. (*Note:* This is an oversimplification of actual practice because a diagnostic decision of this type would be based on additional information, such as the animal's glucose tolerance and insulin response, making the decision rule and subsequent error calculations more complex.) This is an example of a one-sided diagnostic procedure because dogs with a glucose value below the lower limit of the reference interval would not be considered as having Type III diabetes mellitus. Thus the Type I error is concentrated at the upper end of the distribution of glucose values for normal dogs and its magnitude (α) is the area to the right of a glucose value of 125.1 mg/dl in the distribution of glucose values for normal dogs or the area to the right of the corresponding z value, $z = (125.1 - 96.4)/14.6 \sim 1.96$, for the standard Gaussian distribution (see Section II.B); α = 2.5%.

The clinician may be interested in determining the sensitivity and the specificity of the diagnostic procedure. The sensitivity is $1 - \alpha$ = 97.5%. A dog that actually has Type III diabetes mellitus but has a glucose value less than 125.1 mg/dl would be incorrectly classified by the proposed diagnostic procedure as being a normal dog. This is a Type II error and the probability of making this type of error is β, which is the area to the left of a glucose value of 125.1 mg/dl in the distribution of glucose values for dogs with Type III diabetes mellitus or the area to the left of the corresponding z value, $z = (125.1 - 155.6)/32.0 \sim -.953$, for the standard Gaussian distribution. Using Table A-4 from Dixon and Massey (1983), β = 17.62% (or 17.14% by linear interpolation of the information given in Table 1.2), and the specificity of the diagnostic procedure is $1 - \beta$ = 82.38%.

F. Predictive Value of a Decision Based on a Reference Interval

A useful quantity is the probability that a patient having a reference value outside the normal interval actually has the disease. This is known as the predictive value of a positive diagnosis, Prob(D|+). Interest could also be in determining the probability that a patient having a reference value within the normal interval is actually nondiseased or the predictive value of a negative diagnosis, Prob(D|−). The predictive value depends on the sensitivity, specificity, and prevalence (p) of the disease as shown in the following equations:

$$\text{Prob}(D|+) = \frac{p \times \text{Sensitivity}}{p \times \text{Sensitivity} + (1 - p) \times (1 - \text{Specificity})}$$

$$\text{Prob}(D|-) = \frac{(1 - p) \times \text{Specificity}}{(1 - p) \times \text{Specificity} + p \times (1 - \text{Sensitivity})}$$

Fig. 1.6 demonstrates the extent to which the predictive value of a positive diagnosis changes with the prevalence. In general, larger changes are seen in the predictive value of a positive diagnosis for smaller changes in the prevalence for diseases with low prevalence, and smaller changes are seen in the predictive value for larger changes in the prevalence for diseases with high prevalence.

In the example of the diagnostic procedure given in the previous section, assuming the prevalence of Type III diabetes mellitus in the dog population was 2%,

$$\begin{aligned}\text{Prob}(D|+) &= (0.02 \times 0.975)/[(0.02 \times 0.975) + (0.98 \times 0.1762)] \\ &= 0.10 \text{ or } 10\%, \text{ and} \\ \text{Prob}(D|-) &= (0.98 \times 0.8238)/[(0.98 \times 0.8238) + (0.02 \times 0.025)] \\ &= 0.999 \text{ or } 99.9\%.\end{aligned}$$

To demonstrate how specificity and hence the predictive value of a positive test improve with greater separation of the populations, Kaneko (1977) gives estimates (based on a sample of 11

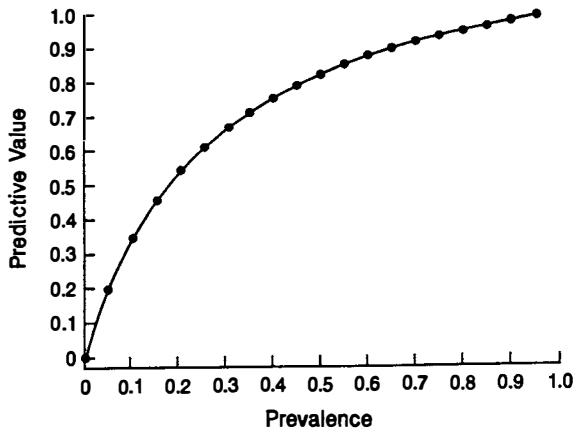

FIGURE 1.6 Impact of disease prevalence on the predictive value of a positive laboratory test having 95% sensitivity and 80% specificity.

dogs) of the mean and standard deviation of the plasma glucose values of the population of dogs with Type I diabetes mellitus (the juvenile or childhood form) as $\hat{\mu}$ = 415.1 mg/dl (23.02 mmol/liter) and $\hat{\sigma}$ = 114.3 mg/dl (6.34 mmol/liter). If we use these values in the preceding calculations with the diagnostic value remaining at 125.1 mg/dl, the specificity improves to 99.44% and the predictive value of a positive test increases to 78%.

III. ACCURACY IN ANALYTE MEASUREMENTS

Accuracy has to do with the conformity of the actual value being measured to the intended true or target value. An analytical procedure having a high level of accuracy produces measurements that on average are close to the target value. An analytical procedure having a low level of accuracy produces measurements that on average are a distance from the target value. Such a procedure in effect measures something other than is intended and is said to be *biased.* Failure of analytical procedures to produce values that on average conform to the target values is due to unresolved problems, either known or unknown, in the assay.

The degree of accuracy of an analytical procedure has been difficult to quantify due to the fact that the target value is unknown. It is now possible for laboratories to compare their assay results with definitive results obtained by the use of isotope dilution-mass spectrometry (Shultz, 1994). Shultz (1994) reports the results of two large surveys of laboratories in the United States (Gilbert, 1978) and Sweden (Björkhem *et al.*, 1981) in which samples from large serum pools were analyzed for frequently tested analytes (calcium, chloride, iron, magnesium, potassium, sodium, cholesterol, glucose, urea-nitrogen, urate, and creatinine). The laboratory averages were compared with the target value obtained using definitive methods, and the results of these surveys indicated that, with the exception of creatinine, all averages expressed as a percentage of the target value were within the accuracy goals published by Gilbert (1975). Results from individual laboratories naturally would vary about the average, and many of these laboratories would not have met the accuracy goal.

IV. PRECISION IN ANALYTE MEASUREMENTS

Precision has to do with how much variability there is about the actual value being measured when the assay is replicated. If in a given laboratory a particular assay is run repeatedly on the same sample and the results obtained have little variability, the assay is said to have high precision. Large variability in the observed results is an indication of low assay precision. Note that precision is defined in reference to what is actually being measured and not to the target value. Clinical analysts have always had a goal of achieving the highest possible level of precision for a particular assay within a laboratory. Emphasis is presently placed on meeting an "average laboratory" level of precision (Shultz, 1994).

The level of precision is stated quantitatively in terms of the coefficient of variation (*cv*). The *cv* is the ratio of the standard deviation to the average of a series of replicated assays and its magnitude depends on the concentration of the analyte. Elevitch (1977) and Harris (1988) provide the guidelines on the desired level of precision in terms of the *cv*. In the case where the analytical results are intended to assist in the diagnostic process or to assist in monitoring a patient's response to treatment, the level of laboratory precision of a given analyte in terms of the *cv* (cv_a) need only be a function of the within day and day-to-day variability or intrasubject variation of healthy subjects. Specifically,

$$cv_a < \tfrac{1}{2} cv_{\text{intrasubject}}.$$

In the case where analytical test results are to be used to screen a population, the laboratory precision goal in terms of the *cv* should be a function of the variability in response among healthy subjects or intersubject variation. Specifically,

$$cv_a < \tfrac{1}{2} cv_{\text{intersubject}}.$$

Use of intrasubject variability as a goal for precision has appeal because this source of variability would be considered in decision processes relating to patients. Unfortunately, a given analysis reflects not only this intrasubject variability, but also imprecision in the assay. Shultz (1994) summarizes the results of a large national survey of laboratory precision. With the exception of high-density lipoprotein and thyroxine (T_4), the precision of the assay for the analytes evaluated from the "average" laboratory met or nearly met the precision goals based on the intrasubject variability. This result has to be regarded as encouraging, no doubt reflecting the tremendous emphasis that has been placed on quality control by laboratories as well as the use of automation in analytical work. On the other hand, there were some analytes for which the assay precision for the "average" laboratory was above the precision goal. It also must be remembered that there would be many individual laboratories that would not have assay precision profiles as good as the "average"

laboratory. Assay precision in excess of the precision goal based on physiological variability makes it nearly impossible to rule out the possibility that very large changes in the level of an analyte are a reflection of assay imprecision.

V. INFERENCE FROM SAMPLES

The basis for everything that has been discussed to this point is probability and distributional theory. No other theory is relevant unless one is operating at the level where inference is to be made on the basis of a sample from the underlying population. Most standard statistical theory assumes that the sample was obtained by simple random sampling.

A. Simple Random Sampling

Simple random sampling (SRS) is a method of sampling whereby, at each step of the sampling process, the elements available for selection have an equally likely chance of being selected. In most applications, it is assumed that the elements are selected without replacement, although the elements could be selected with replacement. If the number of elements to be selected is small relative to the number of elements in the population, then it is rather unlikely that an element will be selected more than a single time with replacement sampling, so that in such situations sampling with replacement produces essentially the same results as sampling without replacement. It is only when a small finite population is being sampled that differences may be noted between the two methods.

Three steps are used to select a sample by SRS without replacement: All elements in the population must first be identified by a unique number from 1 to N, the population size. Then n numbers are selected from a table of random numbers or selected by a random number generator, which gives the numbers 1 to N in random order. Numbers appearing more than once are ignored after their first use. Finally, those elements having numbers corresponding to the n numbers selected constitute the sample. There are other probability-based sampling procedures that should be considered in practice; these methods are found in texts on sampling (Cochran, 1977; Jessen, 1978; Levy and Lemeshow, 1991; Murthy, 1967; Raj, 1968,1972; Scheaffer *et al.*, 1996).

B. Descriptive Statistics

Once the data have been collected, so-called "descriptive statistics" can be computed. As the name suggests, these statistics are useful in describing the underlying populations. For example, because complete information for the entire population is not available, it is not possible to know the population mean, $\mu = \Sigma x_i / N$. (Here x_i designates the value of the ith element in the population and Σ indicates summation. Thus the population mean μ is found by summing the values of all N elements in the population and then dividing the sum by N.) However, a sample mean based on the sample can be computed as $\bar{x} = \Sigma x_i / n$, the sum of the values of all n elements in the sample divided by n. If the sample has been selected in a manner that results in a small bias, $\bar{x}$ should be a reasonably good estimate of the population mean, μ, and will be a better estimate as the sample size increases. Other estimates of the measures of central tendency of the population can be obtained from the sample, such as the sample median and the sample mode. Also, sample-based estimates of the measures of dispersion or spread for the population can be obtained. The sample variance is computed as $s^2 = \Sigma(x_i - \bar{x})^2/(n - 1)$, and the sample standard deviation, s, is obtained by taking the square root of s^2. The descriptive statistics are called *point estimates* of the parameters and represent good approximations of the parameters. An alternative to the point estimate is the *interval estimate*, which takes into account the underlying probability distribution of the point estimate called the sampling distribution of the statistic.

C. Sampling Distributions

In actual practice, only a single sample is taken from a population and, on the basis of this sample, a single point estimate of the unknown population parameter is computed. If time and resources permitted repeated sampling of the population in the same manner, that is, with the same probability-based sampling design, one point estimate would be obtained for each sample obtained. The estimates would not be the same because the sample would contain different elements of the population. As the number of such repeated sampling operations increases, a more detailed description emerges of the distribution of possible point estimates that could be obtained by sampling the population. This is the sampling distribution of the statistic.

Some fundamental facts relating to the sampling distribution of the sample mean follow: (1) The center of the sampling distribution of $\bar{x}$ is equal to μ, the center of the underlying distribution of elements in the population. (2) The spread of the sampling distribution of $\bar{x}$ is smaller than σ^2, the spread of the underlying distribution of elements in the population. Specifically, the variance of the sampling distribution of $\bar{x}$ (denoted $\sigma^2_{\bar{x}}$) *equals* σ^2/n, where n is the sample size. So increasing the sample size serves to increase the likelihood

of obtaining an $\bar{x}$ close to the center of the distribution because the spread of the sampling distribution is being reduced. (3) The central limit theorem (Daniel, 1995; Remington and Schork, 1985; Zar, 1996) states that regardless of the underlying distribution of the population of elements from which the sample mean is based, if the sample size is reasonably large ($n > 30$), the sampling distribution of $\bar{x}$ is approximated well by the Gaussian distribution. So $\bar{x}$ drawn from any distribution has a sampling distribution that is approximately $N(\mu, \sigma^2/n)$ for $n > 30$. If the distribution of the underlying population of elements is Gaussian or approximated well by a Gaussian distribution, the sampling distribution of $\bar{x}$ will be approximated well by the Gaussian distribution regardless of the sample size on which $\bar{x}$ is based.

Probabilities of the sampling distribution of $\bar{x}$, $N(\mu, \sigma^2/n)$, can be evaluated using the method described in Section II.B.

Example 3 Suppose the underlying population of elements is $N(4,16)$ and a sample of size $n = 9$ is drawn from this population using SRS. We want to find the probability of observing a *sample mean* less than 3.1 or greater than 6.2. In solving this problem, the relevant sampling distribution is specified: $\bar{x}$ is $N(4, 16/9)$. Note that the sampling distribution of $\bar{x}$ is Gaussian because the problem stated that the underlying population was Gaussian. (Otherwise the stated sample size would needed to have been 30 or larger to invoke the central limit theorem.) The probability of observing $\bar{x} < 3.1$ in the distribution of $\bar{x}$ is equivalent to the probability of observing $z < (3.1 - 4)/(4/3) = -0.675$ in the standard Gaussian distribution. Going to Table 1.2, $z = 0.675$ is approximately the 75th percentile of the standard Gaussian distribution and by symmetry $z = -0.675$ is approximately the 25th percentile. Thus, the probability of observing a z value less than or equal to -0.675 is approximately 0.25. The probability of observing a sample mean greater than 6.2 is equivalent to the probability of observing $z > (6.2 - 4)/(4/3) = +1.65$. Table 1.2 gives the probability of observing a $z < 1.65$ as approximately 0.95, so the probability of observing a $z > 1.65$ equals $1 - 0.95$ or 0.05. The desired probability of observing a sample mean less than 3.1 or greater than 6.2 is the sum of 0.25 and 0.05, which is 0.3 or 3 chances in 10.

D. Constructing an Interval Estimate of the Population Mean, μ

This brief exposure to sampling distributions and their standardized forms provides the framework for generating an interval estimate for μ. Consider the probability statement $\text{Prob}(-2 < z < +2) = 0.9544$. Because $z = (\bar{x} - \mu)/(\sigma/\sqrt{n})$, this probability statement is equivalent to the statement $\text{Prob}(-2 < (\bar{x} - \mu)/(\sigma/\sqrt{n}) < +2) = 0.9544$. Some standard algebraic manipulation of the inequality within the parentheses gives $\text{Prob}(\bar{x} + (-2\sigma/\sqrt{n}) < \mu < \bar{x} + (-2\sigma/\sqrt{n})) = 0.9544$. This is the form of the confidence statement about the unknown parameter μ. With repeated sampling of the underlying population, 95.44% of the intervals constructed by adding and subtracting $2\sigma/\sqrt{n}$ to and from the sample mean would be expected to cover the true unknown value of μ. The quantities of $\bar{x} - 2\sigma/\sqrt{n}$ and $\bar{x} + 2\sigma/\sqrt{n}$ are called the *lower* and *upper confidence limits*, respectively, and the interval bounded below by $\bar{x} - 2\sigma/\sqrt{n}$ and above by $\bar{x} + 2\sigma/\sqrt{n}$, that is, $(\bar{x} - 2\sigma/\sqrt{n}, \bar{x} + 2\sigma/\sqrt{n})$, is the 95.44% confidence interval for μ. In practice, only one sample is taken from the population and thus there is a 95.44% chance that the one interval estimate obtained will cover the true value of μ. The value of 95.44% or 0.9544 is called the *confidence level.*

The degree of confidence that is to be had is determined by the amount of error that is to be tolerated in the estimation procedure. For a 0.9544 level of confidence, the error rate is $1 - 0.9544 = 0.0456$. The error rate is designated by alpha, α. The size of α determines the magnitude of the value of z that is multiplied by $\sigma/\sqrt{n}$. The convention is to apportion half of α to the lower end and half of α to the upper end of the sampling distribution of $\bar{x}$ so that the relevant values of z are (1) the z value that has $\alpha/2$ area to its left, $z_{\alpha/2}$, and (2) the z value that has $\alpha/2$ to its right or, equivalently (to conform to Table 1.2), the z value that has $1 - (\alpha/2)$ area to its left, $z_{1-(\alpha/2)}$. Therefore, the most general form of the interval estimate statement is $(\bar{x} - (z_{\alpha/2}\sigma)/\sqrt{n}, \bar{x} + (z_{1-(\alpha/2)}\sigma)/\sqrt{n})$ or $\bar{x} \pm (z_{1-(\alpha/2)}\sigma)/\sqrt{n}$ because of the symmetry of the Gaussian distribution.

Example 4 Assuming the distribution in Example 3, construct a 90% confidence interval for μ. A 90% level of confidence implies a tolerated error rate of 10% and the relevant z values are (1) that which has 5% of the distribution of z to its left or $z_{0.05} = -1.645$ and (2) that which has 95% of the distribution to its left or $z_{0.95} = 1.645$. The 90% confidence interval for μ is therefore $(\bar{x} \pm (1.645 \times 4)/3)$ or $(\bar{x} \pm 2.1933)$ where $\bar{x}$ is the sample mean obtained by taking a sample of size 9 from the population.

The form of the interval estimate given earlier assumes that σ, the standard deviation of the underlying population, is also known. Frequently this parameter, like μ, is unknown and must be estimated from the sample drawn from the population using the estimator $s^2 = \Sigma(x_i - \bar{x})^2/(n - 1)$. For small samples ($n < 30$),

the standardized form of $\bar{x}$, $(\bar{x} - \mu)/(s/\sqrt{n})$, does not have a standardized Gaussian distribution, $N(0,1)$, but rather has the t distribution corresponding to the effective sample size, $n - 1$, the degrees of freedom. Table 1.3 gives the percentiles of several t distributions. A given row of Table 1.3 pertains to the t distribution with the indicated effective sample size or degrees of freedom. The entries in the row are percentiles or those points of the given t distribution that have the indicated area to the left. For example, $t_{0.95,10}$ is 1.812, meaning that the 95th percentile of the t distribution with 10 degrees of freedom is 1.812, which is equivalent to saying that 95% of the t distribution with 10 degrees of freedom lies to the left of the t value 1.812. Note

[a] This table is reprinted, with kind permission of the authors and publisher, from Kleinbaum, D. G., and Kupper, L. L. (1988). "Applied Regressing Analysis and Other Multivariable Methods," 2nd ed., Table A-2, p. 647. PWS-Kent, Boston.

[b] Example: The 75th percentile of a t distribution with 11 degrees of freedom or the t value below which is 75% of the t distribution with 11 degrees of freedom equals 0.697, $t_{0.75,11} = 0.697$.

that the 5th percentile of the t distribution with 10 degrees of freedom is -1.812 because the t distributions, like the standard Gaussian distribution, are symmetric about zero. Thus, for smaller sample sizes when the value of σ is unknown, the form of a confidence interval for μ is $\bar{x} \pm [(t_{1-\alpha/2;n-1}s)/\sqrt{n}]$.

As with the mean, interest also centers around estimating the variance, σ^2, and standard deviation, σ, of the population. The estimates for these parameters are s^2 and s, respectively. One might also be interested in constructing confidence intervals for these parameters. Because space does not permit further elaboration, the interested reader is referred to several introductory statistics books for the relevant formulas and their derivations (Daniel, 1995; Dixon and Massey, 1983; Dunn, 1977; Remington and Schork, 1985).

E. Comparing the Mean Response of Two Populations

1. *Independent Samples*

The presentation thus far has focused on estimation of parameters from a single population. Frequently, interest lies in two populations. For example, in a clinical trial, one group of animals might receive some treatment (t) while a second group of animals serves as a control receiving no treatment (c). Among the several points of interest could be that of estimating the difference in central response for the two populations, that is, $\mu_t - \mu_c$, where the subscripts designate the groups. The point estimate of $\mu_t - \mu_c$ is $\bar{x}_t - \bar{x}_c$. If we assume that the variances of the two populations, that is, σ_t^2 and σ_c^2, are unknown but equal and the common variance is designated as σ^2, then the estimate of σ^2 is $s_p^2 = [(n_{t-1})s_t^2 + (n_c - 1)s_c^2]/(n_t + n_c - 2)$ (called the *pooled variance*) and $[(\bar{x}_t - \bar{x}_c) - (\mu_t - \mu_c)]/s_p(1/n_t + 1/n_c)^{\frac{1}{2}}$ has a t distribution with $n_t + n_c - 2$ degrees of freedom. A 100 $(1 - \alpha)$% confidence interval for $\mu_t - \mu_c$ is $(\bar{x}_t - \bar{x}_c) \pm t_{1-\alpha/2;n_t+n_c-2}s_p(1/n_t + 1/n_c)^{\frac{1}{2}}$. If the interval so constructed covers zero, it may be that there is no difference between the central responses for the two distributions; otherwise, it could be concluded that the central responses differ significantly.

2. *Nonindependent Samples*

The procedure just discussed, in addition to assuming that the variances are homogeneous, also assumes that the two samples are drawn independently. An alternative design for comparing two responses involves using each subject as its own control. For example, a pretreatment response in an individual might be compared with a posttreatment response. Clearly in this design, the pretreatment and posttreatment responses may not be and most likely are not independent so the procedure given above for comparing two groups would not be appropriate. Rather, the differences in response (pretreatment minus posttreatment response) are formed and the population of interest is the single population of differences, having as one of its parameters the mean difference, μ_d. The quantity μ_d is estimated by the mean difference for the sample of n differences, $\bar{d} = \Sigma d_i/n$, and an interval estimate is formed by $\bar{d} \pm (t_{1-\alpha/2;n-1}s_d)/\sqrt{n}$ where s_d is an estimate of σ_d. If the interval thus constructed covers zero, then it may be that there is no difference between the mean pretreatment and posttreatment values.

F. Comparing the Mean Response of Three Populations

Comparisons of more than two groups is the natural progression from the methodology discussed to this point. Consider the comparison of three independent groups. The approach that immediately comes to mind is that of estimating the three groups' means and standard deviations and then constructing three sets of confidence intervals (the first group versus the second group, the first group versus the third group, and the second group versus the third group) using the approach described earlier for two independent groups. However, some modifications need to be made. First, because we are assuming that all three groups have equal variances, pooling of the variances for the three groups provides a better estimate of the common variance than does pooling of just the variances for the two groups being compared. The form of the pooled variance is the natural extension of that for two groups, namely: $s_p^2 = [(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2 + (n_3 - 1)s_3^2]/(n_1 + n_2 + n_3 - 3)$. When the group simple sizes are equal, that is, $n_1 = n_2 = n_3$, $s_p^2 = \Sigma s_i^2/3$. The quantity s_p^2 is used for all three interval estimates.

Second, the error rate of each comparison has to be adjusted so that the error rate over all three comparisons will be α. This is required because theoretically it turns out that the error rate over all three comparisons is larger than that for a single comparison. Several approaches are suggested in the literature for circumventing this problem. One such approach attributed to Fisher (1966) is called the *least significance difference* (LSD) procedure (Kleinbaum and Kupper, 1988; Steel and Torrie, 1980). The LSD procedure involves making each single comparison with an error rate of α/m where m is the total number of comparisons to be made, which in the present example is 3. This approach gives an error rate over all comparisons of α. In general, the form of the interval estimate is $(\bar{x}_i - \bar{x}_j) \pm [(t_{1-\alpha/2m;n_1+n_2+\ldots+n_k-k})(S_p)(1/n_i + 1/n_j)^{\frac{1}{2}}]$ where m is the

total number of comparisons to be made and k is the total number of groups. Intervals covering zero would indicate no difference in the central value of the groups being compared.

G. Analysis of Variance and Its Uses

1. *Comparing Population Means*

The process of deciding whether or not there are differences between groups in the central value of the response being evaluated can be approached using the method of analysis of variance (ANOVA). ANOVA involves decomposing the total variability in a given set of data into parts reflective of the amount of variability attributable to various sources. One source of variability is that within the group. Because the groups are assumed to have the same spread, this source of variability is estimated as the pooling of the estimated variances for the k groups considered and is equal to s_p^2 as defined earlier. The second source of variability results from the variability among groups means. If there is no difference in the groups means, then the k samples can be thought of as being k independent samples from a common population, and the k means, therefore, represent a sample of size k from the sampling distribution of $\bar{x}$. Their variance represents an estimate of the variance of the sampling distribution of $\bar{x}$, that is, $\hat{\sigma}^2_{\bar{x}} = \Sigma[\bar{x}_i - \Sigma(\bar{x}_i/k)]^2/(k-1)$, where $\hat{}$ denotes an estimate. Because $\hat{\sigma}^2_{\bar{x}} = \hat{\sigma}^2/n$, where n is the common sample size, inflation of $\hat{\sigma}^2_{\bar{x}}$ by n will produce a second estimate of the variance of the underlying population assuming no differences among the group means. These two estimates of σ^2 should be about equal and their ratio close to 1.

If there is significant separation among some or all of the group means, the second variance estimate, when computed as described, will be larger than the first estimate, indicating that a component of variance is being estimated beyond that embodied only in an estimate of the within-group variability. This additional variance component being estimated is the variance among group means. ANOVA in this example involves generating the two estimates of σ^2 (called *mean squares*) under the hypothesis that all of the group means are equal. The hypothesis is then tested by forming the ratio of the two mean squares (the second mean square divided by the first mean square) called the *F statistic*. The F statistic has a probability distribution called the F distribution. If the computed F value is greater than the table distributional value, then the hypothesis is rejected and subsequently confidence intervals are constructed as described earlier to determine which group means are different. If the hypothesis cannot be rejected, the process stops or perhaps, at most, the data from all the groups might be pooled together and the parameters of this single population estimated. Tables of the percentiles of the F distributions can be found in all introductory texts on statistics (Daniel, 1995; Dixon and Massey, 1983; Dunn, 1977; Remington and Schork, 1985), which also provide instruction on how to read the tables. Also, these texts give the generalization of the among-group mean square when the sample size is not constant for all groups.

The results of an ANOVA are traditionally summarized in a table called the ANOVA table of which Table 1.4 is such an example. The first column of Table 1.4 shows the sources of variability into which the total variability is decomposed. In the present example, these sources are due to the variability within groups and that which is reflective of variability among group means. Column 4 gives the two independent (under a hypothesis of no difference in response among groups) estimates of σ^2 or mean squares, mean square among group means (MS_A) and mean square within groups (MS_W). Columns 3 and 2 give, respectively, the numerator (called the sum of squares) and the denominator (the effective sample size or degrees of freedom) of the corresponding mean square. The sums of squares provide a check on calculations when generating an ANOVA table because the total of the sum of squares attributable to the various sources of variability is equal to the sum of squared deviations of each observation across the k samples from the grand mean of all the observations in the k samples, called the *total sum of squares*. In other words, the total sum of squares is the numerator for estimating the total variability in the data ignoring group membership. Similarly, the degrees of freedom for the sources of variability sum to the effective sample size for estimating the total variability in the data ignoring group membership of the observations [here, $kn - 1 = (k-1) + k(n-1)$].

2. *Identifying Significant Sources of Variability in Experimental Designs*

a. Experimental Design 1: Two Factors Crossed

The ANOVA does not represent a superior method to that of the LSD procedure in the context in which it was presented. In fact, if a significant group effect was noted by the ANOVA, the LSD procedure or any other multiple comparison procedure would be used to identify which group differences were contributing to the overall group effect. The reason analysis of variance has been introduced is that it is a very convenient method for assessing the importance of the various sources of variability encountered in the complex designs of clinical laboratories.

TABLE 1.4 Analysis of Variance Table for Classification of Responses on Basis of One Factor, Equal Responses for Each Class[a]

Source of variation	Degrees of freedom	Sum of squares	Mean square	*F* value
Among group means	$k - 1$	$SS_A = (k - 1)MS_A$	$MS_A = \frac{n\sum_{i=1}^{k}[\bar{x}_i - \sum_{i=1}^{k}(\bar{x}_i/k)]^2}{k - 1}$	MS_A/MS_W
Within group	$k(n - 1)$	$SS_W = k(n - 1)MS_W$	$MS_W = \frac{\sum_{i=1}^{k} s_i^2}{k}$	
Total	$kn - 1$	$SS_T = SS_A + SS_W$		

[a] k is the number of classes or groups, n is the number of responses per group, constant over all groups, s_i^2 is the variability of the responses within the ith group.

As an example of this kind of application of ANOVA, suppose interest centers around an evaluation of the plasma cortisol secretory patterns in dogs with pituitary-dependent hyperadrenocorticism. A part of this type of assessment traditionally involves a determination of the magnitude of intra-animal and interanimal variances. One experiment that would provide estimates of these variances is as follows: Twenty dogs are randomly selected to participate in the experiment. On three randomly selected days of the study period, plasma cortisol samples are obtained at 11:00 A.M. from all 20 dogs. The assay for plasma cortisol is replicated for each sample. This experimental design involves two factors, "animals" and "days." These factors are said to be crossed in that each level of factor "animals" (i.e., each animal) has been evaluated at each level of factor "days" (i.e., at each of the three days on which plasma cortisol samples were drawn). The total variability in this experiment can be decomposed by the method of ANOVA into four parts: that which will identify significant among-animals variability, significant among-days variability, and significant variability attributable to a lack of parallelism among the animals in their response across the three days samples were drawn (called the interaction between the factors "animals" and "days"), and that which will quantify the residual variability embodying all other sources of variability related to the assay.

Table 1.5 lists data that shall be assumed to have been generated from an experiment using the design given in the preceding paragraph. Table 1.6 gives the ANOVA table from these data. In addition to providing the standard entries of an ANOVA table (sum of squares, degrees of freedom, mean square, and *F* statistics with corresponding *p* values), Table 1.6 also gives the expected mean squares, which are the quantities being estimated by the corresponding mean squares in the table. The expected mean squares are functions of the unknown population parameters. Note that each expected mean square involves one or more of the variance components of the design. The expected mean squares indicate which mean squares are appropriate as the denominator for computing the *F* statistic to test the hypothesis for a given effect. For example, to test the hypothesis that the variance component giving the magnitude of the variability attributable to the interaction between the factors "animals" and "days" is not

TABLE 1.6 Analysis of Variance of Canine Plasma Cortisol Level Data Assuming Experimental Design 1 ("Days" Crossed with "Animals")

Source of variation	df	Sum of squares	Mean square	F value	Expected mean square
Among animals	19	70.8316	3.7280	3.32	$\sigma_e^2 + nn_d\sigma_a^2 + n\sigma_{ad}^2$
Among days	2	1.1546	0.5773	0.51	$\sigma_e^2 + nn_a\sigma_d^2 + n\sigma_{ad}^2$
Animals × days	38	42.6787	1.1231	117	$\sigma_e^2 + n\sigma_{ad}^2$
Error	60	0.5750	0.0096		σ_e^2
Total	119	115.2399			

significant, that is, to test $H_0: \sigma_{ad}^2 = 0$, the test statistic is $F_{ad} = MS_{ad} / MS_e$, where MS_e is the correct denominator for this test statistic because if the hypothesis is true and $\sigma_{ad}^2 = 0$, the expected mean square for the interaction between "animals" and "days" reduces to σ_e^2 so that both MS_{ad} and MS_e would be estimating σ_e^2 and it would be expected that the ratio of MS_{ad} to MS_e (F_{ad}) would not differ significantly from 1. This ratio differing significantly from 1 would be an indication that MS_{ad} was estimating something additional to σ_e^2, namely, $n\sigma_{ad}^2$ where n is the number of replications per sample. Likewise, it can be determined by considering the expected mean squares of Table 1.6 that the tests for no significant variability among animals or among days ($H_0: \sigma_a^2 = 0$ or $H_0: \sigma_d^2 = 0$) are made using MS_{ad} in the denominator of the F statistic.

The results of Table 1.6 show that the hypotheses regarding σ_a^2 and σ_{ad}^2 were significant but that regarding σ_d^2 was not significant. This means that σ_a^2 and σ_{ad}^2 are not equal to zero, indicating significant sources of variability among animals that are attributable to the interaction of animals and days in the plasma cortisol levels recorded in the experiment. The quantity σ_d^2, on the other hand, may be equal to zero.

Figure 1.7, a graphical presentation of the results obtained from the analysis of variance, gives each animal's responses (mean of the two determinations) for the three days during which responses were recorded. We can see that for some dogs the response decreased over time, for some the response increased over time, for some the response at day 2 was depressed compared to that at day 1 but then at day 3 was elevated over that observed at day 2, and for others the response at day 2 was elevated compared to that at day 1 but then at day 3 was depressed compared to that observed at day 2. Differing degrees of elevations and depressions were observed with these basic patterns. Figure 1.7 shows that there was a large degree of variability among dogs in the plasma cortisol values on any given day, and that the plasma cortisol profiles across the three days that samples were taken were not parallel across the dogs. This lack of parallelism was identified by the significant interaction in the ANOVA; significance indicated that the observed departures from parallelism were larger than would have been expected as being a result of chance. The mean plasma cortisol levels recorded on the three days were 3.25 *μg/dl* (89.7 *nmol/liter*), 3.36 *μg/dl* (9.27 *nmol/liter*), and 3.12 *μg/dl* (86.1 *nmol/liter*) for a range of 0.24 *μg/dl* (6.6 *nmol/liter*). This range is very small relative to the range of mean response of 3.00 *μg/dl* (82.8 *nmol/liter*) observed for the 20 dogs ($\bar{x}$ max = 4.98 *μg/dl* or 137.4 *nmol/liter* and $\bar{x}$ min = 1.98 *μg/dl* or 54.6 *nmol/liter*). Thus, although the responses of some dogs increased while those of other dogs decreased from one day to the next day, there was practically no change in the overall variability from day to day. This is reflected in the ANOVA by a nonsignificant variance component attributable to the factor "days." The large variability among animals in mean plasma cortisol is identified in the ANOVA by the rejection of the hypothesis that $\sigma_a^2 = 0$.

b. Estimating Variance Components

Once significance has been established for one or more of the variance components in an experimental design, interest focuses on estimating the variance component(s). Estimates are readily obtainable using

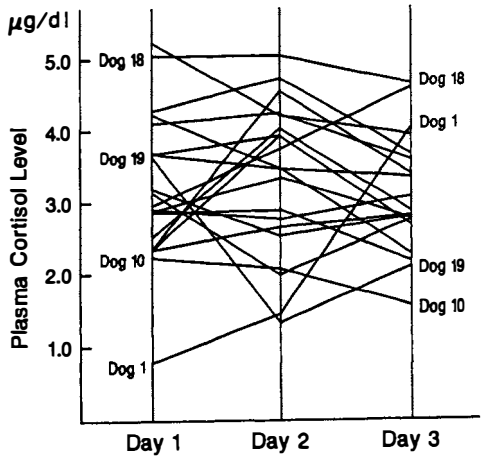

FIGURE 1.7 Interaction between "animal" and "day" factors in the canine plasma cortisol level (μg/dl) based on data from 20 dogs in Table 1.5.

the appropriate expected mean squares in conjunction with the mean squares obtained from the data. For example, Table 1.6 shows that an estimate of σ_e^2 is MS_e (0.0096). An estimate of σ_{ad}^2 can be obtained by noting that MS_{ad} estimates $n\sigma_{ad}^2 + \sigma_e^2$; solving for σ_{ad}^2 followed by substitution of MS_e for σ_e^2 yields $(MS_{ad} - MS_e)/n_e$ as the estimate. Based on the data used in the example, $\hat{\sigma}_{ad}^2 = (1.1231 - 0.0096)/2 = 0.5567$. Estimates of σ_a^2 and σ_d^2, obtained in a similar manner, are $(MS_a - MS_{ad})/n_d n$ (0.4342) and $(MS_d - MS_{ad})/n_a n$ (−0.0136 or zero), respectively, where n_a is the number of animals sampled (here 20) and n_d is the number of days samples were taken (3). Interval estimates for these variance components can be obtained using these point estimates by methods described elsewhere (Dunn and Clark, 1987; Harter and Lum, 1955; Satterthwaite, 1941).

c. Estimating the Variance of the Grand Mean Response

Another way to visualize the importance of these variance components is to analyze their impact on the estimate of the variance of interest. In some applications, there would be interest in estimating the grand mean (μ) of the response. In the present example, this would involve estimating the mean plasma cortisol level taking into account any random animal effect, day effect, and the interaction between the animal and day effects. If it is assumed that the main effects, "days" and "animals," are independent of their interaction in the response model and other distributional assumptions hold (Dunn and Clark, 1987), then the variance of $\hat{\mu}$, $\text{Var}(\hat{\mu})$, is given as $\sigma_a^2/n_a + \sigma_d^2/n_d + \sigma_{ad}^2/n_a n_d + \sigma_e^2/n_a n_d n$ (Dunn and Clark, 1987). In the present example, $\text{Var}(\hat{\mu})$ is estimated as $0.4342/20 + 0.0/3 + 0.5567/60 + 0.0096/120 = 0.0217 + 0.0000 + 0.0093 + 0.0001 = 0.0311$, and by far the greatest contribution to this variance is that due to the variability among animals in their response followed by the contribution of interaction to the response.

d. Estimating the Total Variability of a Single Response

In other applications, interest centers about the total variability (σ_{total}^2) associated with a single response. A single response is a linear combination of the terms in the response model and, using the assumption of the independence of terms in the model, has a variance equal simply to the sum of the variance components. Specifically, $\sigma_{\text{total}}^2 = \sigma_a^2 + \sigma_d^2 + \sigma_{ad}^2 + \sigma_e^2$, which in this example is estimated as $0.4342 + 0.0000 + 0.5567 + 0.0096 = 1.0005$. In this example, the total variability of a single response is determined by two variance components: (1) that associated with the animal variability and (2) that resident in the interaction between "animals" and "days."

e. Experimental Design 2: One Factor Nested within a Second Factor

A second experimental design that would provide estimates of intra-animal and interanimal variances in the plasma cortisol level is as follows: The 20 dogs are randomly selected over a period of time from the population of dogs identified by a clinic as having pituitary-dependent hyperadrenocorticism. At the time the dog is selected, three days within the next two weeks are randomly selected for plasma cortisol samples to be taken at 11:00 A.M. from the dog. Again plasma cortisol assays are replicated for each sample. Because the animals are sampled across time, it is rather unlikely that many and perhaps any of the three days that samples are drawn will be common for the 20 dogs. If the 20 dogs had no sampling days in common, samples would be taken on 60 (20×3) different days. Thus, the factor "days" in this design is not crossed with the factor "animals" but is said to be nested within "animals." The total variability in this experiment can be decomposed by the method of ANOVA into three parts, that which will identify significant variability among animals and significant variability among days (nested within animals), and that which quantifies the residual variability.

The data in Table 1.5 were used again assuming that it had been generated from the nested design described. Table 1.7, the ANOVA table, shows that two hypotheses can be tested. The mean square error is the denominator for testing that the variance component for "days nested within animals" (d/a) is equal to zero, that is, $\sigma_{d/a}^2 = 0$. This hypothesis is rejected based on the data. In this design, $\sigma_{d/a}^2$ is the true intradog variability for this response. The test result that the day effect is significant means that this intradog variability is larger than zero. The second test is that the variance component for "animals" is equal to zero or $\sigma_a^2 = 0$. The expected mean squares given in Table 1.7 show that the denominator for this test is the mean square for days nested within animals, $MS_{d/a}$. This test is also significant. The interpretation of a significant σ_a^2 is the same as that noted for design 1.

Once significance has been established, estimates of these variance components can be computed using the method described earlier for design 1. These estimates are $\hat{\sigma}_a^2 = 0.4387$, $\hat{\sigma}_{d/a}^2 = 0.5431$ and $\hat{\sigma}_e^2 = 0.0096$. The term $\hat{\sigma}_a^2$ is the estimate of the interanimal variability, whereas $\hat{\sigma}_{d/a}^2$ estimates the intra-animal variability in plasma cortisol level for the underlying population of dogs. For those interested in estimating the grand mean plasma cortisol level, the importance of each of these components is obtained by observing their impact on the estimate of the variance of the estimate of the grand

TABLE 1.7 Analysis of Variance of Canine Plasma Cortisol Level Data Assuming Experimental Design 2 ("Days" Nested within "Animals")

Source of variation	df	Sum of squares	Mean square	F value	Expected mean square
Among animals	19	70.8316	3.7280	389	$\sigma_e^2 + n n_d \sigma_a^2 + n\sigma_{d/a}^2$
Days/animals	40	43.8333	1.0958	114	$\sigma_e^2 + n\sigma_{d/a}^2$
Error	60	0.5750	0.0096		σ_e^2
Total	119	115.2399			

mean, $\mathrm{Var}(\hat{\mu})$. The expression for this variance is $\mathrm{Var}(\hat{\mu}) = \sigma_a^2/n_a + \sigma_{d/a}^2/n_a n_d + \sigma_e^2/n_a n_d n$ (Little *et al.*, 1991; Neter *et al.*, 1996), which in the present is estimated as 0.0219 + 0.0091 + 0.0001 = 0.0311. Again by far the greatest contribution to this variance is that due to the variability among animals in their response. The intradog variance component, although slightly larger than the interdog variance component, makes a considerably smaller impact on $\widehat{\mathrm{Var}}(\hat{\mu})$. For those interested in estimating the total variability of a single response, $\sigma_{\text{total}}^2 = \sigma_a^2 + \sigma_{d/a}^2 + \sigma_e^2$ (Kringle, 1994), which in the present example is estimated as 0.4387 + 0.5431 + 0.0096 = 0.9914. Here the total variability of a single response is divided nearly equally between "animals" and "days nested within animals." Other possible designs could be considered. What has been demonstrated is that the method of analysis of variance in conjunction with experimental design can be useful in answering a variety of questions. Design 1 allowed an assessment of how parallel the plasma cortisol profiles of the dog population are across time. It also allowed a determination of whether there are major shifts in the daily overall variability in the plasma cortisol level in light of changes in individual animal responses across time. This information is not provided by design 2; rather design 2 provides an estimate of the true intradog variability in the plasma cortisol level. Both designs provide an estimate of the interdog variability in the response.

Design 2 is frequently used to assess sources of variability in an assay. For example, several laboratories could be involved in doing a particular assay, with several autoanalyzers in each laboratory and multiple technicians running these autoanalyzers. Inference in this context centers around being able to identify if there are significant sources of variation among the laboratories, among autoanalyzers within a given laboratory, and among technicians operating a given autoanalyzer. The goal of analyses of this sort is to identify large sources of variability. Once the larger sources of variability have been identified, changes are made in the system in an effort to reduce the variability associated with each source. The long-term objective is to have an assay with sources of variability that are as small as possible. Clinical analysts conventionally divide the square root of the estimates of the variance components (the sample standard deviations) resulting from such assay experiments by the grand mean to obtain coefficients of variation for each source of variability (Kringle, 1994). These coefficients of variability should be much smaller than those derived as intraanimal and interanimal variability. Interested readers are strongly encouraged to consult texts written on experimental design and ANOVA (Dunn and Clark, 1987; Neter *et al.*, 1996).

CHAPTER

2

DNA Technology in Diagnosis, Breeding, and Therapy

JENS G. HAUGE

I. INTRODUCTION

During the last 20 years an immense expansion has taken place in our understanding of the structure, organization, and regulation of genes. This expansion has to a large extent been the result of the development of new methods to manipulate, multiply, and study DNA fragments. The same new methods have a number of important applications in human medicine and, gradually, also in veterinary medicine. For good introductions, see Old and Primrose (1990) and Watson *et al.*, (1992). An agricultural perspective is given in the book edited by Hansel and Weir (1990). These surveys also discuss the large impact on microbiological diagnosis and vaccine production, as well as hormone production, aspects that are not covered here.

The development of gene technology rests on the foundations of molecular biology laid during the preceding 40 years, with the discovery of the double helical structure of DNA and the breaking of the genetic code as the major milestones. This chapter starts, therefore, with a brief review of the molecular biological basis of gene technology.

II. MOLECULAR GENETICS

A. Structure and Replication of Genes

The notion that heredity was linked to matter, to certain cellular structures, appeared for the first time in 1903 when the chromosomal theory of heredity was formulated. Chromosomes were recognized to have properties that could accommodate the hereditary units discovered by Mendel in his experiments. A bridge was built between cytology and genetics. But the nature of the molecules that carried the hereditary information was not thereby identified. Many felt that chromosomal protein was the most likely candidate.

In 1944, however, Avery and coworkers showed convincingly that genes in pneumococcal bacteria are molecules of deoxyribonucleic acid (DNA). It soon became apparent that pneumococci were no exception in this respect. In animals and plants, as well as in bacteria, hereditary information is carried by DNA.

A section of a DNA molecule has the appearance shown in Fig. 2.1a. DNA is built in the form of a chain, with phosphoric acid and the sugar deoxyribose alternating as the links. Phosphoric acid always connects the 5'-OH group in one deoxyribose to the 3'-OH in the next deoxyribose. The heterocyclic bases adenine, guanine, cytosine, or thymine are bound to the 1' carbons in deoxyribose. The base–deoxyribose moiety is a nucleoside, and the repeating unit in the chain, the combination base–deoxyribonucleoside–phosphoric acid, a nucleotide.

It is impractical to write DNA structures with all the atoms, so simplified writings have come into use. If the bases from the top in Fig. 2.1a are adenine, thymine, and guanine, the most used abbreviation is simply ATG. The first letter in the name of the base is used to designate the corresponding nucleotide.

That such a chainlike DNA molecule could carry hereditary information, genes, was not difficult to conceive. Most genes determine the construction of proteins, which are also chainlike molecules, with amino acids making up the links in the chain. One needs only to postulate a one-to-one relationship between an amino acid and a group of DNA bases. The other fundamental property of the hereditary material, that it is accurately duplicated and distributed on both daughter cells when cells divide, was harder to visualize on the basis of the DNA structure, as given in Fig. 2.1a. Watson felt that the solution to the problem perhaps lay hidden in the three-dimensional structure of DNA, and together with Crick he set out to elucidate this structure. The result was the discovery in 1953 of the double-helix structure of DNA. The double helix is built as shown schematically in Fig. 2.1b. A, T, G, and C represent the bases, which point toward each other and are bound to each other through hydrogen bonds. The DNA strands of the double helix have opposite directions (a DNA chain has a 5'-end and a 3'-end, see Fig. 2.1a). The size of the bases and their hydrogen bonding properties make only two pairings possible, namely, A with T and G with C. One turn of the standard double helix has 10 base pairs (bp) and covers a length of 3.4×10^{-6} mm. The diameter of the double helix is 2×10^{-6} mm. It is so slim a structure

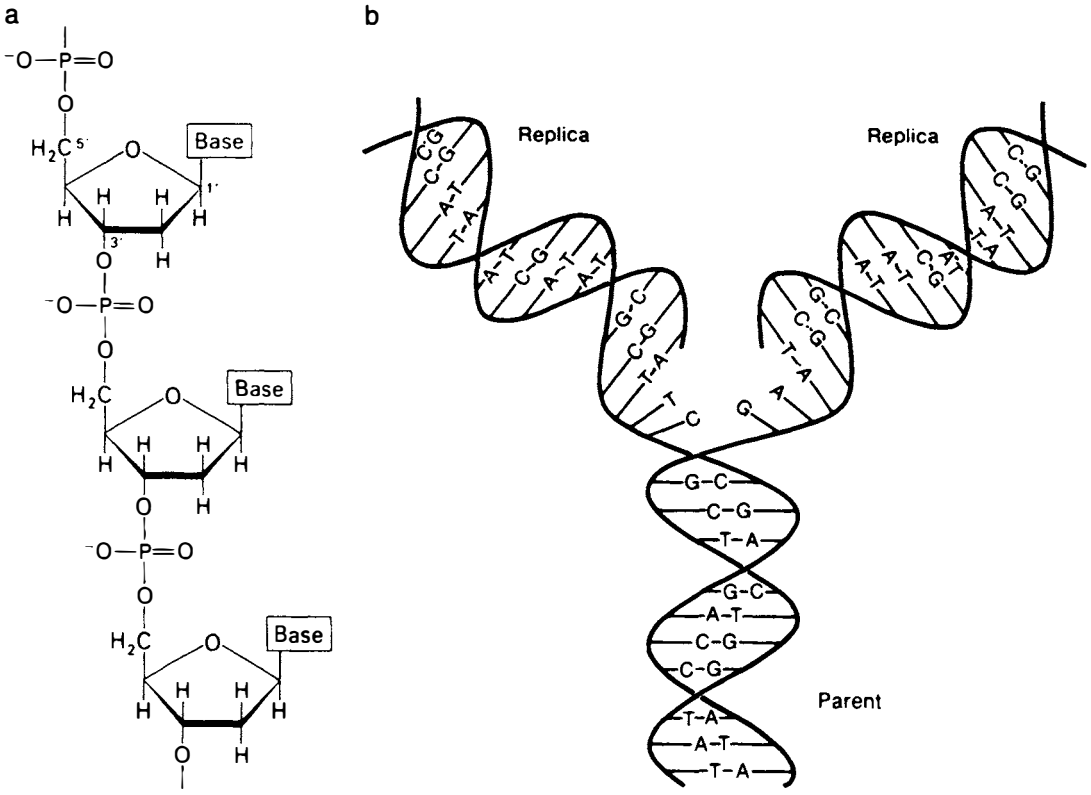

FIGURE 2.1 (a) Structure of part of a DNA chain. (b) DNA double helix during replication. Reproduced from Stryer (1981) and Freifelder (1983), with permission.

that if a DNA molecule could reach from the Earth to the moon, it still would weigh only 1 mg!

The model for the DNA molecule at which Watson and Crick (1953) arrived can in a simple way explain how DNA molecules are duplicated, that is, the process of DNA replication. When the double helix is considered (Fig. 2.1b), we can see that the two strands correspond to each other. The base pairing rules determine which base in one strand must be opposite a given base in the other strand, and the strands are said to be *complementary*. When replication starts, the hydrogen bonds between the two strands are gradually broken (Fig. 2.1b). New DNA chains are constructed from the four deoxynucleoside triphosphates with the help of the enzyme DNA polymerase, one molecule of pyrophosphate being eliminated per nucleotide laid down. Step by step, two new strands, complementary to the original strands, are synthesized. The original strands serve as templates in the process, and the result is two new double helixes that are identical to each other and to the original DNA molecule.

The basic mechanism for DNA replication is simple and elegant. The practical execution of this process in the cells, however, involves a large number of proteins, including some additional enzymes. The unwinding of the DNA molecules causes problems, as does the fact that DNA polymerase lays down a new strand from the 5'-end toward the 3'-end only. Furthermore, for this synthesis to start, a primer nucleic acid is needed for the strand to grow. One important auxiliary enzyme is DNA ligase, which links DNA molecules.

If DNA is heated to 80–90°C, the molecule will denature, and the strands will separate. If the temperature is lowered somewhat, the complementary strands will find each other again and reform the double helix. This property is widely exploited in gene technology (Section III.B.1).

B. From Gene to Gene Product

When the information stored in DNA is used, organisms utilize another type of nucleic acid, namely, ribonucleic acid, RNA. RNA differs from DNA in that it contains ribose instead of deoxyribose, and uracil instead of thymine. Uracil has the same base pairing properties as thymine. RNA does not normally exist in double-helix form, but RNA may form short stretches of double helix when the RNA strand folds back on itself locally. A DNA strand and a complementary RNA strand will form a double helix.

RNA is made by transcription from one of the DNA strands in a double helix (Fig. 2.2). The DNA strand is used as template in a process somewhat similar to DNA replication. The DNA double helix is opened

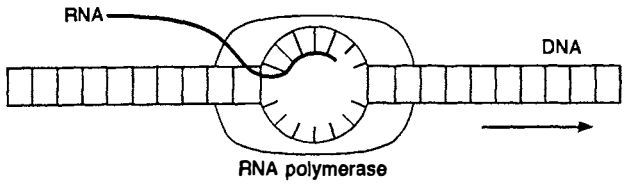

FIGURE 2.2 RNA synthesis (transcription).

locally, and an RNA strand complementary to the template is synthesized with the help of the enzyme RNA polymerase, ribonucleoside triphosphates being used as activated building blocks. Special sequences of bases in front of the genes (promoters) are recognized by the polymerase, causing it to start at the right place and on the right DNA strand. At the other end of the genes, there are termination signals.

In all cells there are three main types of RNA: messenger RNA, ribosomal RNA and transfer RNA. Messenger RNA (mRNA) carries the information specifying the amino acid sequences in the proteins. Ribosomal RNA (rRNA) is a group of RNA molecules that forms part of the structure of the protein-synthesizing machinery of the cells, the ribosomes. Transfer RNA (tRNA) participates in protein synthesis (translation) by carrying amino acids to the ribosomes.

The mRNA type is of special importance. For each kind of protein chain the cell makes, there is a corresponding mRNA. The genetic coding system that biochemists discovered between 1960 and 1965 showed that organisms use groups of three nucleotides, triplets, to code for amino acids. It is, therefore, the sequence of triplets in mRNA that directly determines the sequence of amino acids in the corresponding polypeptide chain. The coding group could not have consisted of only two nucleotides. That would have given only $4^2 = 16$ combinations, and 20 amino acids need coding. But $4^3 = 64$ gives more than enough. Nature has chosen this most economical solution, and done it in a way so that 61 of these 64 triplets code for some amino acid. Almost all the amino acids, therefore, have more than one codon.

When ribosomes directed by mRNA link together the amino acids, it is crucial for the result that the ribosomes start at the correct position on the mRNA. Starting one nucleotide too early or late will give a completely different protein. A correct start is secured by having all protein synthesis start with the triplet AUG, which codes for methionine. This means that all proteins initially are synthesized with methionine as their first amino acid. In posttranslational processing, some proteins lose this initial methionine, however. Because methionine also occurs internally in proteins, something more is needed for a correct start. In bacte-

ria, the ribosomes recognize start AUG by the presence of a short stretch of purines a limited distance before the AUG. In animals and plants, the ribosomes choose the AUG that is closest to the 5'-end of the mRNA. The coding triplets UAA, UAG, and UGA do not code for any amino acid, and these codons are used as termination signals.

The amino acids do not by themselves have the ability to recognize their codons on mRNA. They must, furthermore, be activated in order to form peptide bonds with each other. Both of these problems are solved by each amino acid becoming bound to a tRNA by means of a specific activating enzyme, utilizing ATP. tRNA has in its structure an anticodon, a set of three nucleotides that forms base pairs with the codon on mRNA for the corresponding amino acid. On the ribosome surface the amino acids leave their tRNA carriers as they are linked together to form polypeptide chains. Briefly then, the information flow is as illustrated here for the start of a hypothetical gene:

```
3' . . . TAC AAA AGT GAC TGT CCG . . . 5' DNA
5' . . . ATG TTT TCA CTG ACA GGC . . . 3'
                    ↓ transcription
5' . . . AUG UUU UCA CUG ACA GGC . . . 3' mRNA
                    ↓ translation
      Met Phe Ser Leu Thr Gly          protein
```

III. GENE MANIPULATION

A. Basic Features

The core of the new gene manipulation techniques is that one can join two pieces of DNA to form a recombinant DNA molecule, which then is multiplied, or cloned, in a suitable host organism so that a sufficient amount of the piece of DNA desired is obtained. The one piece of DNA is often used as a *plasmid*, a ring-shaped, extrachromosomal DNA molecule that occurs in many bacteria and carries genes, for example, for antibiotic resistance. Figure 2.3 illustrates molecular cloning of a piece of DNA with the help of a plasmid vector. The plasmid vector is opened with the help of a special endonuclease and joined to the foreign DNA with the help of another enzyme. Under proper conditions, some of the bacteria will take in the recombinant DNA molecule, which will be replicated as the bacteria grow and multiply. Most of the bacteria will not have taken in any plasmid. A selection process is therefore necessary, usually based on the plasmid carrying an antibiotic resistance gene. From the bacteria, the plasmid and the foreign DNA piece can be isolated in such

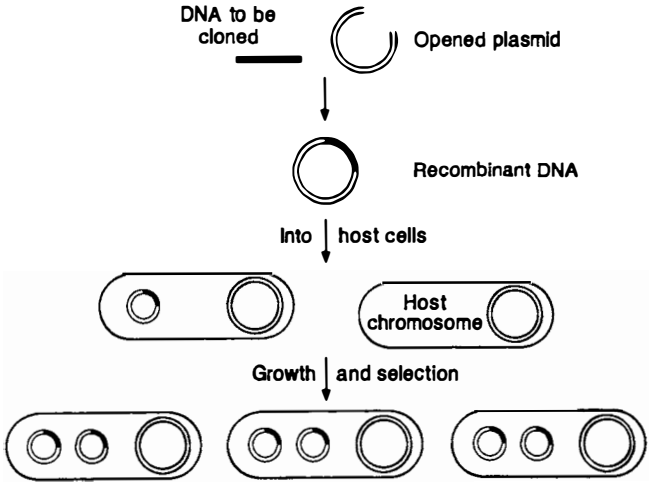

FIGURE 2.3 Basic steps in cloning of DNA in a plasmid.

amounts that it is possible to study the DNA in the electron microscope, determine its base sequence, inject it in fertilized ova, or use it as a diagnostic probe, to mention some important uses.

As is often the case, when a homogeneous DNA preparation is not available as starting material for cloning, but rather a mixture of many types of DNA pieces, special selection techniques are required afterward to find the interesting clone or clones. Plasmids are but one type of vector for DNA cloning. Viruses from bacteria or animals are also used quite often.

B. Methods and Tools

1. Nucleic Acid Hybridization

Nucleic acid hybridization is fundamental both in basic and applied gene technology. This is the process whereby sequence-specific DNA : DNA or RNA : DNA duplexes are formed from single-stranded nucleic acids. For most uses, one of the components in the hybridization is radioactively labeled, or labeled by other means, so that the hybrid can be identified. The labeled molecule is referred to as a *probe* and is used to probe nucleic acid mixtures for the presence of complementary sequences (Fig. 2.4).

The factors affecting the stability of the hybrid and the rate of the hybridization reaction are fairly well known (Marmur and Doty, 1961; Nygaard and Hall, 1964; Young and Anderson, 1985). The stability depends on the temperature, the ionic strength of the medium (high ionic strength reduces the repulsion between the negatively charged phosphate groups and thus stabilizes the duplex), the presence of formamide (which breaks hydrogen bonds), the G + C content of

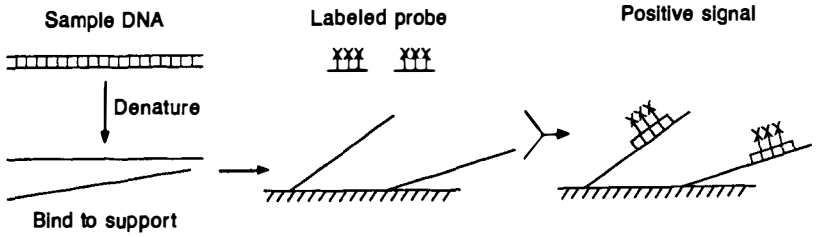

FIGURE 2.4 Hybridization.

the probe (G and C rich probes are bound more tightly because there are three hydrogen bonds linking G to C, compared to two bonds between A and T), and the length of the probe. The temperature at which the duplex is 50% denatured is called its T_m, which can be calculated from the following formula:

$$T_m = 81.5°C + 16.6 \log M + 0.41(\%G + \%C) - 500/n - 0.61\ (\%\ \text{formamide}).$$

This formula assumes perfect complementarity between the hybridizing strands. With mismatches present, the T_m is reduced by about 1°C per 1% mismatch.

The factors affecting stability also affect the rate of hybridization. The rate is optimal about 25°C below T_m. For a reaction in solution, the rate is proportional to the concentrations of the reacting species. When the DNA or RNA to be investigated is immobilized on a membrane, which is often the case, the reaction is slower by a factor of 7 to 10, but the general effects of the factors listed earlier are the same.

The reaction conditions are manipulated to give hybridizations at a desired level of stringency. High stringency, that is, high temperature and/or low ionic strength, will allow only the most stable hybrids, those having perfect complementarity, to form. In certain situations, one may want to probe for a family of related DNA molecules with some sequence differences, and hybridization at a lower stringency will be chosen. The same may be necessary when using a probe from one species to look for a homologous gene in another species.

Several methods are in use for labeling a probe with radioactivity (Arrand, 1985). In our experience, the random primer method (Feinberg and Vogelstein, 1983) is a convenient way of obtaining high specific activity, better than the so-called nick translation method. The probe DNA is denatured, and both strands are used as template for DNA synthesis, using short random oligonucleotides as primers and one or more of the triphosphates being labeled with ^{32}P.

Nonradioactive labeling is also used because it has certain advantages for routine, diagnostic purposes. Attaching biotin to one of the bases (Leary *et al.*, 1983) has received particular attention. The biotinylated probe is localized with streptavidin and a biotin-coupled enzyme for which a substrate is used that gives a colored precipitate. Nonradioactive probes have the drawback of multistep detection procedures and a somewhat lower detection sensitivity than radioactive probes (Syvanen, 1986).

2. *Restriction Endonucleases*

Restriction endonucleases of type II, usually referred to as restriction enzymes, are a major tool in gene analysis and gene manipulation. These enzymes bind to particular sequences on DNA and cut both strands within this DNA site. The majority of the enzymes have sites of tetra-, penta-, hexa-, or heptanucleotides which have an axis of rotational symmetry (Fig. 2.5a). Enzymes corresponding to more than 150 different sites have been discovered so far. The names of the enzymes have been constructed from names of the bacteria and the particular substrain from which they have been isolated. The arrows in Fig. 2.5a indicate where the DNA strands are cut by these five enzymes. Treatment of a DNA molecule with a restriction enzyme yields a reproducible set of fragments. An enzyme with a recognition site of four nucleotide pairs will cut relatively often, statistically once every 4^4 (i.e., 256) nucleotide pairs, whereas an enzyme with a hexanucleotide recognition site will cut less frequently, once every 4^6 (i.e., 4096) nucleotide pairs. Figure 2.5b shows the pattern of fragments into which three different restriction enzymes cut the SV40 virus chromosome. After enzyme treatment, the fragments were separated by electrophoresis in an agarose gel and made visible by binding of ethidium bromide, which fluoresces in ultraviolet light. The size of the fragments can be found by running molecular weight markers in the same gel. Short fragments move farther, and long fragments move a shorter distance.

The fragments produced by the restriction enzymes will, for most enzymes, have single-stranded, complementary end sections, because the cuts are not made straight across (Fig. 2.5a), and the fragments are said to have sticky ends. If a plasmid is opened with the same restriction enzyme that has been used to produce

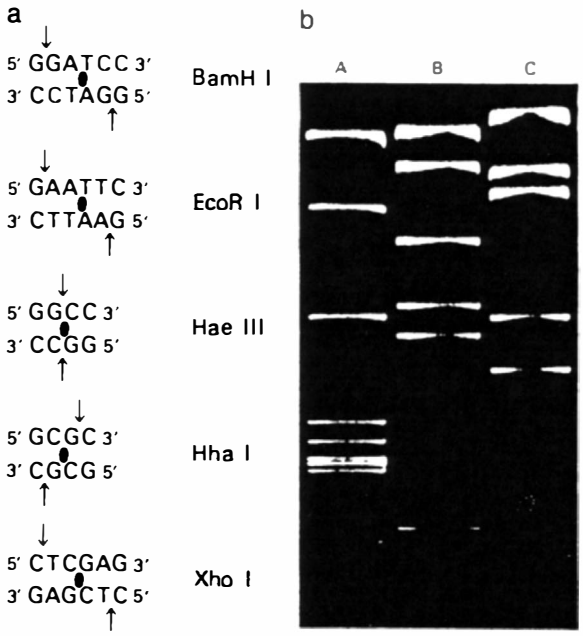

FIGURE 2.5 (a) Specificities of some restriction enzymes. (b) Gel electrophoresis pattern showing SV40 DNA fragments produced with each of three restriction enzymes. Reproduced from Stryer (1981), with permission.

the DNA fragments to be cloned, this DNA will have sticky ends of a type that allows its insertion in the plasmid. Fig. 2.6a shows what the situation would have been in Fig. 2.3 if the enzyme *Eco*RI had been used.

3. *DNA Ligase*

To form a stable, recombinant DNA molecule from two molecules, the strands of these two molecules must be joined. This is effected by the enzyme DNA ligase, which requires for its action a 5'-phosphate and a 3'-OH group. The enzyme from phage T4 uses ATP as energy donor, whereas the *Escherichia coli* enzyme uses NAD. The ligation reaction is carried out at a low temperature, 4–15°C, in order to increase the stickiness of the sticky ends.

4. *Terminal Deoxynucleotidyltransferase*

Terminal Deoxynucleotidyltransferase, or briefly, terminal transferase, is useful when the object is to insert in a plasmid a DNA molecule that has not been produced with the help of a restriction enzyme, a frequently occurring situation. With this enzyme, tails of identical nucleotides can be attached to the 3'-end of DNA strands. The plasmid is opened with a suitable

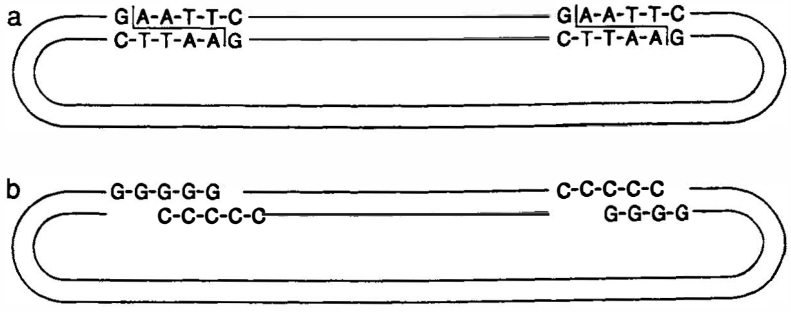

FIGURE 2.6 (a) Fitting a piece of DNA into an *Eco*RI site of a plasmid. (b) Fitting a piece of DNA into a plasmid after tailing the plasmid with G and the insert with C by using terminal transferase.

restriction enzyme and furnished with a tail of about 20 G residues, whereas the DNA to be inserted is furnished with a C tail (Fig. 2.6b).

5. Adaptors

Use of an adaptor DNA containing a restriction site is a common alternative strategy when a DNA molecule is to be inserted in a plasmid opened with the corresponding restriction enzyme. A piece of DNA, 6 to 10 base pairs long and containing the desired restriction site, is synthesized or purchased. The ends of the DNA to be inserted are first made blunt by filling in with DNA polymerase. All 5'-ends are phosphorylated with the enzyme, polynucleotide kinase, and the adaptor is attached to both ends of the insert DNA with DNA ligase. Treatment with the restriction enzyme then produces the proper sticky ends for insertion in the plasmid. This method illustrates well the role of both chemistry and enzymology in recombinant DNA technology.

C. Vectors

Through stepwise modifications of natural *E. coli* plasmids, new plasmids have been constructed that are safe and convenient for different types of gene manipulation. One much used plasmid is pBR322 (Fig. 2.7a). This plasmid carries two antibiotic resistance genes, one for tetracycline and one for ampicillin. Within these two genes, there are several restriction sites for enzymes that have only these sites in the pBR322 molecule. If one uses the *Bam*HI site to insert a foreign DNA, the tetracycline resistance will be eliminated. It is then possible to select for bacteria that have taken up the plasmid by using ampicillin in the medium, and then finding those that have an insert in the *Bam*HI seat by investigating which bacterial colonies have lost tetracycline resistance. This approach is useful since there can be some regeneration of the original plasmid in the ligation step.

Lambda virus DNA has also been modified so that it is suitable as a vector. Three of its five *Eco*RI sites have been removed. The DNA between the two remaining sites is not necessary for the infection process and can be exchanged with a foreign piece of DNA of 10–20 kilobase pairs (kbp). The recombinant DNA is packed *in vitro* using lambda coat and tail proteins. These phage particles enter *E. coli* bacteria very efficiently and reproduce as in a normal lytic infection.

For other bacteria, yeast, and animal and plant cells, other vectors exist. Shuttle vectors, which have specificity for two different hosts, have also been constructed.

D. Studies of Gene Structure

Comprehensive solutions to a wide range of biological problems require knowledge of the structure of the gene and regulatory sequences that govern the particular biological phenomenon.

1. cDNA Cloning

For studies of genes of viruses and bacteria, cloning can start with fragments of their chromosomal DNA. With genes from animals and plants, the situation is different. Here the genome is so large and contains so many noncoding sections that often one must start with mRNA molecules and preform what is called a copy DNA (cDNA) cloning. Total RNA is isolated with chemical methods from a tissue of interest, and mRNA adsorbed on a column of poly(T)-cellulose. mRNA is bound due to the 3'-tail of poly(A), which mRNA possesses in higher organisms. mRNA is eluted and used as the template for RNA-directed DNA polymerase, so-called "reverse transcriptase." This enzyme occurs in retroviruses, where its role during viral infection is to produce double-stranded DNA corresponding to the viral RNA genome. In principle, the same reaction can take place *in vitro*, and a mixture of cDNA is formed, corresponding to the mixture of mRNA isolated.

After attachment of sticky ends, the mixture of cDNA molecules can be inserted in a plasmid. If the bacteria to be transformed have been made competent by a special treatment, 10^5 to 10^7 transformed bacteria per microgram of recombinant plasmid can be expected. The clones from these bacteria make up a cDNA library for that particular tissue.

The library will have cDNA clones corresponding to different mRNA in the tissue. Clones for the particular gene of interest can be found by various means. The simplest situation exists if something is known about the amino acid sequence of the protein for which the gene codes. Then, a DNA probe of 17 to 19 bases, corresponding to a suitable hexapeptide, can be synthesized. This probe will be long enough that the search will be specific at high stringency. The probe preparation will have to be a mixture of DNA molecules, however, since most amino acids have more than one codon. An imprint of the bacterial colonies is made on a nitrocellulose filter, the cells are opened, and their DNA is denatured. If a radioactive probe is used, it will hybridize to a few colonies, those containing cDNA corresponding to the gene of interest. Plasmid DNA is purified, treated with the proper restriction enzyme, and the cDNA isolated from a hybridizing band on an agarose gel after electrophoresis.

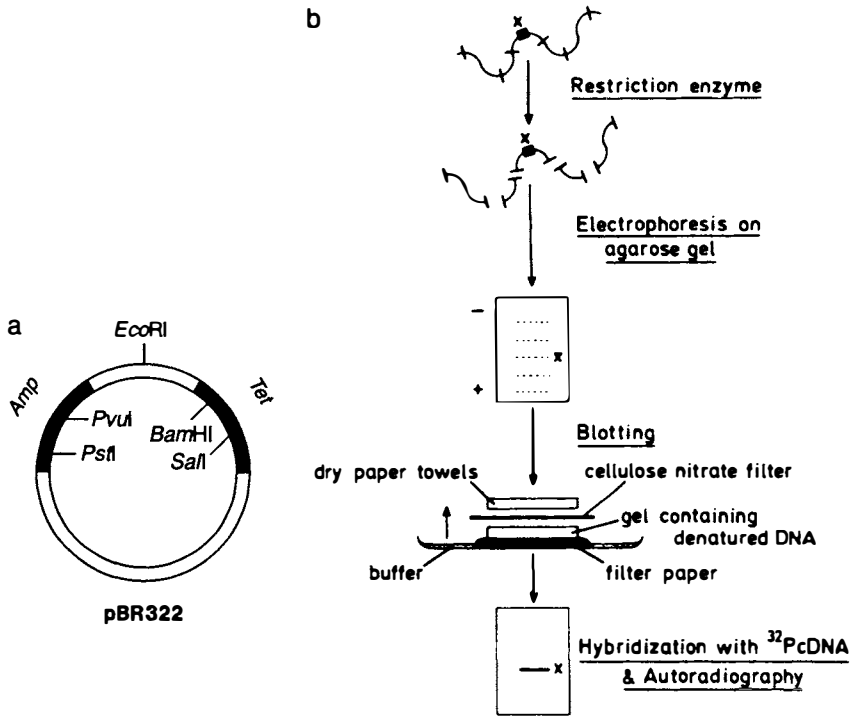

FIGURE 2.7 (a) The cloning vector pBR322 (4362 bp). *Amp* is the gene for ampicillin resistance, and *Tet* is the gene for tetracycline resistance. (b) The Southern blot technique. The symbol x indicates the gene or sequence of interest. Reproduced from Emery (1984), with permission.

2. *Gene Cloning*

A collection of clones, which includes all DNA in an organism, is called a *genomic library* and is usually made in a lambda vector. DNA from the organism is subjected to incomplete digestion with a frequently cutting restriction enzyme, so that fragments of about 20 kbp are formed. Vector arms are ligated to both sides of these fragments, and the resulting DNA molecules packed into lambda proteins, as described in Section III.C. The lambda clones that result from the infection will, if one has close to a million different clones, represent all the DNA and genes of a mammal. If one has a cDNA clone for a gene of interest, this cDNA can be radioactively labeled and used as a probe to find the lambda clones that contain the gene or parts of it.

3. *Splitting of Eukaryotic Genes*

One of the big surprises in molecular biology research was a discovery made in 1977 on cloned eukaryotic genes. The chicken gene for ovalbumin was found to be 7700 bp long, while only 2000 bp would be required to code for the protein. Closer investigation of the cloned DNA with restriction enzymes and DNA sequencing revealed that the coding part of the gene was divided into eight pieces, *exons*, separated by larger pieces of noncoding DNA, *introns*.

4. *Restriction Maps, Southern Blots, and DNA Sequencing*

Characterization of gene structure is done in broad outline by restriction mapping and in detail by establishing the DNA sequence. A restriction map identifies the positions of sites for a set of restriction enzymes. The correct order for the fragments produced by a given enzyme is determined in several ways, for example, through comparison of DNA fragment lengths corresponding to different degrees of partial digestion with the enzyme. The approximate distances between the cut sites are obtained by including molecular weight markers in the electrophoresis. Accurate distances require DNA sequencing.

If one has a cDNA probe for a gene, it is possible to obtain some information on the structure of the gene without having cloned it by using the technique developed by Southern (1979) (Fig. 2.7b). After digestion with a restriction enzyme and separation by agarose electrophoresis, the DNA fragments are denatured in alkali and transferred to a nitrocellulose or nylon membrane with a flow of buffer. A replica of the gel

pattern of DNA is thereby produced on the membrane. When the membrane is then treated with the radioactive probe, it will hybridize to those bands that have DNA sequences complementary to the probe and become visible on X-ray film. In this way, information can be obtained about restriction sites in the gene region corresponding to the cDNA.

DNA sequencing is carried out by means of a chemical method developed by Maxam and Gilbert (1977) or by an enzymatic method developed by Sanger *et al.* (1979). The chemical method starts with a cloned DNA fragment that has a few hundred bases and the 5′-end radioactively labeled. From this cloned DNA, a spectrum of radioactive fragments is produced in which all sizes—from the full length down to zero—are represented. In principle, this procedure is done in four reactions, one reaction each for fragments ending with a G, C, T, or A. The fragments are separated by gel electrophoresis at a voltage of about 3000 V, and an autoradiograph is made from the gel (Fig. 2.8a). The sequence can be read directly from the autoradiograph, as indicated in the figure. The enzymatic method gives a similar end result. In this method, DNA polymerase synthesizes DNA in four reactions in the presence of small amounts of 2′,3′-dideoxynucleoside triphosphates, which cause chain termination when incorporated.

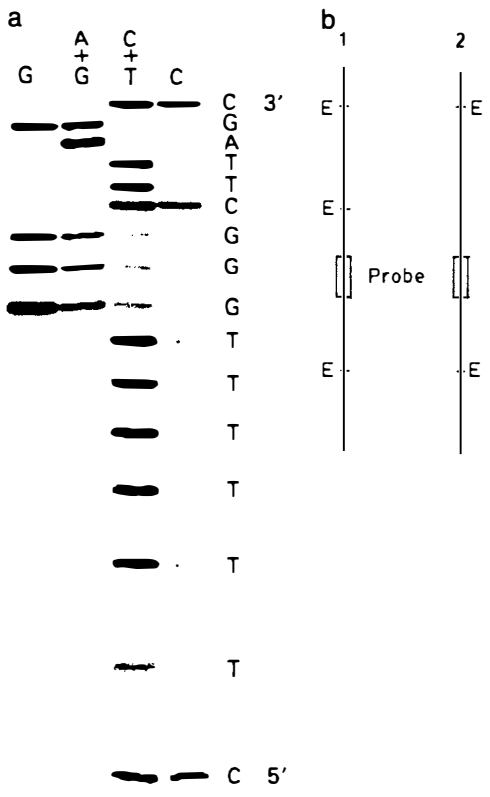

FIGURE 2.8 (a) Autoradiograph of a gel showing labeled fragments obtained in the Maxam and Gilbert DNA sequencing method. The reaction used for adenine affects both adenine and guanine, and the reaction used for cytosine affects both cytosine and thymine. Reproduced from Stryer (1981), with permission. (b) A restriction fragment length polymorphism caused by the presence or absence of a site for restriction enzyme E.

DNA sequencing work has yielded a wealth of information on gene structure and chromosome organization in viruses and bacterial and eukaryotic cells. The following are important examples. Sequencing of the 5375-bp ϕX174 virus showed how the DNA could code for proteins of 2000 amino acids in aggregate by having an overlap between some of the genes. The transition between exons and introns was shown to have certain characteristic bases, common to all genes. The promoter region in front of the genes, the site for attachment of RNA polymerase, was also found to have a common base pattern. DNA sequencing has help elucidate the structure and the function of immunoglobulin genes, histocompatibility genes, and oncogenes.

The sequencing technique has developed quickly. By 1982, the full sequence of lambda DNA with its 48,502 bp was published (Sanger *et al.*, 1982). Now under way is a gigantic international project that calls for sequencing of the total human genome with its 3×10^9 base pairs by the year 2005.

5. Polymerase Chain Reaction

An important use of sequence data is in enzymatic amplification of segments of DNA in the polymerase chain reaction (PCR). PCR amplification involves two oligonucleotide primers that flank the DNA segment to be amplified and repeated cycles of heat denaturation, annealing of the primers to the complementary sequences, and extension of the annealed primers with DNA polymerase. The primers hybridize to opposite strands of the target DNA and are oriented so that DNA is synthesized for the region between the primers. Since the extension products are also complementary and capable of binding the primers, each cycle doubles the amount of DNA resulting from the previous cycle.

The basic idea of this method was described in 1971 by Kleppe *et al.* and later developed by Saiki *et al.* (1985). Its full potential appeared when Saiki *et al.* (1988) introduced the thermostable DNA polymerase from *Thermus aquaticus* (*Taq*), thus eliminating the need to add fresh polymerase during each cycle. This modification not only simplified the procedure, making it amenable to automation, but also substantially increased its specificity, sensitivity, yield, and the length of targets that could be amplified. Amplification of 10

million times was demonstrated, and segments up to 2000 bp were readily amplified, although longer segments have reduced yield.

The PCR technique has found wide application (Erlich, 1989; Erlich *et al.*, 1991b). Isolation of cloned segments from their vectors is simplified by PCR amplification of these, using vector-specific primers that flank the insertion site. RNA and cDNA can be amplified from the products of reverse transcription (Todd *et al.*, 1987). DNA sequencing with the enzymatic method can be done directly on the PCR product without ligation into a sequencing vector. For this purpose, however, it is advantageous to purify the sequencing template by incorporating biotin in one of the primers. After immobilization of the PCR product on streptavidin-coated magnetic beads, the unbiotinylated DNA strand is removed by alkali (Hultman *et al.*, 1989). In diagnostic work and genetic mapping, PCR methods are used extensively as will be apparent in later sections. For some applications, it is important to be aware that the *Taq* enzyme allows incorporation of 1 incorrect nucleotide for about 20,000 nucleotides incorporated.

IV. STUDIES OF METABOLIC AND GENE REGULATION

Students of metabolic regulation now have new tools at their disposal through the advent of recombinant DNA technology. The impact has been the largest in the area of analysis of gene expression and its regulation by hormones due to the availability of cDNA probes for a broad variety of genes of metabolic interest. These probes make possible quantification of the level of specific messengers. A number of such studies, covering enzymes in glycolysis, gluconeogenesis, lipid metabolism, and amino acid metabolism, are described by Goodridge and Hanson (1986).

A. Tissue Culture Studies

Several of the corresponding genes have been isolated, and their promoter–regulator regions are being identified and characterized. One example is the rat gene for cytosolic phosphoenolpyruvate carboxykinase (PEPCK), studied by Hod *et al.* (1986). The promoter–regulator region had been localized to be within a 621-bp *Bam*H1/*Bgl*II fragment present at the 5′-end of the gene. The hormonal control region was studied by linking the 621-bp fragment to the structural segment of the herpes simplex thymidine kinase (TK) gene in a plasmid vector. This construct was used to transfect cells of a TK-deficient rat hepatoma cell line. The addition of dibutyryl-cAMP to the cells resulted in a fourfold to sixfold induction of both TK activity and the level of its mRNA. To define the sequences in the PEPCK promoter that are necessary for this cAMP effect, a series of graded deletions was constructed. The transfected chimeric genes retained their responsiveness to cAMP as long as they included the sequence from −61 to −108. Deletion of this 47-bp fragment completely eliminated cAMP inducibility.

Further studies of this and other cAMP-regulated genes have shown that a palindromic DNA sequence, TGACGTCA, termed *CRE* (cAMP response element) is sufficient for the effect. Other hormones, such as glucocorticoids, androgens, mineralocorticoids, estrogen, thyroxin, and retinoic acid, have their specific response segments, where the hormone–receptor complexes bind (Lucas and Granner, 1992). cAMP normally exerts its effect through activation of protein kinase A (PKA), and such is the case here as well. A CRE-binding protein (CREB) was discovered that is phosphorylated by PKA and thereby activated (Yamamoto *et al.*, 1988).

PEPCK is actually regulated by several hormones and the dietary state. Further transfection studies have uncovered eight protein-binding domains between −460 and +73 and identified proteins binding to these response elements (Park *et al.*, 1993). The interaction of these partially tissue-specific transcription factors with the basic transcriptional complex is currently being studied.

B. Regulation in Transgenic Animals

Although much can be learned from studies with cell cultures, including how they react when recombinant DNA is introduced, this approach has its limitations. One fundamental set of regulatory problems is connected to the development of an animal from a fertilized ovum. What sort of mechanisms are responsible for tissue- and time-specific transcription of genes? Such questions are addressed through the use of transgenic organisms, particularly mice (Westphal, 1987; Grosveld and Kollias, 1992). This important technique was introduced by Gordon *et al.* (1980). The DNA to be investigated has been injected into the male pronucleus of a fertilized ovum, and the ovum implanted. Some of the ova develop into mice with the extra DNA integrated into their chromosomes, usually with many copies arranged head to tail.

The first successful experiments dealing with tissue-specific regulation were reported by Chada *et al.* (1985). These investigators showed that a human β-globin gene, in which the front end had been replaced by the

corresponding mouse gene, together with 1200 bp of flanking DNA, was expressed in transgenic mice exclusively in erythroid cells. They also showed that the hybrid β-globin gene was expressed at the proper time during development (Magram *et al.*, 1985). The 5'-flanking region must have been responsible for this specificity, along with corresponding tissue-specific regulatory proteins.

Similar results have been found for a number of other genes and tissues (Palmiter and Brinster, 1986). A particularly striking example is the work on elastase I (Swift *et al.*, 1984). Mice were made transgenic with the rat elastase I gene and its flanking regions. A marked tissue specificity was observed, rat elastase mRNA being 500,000 times more abundant in the pancreas than in the kidneys. Experiments with trimmed 5'-flanking DNA showed that 205 bp were sufficient to uphold the pancreas-specific expression (Ornitz *et al.*, 1985). When this regulatory region was joined to the human growth hormone gene, human growth hormone was found in pancreas and not in other tissues. Furthermore, immunofluorescence analysis demonstrated that the growth hormone was present in the acinar cells, not in the endocrine or connective tissue cells of the pancreas.

The faithful tissue specificity observed with this kind of construct has been exploited in the study of oncogene expression (Section V.E). In one such study, Hanahan (1985) directed the expression of the SV40 oncogene to pancreatic β cells using an insulin gene regulator sequence.

This technique has also been used, for instance, to further understand the complex and tissue-specific regulation of the PEPCK gene. McGrane *et al.* (1988) fused the promoter–regulatory sequence of the PEPCK gene to the bovine growth hormone gene as a reporter gene. The transgene was expressed only in liver and kidney and showed dietary and hormonal responsiveness. Further, in order to establish their regulatory roles, mutations in specific regulatory domains were produced in transgenic mice (Patel *et al.*, 1994).

Another method for producing transgenic animals uses embryonic stem (ES) cells. These ES cells are derived from an early embryo, cultivated, and infected with a retrovirus construct (Robertson *et al.*, 1986) or transfected through the phosphate/DNA precipitation technique (Lovell-Badge *et al.*, 1985). When they are reintroduced into the blastocyst, the ES cells contribute to the production of a chimeric animal. In the next generation, some pure transgenic animals appear. This approach has the advantage that somatic cell genetic techniques can be used to modify and to select cells with a desired potential.

V. DIAGNOSIS OF GENETIC DISEASE

A. Gene Changes in Hereditary Disease

Mutations could affect the production of a given gene product in many different ways. Studies of hemoglobin synthesis in humans have found examples of most of these possibilities. Replacement of a single base with another base can have the effect that an amino acid is replaced by another amino acid. One hundred and eighty-nine such structural variants are known for the human β-globin chain (Little, 1981). Not all of these variants cause disease, however. The mechanism of polypeptide chain termination is the source of other disturbances. In individuals with hemoglobin Constant Spring, the stop codon TAA for α-globin is replaced by CAA. In a type of β^0-thalassemia (no production of β chains), the seventh codon, AAG, is replaced by TAG, terminating the chain prematurely.

Single base mutations may also affect transcription and RNA processing, which is often observed in β-thalassemia (low production of β chains). Some mutations in the promoter region reduce transcription markedly. Changes at exon–intron junctions lead to errors in the removal of introns from the primary transcript, with unusable mRNA as the result. Mutations can also generate new, false exon–intron border sequences, again with defective mRNA as the result.

Deletions and insertions are other common types of mutations. Deletions or insertions of one, two, or four bases are the cause of several β^0-thalassemias. Such a mutation destroys the reading frame completely because the wrong set of triplets is read by the ribosomes. Deletions of $n \times 3$ bases can also occur, and the reading frame is not affected. Mutants with β-chain shortening from one to five amino acids are known. Larger deletions also occur; for hemoglobin genes, deletions from 0.6 kbp up to about 20 kbp are known.

Studies have uncovered a similar mutational heterogeneity for many other genes. In addition, a new type of mutation has been discovered for myotonic dystrophy (DM) and six other diseases (Miawa, 1994). The DM gene contains the triplet repetition $(GCT)_n$, with n varying somewhat in the population. For affected individuals n is increased and appears to correlate with the severity of the disease.

B. Detection of Gene Changes with DNA Probes

Recombinant DNA technology makes possible a direct approach to the study and diagnosis of a genetic disease, instead of being limited to study of its pheno-

typic expression. For animal owners and animal breeders, it is worthwhile to be able to detect carriers of recessive disease genes in order not to propagate the disease gene or to avoid mating the animal to another carrier of the same defect. Furthermore, it is not always the case that the homozygous state for a recessive gene, or the heterozygous state for a dominant gene, is expressed phenotypically. The disease may be dependant on an environmental factor for its expression or have a late onset in the life of the animal. In this case, DNA analysis could provide an early diagnosis.

Application of recombinant DNA methods in diagnosis and gene defect studies have made great advances in the human sector and are well under way in the veterinary sector also. Common to the methods is the need to have cloned or synthetic DNA probes for the disease gene or its neighborhood and/or sequence knowledge that permits the use of PCR methods.

1. Mutations That Create or Destroy a Restriction Site

The ideal situation exists when the mutation either creates a new restriction enzyme site or removes one that was present in the wild type. This is the case for sickle cell anemia in man. In sickle cell anemia, the sixth amino acid in the β chain of hemoglobin, glutamate, has been replaced by valine because an A in the corresponding codon has been replaced by T. The restriction enzyme *Dde*I for normal individuals cuts three places in the β-globin gene, whenever the sequence CTNAG occurs (N can be any base). The mutation has the effect that the second of these sites is destroyed. Sickle cell patients thus will have one longer DNA fragment hybridizing with a β-globin probe, whereas normal persons will have two shorter fragments, which is revealed by Southern blotting as described in Section III.D.4. A heterozygote would be revealed by all three bands being present.

Each restriction digest requires 5^{-10} μg of patient DNA, which is usually obtained from the buffy coat of peripheral blood samples. The leukocytes present in 10–20 ml of human blood can yield as much as 200 μg of DNA after treatment with proteinase K and extraction with phenol and chloroform.

There are many other examples of diagnosis based on change in a restriction site, for example, in the *ras* family of oncogenes and for induced H-*ras* mutations in the rat (Zarbl *et al.*, 1985). A more convenient version of this test amplifies the region around the mutation with PCR and subjects the PCR product to restriction enzyme treatment. Sufficient DNA is often present to allow direct detection of the restriction fragments after electrophoresis using ethidium bromide and UV light.

2. Deletion/Insertion Mutations

A favorable situation exists when deletions or insertions of a few hundred base pairs or more are the cause of the disease. These mutations will directly affect the length of the DNA fragment between two given restriction sites. Deletions occur in human globin genes, the gene causing Duchenne muscular dystrophy, the gene for coagulation factor VIII and others.

3. Single Base Replacement in a Known DNA Sequence

Base replacement mutations that do not affect any restriction site may still be diagnosed if one knows the DNA sequence around the mutation site. One can then synthesize a wild-type allele-specific oligonucleotide (ASO) of 18 to 20 bases, label it with radioactivity, and observe its hybridization with DNA fragments on a membrane. Under stringent hybridization conditions, it is possible to detect a mismatch of only one base between the probe and the DNA investigated. Additionally, it is prudent to make a probe corresponding to the mutant and demonstrate its reduced hybridization to normal DNA. This method is used in diagnosis of α_1-antitrypsin deficiency (Kidd *et al.*, 1984), H-*ras* mutations in rats (Zarbl *et al.*, 1985), and several other mutations.

The method is more reliable and convenient when carried out on a PCR-amplified segment containing the mutation. The sensitivity thus reached makes possible the use of nonradioactive, enzyme-labeled ASO probes in dot blot hybridization (Scharf *et al.*, 1991). The occurrence of many different mutations in the same gene in the population can be handled using a "reverse dot blot" method. Instead of having numerous membranes with the PCR product applied, each to hybridize with a different ASO probe, a membrane that contains an immobilized array of ASO probes is hybridized to the PCR product (Erlich *et al.*, 1991a).

4. Restriction Fragment Length Polymorphisms Linked to the Gene of Interest

Earlier, the most widely used and general diagnostic method was that of restriction fragment length polymorphism (RFLP) linked to the gene that was investigated. With this technique, one needs no knowledge of the structure of the gene. It is based on the fact that the heterozygosity at the level of DNA is large. If the base sequences of two homologous chromosomes are compared in humans, a difference for each 200 to 400 bp is found (Cooper and Schmidtke, 1984). The majority of these differences are neutral mutations. A few of them reside in the coding triplets, but most of

them are in introns and in the region between the genes.

Some of these mutations will affect known restriction enzymes and be within or close to the gene of interest, so that they can be observed as RFLP with a probe from the same region (Fig. 2.8b). Such an RFLP can be used as a marker for the gene studied. The procedure is essentially the same as in Fig. 2.7b. Presence and absence of the restriction site will give two different restriction fragment lengths that move different distances on the gel.

a. Study of Linked RFLP in Families

The use of RFLP for diagnosis has one drawback. An answer cannot be obtained by investigating the DNA of a single individual, as was possible with the methods in Sections V.B.1 through V.B.3. The chromosome with the mutant form of the gene will not always have the same restriction site allele, for instance, presence of the restriction site, that may have been the original constellation. However, only a fraction of chromosomes with this restriction site need have the gene mutation. By recombination, the mutant gene may also have landed on a chromosome with this restriction site absent. If the distance between the restriction site of concern and the gene studied is small, it is probable that the constellation will remain the same within a given family.

The use of this method is illustrated in the following example from a family with β-thalassemia. Both parents were healthy, but a child was affected. During the following three pregnancies, prenatal diagnosis was performed. Using the restriction enzyme *Ava*II, Southern blotting, and a labeled β-globin probe, the band pattern shown in Fig. 2.9 was observed. Both parents were RFLP $+-$, one chromosome having the restriction site, the other not. The affected child was $++$; therefore, it must thus have been the $+$ chromosome from both parents that carried the disease gene. For the fetuses, one could conclude that they were noncarrier, affected, and carrier, respectively. The probe cross hybridizes with δ-globin sequences common to all.

b. Usefulness of Having More Than One RFLP

The example just described was a favorable situation. It would only have been possible to diagnose 50% of the offspring correctly if the thalassemia gene in one parent had been on an RFLP chromosome. The situation might have been helped if one had another RFLP close by. With two RFLPs, one would have four combinations, so-called "haplotypes." This circumstance is equivalent to having four alleles for the marker locus, which gives a favorable degree of heterozygosity.

If the distance between the gene and the RFLP site is large, for example, some thousand kilobase pairs, it is important to have a second RFLP situated on the opposite side of the gene. A crossing over during meiosis between the first RFLP and the gene would then be detected since a double crossing over is unlikely. Such a flanking RFLP is also useful in work attempting to localize and study the gene if it is not yet characterized.

c. Searching for RFLP

The search for RFLP does not have to be a random trial-and-error test of the large battery of commercially available enzymes. Cooper and Schmidtke (1984), Wijsman (1984), and Feder *et al.* (1985) describe rational approaches and give lists of relative efficiency for many enzymes. Enzymes containing the dinucleotide CG in their recognition sequences detect more variation of the base replacement type than other enzymes, probably because of mutations from methylated CG to TG. Larger probes have been found to be more efficient than small probes.

Screening should be limited, as suggested by Skolnick and White (1982), to a panel of about 10 unrelated individuals in order not to pick up rare polymorphisms. These have low degrees of heterozygosity and therefore are inferior in diagnostic work.

When multiple restriction fragments are found, it must be shown that they represent alleles at the same locus. A probe might recognize nonallelic fragments due to sequence homology with a different chromosomal region. If the fragments are alleles, they will segregate in a Mendelian fashion.

d. Minisatellites

Studies of gene structure have uncovered situations in which a single restriction enzyme reveals a multiallele polymorphism, a polymorphism that does not affect sites for the enzyme. Between two fixed restriction

sites, one finds a region consisting of tandem repetition of 15- to 100-bp units, and the number of these repeats varies considerably in the population. Such variable tandem repeat (VNTR) regions, also called minisatellites, have been found in humans close to the insulin gene (Bell *et al.*, 1982), α-related globin genes (Proudfoot *et al.*, 1982), and the c-H-*ras* oncogene (Capon *et al.*, 1983), but similar VNTR regions appear widely dispersed (Jeffreys *et al.*, 1985b). The presence near a disease gene of a VNTR region is very useful, because the multiallelic nature of the corresponding RFLP leads to high degrees of heterozygosity. A method for a systematic search for such RFLP has been reported (Nakamura *et al.*, 1987).

e. Microsatellites

Weber and May (1989) reported the existence of a large set of highly polymorphic microsatellites, consisting of dinucleotide repeats, that could be typed using PCR. Such microsatellites have become the most important source of markers for high-resolution genetic maps. A human map was presented in 1992 with 814 microsatellites (Weissenbach *et al.*, 1992). Two years later the map included 2066 $(AC)_n$ markers, flanked by unique sequences for which PCR primers could be synthesized (Gyapay *et al.*, 1994). The average distance between the markers was 2.9 cM, which means that there are now polymorphic microsatellite markers close enough to most disease genes for diagnostic purposes. These markers are also starting points for work to identify the genes and their mutations. This latter task is being made easier by the parallel development of physical maps of yeast artificial chromosome clones (Cohen *et al.*, 1993) that have been ordered using sequence-tagged sites (Olson *et al.*, 1989).

5. Disease Gene Identification

Rapid progress has been made in the identification and characterization of disease genes in humans, a prerequisite for application of the direct methods of diagnosis described in Sections V.B.1 through V.B.3. Many genes have been identified by functional cloning, using information about the protein product (sequence or antibodies). Mapping of the gene then followed cloning. Starting in 1986, another approach, positional cloning, came into use. In this approach, mapping to a precise location on a chromosome is the basis for the cloning effort. Some 20 disease genes have been identified in this way (Collins, 1992). As the Human Genome Project produces high-resolution genetic maps and physical maps based on overlapping clones, positional cloning will be simplified.

In other instances, map position has been important in order to verify gene identification, but the availability of a plausible candidate protein and its cDNA has made it possible to avoid exhaustive cloning in the specified chromosome region. This positional candidate approach will probably become increasingly common (Ballabio, 1993). In all, about 400 human disease genes can now be diagnosed directly.

6. Genetic Screening

Carrier screening programs have been attempted for some human genetic diseases even before DNA tests became available, notably sickle cell anemia, thalassemia, and Tay–Sachs disease. The thalassemia program in Cyprus for testing couples at marriage has been very successful. Pilot programs that test pregnant women for the cystic fibrosis gene and the partner if the test is positive have taken place in Britain and the United States (Williamson, 1993). Although there are legitimate concerns that screening data may be used to coerce families to make reproductive decisions that meet economic or societal objectives rather than personal wishes, the availability of a screening service is generally welcomed.

For human diseases, there is, however, often the problem of genetic heterogeneity. The number of different cystic fibrosis mutations is now greater than 260. Although most of these are rare, 11 mutations making up 91.5% of the mutations in Northwest England (Ferec *et al.*, 1992), a screening program for cystic fibrosis will clearly leave a small residual risk for unexpected development of the disease. For animal genetic diseases, there is less heterogeneity, making screening an effective and widespread tool (Section V.D).

C. DNA Probes and Disease Susceptibility

For the first time recombinant DNA technology has also made it possible to begin analyzing polygenic diseases, that is, diseases where a combination of unfavorable genes may predispose to the development of disease.

1. HLA Genes

Genes determining susceptibility or resistance to a broad variety of diseases in humans have been localized to the HLA region, the major histocompatibility complex in humans (Vogel and Motulsky, 1986; Kostyu, 1991). Among these diseases are ankylosing spondylitis, celiac disease, dermatitis herpatiformis, and insulin-dependent diabetes mellitus (IDDM). The latter three are associated with the HLA serologic speci-

ficity DR3, and IDDM also with DR4. Seventy-five percent of IDDM patients have HLA-DR4, whereas only 32% of controls do. This outcome gives a DR4 individual a relative IDDM risk of 6.4, and the risk is increased in DR3,4 heterozygotes (Knip *et al.*, 1986). The association of HLA-DR genes with IDDM susceptibility is related to the fact that IDDM pathogenesis often involves autoimmune phenomena (Nepom and Erlich, 1991).

With recombinant DNA technology, it became possible to ask whether there might be DNA differences, detectable as restriction fragment length differences, between patients and controls of the same DR3 and/or DR4 specificity. This was indeed found to be the case by Owerbach *et al.* (1983). Using a DQβ probe, these investigators found a significantly decreased frequency of a *Bam*H1 3.7-kbp fragment among DR4 IDDM patients. These studies have been confirmed and extended by others, including Michelsen and Lernmark (1987).

The full impact of DNA technology came, however, with PCR amplification of cDNA from the first exons of α and β chains, the exons containing most of the polymorphisms, followed by sequencing (Todd *et al.*, 1987). This procedure has identified a large number of α- and β-chain alleles, denoted by a four-digit code. Typing of DNA sequence polymorphisms at HLA loci is conveniently done by PCR amplification of genomic DNA with appropriate primers, followed by probing with sequence-specific oligonucleotide probes (Erlich *et al.*, 1991a). Such studies have shown that molecules of DQ(α1*0301,β1*0302), associated with DR4, and DQ(α1*0501,β1*0201), associated with DR3 give a relative IDDM risk of 6 to 18 for Caucasians. In heterozygotes, two further DQ molecules may form by transcombination of the subunits (Thorsby and Rønningen, 1993; Nepom and Erlich, 1991). Results of this nature have been reported for malaria, where DRB1*1302–DQB1*0501 gives some protection (Hill *et al.*, 1991), and for papillomavirus-associated cervical carcinoma (Apple *et al.*, 1994), where DRB1*1501–DQB1*0602 gave increased risk (relative risk of 4.8).

2. *Insulin Gene 5'-VNTR Alleles*

As mentioned in Section V.B.4.d, there is a VNTR associated with the human insulin gene on chromosome 11. The variable region falls in three size classes (class I averaging 570 bp, class II averaging 1200 bp, and class III averaging 2200 bp). A strikingly higher frequency of class I alleles was observed for Caucasian individuals with IDDM (Bell *et al.*, 1984). By sequencing the insulin gene locus from patients and controls, Lucassen *et al.* (1993) have identified the region of association with IDDM to be 4.1 kbp. Ten polymorphisms, including the VNTR, are in strong linkage disequilibrium with each other and show a relative risk for IDDM of 3.8 to 4.5. Analysis of other ethnic groups may reveal which exact polymorphism(s) confer susceptibility. It is possible that the VNTR length directly affects transcription.

The insulin gene associated polymorphism and the HLA variation are not sufficient to account for the development of IDDM. Extensive mapping of the disease in the nonobese diabetic mouse, using microsatellite markers, has revealed eight additional loci that make a contribution to this polygenic disease (Ghosh *et al.*, 1993). One of these codes for interleukin-2, which has a role in autoimmunity, and different sequences were found in nonobese diabetic and normal mice.

3. *Atherosclerosis*

The most plausible link between genes and atherosclerosis is found in the structure and regulation of genes for lipoproteins, the enzymes that are involved in their metabolism, and lipoprotein receptors. Genes for the apolipoproteins and the low-density lipoprotein (LDL) receptor in humans have been cloned and localized on chromosomes. One of every 500 persons is heterozygous for a mutant allele of the LDL receptor, leading to two to three times normal levels of cholesterol. Hobbs *et al.* (1992) have unraveled the mechanisms involved and characterized different types of mutations in the gene. Mapping of the defects in a population can start with a determination of mutation-associated RFLP haplotypes. This information is useful for diagnosis within families (Rødningen *et al.*, 1992). To establish direct gene tests, DNA from affected individuals was screened for mutations (Leren *et al.*,, 1993).

LDL is bound to its receptor via $apoB_{100}$, and hypercholesterolemia may be caused by mutations in the $apoB_{100}$ gene as well (Innerarity *et al.*, 1990). Mutations are known also in the *apoA-I* gene and cause low levels of high-density lipoprotein (HDL) accompanied by atherosclerosis. Type III hyperlipoproteinemia patients have a particular allele for the *apoE* gene. With the knowledge of DNA structure, oligonucleotide probes that differentiate between normal and mutant genes can be made, allowing screening of people at risk.

D. Application to Domestic Animals

The application of recombinant DNA techniques to diagnosis in domestic animals is now quite widespread. The availability of DNA clones, or knowledge of primer sequences from humans and small experimental animals, has enhanced this development.

1. *Diagnosis of Disease Mutations*

a. Citrullinemia in Cattle

The first disease to benefit from a DNA test was citrullinemia, which is widespread in Australian Friesian cattle. Three conditions were helpful for the establishment of a DNA test for the mutation in 1989: Bovine cDNA libraries were available, sequenced cDNA for the enzyme (argininosuccinate synthetase) for humans and rats was available, and the protein is fairly small, only 412 amino acids.

Normal bovine cDNA for the enzyme was isolated with a rat probe and sequenced by Dennis *et al.* (1989). To identify the mutation, total mRNA was prepared from the liver of an affected animal and cDNA synthesized. The product was amplified with PCR using primers corresponding to sequences immediately before and after the coding region of the cDNA. These primers had been extended with *Bam*HI linkers, so the amplification product could be ligated into the *Bam*HI site of the DNA sequencing vector. In clones from the mutant, a C to T transition in the first position of codon 86 was found that generates a TGA termination codon leading to a truncated and inactive protein.

The change in codon 86 leads to the disappearance of an *Ava*II restriction site. This deficiency was utilized by Dennis *et al.* (1989) to design a simple, PCR-based gene test on genomic DNA. A 194-bp DNA could be amplified from within the exon containing the mutation. A portion of the product was digested with *Ava*II, and both digested and undigested DNA were analyzed by electrophoresis. The normal calf has two bands of 72 and 118 bp, the homozygous (affected) calf has one band of 194 bp, and a carrier has all three bands.

b. Malignant Hyperthermia in Pigs

Work with malignant hyperthermia (MH) in pigs had started earlier. We isolated clones for the glucose-phosphate isomerase (GPI) gene, a closely linked gene (Davies *et al.*, 1987). With this DNA as probe, a multiallelic RFLP was detected that was confirmed to be tightly linked to the MH gene (Davies *et al.*, 1988), so that it could serve as a marker. A further search for the MH mutation was based on reports that calcium is more easily released from the sarcoplasmic reticulum of MH pigs. Meissner (1986) had shown that the alkaloid ryanodin interacts directly with the calcium release channel (CRC) of rabbits. Using tritiated ryanodin as a label, Lai *et al.* (1988) purified the channel.

This work prepared the way for the cloning of the rabbit CRC cDNA by Takeshima *et al.* (1989), a 15,100-bp-long cDNA. With a small rabbit cDNA clone as a probe, we isolated a porcine cDNA clone and showed it hybridized *in situ* to metaphase chromosomes in the same chromosomal band that hybridized with GPI DNA (Harbitz *et al.*, 1990). This result confirmed CRC as a good candidate for the product of the MH locus. Sequencing CRC cDNA from a normal and an affected pig, Fujii *et al.* (1991) identified the mutation, a substitution of T for C at nucleotide 1843, which changes an arginine to cysteine. The mutation was found to be the same in five Canadian pig breeds and in British Landrace (Otsu *et al.*, 1991) and Norwegian Landrace pigs (Harbitz *et al.*, 1992).

The mutation destroys a *Hin*P site and creates a *Hgi*AI site. Fujii *et al.* (1991) amplified a 74-bp piece from the exon containing the mutation and made restriction site changes in the product the basis for their diagnosis. A more convenient and reliable method became possible after sequencing of genomic DNA flanking the exon.

c. Leukocyte Adhesion Deficiency in Cattle

Leukocyte adhesion deficiency (LAD) in humans is an autosomal recessive disease characterized by greatly reduced expression of the heterodimeric beta-2 integrin adhesion glycoproteins on leukocytes. Without this protein, neutrophils are unable to enter tissues to destroy invading pathogens. All human cases have been traced to the integrin beta-subunit, CD18. A granulocytopathy syndrome had been described in Holstein cattle, and Schuster *et al.* (1992a) investigated whether it was also caused by a CD18 mutation. These investigators isolated bovine CD18-encoding cDNA by screening a lymphocyte library with a murine CD18 probe and sequenced the clone. Leucocyte RNA was then isolated from a calf with LAD symptoms and from a normal cow (Schuster *et al.*, 1992b). Northern blot analysis revealed a CD18 transcript at normal level and size from the affected calf, ruling out a large deletion or a transcription defect. mRNA was reverse transcribed, and the cDNA was amplified using bovine CD18-specific primers. To sequence the amplified product, single-stranded DNA was generated with a single primer and sequenced directly. A mutation was detected at nucleotide 383, replacing aspartic acid with glycine (D128G). The mutation occurs in a row of 26 consecutive amino acids that are identical in normal bovine, human, and murine CD18.

This mutation introduces a *Hae*III site and eliminates a *Taq*I site. Schuster has utilized this in an assay that PCR amplifies a 58-bp DNA from the mutated exon. Fifteen other LAD calves were found to be homozygous for the D128G mutation. To determine the prevalence of this allele, 2025 U.S. Holstein bulls used as semen donors were screened. The carrier frequency was 14.1% before selection against the disease began. In addition, cows (1559 Holsteins) were screened, and

5.8% were found to be carriers. The LAD incidence in the United States in calves at birth should therefore be about 0.2%. All the LAD calves had pedigrees leading back over five generations to a certain bull, Osborndale Ivanhoe, born in 1952. The carriers with pedigree information also descended from this bull or, in a few cases, his immediate relatives. This bull was demonstrated to be a carrier of D128G by testing frozen semen.

Recently, an improved detection method has been presented by Batt *et al.* (1994), using a thermostable ligase in an oligonucleotide ligation assay, combined with PCR (Barany, 1991). Ligation/amplification fails when a single base mismatch is present. Using biotin in one oligonucleotide, for product capture, and a nonisotopic reporter group in the other, the method can be automated.

d. Hyperkalemic Periodic Paralysis in Quarter Horses

Hyperkalemic periodic paralysis (HYPP) is a genetic disease observed among quarter horses. The disease causes attacks of paralysis, inducible by ingestion of potassium. In humans, HYPP is caused by a single base substitution within the skeletal muscle sodium channel gene. Rudolph *et al.* (1992a) studied a quarter horse pedigree to see if the sodium channel gene was also involved in the horse. Starting with reverse-transcribed horse mRNA, horse sodium channel cDNA was produced by PCR, using rat primer sequences. This procedure revealed a polymorphism that was used to investigate whether the horse sodium channel gene was genetically linked to HYPP, which was found to be the case.

To identify the putative mutation, they used single-strand conformational polymorphism (SSCP) analysis (Orita *et al.*, 1989) of reverse-transcribed mRNA PCR products from muscle biopsies of normal and affected horses (Rudolph *et al.*, 1992b). This method is capable of detecting existing two-allele polymorphic markers (Neibergs *et al.*, 1993). Rat and human sodium channel sequences were used to design primers. A single-strand specific for an affected horse was seen in the PCR product from amino acid region 1348–1524. This region was cloned and sequenced.

In the affected horse, there was a C to G change, replacing phenylalanine with leucine in transmembrane region IV of the channel. All nine normal sodium channel sequences sequenced to date have phenylalanine in this position, indicating its importance for activity. To test whether the leucine substitution cosegregated with the disease, allele-specific hybridization and/or *Taq*I restriction enzyme analysis of PCR-amplified genomic DNA sequences was used to study an extended pedigree. All affected horses in the pedigree showed the leucine substitution, whereas all unaffected horses had phenylalanine. It was theoretically possible still that this change was in strong linkage disequilibrium with a separate disease-causing mutation. To check this possibility, 176 unaffected horses from a variety of breeds were tested. All were homozygous for the normal allele (Phe/Phe), which strongly argues against linkage disequilibrium with some other mutation.

Although this disease gene is dominant, the developed test is important because affected horses commonly do not exhibit signs of disease until they are mature. They may then have episodes of weakness and collapse, posing a hazard to their riders and themselves. Current physiological tests do not have the required sensitivity.

e. Bovine Uridine Monophosphate Synthase Deficiency

Deficiency of uridine monophosphate synthase (DUMPS) is an autosomal recessive disorder in Holstein and Red Holstein cattle that results in early embryonic death of homozygous offspring. Heterozygotes are phenotypically normal, but show about one-half the normal enzyme level and elevated levels of orotic acid. Heterozygotes may have a higher genetic merit in milk and protein production. With accurate DNA-based genotyping, it would be possible to preserve the mutation in the population while avoiding matings between carriers.

Schøber *et al.* (1992) isolated and sequenced wild-type bovine UMPS cDNA using a human UMPS-specific cDNA to screen the library. To identify the mutation responsible for DUMPS, liver RNA from DUMPS heterozygotes was reverse transcribed. Amplification of cDNA with sequence-specific primers and subsequent sequencing of the PCR products revealed a C to T transition in codon 405, resulting in a premature stop codon and a truncated protein. The mutation led to the loss of an *Ava*I site. A genomic DNA-based PCR test was developed that looks for presence of the *Ava*I site in a 108-nucleotide segment. Complete concurrence between low levels of UMPS and presence of the point mutation was found in a large Holstein pedigree, confirming this mutation as the basic defect in DUMPS cattle.

f. Bovine Maple Syrup Urine Disease

Maple syrup urine disease (MSUD) results from a deficiency of the branched chain α-ketoacid dehydrogenase, a mitochondrial multisubunit complex of enzymes. The E1 component catalyzes the oxidative decarboxylation. MSUD has been identified both in humans and in cattle and is relatively common in the Polled Hereford breed of cattle in Australia.

Hu *et al.* (1988) isolated and sequenced cDNA for the bovine E1α subunit, screening an expression library with antiserum to bovine E1. To define the mutation responsible for MSUD, Zhang *et al.* (1990) produced cDNA from MSUD calf fibroblasts by reverse transcription of RNA followed by PCR. These investigators chose primers that amplified the complete coding region of the E1α subunit. Subcloning of the product and sequencing revealed replacement of a CAG glutamine triplet with TAG, a stop codon, in the partial coding for the leader sequence that directs the protein to mitochondria. The mutation was verified by hybridization of amplified cDNA from calves with two radioactive 15-*mer* allele-specific oligonucleotides.

MSUD also occurs in the Polled Shorthorn breed. Amplifying DNA with PCR across the glutamine codon and testing for allele-specific oligonucleotide hybridization revealed, however, that the mutation in the Polled Shorthorn must be in a different position from that in the Polled Hereford (Healy and Dennis, 1994).

2. *Diagnosis of Disease Susceptibility*

Association between diseases and alleles of genes in the major histocompatibility complex (MHC) is also known for domestic animals. This is particularly well documented for Marek's disease of chickens, which is caused by a herpes virus (Hanson *et al.*, 1967; Hepkema *et al.*, 1993). Resistance to bovine leukosis, caused by the BLV retrovirus, also has a clear MHC association (Lewin, 1994), and Mejdell *et al.* (1994) found an influence of the bovine MHC on resistance to mastitis. A highly significant association was found between the bovine MHC class I antigen BoLA-A8 and chronic posterior spinal paresis, a form of ankylosing spondylitis, in Holstein bulls (Park *et al.*, 1993). The relative risk was 34.6. The special interest in developing RFLP to establish haplotypes for the MHC genes in domestic animals must be viewed in this light. MHC RFLP have been found with human probes in a large number of species (Andersson *et al.*, 1986; Juul-Madsen *et al.*, 1993). More informative studies are now being conducted based on sequencing of the MHC polymorphic exons. Such data were presented for cattle (Andersson *et al.*, 1991), sheep (Fabb *et al.*, 1993), chickens (Moon Sung *et al.*, 1993), horses (Szalai *et al.*, 1993), and pigs (Våge *et al.*, 1994).

E. Gene Changes in Cancer

Cancer is, like genetic diseases, a result of changes in the hereditary material, but in the latter case, mainly in somatic cells. A great deal of light has been thrown on the phenomenon of neoplastic growth via the use of recombinant DNA techniques. The molecular structures of a long series of viral oncogenes and cellular proto-oncogenes, often coding for proteins participating in signal transduction from the cell surface to the nucleus, have been elucidated, and the mechanisms for the activation of proto-oncogenes to oncogenes to a large extent clarified (Land *et al.*, 1983; Van de Woude *et al.*, 1984). For the *ras* family of oncogenes, this activation takes place by a base replacement, for others, for example, *myc*, *myb*, and *ets-1*, by translocation and/or amplification. Oncogene probes are available for such studies. Translocations, and sometimes mutations, result in restriction fragment size changes. Amplification leads to stronger bands of hybridizing DNA. Amplification, or stimulated transcription, leads to increased hybridization to mRNA.

These developments have clinical relevance. DNA methods are becoming useful in tumor diagnosis, and they give new information as to the stage of development of the tumor. Oncogenes are highly conserved in evolution, so it is likely that human and murine oncogene probes can be used for investigation of cancer development in domestic animals. Human probes for c-*myc*, *myb*, *HER-2/neu*, H-*ras*, K-*ras*, and N-*ras* thus were found to hybridize to DNA fragments from dogs (Hauge *et al.*, 1988).

While activated oncogenes act in a dominant manner, mutations in tumor suppressor genes are recessive. Their gene products inhibit cell division, and thus balance the stimulatory properties of the proto-oncogene products. Loss of function of the suppressor gene on both chromosomes leads to increased cell division. Because the first mutation is often transmitted from a parent, whereas the second arises somatically, such tumors are found to be hereditary. Well-studied examples are the genes for retinoblastoma and p53, as well as several suppressor genes involved in colorectal cancer (Weinberg, 1991). Gene tests for these mutations are of obvious value for early diagnosis and treatment.

VI. THERAPY OF GENETIC DISEASES

In the foreseeable future, gene therapy may not be of practical value in regular veterinary medicine because of the cost involved. But work with gene therapy in animals will nonetheless be important as preparation for such therapy in humans (Anderson, 1984). What needs to be shown in animals is (1) that the gene is integrated in the target cells, (2) that it is expressed on a suitable level, and (3) that the gene does not harm the cells or the animal. The ideal would be to exchange the mutated gene with a wild-type gene. Techniques for accomplishing this exchange by homologous re-

combination in ES cells have been developed (Smithies *et al.*, 1985; Thomas and Capecchi, 1986).

Gene therapy can be conceived at different levels: introduction of DNA into the fertilized ovum or early embryo; into cells or tissues that are taken out, modified, and reimplanted; and into the whole animal with the help of an infective vector.

A. Germ Line Gene Therapy

Several successful experiments of this type have been reported. Hammer *et al.* (1984) describes how injection of the rat growth hormone (GH) gene, linked to the mouse metallothionein promoter, into fertilized ova from dwarf mice with low GH levels yielded mice with normal growth. Le Meur *et al.* (1985) restored the immune response to a tripeptide in mice from a line with a defective MHC class II E gene, by injection of DNA containing this gene. β-Thalassemia has also been successfully corrected by injection of β-globin DNA in a murine model of human β-thalassemia (Costantini *et al.*, 1986).

B. Somatic Gene Therapy

Human gene therapy is coming of age (Miller, 1992; Friedman, 1993; Tolstoshev and Anderson, 1993). Protocols for treatment of 14 diseases have been approved (Wivel, 1993) based on results obtained with animals. The first disease treated was adenosine deaminase (ADA) deficiency, which causes immunodeficiency. A retrovirus vector was used to introduce the normal cDNA in lymphocytes. Among the diseases recently attacked are cystic fibrosis and hypercholesterolemia.

Cystic fibrosis affects about 1 of every 2000 Caucasians. Mouse models for cystic fibrosis have been generated by homologous recombination in embryonic stem cells, in one case by replacement of part of the cystic fibrosis transmembrane conductance regulator (CFTR) gene with a mutated gene section (Snouwaert *et al.*, 1992), in the other case by insertion of a mutated gene in the host gene (Dorin *et al.*, 1992). The first type is a null mutation, whereas the latter has a small degree of leakiness. Hyde *et al.* (1993) showed that CFTR cDNA could be delivered to the lungs of the replacement mutant by direct instillation of a cDNA-liposome cocktail, resulting in correction of the ion conductance defect. Other workers have used adenovirus as a vector. Unlike retrovirus, adenovirus is capable of infecting terminally differentiated cell types and is naturally drawn to airway epithelial cells. Good expression of human CFTR cDNA, carried on replication-deficient adenovirus, was observed after intratracheal introduction in cotton rats. Adenovirus is not integrated into host DNA. Studies have therefore been performed on the safety and efficiency of repeated CFTR cDNA transfer in cotton rats and primates (Zabner *et al.*, 1994).

Another cDNA that has been carried on adenovirus into rat lung epithelium and expressed is cDNA for α_1-antitrypsin (Rosenfeld *et al.*, 1991). Adenovirus can also be used for muscle diseases. Vincent *et al.* (1993) have observed long-term correction of dystrophic degeneration in a mouse model for Duchenne muscular dystrophy after intramuscular injection of adenovirus carrying a human dystrophin minigene.

Familial hypercholesterolemia (FH) affects individuals heterozygous for LDL receptor mutations (Section V.C.3) and is very severe in those who are homozygous. A strain of rabbits genetically deficient in LDL receptors was used to demonstrate the potential efficacy of *ex vivo* gene therapy. Part of the liver was resected and perfused with collagenase to free hepatocytes. The isolated hepatocytes were transduced with LDL receptor retrovirus and infused into the rabbit liver with good effect (Chowdhury *et al.*, 1991). The experiment was followed up using dogs and baboons. The first results in humans have been reported (Grossman *et al.*, 1994). A 29-year-old woman, homozygous for the disease, underwent the same procedure, and her LDL/HDL ratio declined from 10 to 13 before treatment to 5 to 8 following gene therapy.

VII. USE OF RECOMBINANT DNA METHODS TO IMPROVE DOMESTIC ANIMALS

A. Markers and Maps

One important use of DNA methods for the improvement of domestic animals has been discussed already: marker-assisted selection against animals that carry a disease gene that has been characterized at the molecular level. On the whole, however, specific genetic disorders are less important than traits affecting growth, reproduction, disease resistance, and the quality of the end product. These traits are usually determined by several genes, by quantitative trait loci (QTL). To enable marker-assisted selection for a QTL, it must be fairly precisely localized on a chromosome. This localization requires genetic and physical maps of high resolution. Much effort has gone into establishing such maps.

The work is furthest advanced for pigs. At the First Pig Gene-Mapping Workshop, the number of mapped loci was 170 (Andersson *et al.*, 1993). Sixty of these loci were anonymous DNA segments, mostly microsatellites, and the rest were polymorphic blood groups and

protein polymorphisms. Using a two-generation reference population, Rohrer *et al.* (1994) established a genetic linkage map with 376 microsatellite and 7 RFLP loci. The average distance between adjacent markers was 5.5 cM. Ellegren *et al.* (1994) reported a genetic linkage map for a cross between the European wild boar and a domestic breed (large white) that had a somewhat lower resolution (11-cM average spacing), but had 60 reference markers for comparative mapping and 47 markers physically assigned by *in situ* hybridization. This material has been analyzed with respect to some quantitative traits, and evidence for QTL with large effects on growth, length of the small intestine, and fat deposition was found on chromosome 4 (Andersson *et al.*, 1994). Comparative gene mapping for pig chromosome 4 could indicate candidates for these QTL because clusters of neighboring genes tend to be preserved between species.

An example of the comparative approach was the focus on the long arm of human chromosome 19 in the search for the MH locus. It was known that the GPI gene was located here, and that GPI and MH were closely linked in pigs. Another striking example is the observation of linkage for the human secreted phosphoprotein 1 (SSP1) locus to the sheep Booroola fecundity (FecB) gene, and the subsequent finding of linkage to human epidermal growth factor and complement I genes, near SSP1 in 4q in man. The latter genes define a candidate region on sheep chromosome 6 (Montgomery *et al.*, 1993).

Good progress has also been achieved for genome mapping in cattle. Barendse *et al.* (1994) mapped 171 loci, with an average distance between markers of 15 cM. Fifty-six loci represent DNA information from other species. An American–Swiss collaboration produced a bovine map with 313 polymorphic markers, with an average spacing of 8 cM (Bishop *et al.*, 1994). An extensive comparison between cattle, cats, mice, and humans has been presented by O'Brien *et al.* (1993). A good foundation now appears to exist for the isolation of bovine QTL, as well as for the study of mammalian genome evolution.

B. Parentage Identification

Errors may occur in marking semen portions used in artificial insemination. Piglets may jump from one pen to another and be falsely marked when marking takes place. And it may, at times, be a temptation for a breeder to report a false father or mother. These problems can be addressed using core sequences for minisatellites, which hybridize with the VNTR of many genes, producing a DNA fingerprint (Jeffreys *et al.*, 1985a). Because each band represents a minisatellite locus, the probability that two individuals will have the same pattern is nearly zero except for monozygotic twins. A multilocus microsatellite probe, such as $(GTG)_5$, yields a similar result, with better coverage of the genome (Mørsch and Leibenguth, 1994). Alternatively, the PCR results for a set of highly polymorphic microsatellites can be combined (Marklund *et al.*, 1994).

C. Transgenic Animals

When improving livestock by traditional breeding, one is limited to an exploitation of the alleles that are already present in the animal population. The results 14 years ago of introduction of extra DNA into pronuclei of fertilized mouse eggs suggested the possibility of a quicker and larger improvement of production animals. Experiments with injection of growth hormone (GH) in lactating cattle had demonstrated a significant boost in milk yields. It was natural to ask whether the same result could be obtained with extra gene copies for the hormone or whether pigs with extra GH genes could reach slaughter weight sooner and with lower feed consumption.

The first report on transgenic livestock animals appeared in 1985 (Hammer *et al.*). In the following years, these initial experiments were extended. In a review, Pursel and Rexroad (1993) listed 24 reports on transgenic pigs, 11 on sheep, 6 on cattle, and 2 on goats. The average frequency of success (transgenic animals / eggs transferred) was 0.8–0.9% for these species, compared to 2–5% routinely obtained with mice. This result puts a severe constraint on the adoption of this technology. For sheep and cattle there is, however, a promising development in that viable embryos can be obtained by *in vitro* maturation and fertilization of oocytes removed from slaughterhouse ovaries (Lu *et al.*, 1987).

1. Improving Productivity Traits

Transfer of genes affecting feed conversion, rate of gain, reduction of fat, and improved quality of meat, milk, and wool would be of great importance for both producer and consumer. These traits are, however, usually determined by several genes, by QTL, of which few are presently known. The mapping efforts discussed earlier will gradually change this situation.

Many of the pig and sheep experiments have involved GH and GH-releasing factor genes from various species. The promoter has often been that of metallothionein from mouse and other species, but other promoters have also been used (mouse albumin, Moloney leukemia virus, rat PEPCK).

Pursel *et al.* (1989) found concentrations of GH in expressing founder pigs to be in the range of

14–4000 ng/ml for human GH. The variation could reflect the influence of the chromosomal position for the inserted gene. To obtain a reliable assessment of the effect of the GH transgene on growth, the daily weight gain and feed efficiency were measured for two generations of transgenic and control pigs. The combined transgenic progeny showed 11% faster weight gain than the controls, and there was a 16–18% increased feed efficiency. Equally dramatic was the effect on subcutaneous fat accretion. Mean back fat thickness was reduced from 21 to 7.5 mm. In a follow-up study with bovine GH transgenic pigs, Solomon *et al.* (1994) studied whole-carcass ground tissue lipid composition. At 92 kg, these pigs contained 85% less carcass fat than control pigs, and the reduction in poly-unsaturated fatty acids was somewhat lower.

These favorable traits were, however, offset by considerable deleterious side effects. Many of these could be the results of the lasting, high concentrations of GH. There was a high incidence of joint pathology, gastric ulcers, and infertility. What appears necessary is to achieve a tightly controlled GH gene expression, so that it can be confined to 1–2 months during the period of rapid growth. It should be possible to devise a promoter construct that is turned on by a substance added in the feed.

2. *Disease Resistance*

One route to specific disease resistance is introduction of one or more immunoglobulin genes that produce antibodies against a particular pathogen. Model experiments with mice have shown that this could work (Rusconi and Kohler, 1985). Weidle *et al.* (1991) produced transgenic pigs that harbored mouse lambda heavy chain and kappa light chain transgenes from antibodies against the hapten, 4-hydroxy-3-nitrophenylacetate. Titers up to 1 mg/ml were obtained in one founder and its progeny.

An interesting suggestion for reducing mastitis is to fuse the lysostaphin gene with regulatory elements from the betalactoglobulin (BLG) gene before injection in fertilized bovine eggs. The transgenic cow would then produce lysostaphin in its udder. Lysostaphin hydrolyzes the cell wall of *Staphylococcus aureus*. The idea is being tested in mice (Clark *et al.*, 1992).

In chickens, Salter and Crittenden (1989) have described a transgenic line carrying a defective ALV retrovirus genome that expresses only the envelope proteins of the virus. This expression leads to resistance since the produced viral protein competes for the virus receptor binding sites on the cell surface. This approach is similar to a successful technique for making plants virus resistant. The technique has been used to make sheep resistant to visna virus, which causes ovine progressive pneumonia (Pursel and Rexroad, 1993).

3. *Milk Modification*

Various ways of modifying milk protein composition can be envisaged (Clark *et al.*, 1992). Caseins could be altered in their phosphorylation sites and, thereby, in micelle properties. Reduction in the amount of BLG could reduce allergies and inhibit the synthesis of lactose, a disaccharide not tolerated by 90% of the adult world population. It would also seem useful to try to introduce into cows the gene for human lactoferrin, an antimicrobial agent and iron transporter, in order to make bovine milk better suited for human infants. Experiments have been initiated to achieve this (Krimpenfort *et al.*, 1991).

4. *Pharmaceutical Proteins*

The lack of α-1-antitrypsin (AAT) is one of the most common human genetic disorders. It leads to life-threatening emphysema, requiring repeated administrations of intact enzyme (200 g per patient per year). The source has hitherto been human blood plasma with its limitations and dangers. Wright *et al.* (1991) reported that high levels of AAT expression had been obtained in milk of transgenic ewes, in which a sheep BLG regulatory sequence was ligated to a human AAT genomic sequence. One sheep produced AAT at 30 g/liter, 50% of the milk protein. Earlier investigations using cDNA of AAT or human factor IX resulted in much lower yields. Several lines of sheep have now produced AAT stably during several lactations (Carver *et al.*, 1993).

Human protein C (hPC), which has an important role in hemostasis, is produced in the milk of transgenic pigs, the construct here consisting of hPC cDNA inserted into the first exon of the mouse whey acidic protein gene (Velander *et al.*, 1992).

Milk is not the only possible vehicle for medically important proteins from transgenic animals. Swanson *et al.* (1992) have succeeded in making pigs transgenic for human globin genes, expressed in pig erythrocytes. Human hemoglobin could be separated from pig hemoglobin by ion exchange chromatography. Its use would be in crisis treatment. It lacks red cell antigenic components and does not require refrigeration.

5. *Use of Embryonic Stem Cells*

A major limitation in the production of transgenic animals by microinjection of DNA in fertilized ova is that there is no control as to where in the genome the extra DNA finds it place. Sometimes it will disrupt a

gene, introducing defects in development or function of the animal, or it may land in a region where it is poorly expressed. Work with mice has shown that for ES cells in culture, one can achieve a site-specific integration of the new DNA with the help of homologous recombination. Cells that are shown to have incorporated the gene properly are then introduced into the blastocyst. Chimeric animals result, but in the next generation, animals with the new gene in their germ cells can be found. For domestic livestock, the ES technique has met with some problems. However, Notarianni *et al.* (1990) described the derivation of apparently pluripotent cell lines from porcine and ovine blastocysts.

In cattle and sheep (but not in mice), young have been born following transfer of nuclei from cells of the inner cell mass of blastocysts to enucleated oocytes (Marx, 1988). It is possible, therefore, if gene-modified ES cells can be established from these species, that we could transfer nuclei from them and avoid the chimeric stage.

CHAPTER

3

Carbohydrate Metabolism and Its Diseases

J. JERRY KANEKO

I. INTRODUCTION

The biochemical mechanisms by which the chemical energy contained in foodstuffs is made available to the animal are collectively described as metabolism. Thus, the description of the metabolism of a foodstuff encompasses the biochemical events that occur from the moment of ingestion to its final breakdown and excretion. Classically, these biochemical events have been divided into the metabolism of the three major constituents of food: carbohydrates, proteins, and lipids. The metabolism of the lipids and proteins is discussed in other chapters.

The major function of ingested carbohydrates is to serve as energy sources and their storage function is relatively minor. Carbohydrates also function as precursors of essential intermediates for use in synthetic processes. When the metabolic machinery of an animal is disrupted, a disease state prevails, for example, diabetes. The literature of the biochemistry of metabolism

and disease continues to expand as the intricate details of individual and overall reaction mechanisms are continually refined and elucidated. Additionally, modern molecular approaches have significantly increased our understanding of disease mechanisms and remain fertile fields for investigations into the disease processes. This chapter is presented as a basis for the better understanding of the biochemical mechanisms underlying those diseases associated with carbohydrate metabolism. Exhaustive treatment of carbohydrate metabolism in health and disease is beyond the scope of this chapter.

II. DIGESTION

The digestion of carbohydrates in the animal begins with the initial contact of these carbohydrates with the enzymes of salivary juice. Starch of plant foods and glycogen of meat are split into their constituent monosaccharides by the action of amylase and maltase. This activity ceases as the food matter passes into the stomach, where the enzymatic action is destroyed by the hydrochloric acid. Within the stomach, acid hydrolysis may occur, but the stomach empties too rapidly for complete hydrolysis to take place. Thus, only a small portion of the ingested carbohydrate is hydrolyzed prior to passage into the small intestine. In the small intestine, digestion of carbohydrate takes place quickly by the carbohydrate splitting enzymes contained in the copious quantities of pancreatic juice and in the succus entericus. Starch and glycogen are hydrolyzed to glucose by amylase and maltase; lactose to glucose and galactose by lactase; and sucrose to glucose and fructose by sucrase (sucrose-α-glucosidase). The monosaccharide products of enzymatic hydrolysis of carbohydrates, glucose, fructose, and galactose, are the principal forms in which absorption occurs in the monogastric animal.

III. ABSORPTION

The monosaccharides are almost completely absorbed through the mucosa of the small intestine and appear in the portal circulation as the free sugars. Absorption occurs by two methods: (1) facilitated diffusion and (2) sodium-dependent active transport. Glucose and galactose are absorbed rapidly and by both methods. Fructose is absorbed at about half the rate of glucose with a portion being converted to glucose in the process. Other monosaccharides, for example, mannose, are absorbed slowly at a rate consistent with a diffusion process. The active absorption of glucose across the intestinal mucosa is thought to be by phosphorylation in the mucosal cell. The phosphorylated sugars are then transferred across the mucosal cell, rehydrolyzed, and free glucose appears in the portal circulation for transport to the liver.

The possible role of glucose transporters in this event is not yet elucidated but they are very likely to be involved. Glucose transporters are known to be involved in many tissues, including brain, erythrocytes, kidney, liver, pancreas, skeletal muscle, heart muscle, and fat cells.

IV. METABOLISM OF ABSORBED CARBOHYDRATE

A. General

Liver cells are readily permeable to the absorbed glucose. This process is facilitated by glucose transporter (GLUT) proteins within the plasma membrane, in particular, GLUT-2 is the transporter in the liver cell plasma membrane (Thorens *et al.*, 1988). Within the liver, there are several pathways by which the immediate fate of the absorbed hexose is determined. Glucose, fructose, and galactose first enter the general metabolic scheme through a series of complex reactions to form glucose phosphates (Fig. 3.1). The enzyme, galactose-1-P uridyl transferase, which catalyzes the reaction

$$\text{galactose-1-P} + \text{UDP-glucose} \rightarrow \text{UDP-galactose} + \text{glucose-1-P},$$

is blocked or deficient in congenital galactosemia of humans. The glucose phosphates are then converted

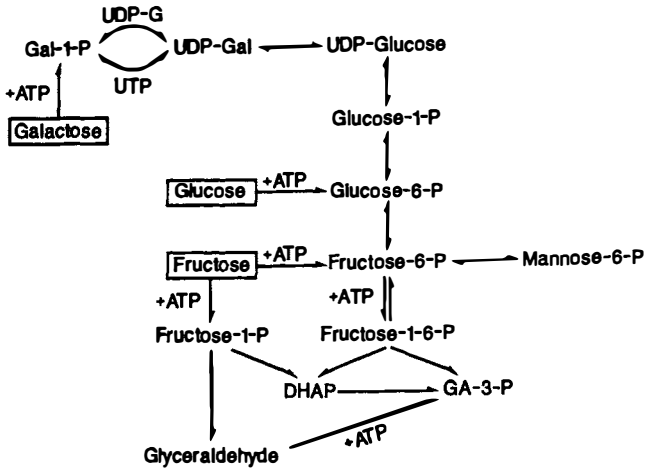

FIGURE 3.1 Pathways for hexose metabolism. ATP, adenosine triphosphate; UTP, uridine triphosphate; UDP-G, uridine diphosphate glucose; DHAP, dihydroxy acetone phosphate; GA-3-P, glyceraldehyde-3-phosphate.

TABLE 3.1 Liver Glycogen Content of Animals

Species	Glycogen in liver (%)	Reference
Dog	6.1	Lusk (1928)
Sheep	3.8	Roderick *et al.* (1933)
Cow (lactating)	1.0	Kronfeld *et al.* (1960)
Cow (nonlactating)	3.0	Kronfeld *et al.* (1960)
Baby pig	5.2	Morrill (1952)
Baby pig (newborn)	14.8	Swiatek *et al.* (1968)

to and stored as glycogen, catabolized to CO_2 and water or, as free glucose, returned to the general circulation. Essentially, intermediate carbohydrate metabolism of animals evolves about the metabolism of glucose, and the liver is the organ of prime importance.

B. Storage as Glycogen

Glycogen is the chief storage form of carbohydrate in animals and is analogous to the storage of starch by plants. It is found primarily in liver and in muscle, where it occurs at about 3–6% and about 0.5%, respectively (Table 3.1). Glycogen is comprised solely of α-D-glucose units linked together through carbon atoms 1 and 4 or 1 and 6. Straight chains of glucose units are formed by the 1–4 links and these are cross-linked by the 1–6 links. The result is a complex ramification of chains of glucosyl units with branch points at the site of the 1–6 links (Fig. 3.2). The internal chains of the glycogen molecule have an average length of four glucosyl units. The external chains beyond the last 1–6 link are longer and contain between 7 to 10 glucose units. The molecular weight of glycogen may be as high as 4×10^6 Mr and contain about 20,000 glucosyl units.

In Table 3.2, the amount of carbohydrate available to meet the theoretical requirements of a hypothetical dog is shown. The amount present is sufficient for about half a day. It is apparent that the needs of the body which must be continually met are satisfied by alternate means and not solely dependent on continuous ingestion of carbohydrates. During and after feeding (postprandial), absorbed hexoses are converted to glucose by the liver and enter the general circulation. Excesses are stored as glycogen or as fat. During the fasting or postabsorptive state, glucose is supplied by the conversion of protein (gluconeogenesis) and by the breakdown of glycogen (glycogenolysis). The continued rapid synthesis and breakdown of glycogen that

TABLE 3.2 Carbohydrate Content of a Dog[a]

Muscle glycogen (0.5%)	25.0 g
Liver glycogen (6%)	18.0 g
Carbohydrate in fluids 5.5 mmol/liter (100 mg/dl)	2.2 g
	45.2 g

Caloric value (45.2×4 kcal/g) = 181 kcal

Caloric requirement ($70\ kg^{\frac{3}{4}} = 70 \times 5.6$) = 392 kcal/day

$$\frac{181}{392} \times 24 \text{ hours} = 11 \text{ hours}$$

[a] Body weight, 10 kg; liver weight, 300 g; muscle weight, 5 kg; volume of blood and extracellular fluid, 2.2 liters.

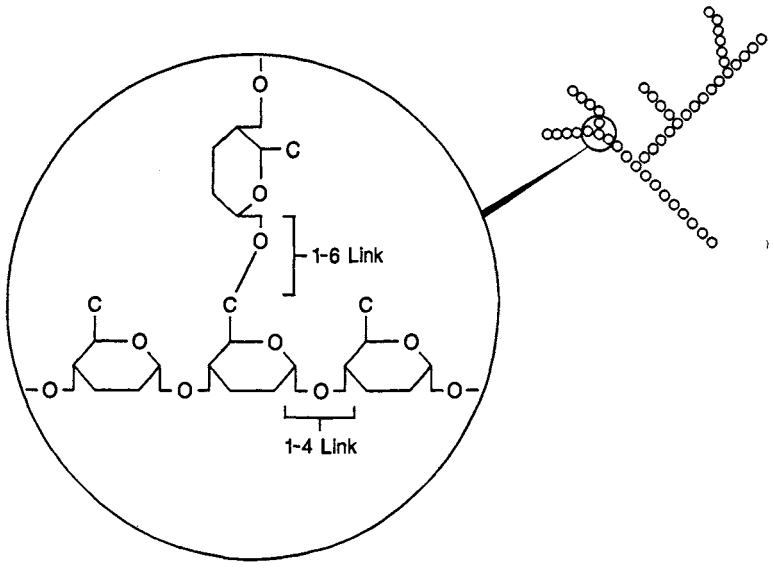

FIGURE 3.2 Glycogen structure. Note that hydrolysis of a 1–6 link by the debrancher enzyme yields a mole of free glucose.

is, turnover, is well illustrated by the biological half-time of glycogen, which is about a day.

C. Glycogen Metabolism

1. Glycogenesis

The initial reaction required for the entrance of glucose into the series of metabolic reactions that culminates in the synthesis of glycogen is the phosphorylation of glucose at the C-6 position. Glucose is phosphorylated with adenosine triphosphate (ATP) in liver by an irreversible enzymatic reaction catalyzed by a specific glucokinase (GK):

$$\text{glucose} + \text{ATP} \xrightarrow[(\text{HK-IV})]{\text{GK}} \text{glucose-6-P} + \text{ADP}. \qquad (3.1)$$

Glucokinase (GK) [also called hexokinase-IV (HK-IV)] is one of the four hexokinase isoenzymes that occurs in all tissues. Glucokinase or HK-IV, which is glucose specific, is the predominant isoenzyme found in liver. The nonspecific hexokinase-I (HK-I) is the isoenzyme found in red cells, brain, and nerve tissue.

Liver contains both GK (HK-IV) and HK-I but GK is the predominant isoenzyme. GK has a high Michaelis constant ($Km = 2 \times 10^{-2}$ mol G/liter) indicating a low affinity for glucose. The rate of the phosphorylation reaction catalyzed by GK is therefore controlled by the glucose concentration. The activity of GK is increased by glucose feeding and by insulin and is decreased during fasting and in insulin lack (i.e., diabetes). In this regard, GK is an inducible enzyme whose activity is increased by glucose or by insulin. The nonspecific HK-I is found in all tissues including liver, brain, and erythrocytes and has a low Michaelis constant ($Km = 5 \times 10^{-5}$ mol G/liter), indicating a high affinity for glucose. HK-I catalyzed phosphorylation in all tissues, therefore, is not controlled by glucose concentration. The activity of HK-I is not affected by fasting or carbohydrate feeding, by diabetes, or by insulin. Therefore, in contrast to GK, HK-I is not an inducible enzyme.

The initial unidirectional phosphorylation reaction permits the accumulation of glucose in the liver cells because phosphorylated sugars do not pass freely into and out of the cell in contrast to the readily transported free sugars. The glucose-6-phosphate (G-6-P) accumulated in the cell next undergoes a mutation in which the phosphate group is transferred to the C-1 position of the glucose molecule. This reaction is catalyzed by the enzyme, phosphoglucomutase (PGM) and involves glucose-1-6-diphosphate as an intermediate:

$$\text{Glucose-6-P} \rightarrow \text{glucose-1-P}. \qquad (3.2)$$

Glycogen is synthesized from this glucose-1-phosphate (G-1-P) through a series of reactions involving the formation of uridine derivatives. Uridine diphosphoglucose (UDPG) is synthesized by the transfer of glucose from G-1-P to uridine triphosphate (UTP). This reaction is catalyzed by the enzyme UDP-G-pyrophosphorylase (UDP-G-PPase):

$$\text{UTP} + \text{G-1-P} \rightarrow \text{UDP-G} + \text{PP} \qquad (3.3)$$

In the presence of a polysaccharide primer and the enzyme glycogen synthase (glucosyl transferase), the glucose moiety of UDP-G is linked to the polysaccharide chain by an α-1-4 link:

$$\text{UDP-G} + (\text{glucose } 1\text{–}4)_n \xrightarrow[\text{synthase}]{\text{glycogen}} (\text{glucose } 1\text{–}4)_{n+1} + \text{UDP}. \qquad (3.4)$$

Through repeated transfers of glucose, the polysaccharide chain is lengthened. When the chain length of the polysaccharide reaches a critical level between 11 and 16 glucosyl units, the brancher enzyme, α-glucan glycosyl 4:6 transferase, transfers the terminal 7 residue portion from an α-1-4 linkage to an α-1-6 linkage. The newly established 1–6 linkage thus becomes a branch point in the expanding glycogen molecule. The remaining stub can again be lengthened by the action of glycogen synthase. Approximately 7% of the glucose units of the glycogen molecule are involved in these branch points.

2. Glycogenolysis

The breakdown of liver glycogen to glucose (glycogenolysis) takes place via a separate pathway. The key initiating and regulating factor in glycogenolysis is the action of epinephrine on liver and muscle glycogen and of glucagon on liver glycogen only. The mechanism of action of glucagon and epinephrine is through a series of reactions that culminates in the phosphorolytic cleavage of the 1–4 glucosyl links of glycogen. In the liver cell, glucagon and epinephrine stimulate the enzyme adenylate cyclase to form 3′-5′ cyclic adenosine monophosphate (cAMP) from ATP. In turn, cAMP activates a protein kinase, which in its turn activates liver phosphorylase (LP), the phosphorolytic enzyme. As with many enzymes, LP is present in an inactive form, dephospho-liver phosphorylase (dLP), which is converted to its active form, LP (Cherrington and Exton, 1976) by the protein kinase, phosphorylase kinase.

The action of the LP is to cleave the 1–4 glucosyl links of glycogen by the addition of orthophosphate in a manner analogous to a hydrolytic cleavage with water, hence the analogous term *phosphorolysis*. Phosphate is added to the C-1 position of the glucose moiety while H^+ is added to the C-4 position of the other.

cAMP is also a key regulating factor in cellular processes in addition to LP activation. It is required for the conversion of inactive muscle phosphorylase b to active muscle phosphorylase a, again via phosphorylase b kinase. The actions of other hormones known to be mediated by activating adenylate cyclase and cAMP include ACTH, LH, TSH, MSH, T_3, and insulin. From these findings, a general concept of hormone action has evolved in which the hormone elaborated by the endocrine organ is described as the first messenger and cAMP within the target cell is the second messenger.

Glucagon acts only on liver glycogen, whereas epinephrine acts on both liver and muscle glycogen. In liver, glucagon promotes the formation and release of glucose by increasing glycogenolysis and decreasing glycogenesis. In liver, the hydrolysis of G-6-P is catalyzed by the enzyme glucose-6-phosphatase (G-6-Pase) to release free glucose, thus promoting hyperglycemia. Additionally, glucagon promotes hyperglycemia by stimulation of hepatic gluconeogenesis and, thus, glucagon is a potent hyperglycemic factor. With muscle glycogen, however, since the enzyme G-6-Pase is absent from muscle, glycogen breakdown in muscle results in the production and release of pyruvate and lactate rather than glucose. Mainly lactate and some pyruvate is transported to the liver where glucose is resynthesized via reverse glycolysis (Cori cycle; Section IV.D).

The continued action of LP on the 1–4 linkages results in the sequential release of G-1-P units until a branch point in the glycogen molecule is reached. The residue is a limit dextrin. The debrancher enzyme, amylo-1-6-glucosidase, then cleaves the 1–6 linkage, releasing free glucose. The remaining 1–4 linked chain of the molecule is again open to attack by LP until another limit dextrin is formed. Thus, by the combined action of LP and the debrancher enzyme, the glycogen molecule is successively reduced to G-1-P and free glucose units.

G-1-P is converted to G-6-P by the reversible reaction catalyzed by phosphoglucomutase (PGM, Section IV.C.1, Reaction 3.2). The G-6-P is then irreversibly cleaved to free glucose and phosphate by the enzyme G-6-Pase, which is found in liver and kidney. The free glucose formed can, unlike its phosphorylated intermediates, be transported out of the hepatic cell and enter the general circulation, thereby contributing directly to the blood glucose pool. In muscle tissue, there is no G-6-Pase and muscle glycogen cannot supply glucose directly to the circulation by glycogenolysis. Muscle glycogen contributes to blood glucose indirectly via the lactate or Cori cycle (Section IV.D). The series of reactions described is illustrated schematically in Fig. 3.3.

3. Hormonal Influences on Glycogen Metabolism

The biochemical basis of the glycogenolytic and hyperglycemic action of glucagon and epinephrine has been discussed in Section IV.C.2. These hormone actions are the bases for the epinephrine and glucagon stimulation tests that are used to assess the availability of liver glycogen and the sensitivity of the carbohydrate regulatory mechanisms to these hormones. Many other hormones influence carbohydrate metabolism to a greater or lesser degree in keeping with the concept that carbohydrate metabolism is a totally integrated metabolic mechanism.

One of the results of successful insulin therapy is a restoration of the depleted glycogen reserve. The mechanism of insulin action on carbohydrate metabolism continues to be a subject for intense study and is discussed more fully in Section VI. Briefly, the primary role of insulin is to promote glucose entry into peripheral cells, mainly muscle and fat cells, and to enhance glucose utilization by liver cells by its effect on enzyme systems at control points in the glycolytic pathways. In the presence of insulin, glucose removal from the blood is enhanced by shifting the direction of glucose metabolism toward utilization by increasing glycogen synthesis and glucose uptake oxidation. The result is a hypoglycemia.

Promotion of liver glycogen storage is also one of the effects of the glucocorticoids. This effect may be attributed to their enhancement of gluconeogenesis, hyperglycemia, decreased glycogenolysis, and decreased glucose oxidation. A tendency toward a mild hyperglycemia is also present in hyperthyroid states, as the result of an overall increase in carbohydrate metabolism. Thyroxine is thought to increase the sensitivity of the liver cell to the action of epinephrine, thereby increasing glycogenolysis and promoting hyperglycemia. Increased glycogenolysis, gluconeogenesis, and the hyperglycemia may also be the compensatory result of an increased rate of tissue metabolism. In rats made hyperthyroid, hepatic G-6-Pase activities are increased, which would enhance hepatic glucose production and hyperglycemia in the hyperthyroid states. An additional factor contributing to the overall tendency for hyperglycemia is the stimulation of glucose absorption by the gastrointestinal tract by thyroxine.

4. Glycogen in Disease

In systemic disease, changes in glycogen concentrations in tissues or organs are generally observed as decreases. Depletion of liver glycogen stores is seen in diabetes mellitus, starvation, bovine ketosis, ovine pregancy toxemia or in any condition with nutritional

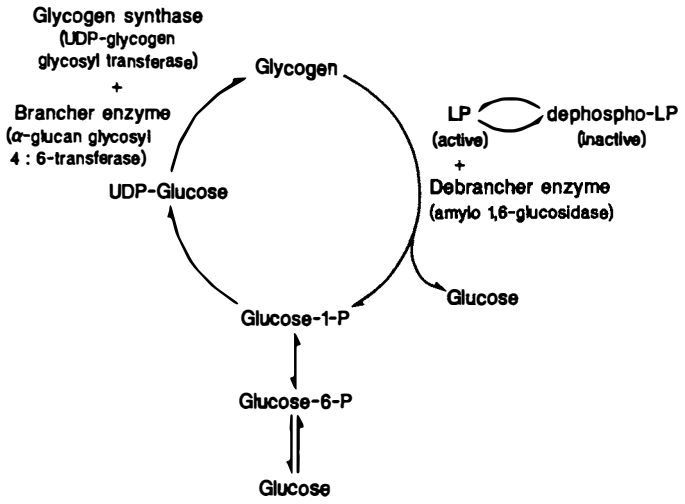

FIGURE 3.3 Summary of liver glycogen metabolism. In muscle, phosphorylase a is the active form and phosphorylase b is the inactive form. UDP, uridine diphosphate; LP, liver phosphorylase.

carbohydrate deficiency or increased carbohydrate turnover. Pathological increases in liver glycogen occur in the rare glycogen storage diseases (GSDs) and are described in Section IX.D.

D. Catabolism of Glucose

Carbohydrate in the form of glucose is the principal source of energy for the life processes of the mammalian cell. All cells require a constant supply of this indispensable nutrient and only relatively small changes are tolerated without adverse effects on the health of the animal. Glucose is not oxidized directly to CO_2 and H_2O but rather through a series of stepwise reactions involving phosphorylated intermediates. The chemical energy of glucose is "stored" through the synthesis of "high-energy" phosphate bonds during the course of these reactions and used in other metabolic reactions. The details of the individual reactions in the pathways of glucose catabolism have been largely elucidated but emphasis here is being placed on the interrelationships of the pathways rather than on the details of the individual reactions.

1. Pathways of Glucose-6-Phosphate Metabolism

The fundamental conversion required to initiate the oxidation of glucose by a cell is its phosphorylation to form G-6-P. This reaction has been described in Section IV.C.1. The G-6-P formed as a result of the GK (HK-IV) catalyzed reaction is central to glucose catabolism. At least five different pathways can be followed by G-6-P: the free glucose, glycogenesis, glycolysis, hexose monophosphate, and glucuronate pathways.

a. Free Glucose Pathway

The simplest direction for G-6-P is a reversal of phosphophorylation by a separately enzyme catalyzed reaction in which G-6-P is hydrolyzed to form free glucose and inorganic phosphate. This reaction is catalyzed by the enzyme G-6-Pase:

$$\text{Glucose-6-PO}_4 \xrightarrow{\text{G-6-Pase}} \text{glucose} + P_i.$$

This is an irreversible reaction that opposes the previously described unidirectional GK (HK-IV) reaction. These two opposing and independently catalyzed enzyme reactions are the site of metabolic control for glucose because the balance of these enzyme activities regulates the net direction of the reaction. Significant amounts of G-6-Pase are found only in liver and to a lesser extent in the kidney. This is in accord with the well-known function of the liver as the principal source of supply of glucose for the maintenance of blood glucose concentration. The G-6-Pase activity is generally higher than the GK activity for most of a 24-hour day except for a few hours after each meal. This means that for most of the day, the liver is supplying glucose rather than using glucose.

Muscle G-6-P, however, because of the absence of G-6-Pase, does not contribute glucose from its glycogen to blood directly. Muscle G-6-P does, however, contribute glucose to blood indirectly via the lactate or Cori cycle. Lactate formed in muscle by glycolysis is trans-

ported to the liver, where it is resynthesized to glucose and its precursors as outlined in Fig. 3.4.

b. Glycogenesis Pathway

This pathway for G-6-Pase leading to the synthesis of glycogen has been discussed in Section IV.C.1.

c. Anaerobic Glycolysis

One of the three oxidative pathways of G-6-P is the classic anaerobic glycolytic or Embden–Meyerhof pathway (EMP). The intermediate steps involved in this pathway of breakdown of G-6-P to three-carbon compounds are summarized in Fig. 3.5. A mole of ATP is used to phosphorylate fructose-6-phosphate (F-6-P) to form fructose-1,6-diphosphate (F-1,6-P). This phosphorylation reaction is also irreversible and catalyzed by a specific kinase, phosphofructokinase (PFK). The opposing unidirectional reaction is catalyzed by a specific phosphatase, fructose-1,6-diphosphatase (F-1,6-Pase). The opposing PFK and F-1,6-Pase catalyzed reactions are a second site of metabolic control regulated by the activities of these two highly specific enzymes. At this point in the process, starting from glucose, a total of two high-energy phosphates from ATP have been donated to form a mole of F-1,6-P.

F-1,6-P is next cleaved to form two three-carbon compounds as shown in Fig. 3.5. The next step is an oxidative step catalyzed by the enzyme glyceraldehyde-3-phosphate dehydrogenase (GA-3-PD) with oxidized nicotinamide adenine dinucleotide (NAD^+) as the hydrogen acceptor. During the process, the molecule is phosphorylated. In the succeeding steps, the molecule is dephosphorylated at the points indicated, and a mole of ATP is generated at each point.

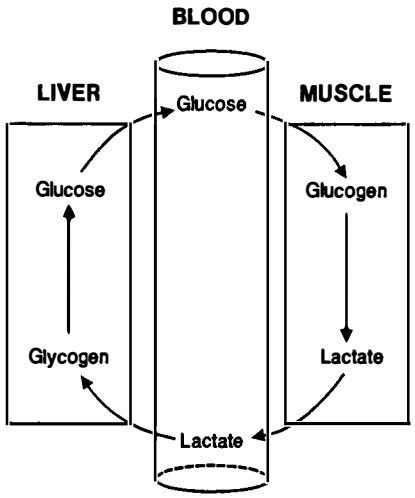

FIGURE 3.4 The lactate or Cori cycle. Muscle cells are devoid of glucose-6-phosphatase, therefore muscle glycogen contributes indirectly to blood glucose by this pathway.

A third site of control of glycolysis is the irreversible formation of pyruvate catalyzed by the enzyme pyruvate kinase (PK). In the reverse direction, two enzymatic reactions operate. Pyruvate carboxylase (PC) first catalyzes the carboxylation of pyruvate to oxaloacetate (OAA) and the OAA is then converted to phosphoenolpyruvate (PEP) by the enzyme PEP carboxykinase (PEPCK) (Figs. 3.5 and 3.8).

Thus, the overall conversion of a mole of glucose to 2 moles of pyruvate requires 2 moles of ATP for the initial phosphorylations. A total of 4 moles of ATP is generated in the subsequent dephosphorylations. This net gain of 2 moles of ATP represents the useful energy of anaerobic glycolysis.

For repeated function of the glycolytic pathway, a supply of NAD^+ must be available for use in the oxidative (GA-3-PD) step. Normally in the presence of molecular O_2, that is, aerobic glycolysis, reduced NADH is reoxidized via the cytochrome system

$$H^+ + NADH + \tfrac{1}{2}O_2 \xrightarrow[\text{(system)}]{\text{(cytochrome)}} NAD^+ + H_2O,$$

which provides a continuous source of NAD^+.

In the absence of O_2, that is, anaerobic glycolysis, NADH is reoxidized to NAD^+ in the reaction catalyzed by lactate dehydrogenase (LDH) where pyruvate is reduced to lactate and the NADH is the H^+ donor. Therefore, by this "coupling" of the LDH system to the GA-3-PD system, anaerobic breakdown of glucose to lactate proceeds in the absence of O_2. As noted earlier, this anaerobic system generates only 2 moles of ATP and when compared to the 36 moles of ATP generated in aerobic glycolysis, anaerobic glycolysis is not very efficient.

d. Hexose Monophosphate Pathway

This alternate route of G-6-P oxidation has been variously referred to as the pentose phosphate pathway (PPP), direct oxidative pathway, Warburg–Dickens scheme, the hexose monophosphate pathway (HMP), or the hexose monophosphate shunt. The initial step of the shunt pathway involves the oxidation of G-6-P at the C-1 position to form 6-phosphogluconate (6-PG) as summarized in Fig. 3.6. The reaction is catalyzed by glucose-6-phosphate dehydrogenase (G-6-PD) and in this pathway, oxidized nicotinamide adenine dinucleotide phosphate ($NADP^+$) serves as the hydrogen acceptor. In the second oxidative step, 6-P-G is oxidatively decarboxylated by 6-phosphogluconate dehydrogenase (6-P-GD) to yield a pentose phosphate, ribulose-5-phosphate (Rib-5-P) again in the presence of $NADP^+$. Thus, in the initial reactions, which are essentially irreversible, 2 moles of NADPH are formed.

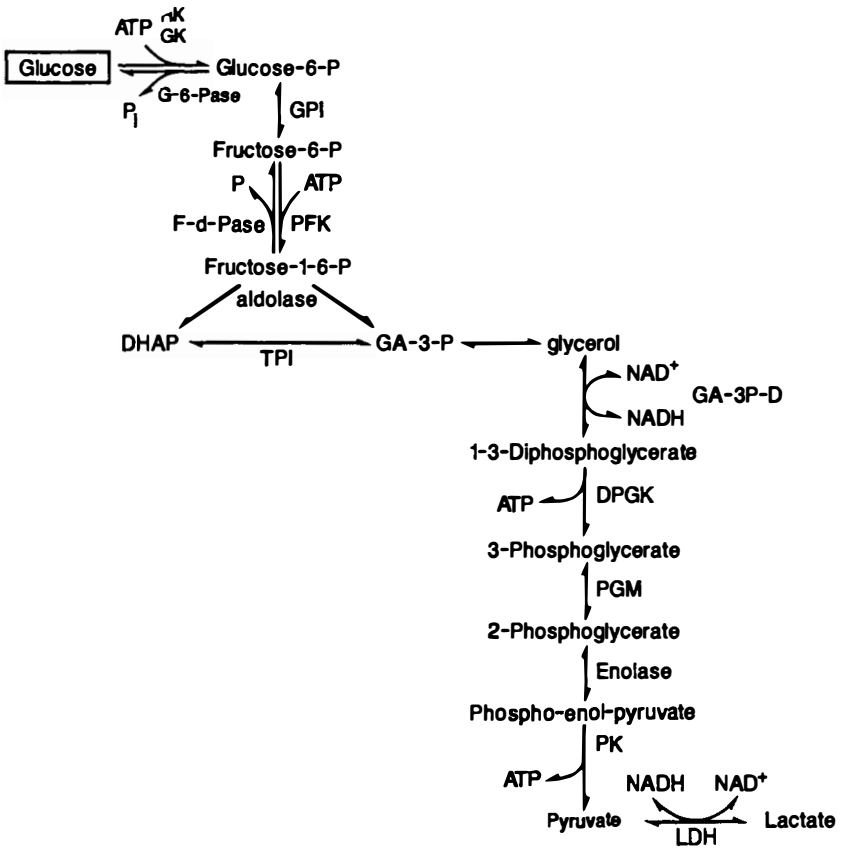

FIGURE 3.5 The glycolytic or classic Embden–Meyerhof pathway. Note that 2 moles of ATP are used and 4 moles of ATP are generated. ATP, adenosine triphosphate; DHAP, dihydroxy acetone phosphate; GA-3-P, glyceraldehyde-3-phosphate; NAD^+, nicotinamide adenine dinucleotide; Pi, inorganic phosphate.

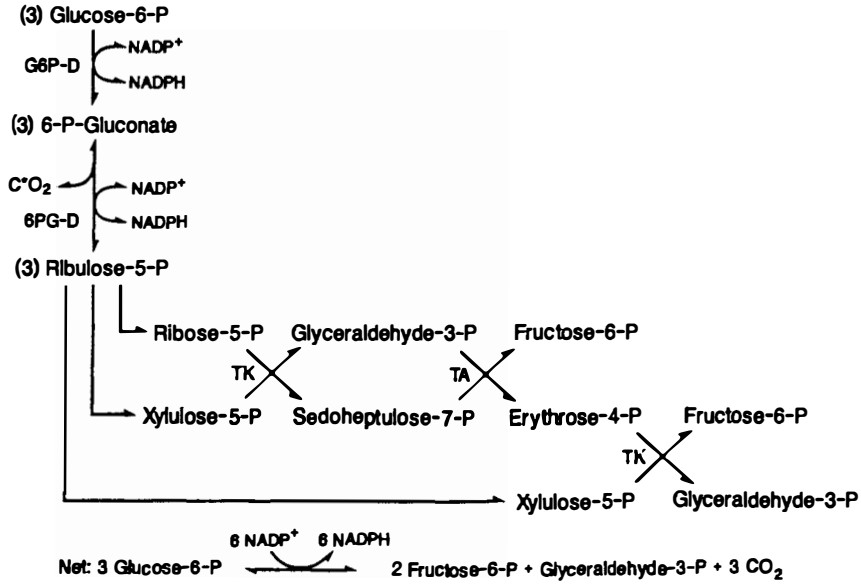

FIGURE 3.6 The pentose phosphate pathway (PPP) or the hexose monophosphate pathway (HMP). $NADP^+$, nicotinamide adenine dinucleotide phosphate; TK, transketolase; TA, transketolase; TA, transaldolase; C^*O_2, is derived from C_1 of glucose.

In this pathway only the C-1 carbon atom of the glucose molecule is evolved as CO_2. By contrast, glucose catabolism via the glycolytic scheme results in the loss of both the C-1 and C-6 carbon atoms as CO_2 when pyruvate is oxidatively decarboxylated to form acetyl-CoA. This difference in CO_2 evolution is used to study partitioning of glucose metabolism through the glycolytic (EMP) pathway and the HMP shunt pathway in domestic animals. The subsequent metabolism of the Rib-5-P in the HMP shunt is also shown in Fig. 3.6. As a result of the series of transformations, F-6-P and GA-3-P are formed and serve as recycling links into the glycolytic pathway.

For continued functioning of the HMP shunt pathway, a supply of $NADP^+$ must be available to act as the hydrogen acceptor. Oxidized $NADP^+$ is regenerated from NADPH via the cytochrome system in the presence of O_2 so the HMP pathway is an aerobic pathway of glucose oxidation. Reduced NADPH is also required as a hydrogen donor in the synthesis of fatty acids. Through generation of NADPH, the HMP shunt route of carbohydrate metabolism is linked to that of fat synthesis. Accordingly, glucose oxidation through the HMP shunt pathway is essential for the synthesis of fat. In general, the HMP pathway is the major source of the NADPH, which maintains the reductive environment for all biosynthetic processes using NADPH as a cofactor.

e. Glucuronate Pathway

This is an alternate pathway of G-6-P oxidation, which has been named the uronate pathway, glucuronate pathway, or the C_6 oxidative pathway. This pathway is shown in Fig. 3.7. The initial steps of this pathway involve the formation of UDPG, which as noted earlier, is an intermediate in glycogen synthesis. G-6-P is first converted to G-1-P, which then reacts with UTP to form UDPG. This product is then oxidized at the C_6 position of the glucose moiety in contrast to the C_1 position, which is oxidized in the HMP shunt pathway. This reaction requires NAD^+ as a cofactor and the products of the reaction are uridine diphosphoglucuronic acid (UDPGA) and NADH. This UDPGA is involved in a large number of important conjugation reactions in animals, for example, bilirubin glucuronide formation, synthesis of mucopolysaccharides (chondroitin sulfate), which contain glucuronic acid, and generally in detoxification reactions. UDPGA is cleaved to release D-glucuronate and UDP.

D-Glucuronate is next reduced to L-gulonate in a reaction catalyzed by the enzyme gulonate dehydrogenase (GUD), with NADPH as the hydrogen donor. The L-gulonate may be converted to a pentose, L-xylulose, or to vitamin C. When converted to L-xylulose, the C-6 carbon of L-gulonate is oxidatively decarboxylated and evolved as CO_2. The L-xylulose is then reduced to xylitol, catalyzed by the enzyme L-xylulose reductase. This is the enzyme that is deficient in pentosuria of humans. As shown in Fig. 3.7, xylitol is converted to D-xylulose, which is then phosphorylated to D-xylulose-5-P, and a cyclical pathway involving the HMP shunt pathway may occur. L-Gulonate is also converted by enzyme catalyzed reactions to L-ascorbate in those species that can synthesize their own vitamin C, that is, all domestic animals. The enzyme, L-gulonolactone oxidase (GLO), is lacking in humans, nonhuman primates, and guinea pigs and therefore vitamin C must be supplied in their diets. The enzyme is present only in the liver of the mouse, rat, pig, cow, and dog. In the dog, the liver GLO activity is low and the ascorbate hydrolytic activity is high so dogs may have additional needs for vitamin C during

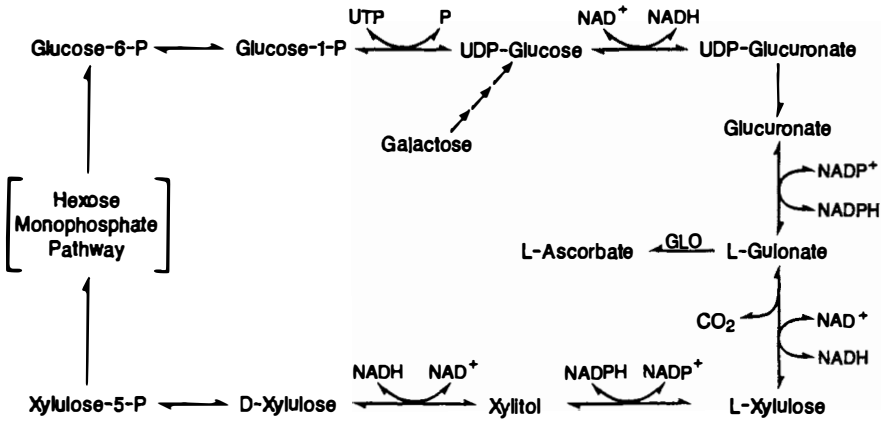

FIGURE 3.7 Glucuronate pathway or the C_6 oxidation pathway. Note that vitamin C is synthesized via this pathway. UTP, uridine triphosphate; NAD^+, Nicotinamide adenine dinucleotide; $NADP^+$, nicotinamide adenine dinucleotide phosphate; P, phosphate.

stress, for example, wound healing or postsurgical stress. For vitamin C synthesis, D-galactose may be an even better precursor than D-glucose. This pathway is also included in Fig. 3.7.

2. *Terminal Oxidation—Aerobic Glycolysis*

The metabolic pathways described thus far are those of the carbohydrates. In analogous fashion, the breakdown of fats and of proteins also follows independent pathways leading to the formation of organic acids. Among the organic acids formed from lipids are acetyl-CoA (AcCoA), acetoacetate (AcAc) and 3-OH-butyrate (3-OH-B) from the β-oxidation of fatty acids. From proteins, pyruvate, OAA, and α-ketoglutarate (α-KG) form from transamination of their corresponding α-amino acids. Direct deamination of amino acids is also a route of formation of organic acids. These organic acid intermediate metabolites are indistinguishable in their subsequent interconversions. Thus, the breakdown of the three major dietary constituents converges into a final common pathway, which also serves as a pathway for the interconversions between them.

a. Pyruvate Metabolism

The pathway for breakdown of glucose to pyruvate has been described in Section IV.D.1. Pyruvate, if it is not reduced to lactate, is oxidatively decarboxylated in a complex enzymatic system requiring the presence of lipoic acid, thiamine pyrophosphate (TPP), coenzyme A (CoA), NAD^+, and pyruvate dehydrogenase (PD) to form AcCoA and NADH. Pyruvate may follow a number of pathways as outlined in Fig. 3.8. The conversion of pyruvate to lactate has already been described in Section IV.D.1. By the mechanism of transamination or amino group transfer, pyruvate may be reversibly converted to alanine. The general reaction for an amino group transfer is

$$\underset{\alpha\text{-keto acid}}{R_1\text{-}C(=O)\text{-}COO^-} + \underset{\alpha\text{-amino acid}}{R_2\text{-}C(NH_2)\text{-}COO^-} \xrightarrow{\text{transferase}} \underset{\alpha\text{-amino acid}}{R_1\text{-}C(NH_2)\text{-}COO^-} + \underset{\alpha\text{-keto acid}}{R_2\text{-}C(=O)\text{-}COO^-}$$

where the amino group of an amino acid is transferred to the α position of an α-keto acid and, as a result, the amino acid is converted to its corresponding α-keto acid. This reaction requires the presence of vitamin B_6 as pyridoxal phosphate and is catalyzed by a specific transferase, in this case alanine aminotransferase (ALT). Serum levels of several of these transferases, for example, ALT and aspartate aminotransferase (AST) have been particularly useful in the diagnosis and evaluation of liver and muscle disorders, respectively. These aspects are discussed in the individual chapters on liver and muscle function.

The energetics of the reaction from PEP to form pyruvate and catalyzed by PK are such that this is an irreversible reaction, as is the PD catalyzed conversion of pyruvate to AcCoA. A two-step separate pathway to reverse this process is present at this step so this is a fourth site of directional metabolic control. Through a CO_2 fixation reaction in the presence of $NADP^+$-linked malate dehydrogenase (MD), malate is formed from pyruvate. Malate is then oxidized to OAA in the presence of NAD^+-linked MD. OAA may also be formed directly from pyruvate by the reaction catalyzed by pyruvate carboxylase (PC). OAA formed by either route may then be phosphorylated and decarboxylated to form PEP in a reaction catalyzed by PEPCK. Thus, a pathway in the reverse direction of the PK reaction is present for gluconeogenesis from lower intermediates. These pathways for pyruvate metabolism are outlined in Fig. 3.8, which includes the dicarboxylic acid cycle.

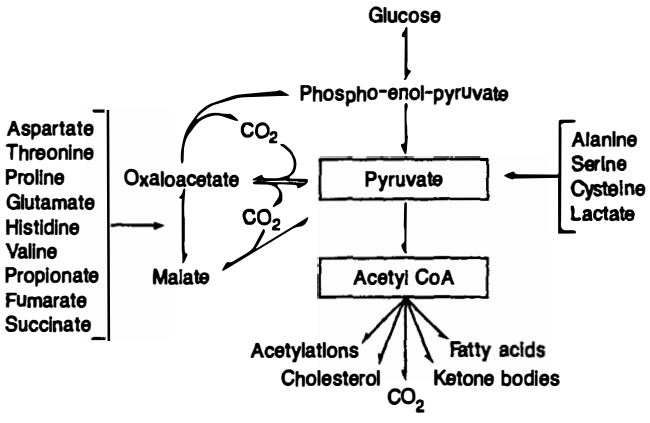

FIGURE 3.8 Pathways of acetate and pyruvate metabolism.

b. Tricarboxylic Acid Cycle

AcCoA formed by the oxidative decarboxylation of pyruvate also has a number of metabolic routes available. AcCoA occupies a central position in synthetic and in oxidative pathways as shown in Fig 3.8. The oxidative pathway leading to the breakdown of AcCoA to CO_2 and H_2O follows a cyclical pathway which is the tricarboxylic acid (TCA) cycle, citric acid cycle, or the Kreb's cycle. The major steps involved are given in Fig. 3.9. In a single turn of the cycle 1 mole of AcCoA enters, 2 moles of CO_2 are evolved and 1 mole of OAA is regenerated. The regenerated OAA may then condense with another mole of Ac CoA, and the cycle continues. Citric acid is a symmet

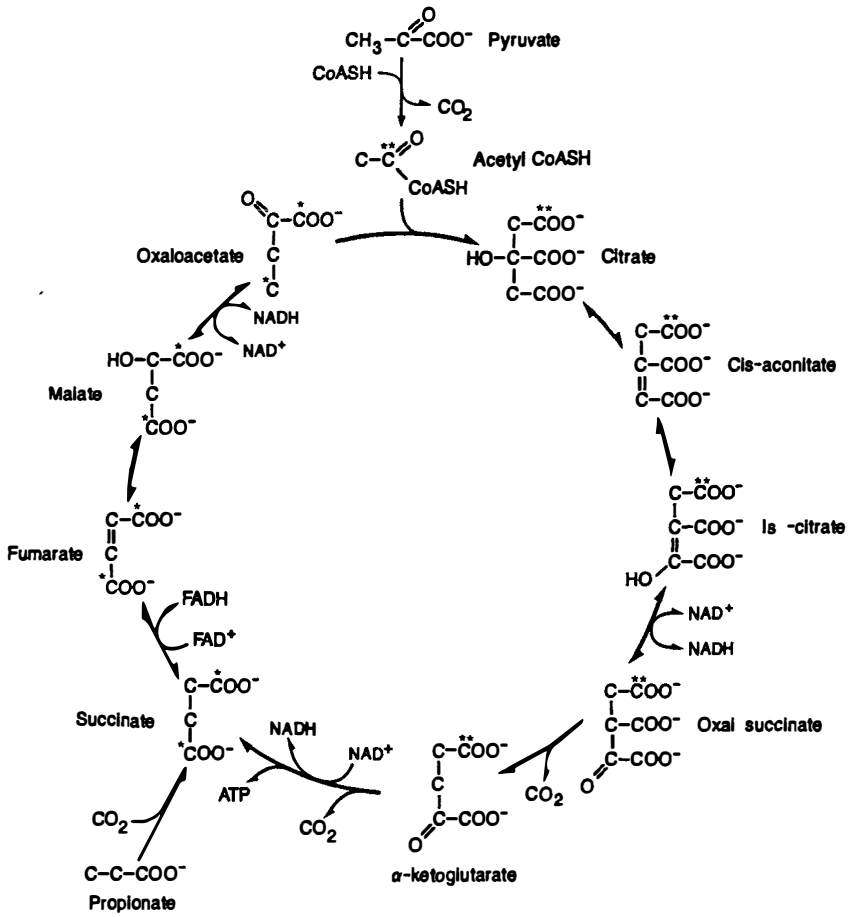

FIGURE 3.9 Tricarboxylic acid cycle. The pathway for the entry of propionate into the metabolic scheme is also included. The asterisks give the distribution of carbon in a single turn of the cycle starting with acetyl-CoA. Note the randomization of carbon atoms at the succinate step.

rical molecule that behaves asymmetrically as shown in Fig. 3.9. Also, the CO_2 that evolves is derived from that portion of the molecule contributed by OAA during each turn of the cycle. The expected distribution of carbon atoms from AcCoA in one turn of the cycle is also given in Fig. 3.9. During one turn of the cycle, a randomization of carbon atoms occurs at the succinate level such that CO_2 derived from the carboxyl group of acetate will be evolved during the next turn of the cycle.

In the process, 3 moles of NAD^+ and 1 mole of a flavin nucleotide (FAD) are reduced and 1 mole of ATP generated as noted in Fig. 3.9. In animal tissues, there is a cytoplasmic $NADP^+$-linked isocitric dehydrogenase (ICD), which is not associated with the mitochondrial NAD^+-linked ICD or other enzymes of the TCA cycle. The $NADP^+$-ICD is another enzyme used as an aid to diagnosis of liver disease.

3. Carbon Dioxide Fixation in Animals

According to Fig. 3.9, the TCA cycle is a repetitive process based on the regeneration of OAA at each turn. In addition, other metabolic pathways are available for intermediates in the cycle. Reversal of the transamination reactions previously described to form aspartate or glutamate would result in a withdrawal of OAA and α-KG, respectively, from the cycle. By decarboxylation, OAA may also be withdrawn to form PEP, and malate may form pyruvate and thence other glycolytic intermediates as shown in Fig. 3.8. Continued losses of these intermediates into other metabolic pathways would theoretically result in a decrease in the rate of operation of the cycle. A number of metabolic pathways are known whereby the losses of cycle intermediates may be balanced by replacement from other sources and are shown in Fig. 3.8. The amino acids, aspartate and glutamate, may function as sources of supply as well

as routes for withdrawal. The CO_2 fixation reactions, which are the reversal of the reactions previously described:

Phosphoenolpyruvate + CO_2 → oxaloacetate,
Pyruvate + CO_2 → malate,
Pyruvate + CO_2 → oxaloacetate,

may also function as important sources of supply. A fourth CO_2-fixing reaction,

Propionate + CO_2 → succinate,

is especially important in ruminants because propionate is a major product of rumen fermentation and is a major supplier of intermediates for the TCA cycle. Propionate is one of the three major fatty acids, with acetate and butyrate, involved in ruminant metabolism.

4. Energy Relationships in Carbohydrate Metabolism

The energy of carbohydrate breakdown must be converted to high-energy phosphate compounds to be useful to the organism, otherwise the energy is dissipated as heat. The total available chemical energy in the reaction

Glucose → 2 Lactate

is about 50 kcal/mol or about 7% of the 690 kcal/mol that is available from the complete oxidation of glucose to CO_2 and water. The useful energy of anaerobic glycolysis is represented by the net gain of 2 moles of ATP and the available energy of each is about 7 kcal. Thus, the efficiency of glycolytic breakdown of glucose to pyruvate is 14 kcal or 28% of the available 50 kcal or only 2% of the total available 690 kcal in glucose.

The major portion of the energy of glucose is generated in the further aerobic oxidation of pyruvate to CO_2 and H_2O. In the oxidative or dehydrogenation steps, NADH or NADPH (FAD in the succinate step) is formed. In the presence of molecular O_2, these compounds are reoxidized to NAD^+ or $NADP^+$ in the cytochrome system. In the sequence of reactions of this system, 3 moles of ATP are formed per mole of NADH or NADPH oxidized to NAD^+ or $NADP^+$. This transfer of energy to ATP is known as *oxidative phosphorylation* or *ox-phos*. The yield of high-energy phosphate bonds in the form of ATP in the system per atom of oxygen consumed ($\frac{1}{2}O_2$) is conventionally referred to as the P:O ratio, which in this case, is 3.

In Table 3.3, a balance sheet of the ATPs formed in the various steps is given and 36 of the total 38 ATPs are generated in aerobic glycolysis. The complete oxidation of 1 mole of glucose to CO_2 and water yields

TABLE 3.3 ATP Yield in Glucose Oxidation

Glucose	
↓ ATP (2×)	−2
Fructose-1-6-diphosphate	
→ NADH → 3 ATP (2×)	+6
↓ → ATP (4×)	+4
2 Pyruvate	
↓ → NADH → 3 ATP (2×)	+6
2 Acetyl-CoA	
→ NADH → 3 ATP (6×)	+18
→ ATP (2×)	+2
↓ → FADH → 2 ATP (2×)	+4
4 CO_2	
Net: Glucose → 6 CO_2	+38 ATP

690 kcal and, therefore, the net gain of 38 ATPs in anaerobic plus aerobic glycolysis represents 266 kcal for an overall efficiency of 38%. In comparison, the efficiency of the modern internal combustion engine is about 20%.

V. INTERRELATIONSHIPS OF CARBOHYDRATE, LIPID, AND PROTEIN METABOLISM

The pathways by which the breakdown products of lipids and proteins enter the common metabolic pathway have been described in previous sections. The principal points at which carbohydrate carbon may be interconverted between amino acids and fatty acids are outlined in Fig. 3.10. Thus, certain amino acids (glycogenic) can serve as precursors of carbohydrate through the transamination reactions and by reversal of these transaminations, carbohydrates can serve as precursors of amino acids.

The relationship between carbohydrate and lipid metabolism deserves special mention because the carbohydrate economy and the status of glucose oxidation strongly influences lipid metabolism. A brief description of lipid metabolism follows, and greater detail may be found in the chapter on lipid metabolism.

A. Lipid Metabolism

1. Oxidation of Fatty Acids

Intracellular fatty acids are either synthesized in the cytoplasm or taken up as free fatty acids. Fatty acid oxidation begins in the cytoplasm with the activation

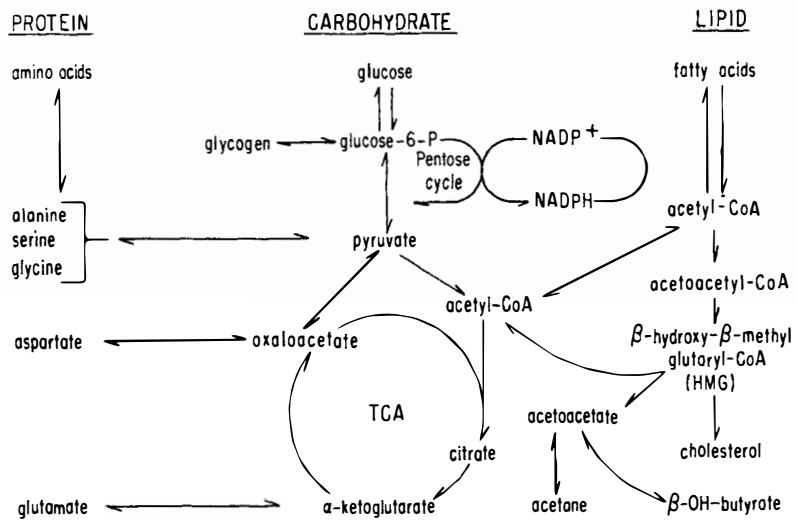

FIGURE 3.10 Interrelationships of carbohydrate, protein, and lipid metabolism.

of fatty acids to form fatty acyl-CoA. The activated fatty acyl-CoA is bound to carnitine for transport into the mitochondria where fatty acyl-CoA is released for intramitochondrial oxidation.

The classical β-oxidation scheme for the breakdown of fatty acids whereby two-carbon units are successively removed is a repetitive process involving four successive reactions. After the initial activation to form a CoA derivative, there is (1) a dehydrogenation, (2) a hydration, (3) a second dehydrogenation, and (4) a cleavage of a two-carbon unit. The result is the formation of AcCoA and a fatty acid residue shorter by two carbon atoms. The residue can then recycle to form successive AcCoA molecules until final breakdown is achieved In the case of odd-chain fatty acids, propionyl-CoA is formed in the final cleavage reaction. The hydrogen acceptors in the oxidative steps are NAD^+ and FAD. The further oxidation of AcCoA to CO_2 and water proceeds in the common pathway of the TCA cycle. In the process, 2 moles of CO_2 are evolved per mole of AcCoA entering the cycle. Therefore, fatty acids could not theoretically lead to a net synthesis of carbohydrate. Net synthesis of carbohydrate from fatty acids would require the direct conversion of AcCoA into some glucose precursor, that is, pyruvate. The reaction

$$\text{Pyruvate} \longrightarrow \text{acetyl CoA} + CO_2,$$

however, is irreversible and the only route by which fatty acid carbon could theoretically appear in carbohydrate is through the TCA cycle intermediates and this occurs without a net synthesis.

2. *Synthesis of Fatty Acids*

The pathway for fatty acid synthesis is separate from that of the β-oxidation mechanism for fatty acid breakdown. Malonyl-CoA is first formed by the addition of CO_2. Subsequently, two-carbon units from malonyl-CoA are sequentially added to the growing chain with a loss of CO_2 at each addition. At each step, there is also a reduction, dehydration, and a final reduction to form a fatty acid that is two carbons longer than the previous one.

The synthesis of fatty acids also requires NADPH as the hydrogen donor rather than NADH or FADH. The major source of NADPH is during the oxidation of glucose in the HMP shunt pathway. NADPH concentration is also high in the cytoplasm of liver and adipose cells where HMP shunt activity is also high. The availability of this NADPH is the basis for the linkage of carbohydrate oxidation to lipid synthesis.

3. *Synthesis of Cholesterol and Ketone Bodies*

AcCoA is also the precursor of cholesterol and the ketone bodies, AcAc, 3-OH-B, and acetone. The synthesis of cholesterol proceeds through a series of reactions beginning with the stepwise condensation of 3 moles of AcCoA to form β-hydroxy-β-methyl glutaryl-CoA (HMG-CoA). As shown in Fig. 3.10, HMG-CoA is a common intermediate for the synthesis of cholesterol and ketone bodies in the liver cell. In liver, a deacylating enzyme is present that cleaves HMG-CoA to yield AcCoA and free AcAc. This is the HMG-CoA cycle. The free AcAc then diffuses out of the cell and enters the general circulation. For further oxidations to occur, AcAc is "reactivated" with CoA in extrahepatic tissues (muscle) by the transfer of CoA from succinyl-CoA to form AcAcCoA. Increased ketogenesis and ketonemia are the net result of alterations in metabolic pathways and/or enzymes that favor the accumulation of AcAcCoA. Prime examples are diabetes mellitus and bovine ketosis.

The increased mobilization and utilization of fatty acids is a well-known requisite for ketogenesis under conditions of starvation and diabetes. Under these same conditions, lipid synthesis from AcCoA is also depressed. The net effect of either or both of these alterations favors the accumulation of AcCoA and thus ketogenesis.

Increased ketogenesis is always associated with an increased rate of gluconeogenesis in association with an increased activity of the key gluconeogenic enzyme, PEPCK. The increased rate of gluconeogenesis in turn depletes OAA. There is an increase in the NADH/NAD ratio, which would promote the conversion of OAA to malate, thereby depleting OAA. With the depletion of OAA and OAA deficiency, there is insufficient condensing partner for AcCoA for the Kreb's cycle. The AcCoA is then be readily diverted to ketone bodies.

Hepatic ketogenesis is regulated by the rate-limiting transfer of FFA across the mitochondrial membrane. Carnitine acyl transferase, the enzyme system responsible for the mitochondrial uptake of FFA, is increased in diabetes and contributes to the ketogenesis.

B. The Influence of Glucose Oxidation on Lipid Metabolism

In addition to the separation of the biochemical pathways for lipid oxidation and lipid synthesis, an anatomical separation of lipid metabolism is also present. The liver is the major site of fatty acid oxidation and the adipose tissue is the major site of lipid synthesis. Adipose tissue, *in vitro*, converts glucose carbons to fatty acids faster than does liver tissue.

It is well known that, with excessive carbohydrate feeding, fat depots in the body increase. Fasting, on the other hand, depresses the respiratory quotient (RQ) indicating that the animal is now using body fat as the energy source. During fasting, plasma FFAs also increase and when carbohydrate is supplied, they decrease. The presence of glucose both stimulates lipogenesis and spares fatty acid from oxidation. In diseases with an inability to utilize glucose, for example, diabetes, depression of lipogenesis is a characteristic finding. When there is adequate glucose oxidation, for example, successful insulin therapy in diabetes, lipid synthesis is restored and the animal regains its weight.

In those conditions with decreased glucose use or availability, such as diabetes, starvation, and ruminant ketosis, there is an increased release of glucose precursors (amino acids) from muscle and FFA from adipose tissues mediated by activated hormone sensitive lipases (HSLs) (Khoo *et al.*, 1973). The amino acids and FFA are transported to the liver where the amino acids follow gluconeogenic pathways. Fatty acids follow pathways toward oxidation and ketogenesis and, additionally, glucagon promotes hepatic ketogenesis. There is also an underutilzation of ketones in the peripheral tissues of dogs (Balasse and Havel, 1971; McGarry and Foster, 1976). The net result is an overproduction of glucose and ketones in liver and an underutilization of both in the peripheral tissues.

VI. INSULIN AND CARBOHYDRATE METABOLISM

The internal secretions of the anterior pituitary, adrenal cortex and medulla, and the pancreas are closely associated with carbohydrate metabolism. The pituitary and adrenal factors have previously been discussed in Section IV.C together with glucagon. More detailed information is available in the chapters on pituitary and adrenal function. After the successful extraction of insulin by Banting and Best in 1921, a vast amount of literature has accumulated on its role in carbohydrate metabolism and continues to this day. The fine details of insulin action are still being studied and a basic understanding of the major biochemical events that occur in animals with and without insulin has evolved.

A. Proinsulin and Insulin

The elucidation of the insulin structure by Sanger in 1959 was soon followed by the discovery of its precursor, proinsulin, and its structure was quickly known. It has been the subject of many reviews (Kitabchi, 1977; Schade and Eaton, 1985; Raptis and Dimitriadis, 1985; Taylor, 1995). Proinsulin is a single-chain looped polypeptide linked by disulfide bridges (Fig. 3.11). It varies in length from 78 amino acid residues in the dog to 86 for the human, horse, and rat. Its molecular weight is near 9,000 Da. Proinsulin is synthesized in the pancreatic β cells on the rough endoplas-

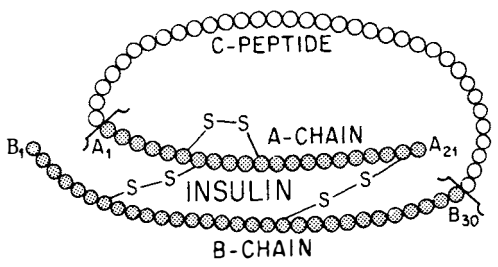

FIGURE 3.11 Insulin and proinsulin. Proinsulin is the coiled polypeptide. When the connecting C-peptide (open circle) is removed, the insulin molecule (solid circle) is released.

mic reticulum (rER) and transported and stored in the secretory granules on the Golgi apparatus. There, the central connecting polypeptide or C-peptide is cleaved from the chain by proteolytic enzymes and the two linked end fragments are the monomeric insulin molecule. C-peptide has a molecular weight of 3600 Da and is devoid of biological activity.

Insulin and C-peptide are released into the circulation in equimolar amounts, but C-peptide's circulatory concentration is higher than that of insulin because of its slower clearance half-time of 20 minutes as compared to 5–10 minutes for insulin. C-peptide is primarily degraded by the kidney and a portion is excreted in the urine (Duckworth and Kitabchi, 1981).

In the pancreatic cells, as the insulin moiety is cleaved from the proinsulin, it crystallizes with zinc for storage in the β-cell granules. The dense central inclusions of these insulin secretory granules consist mainly of crystalline insulin. Insulin release is stimulated by glucose, amino acids, hormones (glucagon, gastrin, secretin, pancreozymin), and drugs (sulfonyl ureas, isoproterenol). Insulin release is inhibited by hypoglycemia, somatostatin, and many drugs, such as dilantin and phenothiazines (Pfeifer *et al.*, 1981). The liver is the primary site of insulin degradation and the kidney is a secondary site. The half-life of insulin in the circulation is between 5 to 10 min (Steiner, 1977).

The A chain of insulin consists of 21 amino acids and the B chain of 30 amino acid residues (Fig. 3.11). The molecular weight of the insulin monomer is 6000 Da and is the smallest unit possessing biological activity. Under physiological conditions, four molecules of insulin are linked to form a tetramer, the active molecule. Insulin obtained from various species differs in amino acid composition in chain A or chain B or both (Table 3.4). Differences occur within species also since rats and mice (Markussen, 1971) have two nonallelic insulins. These structural differences among the various species of animals are not located at critical sites, however, because they do not affect their biological activity. They do, however, affect their immunologic behavior.

The amount of insulin stored in the pancreata of various species also differs. The dog stores about 3.3 units per gram of pancreas, which amounts to about 75 IU in a 10-kg dog. This amount, if suddenly released, would be fatal.

Insulin release is effected by glucose, mannose, leucine, other amino acids, ketone bodies, and fatty acids. This release is mediated by glucagon, a hormone that increases cAMP and potentiates the insulin response. The sulfonylureas are effective as pharmacologic agents to release insulin, the basis for their therapeutic use.

TABLE 3.4 Species Variation in Amino Acid Sequences of Insulin[a]

	Position[b]						
	A chain				B chain		
Species	A-4	A-8	A-9	A-10	B-3	B-29	B-30
Human	Glu	Thr	Ser	Ileu	Asp	Lys	Thr
Monkey	Glu	Thr	Ser	Ileu	Asp	Lys	Thr
Dog	Glu	Thr	Ser	Ileu	Asp	Lys	Ala
Pig	Glu	Thr	Ser	Ileu	Asp	Lys	Ala
Sperm whale	Glu	Thr	Ser	Ileu	Asp	Lys	Ala
Rabbit	Glu	Thr	Ser	Ileu	Asp	Lys	Ser
Horse	Glu	Thr	Gly	Ileu	Asp	Lys	Ala
Cow	Glu	Ala	Ser	Val	Asp	Lys	Ala
Sheep	Glu	Ala	Gly	Val	Asp	Lys	Ala
Sei whale	Glu	Ala	Ser	Thr	Asp	Lys	Ala
Rat 1	Asp	Thr	Ser	Ileu	Lys	Lys	Ser
Rat 2	Asp	Thr	Ser	Ileu	Lys	Met	Ser

[a] From Renold and Cahill Jr. (1966) and Naithani *et al.* (1984).
[b] These are the sites of variation on the A chains and the B chains.
Ala, alanine; Asp, aspartic acid; Glu, glutamic acid; Ileu, isoleucine; Met, methionine; Ser, serine; Thr, threonine.

Blood glucose is the primary regulator of both insulin release and its biosynthesis. This is a highly selective process and only insulin, C-peptide, and proinsulin are released and released rapidly. The insulin response curve to a glucose load exhibits two peaks in humans, the early 5-minute peak representing release and the second 10–30 minute peak representing de novo insulin synthesis and release. This bimodal curve is not clear in dogs (Fig. 3.14, shown later) but it is likely to occur.

During proinsulin hydrolysis, C-peptide also accumulates in the granules. Therefore, when the granule contents are released by glucose stimulation, insulin, C-peptide, and proinsulin all appear in plasma and each can be measured by radioimmunoassay (RIA). Whereas studies in humans have focused on all three, in animals, the focus has been on insulin and little is known of proinsulin or C-peptide in health or disease.

The influence of the various gastrointestinal hormones on insulin secretion is of considerable interest because plasma insulin levels are higher at a given plasma glucose level after an oral glucose load as compared to an intravenous load. The oral glucose tolerance test (OGTT) is known to elicit larger total insulin response than the intravenous glucose tolerance test (IVGTT). A number of GI hormones are known to influence insulin secretion to varying degrees and be sufficient to form an enteroinsular axis (Buchanan, 1975). The hormones implicated are secretin, cholecystokinin-pancreozymin (CCK-PZ), gastrin, glucagon-like activity (GLA) of the gut, and gastric

inhibitory peptide (GIP). GIP is a powerful stimulator of insulin secretion in humans and dogs and this is associated with a rise in blood glucose (Ross *et al.*, 1974). Thus, GIP is central to the enteroinsular axis.

B. Insulin Transport

Insulin is transported in the cirulation bound to a β-globulin. At a tissue, insulin binds to receptors on the cell membrane. The insulin receptor is a very large glycoprotein on the surface of virtually all cells, including liver, kidney, fat, muscle, erythrocytes, and monocytes. The receptor is a posttranslational derivative of a gene product and is a tetramer of two α and two β subunits. The internal β subunit of the receptor anchors the receptor to the membrane. As a result, insulin moves through the plasma membrane and into the cytoplasmic compartment but the mechanism is unclear. All cells, in particular liver and kidney, are able to inactivate insulin by reductive cleavage of the disulfide bonds. Liver inactivates about 50% of the total insulin.

C. Glucose Transport

Insulin binding also activates receptors both on the plasma membrane surface and in the cytoplasm. This activation induces a variety of reactions, for example, phosphorylations, but the details and their implications are not yet known (Taylor, 1995). However, the end result of these interactions—glucose transport across the membrane and into the cell—is defined. Glucose transport proteins [glucose transporters (GLUT-1 through GLUT-4)] are characterized. They are small membrane proteins, 40–50 kDa, and the different transporters are distributed in different cells; GLUT-1 (brain, RBC, placenta, kidney), GLUT-2 (liver, pancreatic cell), GLUT-3 (brain), and GLUT-4 (skeletal muscle, heart muscle, fat). GLUT-4 has been studied extensively because it is found in those tissues where glucose transport into the cells is regulated by insulin. Insulin mobilizes GLUT-4 to the membrane, thereby facilitating glucose transport into the cell. GLUT-2 is the primary transporter in liver cells (Thorens *et al.*, 1988) Recently, glucose transport activity was studied in the erythrocytes of trained and untrained race horses (Arai *et al.*, 1994). Horses in training had glucose transport activities 2 to 3.5 times greater than those of untrained horses. The specific glucose transporter was not identified but presumably is GLUT-1 as in other animals.

D. Insulin Action on Biochemical Systems

The principal sites of insulin action are in the initial phases of glucose metabolism. Insulin first binds to insulin receptors of the target cell plasma membranes and then facilitates glucose entry into cells such as muscle and fat by activation of glucose transporters, in this case GLUT-4. There is also a high degree of stereospecificity because D-glucose is transported but L-glucose is not. With increased accumulation of glucose in the cells, the movement of glucose into the metabolic scheme is enhanced and glucose utilization is increased.

Insulin influences the metabolism of glucose by the liver cells, the central organ of glucose homeostasis, but with a slightly different focus. GLUT-2 is not significantly regulated by insulin so the liver cell is freely permeable to glucose. Therefore, the major action of insulin in liver is after the initial transport step. The principal step is the first phosphorylation of glucose to form G-6-P in the reaction catalized by GK. This GK reaction is rate limiting and GK activity is influenced by insulin. Additionally, the effect of insulin on other key unidirectional phosphorylative steps directs glucose metabolism toward utilization and FA synthesis. An important effect of insulin is to increase the activity of the pyruvate dehydrogenase (PD) system, which increases AcCoA, thereby promoting increased FA synthesis and oxidation to CO_2 via the Kreb's TCA cycle. These and other reactions are described in Section VII.C. Thus, there are two major roles for insulin, promoting (1) glucose transport across the membranes of muscle and fat cells and (2) glucose utilization by increasing enzyme catalyzed reactions in liver cells.

In nerve cells, insulin binds to receptors and promotes membrane transport of glucose but in this case, the membrane transport system itself appears to be the limiting factor. Thus, even though the HK system is operating maximally [$Km(G) = 5 \times 10^{-5}$], the limited glucose transport of about 1.5 mmols/liter (27 mg glucose/dl) induces the symptoms of hypoglycemia—incoordination, disorientation, weakness—when there is insufficient glucose to compensate by mass action.

In other cells such as the red blood cell, which also has the HK system, insulin does not affect glucose metabolism or limit transport. The HK system is operating maximally and glucose utilization is sufficient to meet the needs of the blood cell at all times.

E. Physiological Effects of Insulin

The principal effects of insulin administration to an animal are summarized in Table 3.5. The most characteristic finding following insulin administration is a hypoglycemia. This occurs regardless of the nutritional state, age, etc., of the animal and is a net result of the increased removal of glucose from the plasma into the tissues. The RQ increases toward unity, indicating that

TABLE 3.5 Effects of Insulin on Animals

Tissue	Increase	Decrease
Whole animal	Anabolism Food intake Respiratory quotient	
Blood		Glucose Ketones Fatty acids Phosphate Potassium Amino acids Ketone bodies
Enzymes	Glucokinase Phosphofructokinase Pyruvate kinase Lipoprotein lipase Acetyl-CoA carboxylase Glycogen synthase	Glucose-6-phosphatase Fructose-1,6-diphosphatase Pyruvate carboxylase PEP-carboxykinase Carnitine acyltransferase Serine dehydratase Hormone sensitive lipase
Liver	Glucose oxidation Glycogen synthesis Lipid synthesis Protein synthesis	Glucose production Ketogenesis
Muscle (skeletal / heart)	Glucose uptake Glucose oxidation Glycogen synthesis Amino acid uptake Protein synthesis Potassium uptake	
Adipose	Glucose uptake Glucose oxidation Lipid synthesis Potassium uptake	

the animal is primarily utilizing carbohydrate. The consequences of this increased utilization of glucose follow a pattern of an increase in those constituents derived from glucose and a decrease in those influenced by increased glucose oxidation. The conversion of glucose to glycogen, fat, and protein is enhanced while gluconeogenesis and ketogenesis are inhibited. The decreases in serum phosphate and potassium levels that parallel those of blood glucose are presumably due to their involvement in the phosphorylating mechanisms.

F. Other Pancreatic Islet Hormones

Numerous hormones oppose the action of insulin and by doing so, prevent or correct the hypoglycemic effects of insulin. Hypoglycemia stimulates a number of counterregulatory hormones including glucagon, epinephrine, and growth hormone. Norepinephrine and cortisol are less responsive to hypoglycemia than the three mentioned.

1. Glucagon

Glucagon is a polypeptide hormone (molecular weight = 3485 Da) secreted by the α (A) cells of the islets. Release of glucagon is stimulated by hypoglycemia. Glucagon acts only in the liver where it stimulates glycogenolysis and gluconeogenesis, thereby increasing blood glucose. The most important physiological role of glucagon is to promote hyperglycemia in response to a hypoglycemia. Glucagon does not act on muscle glycogen, unlike epinephrine, which acts on both liver and muscle glycogen. Like most hormones, glucagon is first bound to surface receptors on a cell, in this case, the hepatocyte. Acting through these receptors, adenylate cyclase is activated, which in turn increases the amount of cAMP. cAMP then activates a phosphorylase kinase, which activates phosphorylase A, which in turn hydrolyzes glycogen. Additionally, glucagon is an insulin secretagogue second only to glucose in the magnitude of the insulin response it elicits. This insulin-releasing action of glucagon is the basis for the glucagon stimulation test (GST), which has been used for the evaluation of diabetes in cats (Kirk *et al.*, 1993).

2. Somatostatin

Somatostatin is secreted by many cells, including the hypothalamus, but its major source is the pancreatic δ (D) cells. Somatostatin has broad inhibitory effects on the release of many hormones, including growth hormone, glucagon, and insulin. Therefore it has a modulating effect on the actions of these two hormones. Administration of somatostatin blocks the secretion of glucagon and, in this way, somatostatin exacerbates an insulin-induced hypoglycemia.

VII. BLOOD GLUCOSE AND ITS REGULATION

A. General

The blood glucose concentration depends on a wide variety of factors and its concentration at any time is the net result of an equilibrium between the rates of entry and of removal of glucose in the circulation. As such, all the factors that exert influence upon entry or removal become of importance in the regulation of blood glucose concentration. Furthermore, when the renal reabsorptive capacity for glucose is exceeded (renal threshold), urinary loss of glucose becomes an ad-

ditional factor influencing the maintenance of the blood glucose concentration. The blood glucose levels at which this occurs vary between species and are listed in Table 3.6.

B. Glucose Supply and Removal

Glucose is supplied by intestinal absorption of dietary glucose or by hepatic glucose production from its precursors, for example, carbohydrates (glycogen, fructose, galactose) and amino acids (gluconeogenesis). The dietary sources of supply of carbohydrates are especially variable among the various species. The absorptive process varies with the degree of systemic hormonal activity (e.g., thyroid) and gastrointestinal hormone activity (e.g., secretin). All conditions affecting gastrointestinal digestive processes (e.g., gastrointestinal acidity, digestive enzymes, disease) substantially affect absorption of glucose. Hence, it is important to evaluate the blood glucose in virtually all diseases.

In the postabsorptive state, hepatic production is the major source of supply for maintaining blood glucose. The hormones epinephrine and glucagon promote the release of glucose from glycogen as described in Section IV.C.2. The glucocorticoids promote gluconeogenesis and oppose the hypoglycemic action of insulin.

Removal of glucose is governed by a variety of factors, most of which ultimately relate to the rate of utilization of glucose. All tissues constantly utilize glucose either for energy purposes or for conversion into other products (glycogen, pentoses, lipids, amino acids). Therefore, an outflow of glucose from the circulation that is governed by the rate of utilization of glucose by a tissue occurs at all times. The level of blood glucose itself partially governs the rate of utilization and therefore, in a sense, is autoregulatory. At high levels, the rate of glucose uptake by tissues such as muscle and liver increases due to mass action. The presence of insulin increases the rate of glucose utilization, either by increased transport (muscle, fat) or increased phosphorylation (liver). The action of insulin is opposed by the diabetogenic factors, growth hormone, glucagon, cortisol, and epinephrine.

The liver occupies a central position in the regulatory mechanism of blood glucose concentration because it supplies and also removes glucose from the system. The major direction of liver glucose metabolism is directed toward supplying rather than using glucose. When liver takes up glucose, 25% is oxidized to lactate or CO_2 and the remainder forms glycogen. This glycogen is the source of the glucose supplied by the liver to the system during the better part of a day. Muscle, on the other hand, does not contain G-6-Pase, cannot provide free glucose, and is therefore primarily a glucose utilizing tissue.

TABLE 3.6 Renal Thresholds for Glucose in Domestic Animals

Species	Thresholds		Reference
	mg/dl	mmol/liter	
Dog	180–220	10.0–12.2	Shannon *et al.* (1941)
Horse	180–200	10.0–11.1	Stewart and Homan (1940)
Cow	98–102	5.4–5.7	Bell and Jones (1945)
Sheep	160–200	8.9–11.1	McCandless *et al.* (1948)
Goat	70–130	3.9–7.2	Cutler (1934)

C. The Role of the Liver

The glucose transporter system across the membrane is rate limiting in peripheral tissues that are sensitive to insulin (muscle, fat). In the liver, however, glucose moves freely across the plasma membrane so this process is not rate limiting at this point. At a blood glucose level of approximately 8.33 mmol/liter (150 mg/dl), the liver does not take up or supply glucose to the circulation. This level is termed the *steady state* or the *glucostatic level* at which the mechanisms of normal supply and removal of glucose are operating at equal rates. Above 8.33 mmol/liter (150 mg/dl), glucose removal is greater than supply; below 8.33 mmol/liter (150 mg/dl), glucose supply is greater than removal. But the fasting blood glucose level in most animals is about 5 mmol/liter (90 mg/dl). This means that the liver supplies glucose throughout most of a day except for the few periods during the day when blood glucose is greater than the steady-state level of 8.33 mmol/liter (150 mg/dl). These periods are the few hours after each meal during a day.

Insulin decreases liver glucose production, output, and glycogenolysis while increasing liver glucose utilization. The net result is an increase in glucose uptake by the liver with increased glucose oxidation, glycogenesis, and hypoglycemia. This directional control is due to the action of insulin on key enzymes of glucose metabolism.

Directional control for glucose production or utilization is governed by coupled sets of opposing and irreversible enzyme reactions at three control points of glucose metabolism. These "key enzyme" couples are GK/G-6-Pase, PFK/F-1-6-Pase, and the PK/PEPCK, PC. The kinases direct metabolism toward glycolysis utilization because they are phosphorylating enzymes and the opposing enzymes reverse the direction so they are gluconeogenic.

The insulin sensitivity of the rate-limiting GK reaction in liver promotes glucose utilization. The opposing G-6-Pase reaction increases during fasting or starvation, which favors liver glucose production. In diabetes mellitus, even though there is a hyperglycemia >8.33 mmol/liter (150 mg/dl), G-6-Pase is increased. Increases in the other key enzymes of gluconeogenesis, F-1-6-Pase, PEP-CK, and PC, are also observed in diabetes. Increases in activity of these gluconeogenic enzymes in insulin deficiency direct metabolic pathways toward excessive production of glucose by the diabetic liver.

The amelioration of diabetes in an experimental animal by hypophysectomy (Houssay animal) is well established. The pituitary factor, which opposes the action of insulin, is growth hormone. The glucocorticoids increase gluconeogenesis and intracellular G-6-P and, by their insulin opposing effect, increase free glucose. An increase also results from the glycogenolytic action of epinephrine and glucagon, and the equilibrium is shifted to favor glucose production. Therefore, it is the balance of hormones that directly (insulin) or indirectly (epinephrine, growth hormone, glucagon, cortisol) affects glucose metabolism, which sets the "steady-state blood glucose" at which the liver uses glucose or produces glucose.

D. Glucose Tolerance

The regulatory events that occur in response to changes in blood glucose concentration are best summarized by a description of the events following ingestion of a test dose of glucose. When administered orally to a normal animal, a typical change in blood glucose concentration with time is observed as shown in Fig. 3.12. During the absorptive phase, phase I, the rate of entry of glucose into the circulation exceeds that of removal and the blood glucose rises. As the blood glucose rises, hepatic glucose output is inhibited and the release of insulin from the pancreas is stimulated by the rising blood glucose. This release of insulin is also influenced by the insulin releasing effect of the GI hormones, secretin, CCK-PZ, and gastrin, and by pancreatic glucagon. In 30–60 minutes, the peak level of blood glucose is reached, after which it begins to fall. During this phase of falling blood glucose, phase II, the rates of removal now exceed those of entry and the regulatory mechanisms directed toward removal of glucose are operating maximally. At the same time, hepatic glucose output decreases and the blood glucose falls rapidly. When the blood glucose reaches its baseline level, it continues to fall below the original level for a short time and then returns to its baseline level. This hypoglycemic phase (phase III) is due to the inertia of the regulatory mechanisms because, in general, the higher the glycemia, the greater the subsequent hypoglycemia. Clinically, this postinsulin hypoglycemia can be marked if there is a defect in the secretion of glucagon.

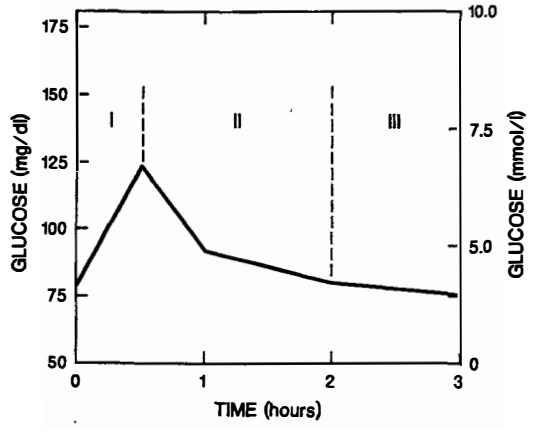

FIGURE 3.12 Oral glucose tolerance in the dog. I, II, and III are phases of the curve.

VIII. METHODOLOGY

A large number of tests have been devised to evaluate the status of the carbohydrate economy of animals but the principal focus continues to lie with the determination of blood glucose levels. The *o*-toluidine, hexokinase, glucose dehdrogenase, and glucose oxidase methods are the four most widely used methods for blood glucose and are used in manual, automated, and point-of-care testing modules.

A. Blood Glucose

1. Methods

The *o*-toluidine (*o*-T) method is still used in some blood chemistry kit systems and in some automated analyzers. The *o*-T condenses with glucose in glacial acetic acid to form a blue green color. It is specific for aldose sugars, galactose, and mannose, and because blood contains no significant amounts of aldoses other than glucose, the values are taken as "true glucose."

Three glucose-specific enzyme methods are in use: the glucose oxidase (GO), HK, and GD methods. The GO method is coupled with peroxidase and a dye. GO catalyzes the conversion of glucose to gluconic acid:

$$\text{Glucose} \xrightarrow{\text{GO}} \text{gluconic acid} + H_2O_2.$$

The hydrogen peroxide, with peroxidase, oxidizes a dye to form a colored product. This principle is also

used in the glucose-specific paper strips for urine glucose.

In the HK method, HK catalyzes the phosphorylation of glucose and the reaction is coupled to a reaction such as G-6-PD for assay:

$$\text{Glucose} + \text{ATP} \xrightarrow{\text{HK}} \text{G-6-P} + \text{ADP},$$

$$\text{G-6-P} + \text{NADP} \xrightarrow{\text{G-6-PD}} \text{6-PG} + \text{NADPH}.$$

Either NADP or NADPH is measured spectrophotometrically.

In the GD method, GD catalyzes:

$$\text{Glucose} + \text{NAD} \xrightarrow{\text{GD}} \text{gluconolactone} + \text{NADH}$$

and NAD or NADH is measured spectrophotometrically.

Of these enzymatic methods, the method of Banauch *et al.* (1975) was found to be best for the quantitative assay of urine glucose (Kaneko *et al.*, 1978a).

No matter how accurate the method for blood glucose, it cannot compensate for loss of glucose in an improperly handled blood sample. Glucose breakdown (i.e., glycolysis) by red blood cells takes place very rapidly, about 10% per hour loss, at room temperature and is even more rapid if the sample is contaminated by microorganisms. For these reasons, the plasma or serum must be separated from the RBCs as quickly as possible, within one-half hour; otherwise, the glucose in the blood sample must be protected from glycolysis. This is best accomplished by refrigeration or by the use of sodium fluoride (NaF) (10 mg/ml blood). The NaF acts both as an anticoagulant and a glucose preservative. The NaF can also be added to a blood sample vial containing an anticoagulant.

2. *Blood Glucose in Animals*

The normal ranges for blood glucose are given in Table 3.7 and in Appendices VIII, IX, X, and XI. A standard sampling procedure must be used to obtain optimum results and to minimize variations in blood glucose, especially those due to diet. This is best accomplished in the nonruminant and in the young ruminant by a standard overnight (12–16 h) fast prior to sampling. This is not necessary in the mature ruminant because feeding elicits no blood glucose response. Methods for establishing statistically valid reference ranges for analytes such as blood glucose, with examples, are given in Chapter 1.

B. Indirect Monitoring of Blood Glucose

The phenomenon of glucose molecules irreversibly binding to proteins is widespread in biological systems and the products are known as *glycated proteins.* The glucose molecules are covalently bound to free amino groups of a protein (i.e., lysine and valine) by a nonenzymatic glycation mechanism. The glycated intermediate in the reaction is unstable and immediately undergoes a classic Amadori rearrangement to form a stable ketoamine. The carbon backbone of this ketoamine is identical to fructose. When the protein of the protein–ketoamine complex is hemoglobin (Hb), the product is called hemoglobin Alc (HbAlc) because it was first identified as a fast moving minor Hb component by electrophoresis. When the protein of the complex is albumin or total serum protein, the product is called fructosamine (FrAm) (Armbruster, 1987). When the albumin–ketoamine is specifically measured, the product is sometimes called glycoalbumin (Galb).

The binding of glucose to proteins occurs firmly and constantly over the lifespan of a particular protein. Therefore, these glycated proteins reflect the average blood glucose concentration over the half-life of the protein. Thus, they offer a means and are used to evaluate long-term average blood glucose levels in diabetics.

TABLE 3.7 Blood Glucose Levels in Domestic Animals[a]

Species	Glucose (Reference Range and Mean ± SD)	
	mmol/liter	mg/dl
Horse	4.2–6.4	75–115
	(5.3 ± 0.4)	(95 ± 8)
Cow	2.5–4.2	45–75
	(3.2 ± 0.4)	(57 ± 7)
Sheep	2.8–4.4	50–80
	(3.8 ± 0.3)	(68 ± 6)
Goat	2.8–4.2	50–75
	(3.5 ± 0.4)	(63 ± 7)
Pig	4.7–8.3	85–150
	(6.6 ± 0.9)	(119 ± 17)
Dog	3.6–6.5	65–118
	(5.0 ± 0.4)	(90 ± 8)
Cat	2.8–4.2	50–75
	(3.5 ± 0.4)	(63 ± 7)
Monkey (*Macaca sp.*)	4.7–7.3	85–130
	(5.9 ± 0.7)	(107 ± 13)
Llama	5.7–8.9	103–160
	(7.1 ± 0.9)	(128 ± 16)
Rabbit	2.8–5.2	50–93
	(4.1 ± 0.5)	(73 ± 10)

[a] Plasma or serum, glucose oxidase method, adult animals.

1. *Hemoglobin Alc*

In the case of canine HbAlc where the canine erythrocyte has a lifespan of 100 days and a half-life of about 60 days, HbAlc reflects the average blood glucose over the previous 2 months prior to sampling. In the cat, with an erythrocyte lifespan of 70 days and a half-life

of about 40 days, HbAlc could be used as a measure of the average blood glucose over the previous 6 weeks. This means that bimonthly samplings for the dog and 6 weekly intervals in the cat for HbAlc could be used to monitor long-term blood glucose control. The use of HbAlc is a well-established means for monitoring long-term average blood glucose in human diabetics. The techniques for measuring HbAlc, however, have not been applicable to animals. The methods are complex as well as labor and equipment intensive. The methods all rely on the structural properties of HbAlc for their separation so that methods for human HbAlc are not directly applicable to animal HbAlc. Methods used for human HbAlc are affinity and ion-exchange high-performance liquid chromatography (HPLC), electrophoresis, immunoassay, and colorimetry to measure 5- hydroxymethylfurfural-thiobarbituric acid (HMF-TBA). Of these, the HPLC method is most widely used in humans. A report evaluating a number of methods for canine HbAlc indicated that the HMF-TBA method is the most promising (Hooghuis *et al.*, 1995).

Because HbAlc is directly related to the amount of red cells, anemias or polycythemias must be ruled out. Also, bimonthly samplings may not detect the long-term changes in glucose in a timely manner.

2. *Fructosamine*

The total serum proteins or albumin have half-lives of 2–3 weeks and 7–9 days, respectively. This means that FrAm or Galb could be used as indicators of the average blood glucose over the previous 2 weeks. This biweekly time interval has the advantage of detecting changes in glucose control more quickly than HbAlc and allows for timely clinical intervention. Furthermore, the FrAm assay is a colorimetric assay based on its reducing properties so it is an assay readily performed in any clinical laboratory. An improved version of the original kit is now available from the manufacturer (Roche Diagnostic Systems, Inc., Rahway, NJ). Using this improved version, Jensen and Aaes (1992) report a reference range for FrAm in dogs of 259–344 μmol/liter (301 $\pm$ 21.3 μmol/liter). This result is lower than that originally reported for dogs by Kawamoto *et al.* (1992) of 1.7–3.38 mmol/liter (2.54 $\pm$ 0.42 mmol/liter) by a factor of about 10. This difference is attributable to the different substrates used in the assays. The reference range for cats as reported by Kaneko *et al.* (1992) is 2.19–3.47 mmol/liter (2.83 $\pm$ 0.32 mmol/liter).

C. Tolerance Tests

1. *Glucose Tolerance Tests*

Glucose tolerance (GT) in its original definition referred to the amount of glucose that could be ingested by an animal without producing a glucosuria, hence, tolerance for glucose. Since in the normal animal, the absence of a glucosuria indicates only a limited rise in blood glucose where the renal threshold is not exceeded, GT now refers to the blood glucose curve following glucose administration. Accordingly, an animal with an increased glucose tolerance is one that has a limited rise and rapid fall in blood glucose, that is, can tolerate extra glucose. The animal with a decreased tolerance has an excessive rise and a slow return to its baseline level, that is, cannot tolerate extra glucose. This is the typical diabetic type of GT curve.

It is important to ascertain the nature of the animal's diet, especially in omnivores and carnivores, prior to performance of this test. A carbohydrate-only diet favors a minimum rise in the tolerance curve, whereas a carbohydrate-free diet (meat only) favors a high or diabetic type of glucose tolerance curve. Therefore, for optimum results, the diet must be standardized by placing the dog on a standard diet of 100–200 g carbohydrate plus fat and protein per day for 3 days prior to performance of the test. The GT curve is also affected by the status of the intestinal absorptive process, that is, inflammation, increased motility, thyroxine. Furthermore, the variations due to absorption and the excitement attending intubation or tranquilization can be avoided by use of the intravenous test.

a. Oral Glucose Tolerance Test

In Section VII.D the blood glucose curve following the oral administration of a test dose of glucose was described. The oral glucose tolerance test is ineffective in the ruminant because the ingested carbohydrate is almost totally fermented by the rumen microflora. The OGTT has been used in dogs by feeding of a test meal consisting of 4 g glucose/kg body weight mixed with a few grams of horse meat. A fasting blood sample is taken, the test meal given and blood samples are taken at 30-minute intervals for 3 hours. The OGTT curves in dogs receiving a standard daily diet of either glucose or galactose with meat had normal curves as described in Section VII.D. The maximum level, 6.6–7.7 mmol/liter (120–140 mg/dl) was reached at 1 hour and returned to the fasting level, 3.6–5.3 mmol/liter (65–95 mg/dl), in 2–3 hours. The OGTT may be simplified by taking a single sample at 2 hours after giving the glucose, that is, 2 hours postprandial glucose. A normal blood glucose level at 2 hours postprandially indicates that diabetes is unlikely. A hyperglycemia at 2 hours is indicative of a diabetic curve and should be confirmed with the complete GTT. The insulin response curve during the OGTT can also be evaluated In the OGTT, for a given level of blood glucose, the total insulin secretion (TIS) is greater than in the

IVGTT. This is most likely due to the insulin releasing effect of the gut hormones (Section VII.D).

b. Intravenous Glucose Tolerance Test and the Insulin Response

The intravenous glucose tolerance test in animals must also be standardized for best results (Kaneko *et al.*, 1978a). This is necessary because glucose clearance half-times ($T_{\frac{1}{2}}$) and urinary glucose losses are directly proportional to the glucose dose. The recommended method gives optimal results because (1) it does not overload the animal with glucose, (2) the infusion can be given easily within the time limits, (3) the blood glucose level is high enough to give a maximal insulin response, and (4) urinary loss of glucose is minimal. After a standard overnight (12–16 hour) fast (except for an adult ruminant) a zero-time heparinized blood sample is taken. Next, 0.5 g glucose/kg body weight is infused IV as a sterile 50% solution in 30 seconds. Timing of the test is begun at the midpoint or at 15 seconds after start of the injection. In large animals, the glucose is given within 2–3 minutes or more quickly if possible. Subsequent blood samples are taken at 5, 15, 25, 35, 45, and 60 minutes. The results are plotted on semilogarithmic coordinates from which the time required for the glucose concentration to fall by one-half, the $T_{\frac{1}{2}}$, is graphically estimated between 15- and 45-minutes postinfusion. From the $T_{\frac{1}{2}}$, the fractional turnover rate, k, can also be calculated:

$$k = \frac{0.693}{T_{\frac{1}{2}}} \times 100 = \%/\text{minute}.$$

The fractional turnover rate, k, can also be calculated without graphing the data and using the relationships:

$$k = \frac{\ln 1 - \ln 2}{T_2 - T_1} \times 100 = \%/\text{minute}.$$

From the k value, the $T_{\frac{1}{2}}$ may be calculated:

$$T_{\frac{1}{2}} = \frac{0.693}{k} \times 100 = \text{minutes}.$$

The fractional turnover rate has been variously expressed as the glucose turnover rate, the glucose disappearance rate, the glucose disappearance coefficient or simply as the k value. The normal $T_{\frac{1}{2}}$ and k in dogs are 25 ± 8 minutes and 2.76 ± 0.91%/minute, respectively (Kaneko *et al.*, 1977). The diabetic animal with a decreased glucose tolerance has a longer $T_{\frac{1}{2}}$ and lower k.

The method is equally applicable to and the only practical method in large animals. The k value in a spontaneously diabetic cow was 0.38%/minute ($T_{\frac{1}{2}}$ = 182 minutes) as compared to a normal of 1.98%/minute ($T_{\frac{1}{2}}$ = 35 minutes) and was comparable to the k values obtained using ^{14}C glucose.

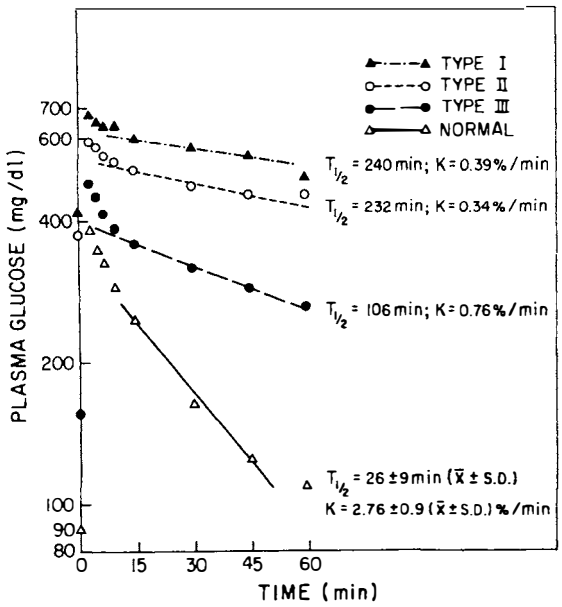

FIGURE 3.13 The IVGTT in normal dogs and in dogs with various types of diabetes mellitus. From Kaneko *et al.*, (1977).

Standardization of the IVGTT as described also has the advantages that an adequate insulin response is provoked, the influence of urinary glucose loss is minimized, and reproducible clearance values are obtained (Fig. 3.13). Other areas of the IVGTT with diagnostic significance for diabetes are the 5-minute peak, which is inordinately high and the 60-minute glucose level, which has not returned to the preinfusion level.

The insulin response curve to the glucose load is obtained from the same samples as is done for glucose (Fig. 3.14). In the normal response curve to a glucose load, the peak insulin response occurs at 5 minutes

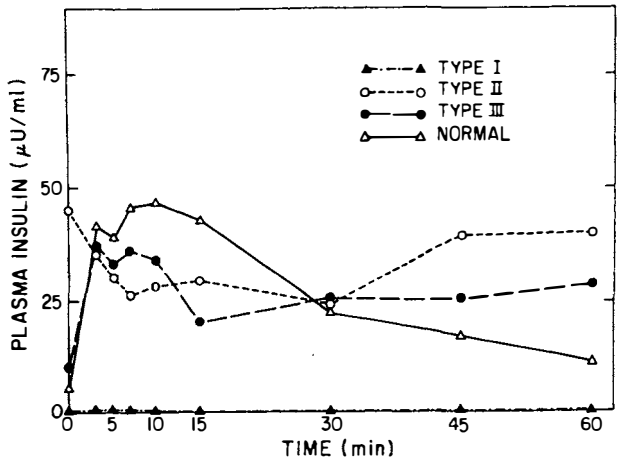

FIGURE 3.14 The insulin response during the IVGTT in normal dogs and in dogs with various types of diabetes mellitus. From Kaneko *et al.*, (1977).

followed by a return to normal at 60 minutes (Kaneko *et al.*, 1977). The early 5-minute peak is due to the stimulation of release of stored insulin by the β cells by glucose. In humans, a second peak is seen at 20–30 minutes, which is attributed to the de novo synthesis of insulin by the β cells. This peak has not been experimentally discernible in dogs (Kaneko *et al.*, 1978b).

The IVGTT and the insulin response are of greatest value in the diagnosis of diabetes, particularly those cases with a mild hyperglycemia and without persistent glucosuria. Furthermore, the insulin response to the IVGTT allows for the accurate differentiation of the different types of diabetes. This has great significance because the Type II diabetic can potentially respond to oral hypoglycemic therapy. Decreased tolerance is also observed, though less consistently, in hyperthyroidism, hyperadrenalism, hyperpituitarism, and in severe liver disease. An increased tolerance is observed in hypofunction of the thyroids, adrenals, pituitary, and in hyperinsulinism.

2. *Insulin Tolerance Test*

The blood glucose response of a normal animal after the administration of a test dose of insulin exhibits a characteristic response as shown in Fig. 3.15. After obtaining a fasting blood sample, 0.1 unit of crystalline zinc insulin per kilogram body weight is injected intramuscularly or subcutaneously and blood samples are taken every 30 minutes for 3 hours. The test measures (1) the sensitivity of the blood glucose level to a test dose of insulin and (2) the response of the animal to insulin-induced hypoglycemia. Normally, the blood glucose level falls to 50% of its fasting level in 20–30 minutes and returns to its fasting level in 1.5–2 hours. Two types of abnormal responses are seen. If the blood glucose level does not fall by 50% or requires longer than 30 minutes to reach the maximum hypoglycemic level, the response is described as *insulin insensitive* or *insulin resistant.* Insulin resistance is found, though inconsistently, in hyperfunction of the pituitary and adrenals. This test has not been used in the Type II diabetic dog or cat but may be of value in evaluating insulin resistance in this type.

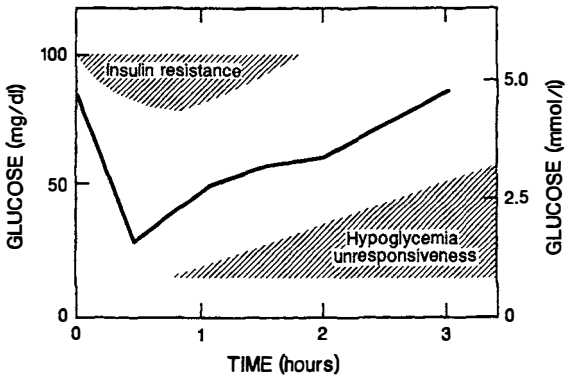

FIGURE 3.15 Insulin tolerance in the dog. Curves falling in the shaded areas are described as noted.

If the hypoglycemia is prolonged and fails to return to the fasting level in 2 hours, the response is described as *hypoglycemia unresponsiveness.* This type of response may be observed in hyperinsulinism, hypopituitarism, and hypoadrenalism and is most often used in suspected cases of the latter two diseases. An inability to secrete sufficient glucagon by the pancreatic δ cells may also be a significant factor in the unresponsiveness. In carrying out this test, because a hypoglycemia is being induced, a glucose solution should be readily available for injection.

3. *Glucagon Stimulation Test*

Glucagon via hepatic glycogenolysis and gluconeogenesis has a hyperglycemic effect that in turn evokes an insulin response. In addition, glucagon is an insulin secretagogue second only to glucose. These are the bases for the glucagon stimulation test (GST) and has been used for the diagnosis of diabetes in cats (Kirk *et al.*, 1993). The test is performed by the IV injection of 30 μg glucagon/kg body weight. Samples for blood glucose and insulin are obtained before injection (0 time) and at 5, 10, 15, 30, 45, and 60 minutes after injection. In cats, the peak insulin response was observed at 15 minutes followed by a rapid decline to baseline levels at 60 minutes. The insulin response curve was flat in the Type I diabetic cats, whereas controls, obese, and Type II diabetic cats had comparable 15-minute peaks and declines to baseline at 60 minutes.

Samplings at half hourly intervals can be continued for up to 3 hours in suspected hyperinsulinism. An exaggerated 15-minute insulin response followed by a marked hypoglycemia at 2–3 hours or longer are characteristic of pancreatic islet cell tumors (Johnson and Atkins, 1977). However, Kruth *et al.* (1982) found that the GST was not diagnostic for these cases.

4. *Epinephrine Tolerance Test*

Epinephrine also has a postinjection hyperglycemic effect via hepatic glycogenolysis. The blood glucose level rises to a maximum of 50% above the fasting level in 40–60 minutes and returns to the original level in 1.5–2 hours. The test is performed by obtaining a fasting blood sample (0 time), injecting 1 ml of 1:1000

epinephrine-HCL (in the dog) intramuscularly and obtaining blood samples every 30 minutes for 3 hours.

The characteristic increase in blood glucose is used as an index of the availability of liver glycogen for the production of blood glucose. On the basis of a lowered response to epinephrine, liver glycogen can indirectly be shown to be depleted in bovine ketosis. This can be confirmed directly by measurement of glycogen in biopsy samples. A lowered glycemic response is also a characteristic response of the glycogen storage diseases where glycogenolysis is inhibited by enzyme deficiencies.

5. Leucine-Induced Hypoglycemia

The oral administration of L-leucine induces a marked and persistent hypoglycemia in hyperinsulinism due to pancreatic islet cell tumors. The hypoglycemia is associated with a rise in plasma insulin due to increased release of insulin by the tumorous islet cells. The test is performed by the oral administration of 150 mg L-leucine/kg body weight as an aqueous suspension to the fasting dog. A fasting blood glucose sample is taken before administration (0 time) and every 30 minutes for 6 hours. A hypoglycemic effect is seen quickly at 0.5–1 hour and may persist for as long as 6 hours in hyperinsulinism. The normal dog exhibits no hypoglycemic effect.

6. Tolbutamide Test

The intravenous administration of tolbutamide, an oral hypoglycemic agent, induces the release of insulin from the pancreas and is used as a test of the availability of insulin from the pancreas. The blood glucose curve during the test parallels the insulin tolerance test. This test has not been used in animals.

D. Ketone Bodies

The methodology and role of ketone bodies in the carbohydrate economy of animals in health and disease are discussed in the chapter on lipid metabolism. The major ketone bodies are acetone, AcAc, and 3-OH-butyrate (3-OH-B). The 3-OH-B is the precursor of acetone and AcAc so that the measurement of any or all in body fluids is a standard method to evaluate ketosis and ketoacidosis. Additionally, 3-OH-B constitutes one-half or more of the total ketone bodies. Recently, a point-of-care enzymatic and colorimetric method has been developed for assay of plasma 3-OH-B (GDS Diagnostics, Elkhart, IN). The method is based on the enzyme 3-OH-B dehydrogenase (3-OH-BD) and nitroblue tetrazolium (NBT):

$$\text{3-OH-butyrate} + \text{NAD}^+ \xrightarrow{\text{3-OH-BD}} \text{acetoacetate} + \text{NADH} + \text{H}^+$$

$$\text{NADH} + \text{NBT (ox)} \xrightarrow{\text{diaphorase}} \text{NAD}^+ + \text{NBT (red)}.$$

A rapid, reliable method would have decided advantages in the management of diabetic ketoacidosis, bovine ketosis, and ovine pregnancy toxemia.

IX. DISORDERS OF CARBOHYDRATE METABOLISM

Although alterations in blood glucose levels occur in a wide variety of disease states, they are of particular importance in the endocrine disorders. Normal blood glucose levels are the result of a finely balanced system of hormonal interaction affecting the mechanisms of supply and removal from the circulation. When a hormonal imbalance occurs, a new equilibrium is established. Whether this equilibrium is clinically evident as a persistent hypoglycemia or hyperglycemia depends on the total interaction of the hormonal influences on carbohydrate metabolism. Further discussions concerning the disorders of the pituitary, adrenals, and the thyroids are given in their respective chapters. The following sections discuss the conditions in which the principal manifestations are closely related to derangements in carbohydrate metabolisms.

A. Diabetes Mellitus

Although diabetes mellitus has been reported in virtually all laboratory animals (gerbils, guinea pigs, hamsters, mice, rats, nonhuman primates) and in horses, cattle, sheep, and pigs, it is most frequently found in dogs and cats. Estimates of the incidence of diabetes range as high as 1:66 (1.52%) for dogs and 1:800 for cats. Diabetes mellitus in animals has been frequently reviewed (Cotton *et al.*, 1971; Foster, 1975; Ling *et al.*, 1977; Engerman and Kramer, 1982; Kaneko and Howard, 1989).

1. Natural History of Diabetes

The disease in dogs occurs most frequently in the mature or older female, often in association with estrus, and in all breeds. In contrast, male cats appear to be more commonly affected than females. In the dog, diabetes is frequently associated with obesity and it is now known that obesity is the single most important contributing factor to the development of diabetes (Mattheeuws *et al.*, 1984). In the obese cat, the GTT is significantly impaired, suggesting that obesity also

predisposes cats to diabetes (Nelson *et al.*, 1990). The obese cat also has a GST response like that of the Type II diabetic (Kirk *et al.*, 1993). Little is known of the genetic aspects of diabetes in animals as compared to humans in which the hereditary predisposition is well known. Insulin genes are identified, cloned, and human insulin produced by biotechnology that is now widely used. Diabetes has, however, been reported in the offspring of diabetic dogs (Gershwin, 1975; Kaneko *et al.*, 1977). Kramer (1977, 1981) and Kramer *et al.* (1980) reported their observations on hereditary diabetes in a family of keeshonds and Williams *et al.*, (1981) reported hereditary diabetes in golden retrievers.

On the basis of serum insulin (I) response patterns during the IVGTT, diabetes mellitus of dogs can be divided into at least three types, Types I, II, and III (Table 3.8; Kaneko *et al.*, 1977, 1979). Type I dogs are characterized by no or very low initial *I* (I^0) level and no *I* response to the glucose load similar to juvenile diabetes (Type I) in children. Type II is characterized by a normal or high I^0 and, again, no increment of *I* response to the glucose, which are features of the maturity onset form (Type II) of diabetes in humans. Type III is characterized by a normal I^0, a normal or delayed *I* response to the glucose, and a delayed return of *I* to normal at 60 minutes as seen in chemical diabetes (Type III). Types II and III were each later further subdivided into the obese and nonobese types (Mattheeuws *et al.*, 1984).

All diabetics are glucose intolerant so their separation into the various types depends on their insulin response patterns in the IVGTT. The importance of defining their type is the likelihood that Types II and III obese diabetics are the most likely subjects for successful dietary therapy and/or oral hypoglycemic therapy. Nelson *et al.* (1993) have successfully treated some diabetic cats with oral sulfonylureas.

It is also likely that in the natural history of diabetes, Type III (chemical) diabetes precedes the development of Types I and II depending on the nature of the insulin deficiency, whether absolute (Type I) due to islet cell absence or relative (Type II) due to insulin antibodies, receptor defects, or deficiencies.

2. *The Etiology of Diabetes*

The most frequent contributory factors to the onset of diabetes are pancreatitis, obesity, infection, stress, and estrum. The possibility of a viral etiology has also been reviewed (Steinke and Taylor, 1974), and Yoon *et al.* (1979) isolated a virus from a patient who died and the virus produced diabetes in mice.

Currently, autoimmunity is considered to be the fundamental cause of Type I diabetes, possibly as an aftermath to the viral infection. Autoimmunity is evidenced by the lymphocytic infiltration associated with immune processes, and lymphocytic infiltration is found in diabetes of cattle and humans. It is also observed in cattle or rabbits immunized with bovine insulin. Eisenbarth (1986) reviewed the evidence that Type I diabetes in the biobreeding (BB) rat and the nonobese diabetic (NOD) mouse and Type I diabetes of humans is an autoimmune disease. Taniyama *et al.* (1995) found lymphocytic infiltration in all pancreata of four diabetic cattle and their studies were suggestive of Type I diabetes as an autoimmune disease.

In the cat, several studies indicate that there is a strong correlation between pancreatic insular amyloidosis and diabetes although the amyloid does not appear to be the primary cause (O'Brien *et al.*, 1985).

The high estimates of the incidence of diabetes is an indication of its importance as a clinical disease entity. Furthermore, the similarities of the clinical picture of diabetes with other wasting diseases characterized by polyuria and polydypsia attest to the importance of laboratory examinations for the early and accurate diagnosis of diabetes. In no other disease is an understanding of the metabolic alternations so important in diagnosis and proper treatment.

The fundamental defect in diabetes mellitus is an absolute (due to absence of pancreatic β cells) or relative (insulin resistance due to insulin antibodies, receptor defect, or deficiency) lack of insulin resulting in an

TABLE 3.8 Diagnostic Criteria for Types of Diabetes Mellitus in Dogs

	IVGTT			Insulin[a]		
Diabetes type	Fasting glucose G_0 (mg/dl)	$T_{\frac{1}{2}}$ (m)	k (%/min)	Fasting insulin I_0 (μU/ml)	Peak insulin I_0 (μU/ml)	$\Delta I/\Delta G$
I	>200	>70	<1.0	L	L	L
II	>200	>70	<1.0	N, H	L	L
III	100–200	>45	<1.5	N, H	N, D	L, N
Normal	70–110	15–45	>1.5	N	N	N

[a] N, normal; L, low; H, high; D, delayed.

inability to utilize glucose. The lack of insulin using the bioassay technique was demonstrated in the early 1960s in the diabetic cow by the failure of the IVGTT to elicit a serum insulin response. The development of the RIA technique has since provided the impetus for modern advances in diabetology. Using the IVGTT and the serum insulin response, diabetes mellitus in dogs has been classified into Types I, II, and III. In all types, the inability to utilize glucose or glucose intolerance is evident in the IVGTT. In the absence of insulin, the inability of the diabetic animal to utilize glucose is clearly shown in its inability to convert glucose-^{14}C to $^{14}CO_2$ (Phillips *et al.*, 1971). This inability is corrected by insulin. The inability to utilize glucose is reflected in the clinical signs of diabetes, loss of weight, polyuria, polydypsia, and in the advanced stages, ketoacidosis.

Several reports have suggested that the development of diabetes mellitus is the result of the interaction of several hormones, principally insulin and glucagon (Unger and Orci, 1975, 1976). Although excess glucagon is seen in diabetes and it can induce glucose intolerance or changes in diabetic control, it can do so only as long as insulin deficiency is present and pharmacological levels of glucagon are induced (Felig *et al.*, 1976). Thus, insulin deficiency is sine qua non the cause of diabetes and that while glucagon may modify the consequences, it is neither necessary nor sufficient for the development of diabetes (Felig *et al.*, 1976). The modifying action of glucagon on diabetes, however, has important implications because excess glucagon will tend to exacerbate the posthypoglycemic hyperglycemia, for example, the Somogyi effect. A deficiency of glucagon will tend to increase the effect of insulin and contribute to a prolonged hypoglycemia after treatment. Thus glucagon plays a significant role in the variability of diabetes.

3. *Hyperglycemia*

A persistent fasting hyperglycemia is the single most important diagnostic criteria of diabetes mellitus. In the normal animal, the homeostatic level of blood glucose is maintained by the equilibrium between glucose supply and removal, which in turn is based on the endocrine balance. The effect of insulin tends to lower blood glucose, whereas the opposing effects of growth hormone, glucagon, and adrenal cortical hormones tend to raise it. In the diabetic animal with an absolute or relative lack of insulin, the equilibrium is shifted to a higher level of blood glucose. Glucose utilization in the peripheral tissues is decreased while at the same time, hepatic glucose production is increased due to increases in their gluconeogenic enzyme activities.

In the diabetic, the hyperglycemia itself tends to compensate in part for the decrease in peripheral utilization. This occurs as a mass action effect, which promotes the flow of glucose into the peripheral tissues. In this way, the diabetic can continue to use some glucose when insulin is decreased but only at the expense of increased glucose production and hyperglycemia. As the deficiency of insulin progressively becomes more severe, the equilibrium level of blood glucose is established at higher and higher levels and equilibrium is never established without therapeutic intervention. Blood glucose levels in canine diabetics have reached 70 mmol/liter (1260 mg/dl). When the renal threshold of 11.1 mmol/liter (200 mg/dl) for glucose is exceeded, the diabetic is faced with excessive loss of glucose in the urine. It is evident that the blood glucose level is exquisitely sensitive to insulin and, conversely, the blood glucose level is the mainstay for monitoring the success of diabetes therapy. However, a marked posthypoglycemic hyperglycemia or the Somogyi effect has long been known to occur in humans after insulin therapy (Bolli *et al.*, 1984), which indicates that glucose regulation by insulin is not complete. This hyperglycemic effect is thought to be due to an excess of glucagon, growth hormone, adrenal cortical hormones, or epinephrine. This phenomenon has been seen in diabetic cats given an inadvertent insulin overdose (McMillan and Feldman, 1986), which points to the need for effective monitoring of diabetes.

4. *Glycated Proteins*

The biochemical and physiological bases for using glycated proteins as a monitor for long-term glucose control are now commonplace in human diabetolgy (Section VIII.B). Successful management of diabetes depends on the reliable evaluation of blood glucose levels, and any blood glucose sample only reflects the blood glucose level at the moment of sampling. An effective method for estimating the average blood glucose over an extended time period offers a way of evaluating successful insulin therapy. This can be done by use of the glycated proteins, HbA1c or FrAm. Of these, FrAm offers the most cost-effective method for evaluating the average blood glucose over the preceding 2 weeks.

a. Hemoglobin A1c

The glycated hemoglobin, HbA1c, is known to reflect the average blood glucose level over the preceding 60 days and is widely used to monitor human diabetics (Gabbay *et al.*, 1977; Bunn *et al.*, 1978; Nathan *et al.*, 1984). Several studies in diabetic dogs (Wood and Smith, 1980; Cornelius and Mahaffey, 1981) have also

shown that HbA1c is potentially useful for monitoring purposes. Although the reference values for % HbA1c differed in the two studies, 2.29% and 6.43%, the means for the diabetics were increased in each to 4.97% and 9.63%, respectively. Hooghuis *et al.* (1995), using thiobarbituric acid colorimetry (HMF-TBA), report a reference range of 1.4–3.2% HbA1c (2.3 ± 1.96 SD). Previous assays for HbA1c have been time, labor, and equipment intensive as well as giving variable results. The colorimetric HMF-TBA method shows promise of being a clinically viable method.

b. Fructosamine

The fructosamines (FrAm) reflect the average blood glucose over the preceding 2 weeks in a manner analgous to HbAlc. This means that FrAm could be used to monitor the average blood glucose on a biweekly interval. This has the advantage that changes in blood glucose can be detected more quickly than with HbAlc and allows for timely clinical intervention. Furthermore, the FrAm assay is a colorimetric assay that can be readily performed in any clinical laboratory. An improved version of the original kit is now available from the manufacturer (Roche Diagnostic Systems, Inc., Rahway, NJ). Using this improved version, Jensen and Aaes (1992) report a reference range for FrAm for dogs of 259–344 μmol/liter (301 ± 21.3 SD). This result is 10-fold lower than that originally reported by Kawamoto *et al.* (1992). The reference range for cats as reported by Kaneko *et al.* (1992) is 2.19–3.47 mmol/liter (2.83 ± 0.32 SD). In all cases, FrAm was shown to be significantly elevated in diabetes, indicating that they can be of clinical value to monitor glucose control in treated diabetics. On occasion, especially in cats, hyperglycemia and/or glucosuria is seen on initial presentation and without other indications of diabetes. A FrAm sample taken at this time can be used to differentiate a transient from a persistent hyperglycemia.

5. *Glucose Tolerance and the Insulin Response*

The GTT is the most important test of carbohydrate function and is of particular value in those cases of diabetes in which the fasting blood glucose is only moderately elevated and the diagnosis is equivocal (Section VIII.C). The diabetic oral GGT curve is high and relatively flat, indicating a decreased tolerance for glucose (Fig. 3.12). The nature of the diabetic curve can be quantitated by using the intravenous GTT. The diabetic curve is characterized by a long $T_{\frac{1}{2}}$ or low k value, which reflects the inability of the animal to use the test dose of glucose. The insulin response curve in Type I (absolute insulin deficiency) diabetes clearly demonstrates the inability of the pancreas to release insulin in response to the glucose load. It is the absence of an insulin response that is responsible for the failure of the diabetic to utilize the added glucose and the prolonged hyperglycemia occurs. An important factor adding to the hyperglycemia is the overproduction of glucose by the liver. The test dose of glucose is in effect added to the already existing oversupply of glucose. Because the steady-state level at which the liver ceases to supply or remove glucose is elevated in diabetes, the liver continues to oversupply glucose, which contributes to the slow return of the tolerance curve to its original level.

In Types II and III diabetes (discussed later), there is also glucose intolerance but this occurs in the presence of a normal to elevated insulin. This would mean that the insulin in the plasma of these types is ineffective, that is, relative deficiency, due to a number of factors including insufficient receptors, receptor blockage, abnormal receptor structure, or antibody binding all of which lead to the glucose intolerance and the phenomenon of insulin resistance. Therefore, glucose intolerance is seen in all types of diabetes whether there is an absolute (Type I) or relative (Types II and III) deficiency of insulin. The insulin response must be evaluated in order to establish the type of diabetes.

6. *Insulin and the Insulin Response*

Serum insulin is characteristically very low or absent in Type I diabetes, whereas it is normal or even very high in Types II or III. Type I diabetes can be readily differentiated from the other types by an absent or low fasting insulin level. On the other hand, about 40% of diabetics have normal to very high insulins. The classification of these diabetic types is based on the nature of the insulin response curve during the IVGTT. Type II has a normal to high insulin with no increment of insulin response to the glucose load. Type III also has a normal to high insulin; the insulin response is inadequate and there is a delayed return to preinjection levels (Kaneko *et al.*, 1977). Types II and III have been further subdivided on the basis of obesity or nonobesity (Mattheeuws *et al.*, 1984) and their insulin levels are given in Table 3.9.

The classification of diabetes into types has important therapeutic and prognostic implications. Insulin replacement therapy is the only effective treatment for the Type I and Type II nonobese diabetic. Type II obese and the Type III dogs with even a small insulin reserve would be the most likely subjects for successful oral hypoglycemic therapy. The early detection of diabetes and being able to treat these patients using oral drugs would have obvious advantages. Nelson *et al.* (1993)

TABLE 3.9 Insulin Concentrations in the Various Types of Canine Diabetes

Classification	Serum insulin (μU/ml)
Normal	5–20
Type I	0–5
Type II, nonobese	5–20
Type II, obese	20–130
Type III, nonobese	5–20
Type III, obese	8–60

have successfully treated cats with diabetes using oral hypoglycemic drugs. Prognostically, the severity of the diabetes can be assessed by the degree of glucose intolerance and the nature of the insulin response.

Atkins *et al.* (1979) identified diabetes in dogs less than 1 year of age and Atkins and Chin (1983) examined their insulin responses to glucose loading. All dogs were glucose intolerant but could mount a minimal insulin response somewhat akin to the Type II diabetic dogs. It could also be that these young diabetic dogs were identified during the early stages of their natural history of progression of their diabetes to Types I or II.

7. Glucagon Stimulation and the Insulin Response

The GST has been used in humans and cats to differentiate Type I from Type II diabetes. Type I diabetic cats have a minimal or no insulin response to glucagon. Type II diabetic cats have a significant insulin response in the GST. Nondiabetic obese cats also have an insulin response that is similar to the Type II diabetic cats. Thus, obesity is predisposing to the development of diabetes in animals as well as in humans. Type II diabetes is known to be characterized by various forms of insulin resistance (Section VIII.C.2).

8. Ketonemia and Lipemia

As the utilization of glucose progressively decreases in the diabetic, the utilization of fatty acids for energy purposes progressively increases in order to compensate. The supply of fatty acids for hepatic utilization is obtained by mobilization from the body fat depots. Mobilization progressively increases as insulin deficiency becomes more severe due to increases in hormone sensitive lipase. This enzyme is separate and distinct from the hepatic lipoprotein lipase.

In severe diabetes, hyperlipemias are often so marked that the blood appears as "tomato soup." A cream layer may separate out on storage in the cold due to hyperchylomicronemia. The plasma is turbid due to the presence of very low density lipoproteins (VLDLs). On chemical analysis, total triglycerides and cholesterol are elevated (Rogers *et al.*, 1975). Diabetic hyperlipemia appears to be caused by impaired lipolysis of chylomicra secondary to a deficiency of hepatic lipoprotein lipase rather than to an overproduction of VLDLs.

Concurrently with increased fatty acid oxidation in liver, a progressive decrease in fatty acid synthesis occurs. The net effect of the alterations in hepatic fatty acid metabolism is that AcCoA is generated in excess by the liver due to the increased rate of fatty acid β-oxidation catalyzed by the increased activity of the enzyme carnitine acyltransferase. Fatty acyl-CoA from fat mobilization is also a strong inhibitor of citrate synthase, which removes another route for disposal of AcCoA. The accumulated AcCoA units are then diverted into alternate pathways as described in Section V.B and, with the activation of ketogenic mechanisms, excessive synthesis of ketone bodies (Kreisberg, 1978) and cholesterol results. In the peripheral tissues, there is an underutilization of ketone bodies in the diabetic dog (Balasse and Havel, 1971). Ketosis is thus the result of an overproduction of ketone bodies by the liver and an underutilization by the peripheral (muscle) tissues. The Type I diabetic has a greater tendency than the Type II to develop ketoacidosis.

It has been suggested that the development of ketosis requires both a deficiency of insulin and an excess of glucagon (McGarry *et al.*, 1975; McGarry and Foster, 1976). Dobbs *et al.* (1975) and Unger and Orci (1975) proposed that diabetes develops due to a bihormonal interaction of insulin and glucagon because glucagon levels are high in insulin deficiency. The excess glucagon is thought to be caused by an abnormality in the alpha cell. There is also an excessive secretion of glucagon after protein ingestion or amino acid infusions (Unger, 1981). The excess glucagon may then exacerbate the insulin deficiency and lead to the ketoacidosis.

In the ketoacidotic state, marked cholesterolemias as high as 18 mmol/liter (700 mg/dl) have been observed in clinical diabetes of the dog. Net gluconeogenesis from fatty acid does not occur and the precursors for gluconeogenesis are the proteins. Excesses of glucagon, cortisol, and growth hormone in the diabetic also contribute to protein catabolism and gluconeogenesis. The cofactors that provide the reductive environment required for gluconeogenesis can be provided by the increased production of reduced cofactors during the increased fatty acid oxidation. This increase in the reductive environment of the cell is the mechanism that stimulates gluconeogenesis, which is corollary to the development of ketoacidosis.

9. Electrolyte Balance and Ketoacidosis

A mild glucosuria with only a few grams of glucose loss per day does not in itself precipitate the acidotic state because some compensation occurs. The liver increases its production and output of glucose even though there is a hyperglycemia so glucose metabolism continues. However, with continued and severe loss of glucose, all the attendant phenomena of attempts to compensate are exaggerated. Liver glycogen stores are depleted but liver glucose production continues to be increased due to increased protein breakdown and gluconeogenesis. The oxidation of fatty acids is accelerated and, with it, the overproduction of the acidic ketone bodies (AcAc, 3-OH-B, and acetone) occurs. The vapor pressure of acetone (bp 56.5°C) is high at body temperature and, thus, this volatile compound is often detected in the breath of the severely ketotic animal. AcAc and 3-OH-B are acidic anions that increase the "anion gap" and reduce the concentrations of HCO_3^-, Cl^-, Na^+, and K^+. Acidosis develops as the HCO_3^- is reduced and respiratory compensation is inadequate. In addition, there is an underutilization of ketone bodies in starvation (Garber *et al.*, 1974) and a similar underutilization of ketone bodies occurs in diabetes (Sherwin *et al.*, 1976). A rapid point-of-care method for quantifying 3-OH-B is now available and is expected to be very usefull in managing ketoacidosis (Section VIII.D).

In hyperketonemia, large amounts of ketones are wasted in the urine with large losses of water and HCO_3^-. The acidic ketones are buffered by ammonium ions derived from glutamine in the renal tubules, but large amounts of ketones are ultimately lost with Na^+ and K^+ in the urine. Even without ketonuria, the loss of electrolytes in the polyuria of diabetes may be considerable. Thus, the acidosis of the diabetic is a primary base deficit fundamentally related to the ketonemia and to the loss of ketones and HCO_3^- in the urine.

Excess glucose in the glomerular filtrate provokes an osmotic diuresis leading to loss of water and dehydration. The progressively severe loss of water and electrolytes and the dehydration and ketoacidosis ultimately lead to collapse, coma, and death. The condition is aggravated by renal impairment, which fortunately is not a common finding in diabetes of the dog. Not all the extracellular sodium deficit is due to urinary loss, however, because as H^+ increases, it enters the cells. In exchange, K^+ leaves the intracellular compartment and some Na^+ enters the cells. As the dehydration progresses, extracellular K^+ concentration may be very high even though there may be a total body deficit. This is an important consideration in the insulin, fluid, and electrolyte replacement therapy of diabetic ketoacidosis. The electrolyte replacement must include K^+ because correction of the acidosis and the rapid expansion of the extracellular fluid compartment leads to the reverse exchange of K^+ and this results in hypokalemia.

10. Urinalysis

The renal threshold for glucose in the dog is about 11.1 mmol/liter (200 mg/dl) so that the detection of even trace amounts of glucose in the urine is an important finding and warrants further consideration. In virtually all cases of diabetes suspected on the basis of persistent glycosuria alone, the diagnosis can be later confirmed. Renal diabetes, that is, a low renal threshold for glucose, is an extremely rare occurrence. If it does occur, it can be detected by the normal blood glucose in the presence of the glucosuria. Transient glucosurias may occur for 1–1.5 hours after a heavy carbohydrate meal, but a 2-hour postprandial glucosuria is a strong indication of diabetes.

Currently, detection of glucosuria using the urinalysis sticks is the most common method of point-of-care evaluation of the clinical success of insulin therapy. The disadvantages of this system include owner difficulties, inconsistencies, and inaccuracies. The FrAm method, whereby only biweekly blood samplings need be taken, can have decided advantages in following the course of insulin therapy.

An elevated urinary specific gravity (SG) has in the past been considered to be a good indicator of glucosuria and, hence, of diabetes. SG is a measure of the concentration of solutes in the urine, principally the cations (Na^+, K^+, NH_4^+), anions (PO_4^{2-}, SO_4^{2-}, HCO_3^-, Cl^-), and urea. The observed SG of urine is the result of the additive effect of the contributions of all these solutes. It is for this reason that the osmolality of any fluid, urine or plasma, can be estimated by simply adding the major anions and cations expressed in millimoles per liter (see the chapter on acid–base). Albumin in urine increases the SG by 0.003 units for each 10 g/liter (1 g/dl), whereas glucose increases it by 0.004 units for each 55 mmol/liter (1 g/dl). Even though the presence of glucose does increase the SG linearly, a 4^+ reaction, 140 mmol/liter (2.5 g/dl) would increase the SG by only 0.010 unit, an insignificant value on the refractometer. Therefore, although SG is a valuable measure of renal function, it is of no value with respect to the glucosuria of diabetes or to proteinuria. Conversely, by subtracting the contributions of protein and glucose from the observed SG, a more accurate measure of renal function in diabetes may be obtained.

Proteinuria is a common sign of renal disease and is often observed in diabetes in dogs. There is doubt

whether this is associated with chronic nephritis or whether it is due to renal failure as an aftermath of diabetes.

Diabetic nephropathies due to microangiopathies of the glomerular tufts and basement membrane injuries are frequent and serious complications of the chronic, poorly controlled, human diabetic. A degree of renal arteriosclerosis is common in diabetic dogs but this lesion is not comparable to the Kimmelstiel–Wilson lesion seen in humans. Also, only 1 of 10 diabetic dogs at necropsy had a significant renal lesion although most had some degree of nephritis (Cotton *et al.*, 1971). In renal function studies of experimental streptozotocin diabetes (Kaneko *et al.*, 1978b) and in spontaneous diabetes (Kaneko *et al.*, 1979), the urea, creatinine, and phosphate clearances were normal. The blood urea and creatinine concentrations were only slightly elevated and it was concluded that renal disease is not a significant complication in the dog.

The ketone bodies are very low renal threshold substances and their appearance in the urine is an early and significant sign of developing ketonemia and acidosis. They are not, however, diagnostic of diabetes because ketonuria is observed in starvation or any form of increased fat catabolism. Ketonuria is also absent in mild diabetes but ketonurias of varying degrees are common in the advanced diabetic state. Therefore, ketonurias can be useful for prognostication. Generally, the Type I diabetic is prone to ketonuria because there is an absence of insulin. In the Type II diabetic, ketonuria occurs less frequently because there is ample insulin and ketonuria is seen only when the diabetes has advanced to the point of complete failure of production. Urine pH is of little value in detecting acidosis, because only in extreme cases does the pH reflect acidosis.

11. Summary

The alterations in blood plasma that have been described are summarized in Fig. 3.16. In the diabetic state, the uptake and hence utilization of glucose by muscle and adipose tissue are depressed. In these tissues, protein and lipid breakdown are enhanced, and increased amounts of their constituent amino acids and fatty acids are released to the circulation and carried to the liver. Increased hepatic urea production results from the catabolism of these amino acids. Increases in the key gluconeogenic enzymes of the liver, G-6-Pase, PEPCK, and PC, direct glucose metabolism toward an overproduction of glucose. Simultaneously, lipogenesis is suppressed and, with the increased mobilization of fatty acids, AcCoA accumulates and is followed by increased cholesterolgenesis and ketogenesis. In the peripheral tissues there is an underutilization of ketones, all of which results in a net increase in blood ketones and subsequent ketoacidosis. Thus, diabetes mellitus is characterized by a fundamental overproduction of and an underutilization of both glucose and ketones as the result of the absolute or relative deficiency of insulin.

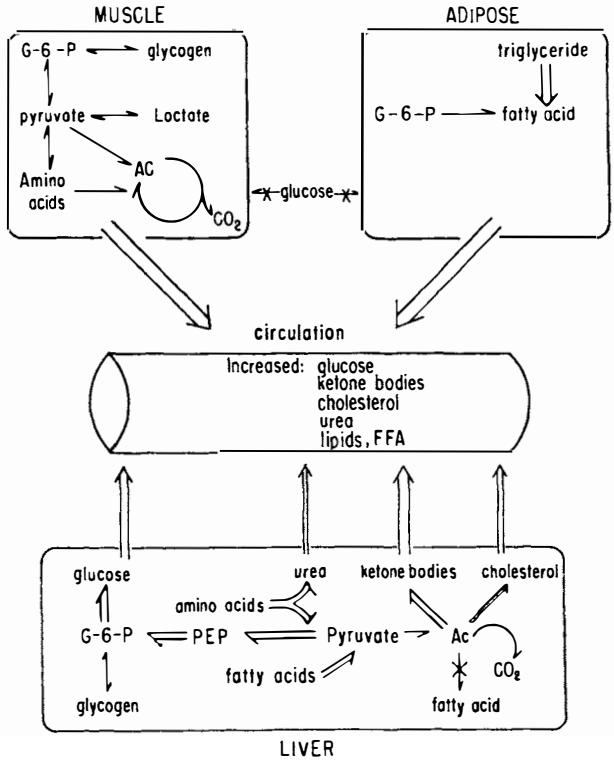

FIGURE 3.16 Summary of metabolic alterations in tissues of major importance in the diabetic animal. Increased flow in the metabolic pathways is noted by larger arrows.

B. Hyperinsulinism

After the discovery of insulin, a clinical state with marked similarities to insulin overdosage was recognized as a disease entity in humans and named *hyperinsulinism.* The disease is now known to be due to a persistent hyperactivity of the pancreas as the result of insulin-secreting islet cell tumors. Excess insulin can be extracted from metastatic foci in liver as well as from the pancreatic tumor. There are many reports on this disease in dogs (Teunissen *et al.*, 1970; Spieth, 1973; Hill *et al.*, 1974; Mattheeuws *et al.*, 1976). Priester (1974) and Kruth *et al.* (1982) reviewed pancreatic islet cell tumors in animals in the United States and Canada.

Hyperinsulinsm is characterized by a persistent hypoglycemia with periods of weakness, apathy, fainting, and during hypoglycemic crises, convulsions, and coma. A history relating the attacks to periods

after fasting or exercise provides a clinical basis for further investigations. Establishment of the diagnosis depends on finding a hypoglycemia of <3mmol/liter (<55 mg/dl) at the time of symptoms and a hyperinsulinemia, usually >20 μU/ml. The symptoms are also relieved by glucose administration. In mild cases, the fasting glucose level may be normal, in which case, diagnostic hypoglycemia may be provoked by sequentially (1) placing on a low-carbohydrate diet (meat only) with frequent feedings for 1 week, (2) placing on a 24-hour fast, and finally (3) by moderate to stressful exercise. Blood glucose is determined at the end of each step and if hypoglycemia is seen at any step, the provocation should be terminated. Serum insulin is determined at this time and a hyperinsulinemia is generally diagnostic of insulinoma. Calculations of ratios—insulin/glucose; glucose/insulin; amended insulin/glucose—do not offer any advantages over the individual insulin and glucose values.

The glucose tolerance curve is generally characteristic of an increased tolerance if the test is modified as follows: (1) The dog is on a standard carbohydrate diet for 3 days, (2) the intravenous test is used, and, most important, (3) blood sampling is continued for 6–8 hours. A prolongation of the hypoglycemic phase (phase III, Fig. 3.12) is the most significant portion of the curve.

A dog with a tendency toward persistent hypoglycemia is likely to have an abnormal response in the insulin tolerance test but this test is not a reliable test of insulinoma. The tolerance curve may have a minimal drop in blood glucose and remain below the original level for a prolonged length of time. Therefore, the curve has "insulin resistance" and "hypoglycemia unresponsiveness." Use of this test carries some risk so a glucose solution for intravenous administration should be at hand. Similarly, the glucagon stimulation test has not been a reliable test for hyperinsulinism.

The hypoglycemia that follows oral administration of leucine in children has been used in human patients with islet cell tumors. Marked hypoglycemia occurs within 30–60 minutes after L-leucine administration. Leucine-induced hypoglycemia is also associated with a rise in plasma insulin. In patients with islet cell tumors, leucine sensitivity disappeared after surgical excision of the tumor, which indicates that the tumorous islet cells alone were being stimulated by the leucine. This test has been used successfully in pancreatic islet cell tumors of dogs.

Currently, the most useful tests are the serum insulin and the fasting plasma glucose taken as described earlier. There is an inappropriately high level of insulin (>20 μU/liter) with a hypoglycemia of <3 mmol/liter (<55 mg/dl).

C. Hypoglycemia of Baby Pigs

Hypoglycemia of baby pigs occurs during the first few days of life and is characterized by hypoglycemias of <2.2 mmol/liter (<40 mg/dl), apathy, weakness, convulsions, coma, and finally death.

The newborn baby pig is particularly susceptible to hypoglycemia. At birth, the blood glucose level is >6 mmol/liter (>110 mg/dl) and, unless the pig is fed, its blood glucose drops rapidly to hypoglycemic levels within 24–36 hours. The liver glycogen, which is high (14.8%) at birth, is almost totally absent at death. In contrast, newborn lambs, calves, and foals are able to resist starvation hypoglycemia for more than a week. If the baby pig suckles, its ability to withstand starvation progressively increases from the day of birth. A 10-day-old baby pig can be starved up to 3 weeks before symptoms of hypoglycemia occur.

Gluconeogenic mechanisms are undeveloped in the newborn pig, which indicates that the gluconeogenic enzymes of the baby pig are inadequate at birth. This also indicates that these enzymes need to be induced by feeding so they can reach their maximal activities within 1 or 2 weeks after birth. The precise hepatic gluconeogenic enzymes and their induceability by feeding have not yet been identified.

The association of baby pig hypoglycemia with complete or partial starvation is shown by the findings that their stomachs are empty at necropsy and the syndrome itself is indistinguishable from experimental starvation of the newborn baby pig. Starvation of the newborn pig under natural conditions can occur due to factors relating to the sow (agalactia, metritis, etc.) or to the health of the baby pig (anemia, infections, etc.), either case resulting in inadequate food intake. The requirement for feeding to induce the hepatic gluconeogenic mechanisms in the newborn baby pig explains its inability to withstand starvation in contrast to the newborn lamb, calf, or foal, which is born with fully functioning hepatic gluconeogenesis.

D. Glycogen Storage Diseases

The glycogen storage diseases are characterized by the pathological accumulation of glycogen in tissues. Based on their patterns of glycogen accumulation, their clinical pathological findings, their enzymes of glycogen metabolism, and the structural analyses of their glycogen, the GSDs in humans have been classified into eight types (Howell and Williams, 1983). All have an autosomal recessive mode of inheritance except for GSD VIII, which is sex linked. Their glycogen structures are normal except for Types III and IV.

Type I or classical von Gierke's disease is characterized by increased liver glycogen leading to a marked hepatomegaly. There is a marked hypoglycemia and the blood glucose response to epinephrine or glucagon is minimal or absent. The liver glycogen structure is normal. The defect in this disease is a deficiency of the enzyme G-6-Pase. Type II or Pompe's disease is a generalized glycogenosis with lysosomal accumulation of glycogen and early death. The defect in this disease is a deficiency of acid-α-glucosidase (AAGase). In Type III or Cori's disease, the debrancher enzyme is deficient, which leads to the accumulation of glycogen of abnormal structure. The branches are abnormally short and there are an increased number of branch points; it is a limit dextrin and the disease is sometimes called a *limit dextrinosis*. There is a variable hypoglycemia, little or no response to epinephrine or glucagon, hepatomegaly, cardiomegaly, and early death. In Type IV or Andersen's disease the brancher enzyme is deficient, which leads to a glycogen with abnormally long branches and few branch points. It is clinically similar to Type III. In Type V or McArdle's disease muscle phosphorylase (MPase) is deficient, whereas in Type VI, it is liver phosphorylase (LPase), which is deficient. Type VII or Tarui's disease is characterized by a deficiency of muscle phosphofructokinase (PFK) with accumulation of glycogen in muscle, and Type VIII is deficient in leukocyte or hepatic phosphorylase b kinase (PBK). This disease is uniquely sex linked.

Of these eight types in humans, only Types I, II, III, and VIII are found in animals. Other forms of glycogen storage in animals are described as GSD-like based on their pathological patterns of glycogen accumulation. GSD in animals has been reviewed by Walvoort (1983).

There is an inherited PFK deficiency in the springer spaniel dog but unlike human Type VII GSD, there is no muscle pathology or glycogen accumulation in muscle. The deficiency in the dog is expressed as a hemolytic anemia caused by a deficiency of the PFK isoenzyme in the erythrocytes and is rightly considered to be an inherited erthrocyte enzyme deficiency rather than a GSD (Giger *et al.*, 1985). Mammalian PFK is present in tissues as tetramers composed of combinations of three different subunits: PFK-M (muscle), PFK-L (liver), and PFK-P (platelets). Human and dog muscle and liver have homogenous tetrameric PFK-M_4 and PFK-L_4, respectively. Human erythrocyte PFK is a mixed tetramer, PFK-L_2/PFK-M_2, whereas the dog erythrocyte PFK is a mixed tetramer, PFK-M_2/PFK-P_2 (Vora *et al.*, 1985). In PFK-M subunit deficiency in the dog erythrocyte, PFK-L replaces PFK-M; PFK-L_2/PFK-P_2. In the human erythrocyte, PFK-P replaces PFK-M; PFK-L_2/PFK-P_2. Although the substituted PFK in the erythrocyte is the same in dog or human, the deficiency in the human is expressed as a GSD, whereas in the dog it is expressed as an exertional hemolytic anemia. The anemia occurs after heavy exertional respiratory stress such as is experienced in vigorous hunting or exercise. Hyperventilation induces a respiratory alkalosis, which in turn increases the fragility of the erythrocyte and the hemolytic anemia occurs (Giger *et al.*, 1985).

A radiation-induced Type I GSD occurs as an autosomal recessive condition in the C3H mouse and is characterized by hypoglycemia, early death, and a deficiency of liver G-6-Pase (Gluecksohn-Welch, 1979).

Type II GSD has been described in Brahman cattle (O'Sullivan *et al.*, 1981), the Lapland dog (Walvoort *et al.*, 1982), and in the Japanese quail (Murakami *et al.*, 1980). In the Brahman cattle, Type II is characterized by early death, generalized glycogen deposition, and a marked decrease in AAGase activity. It is inherited as an autosomal recessive. In the Lapland dog, there is also early death, generalized glycogen deposition, hepatomegaly, and cardiomegaly. There is also a marked decrease in heart and liver AAGase. The Japanese quail with Type II is also characterized by early death, glycogen deposition in the heart, liver, and muscles, and decreased AAGase.

Type III occurs in the German shepherd dog and is characterized by early death, little or no response to epinephrine or glucagon, hepatomegaly, and cardiomegaly with glycogen accumulation. The glycogen has a limit dextrin structure and there is a very low debrancher enzyme activity in liver and muscle (Svenkerud and Hauge, 1978; Ceh *et al.*, 1976).

Type VIII is seen in the rat and the mouse. In the rat, the disease is inherited as an autosomal recessive, appears healthy but is hypoglycemic, has hepatomegaly due to glycogen accumulation in the liver, and also has a very low liver phosphorylase kinase activity (Clark *et al.*, 1980). The affected mouse is apparently healthy but has increased glycogen accumulation in the muscle with a very low muscle PBK. The inheritance is sex linked (Gross, 1975).

X. DISORDERS OF RUMINANTS ASSOCIATED WITH HYPOGLYCEMIA

A. General

The principal disorders of domestic ruminants in which hypoglycemia is a salient feature are bovine ketosis and ovine pregnancy toxemia. Pregnancy toxemia characteristically is a widespread disease of high mortality occurring in the pregnant ewe just prior to

term, the time when carbohydrate demands are highest, especially in those ewes carrying more than one fetus. Bovine ketosis, on the other hand, occurs in the high-producing dairy cow characteristically during the early stages of lactation, when milk production is generally the highest. Abnormally high levels of the ketone bodies, acetone, AcAc, 3-OH-B, and isopropanol appear in blood, urine, and the milk. These alterations are accompanied by the clinical signs of ketosis: loss of appetite, weight loss, decrease in milk production, and nervous disturbances.

The energy metabolism of the ruminant is focused on the utilization of the volatile fatty acids produced by rumen fermentation rather than on carbohydrates as in the nonruminant. The carbohydrate economy of the ruminant is significantly different from that of the nonruminant and an appreciation of these differences is important to the understanding of these metabolic disorders of the ruminant.

B. Carbohydrate Balance

1. *Glucose Requirements*

The heavy demands for glucose in early lactation and in late pregnancy are well known. In the late 1950s, Kleiber calculated that about 60% of the lactating cows' daily glucose requirement is for the production of milk. The balance sheet (Table 3.10) indicates a total daily glucose requirement of 1140 g of which 700 g appear in the milk. For sheep in late pregnancy, about one-third to one-half of the daily glucose turnover of 100 g is utilized by the fetus.

A good approach to assess the glucose requirements of an animal is to measure its turnover rate or the rate at which glucose enters or leaves the circulation. This is best measured by the use of isotopically labeled glucose and has been used in lactating cows. It has been estimated to be 1440 g/day (60 g/hour) in cows and about 144 g/day (6 g/hour) in normal pregnant ewes just prior to term.

2. *Glucose Sources*

The large amounts of indigestible carbohydrates ingested by ruminants are fermented to volatile fatty acids by the rumen microflora. Little, if any, of the digestible carbohydrates (starch, glucose) in the diet escapes this fermentation so that glucose absorption from the digestive tract accounts for virtually none of the daily glucose requirement of ruminants. However, if any glucose escapes rumen fermentation, for example, in gastrointestinal disease, it is readily absorbed.

An indirect source of blood glucose is ruminal lactic acid. Lactic acid is a product of many fermentation reactions and ruminal lactate can be absorbed. The blood lactate can be a source of blood glucose via the lactic acid cycle (Fig. 3.4). However, the principal source of blood lactate is the breakdown of muscle glycogen. Therefore, some of the ruminant's glucose requirement may be met by lactate but this is minimal because excess lactic acid in the rumen is toxic.

TABLE 3.10 Carbohydrate Balance Sheet[a]

	Carbohydrate carbon
A. Cow's daily glucose flux	
1. *In 12.5 kg milk:*	
610 g lactose	257 g C/day
462 g milk fat with 58 g glycerol	23 g C/day
Carbohydrate carbon in milk/day	280 g C/day
2. Daily glucose catabolism:	
Cow produced daily 3288 liters CO_2 = 1762 g C	
Transfer quotient plasma gluocse → CO_2 is 0.1	
Thus glucose to CO_2/day =	176 g C/day
1 + 2 = daily flux of glucose	456 g C/day
$\frac{180}{72} \times 456 = 1140$ g glucose/day	
B. Cow's glucose sources	
Cow secreted daily in urine 34 g N, indicating catabolism of 213 g protein =	100 g C/day
less c in urea =	14 g C/day
Maximum available for glucose synthesis from protein =	96 g C/day
Glucose flow in milk and respiration =	456 g C/day
Thus glucose flow from nonprotein sources =	360 g C/day
$\frac{180}{72} \times 360 = 900$ g glucose daily must have been supplied from a non-protein source	

[a] From Kleiber (1959).

The carbohydrate balance sheet (Table 3.10) provides the contribution of protein as a source of carbohydrate for the lactating cow. Because glucose absorption in the ruminant is minimal, the balance sheet also illustrates the importance of an alternate nonprotein source of carbohydrate carbon. These sources are the ruminal volatile fatty acids. The principal products of rumen fermentation are the volatile fatty acids, acetate, propionate, and butyrate. These acids are absorbed across the rumen wall and are the major source of nutriment for the ruminant. Various authors have used a variety of techniques to estimate the amounts of production and absorption of these acids. These fatty acids are found in blood in proportions of about acetate, 65; propionate, 20; and butyrate, 10. Further details of fatty acid production and absorption by the ruminant may be found in the chapter on lipid metabolism. In general, carbon atoms of acetate, although they appear in carbohydrate (blood glucose, milk lactose) through the mechanism of rearrangement in the TCA cycle (Fig. 3.9), cannot theoretically contribute to the net synthesis of carbohydrate. Thus, acetate is not a glucogenic compound. The large amounts of acetate provided by rumen fermentation are utilized for energy purposes and for the synthesis of fat. A possible mechanism for the direct incorporation of acetate into a glucose precursor is the so-called "glyoxylate pathway," which occurs in plants but not in animals.

Propionate, on the other hand, is a well-known precursor of carbohydrate. The pathway leading to a net synthesis of glucose from propionate is available via the reaction

$$\text{Propionate} + CO_2 \rightarrow \text{succinate},$$

as shown in Fig. 3.9. According to the scheme, 2 moles of propionate are required for the synthesis of 1 mole of glucose so 1 g of propionate theoretically can provide 1.23 g of glucose. The amounts of propionate available from rumen fermentation can theoretically supply the glucose requirements not accounted for by protein sources.

Butyrate, the third major fatty acid of rumen fermentation, influences glucogenesis but does not contribute carbon directly to glucose. Butyrate stimulates glucose production by liver by increasing phosphorylases and gluconeogenesis. The AcCoA derived from β-oxidation of butyrate also activates pyruvate carboxylase, a key gluconeogenic enzyme that further promotes gluconeogenesis.

3. *Utilization of Glucose*

The overall utilization of glucose by the ruminant has significant differences from that of other animals. Acetate oxidation rather than glucose plays the important role in energy metabolism of the ruminant. Only about 10% of the respiratory CO_2 arises from glucose oxidation, which is considerably less than the 25–60% for the rat, dog, and human. The glucose tolerance of the cow, however, is the same as in other animals. The plasma clearance $T_{1/2}$ of 33 minutes in the cow is similar to that of dogs (Kaneko *et al.*, 1977) and humans.

About 60% of the glucose oxidized in the mammary gland of the lactating cow occurs via the HMP pathway (Fig. 3.6), the same as in the rat mammary gland. HMP pathway activity in the ruminant mammary gland is also evidenced by the high activities of the HMP enzymes, G-6-PD and 6-P-GD in sheep and cows' mammary glands. Thus, even though overall glucose utilization is lower in ruminants, their pathways of glucose catabolism are the same as in other animals. As in other animals, the HMP pathway is the major provider of the reductive atmosphere for the synthetic processes of the mammary gland.

Through the TCA cycle pathway, carbons from acetate, from whatever source, appear in milk products (Fig. 3.17). Glucose carbon atoms may be given off as CO_2, appear in the amino acids of milk protein via transamination of oxaloacetate and α-ketoglutarate, or appear in milk fat. The short-chain fatty acids of butterfat are synthesized from acetate in the mammary gland, whereas the long-chain acids of butterfat are derived from blood lipids. The synthetic pathway for fatty acids in the gland is the same as that in other animal tissues (see Section IX).

The major portion of glucose uptake by the mammary gland provides for the biosynthesis of milk. The glucose and galactose moieties of lactose are derived from blood glucose. The rate of lactose synthesis is

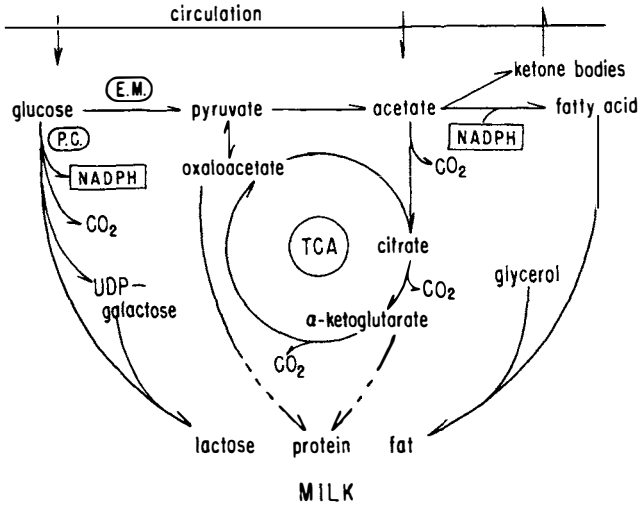

FIGURE 3.17 Summary of some metabolic pathways in the mammary gland.

also constant over a wide range of blood glucose concentrations, 1.1–4.4 mmol/liter (20–80 mg/dl), which indicates that lactose synthesis is maximal even under hypoglycemic conditions. The mammary gland, therefore, is a glucose utilizing tissue, principally for biosynthesis and considerably less is oxidized. The principal metabolic pathways involved are summarized in Fig. 3.17.

Ruminant nervous tissue, that is, brain, is also similar to that of other animals in being an obligatory glucose-utilizing tissue. The HK activity of sheep brain, however, is significantly lower than that of rat brain. This means that even though there is the same obligatory glucose requirement between the ruminant and nonruminant, glucose utilization by ruminant nervous tissue is lower than in the nonruminant. Similarly, ruminant intestine and muscle use less glucose than nonruminants.

With regard to organ distribution of gluconeogenic enzymes, the highest G-6-Pase activities are found in ruminant livers as compared to other organs of ruminants and are generally equal to or slightly lower than the activities found in nonruminant livers. During early lactation, the period when a cow's glucose requirement is highest, hepatic G-6-Pase does not increase. Similarly, cow liver PEPCK, a key gluconeogenic enzyme, is already very high in comparison to that of rat liver. All of this is in keeping with the concept that liver is primarily a glucose producing tissue. This also means that the high-producing dairy cow that has been genetically selected for these qualities is already synthesizing glucose maximally under normal conditions. It follows that any additional demands for glucose from physical stress, disease, etc., are unlikely to be met by increased glucose production. This glucose shortage leads to ketosis, the primary form from excess milk production or secondary form from the stress of a disease.

To summarize, the ruminant appears to be an animal well adapted to a carbohydrate economy based on the endogenous synthesis of glucose from noncarbohydrate sources (gluconeogenesis). The enzymatic mechanisms for gluconeogenesis are already operating at near maximal levels in the high-producing dairy cow. Glucose oxidation by individual tissues as well as by the intact animal is lower in ruminants than in nonruminants. Although overall partitioning of glucose oxidation may be different in ruminants, the pathways by which this oxidation is accomplished are similar to those of other animals (Fig. 3.17). The endocrine relationships of ruminants are also qualitatively similar to those of nonruminants so that the normally low blood glucose concentrations of ruminants are a reflection of their degree of influence or balance rather than their type of action.

C. Biochemical Alterations in Body Fluids

1. Hypoglycemia

Hypoglycemia is such a consistent finding in bovine ketosis and in ovine pregnancy toxemia that *hypoglycemia* has been suggested as another name for bovine ketosis. This hypoglycemia has played an important role in ketosis, as a rationale for therapy and as a basis for the concept of ketosis and pregnancy toxemia as manifestations of a carbohydrate deficiency that occurs under conditions of excessive and insurmountable demands.

2. Ketonemia

Ketonemia is a consistent feature of bovine ketosis and ovine pregnancy toxemia from which the name *ketosis* is derived. The ketone bodies are the same as those previously mentioned (Section V.3), AcAc, 3-OH-B, and acetone. A fourth compound, isopropanol, is included for the ruminant and interconversions can occur between these ketone bodies. The fundamental mechanism of ketosis is covered in a separate chapter and a brief outline is presented here.

a. Site of Ketone Body Production

Increased ketogenesis occurs under conditions that favor the accumulation of acetate. In the nonruminant, the liver is the sole source of ketone bodies and the ketone bodies appear in the body fluids when production exceeds the capacity for utilization. They are low renal threshold substances as well as being highly volatile so they readily appear in urine, milk, and in the breath. In the ruminant, the rumen epithelium and mammary gland are also sources of ketone bodies. The extent of their contribution to the ketone body pool, however, is uncertain but it could be considerable in the ketotic animal.

b. Hyperketonemia

Hyperketonemia is influenced by a number of conditions, all of which relate to the carbohydrate economy of the ruminant. Starvation is the most well known cause of ketosis. Mild to moderate ketonemia is often seen without detrimental effects during early lactation, late pregnancy, underfeeding, and with high fat diets. In all instances, the constant demands of the body for glucose are not adequately met.

Hyperketonemia is a consistent finding in bovine ketosis and pregnancy toxemia, though the degree of ketonemia does not necessarily parallel the severity of

the clinical signs. Normally, total blood ketones in sheep or cows are less than 0.10 mol/liter (0.6 mg/dl).

D. Ruminant Ketosis

The finely balanced carbohydrate economy of the ruminant plays a central role in the development of ketosis in cows and sheep. In the cow, large amounts of glucose must be produced by the liver to meet the heavy demands for lactose, particularly in early lactation, when the demand is highest. Similarly, in the pregnant ewe, especially when carrying twins, there is a progressive and large obligatory demand for hexoses (fructose), which is maximal near term. The precise mechanisms whereby internal metabolic imbalances occur in trying to meet these demands and manifest as ketosis, however, are uncertain. The fundamental imbalance is an inability of hepatic gluconeogenesis to respond to meet the demands of lactation or pregnancy and a hypoglycemia occurs, followed by hyperketonemia, and clinical ketosis develops.

CHAPTER

4

Lipids and Ketones

MICHAEL L. BRUSS

I. INTRODUCTION

This chapter covers the biochemistry and clinical chemistry of long-chain fatty acids, triacylglycerols, phospholipids, cholesterol, and ketones, a list that includes the majority of lipids found in vertebrates. The only remaining major classes are sphingolipids and waxes, which are not discussed. Although lipids have many functions, two of the most important are energy storage and membrane structure. Triacylglycerols are by far the most important lipid with regard to energy storage, and phospholipids and cholesterol are the most important lipoid membrane constituents. Lipids serve other functions, including being precursors for steroids and bile acids (cholesterol), thermal insulation (triacylglycerols), and electrical insulation (various lipids). Virtually all lipids are insoluble in water, which greatly complicates their handling in the body. Because of their insolubility, lipids must rely on proteins for transport for any significant distance in the body and various proteins have evolved to provide this function. The insolubility of lipids is an asset as well as a liability.

Because of their insolubility, lipids generate no osmotic force, so large amounts of triacylglycerol can be stored in adipose without the weight gain due to water that would accompany it if it were soluble. The insolubility of lipids is vital to many of their functions in membranes.

II. LONG-CHAIN FATTY ACIDS

A. Structure, Properties, and Assay of Long-Chain Fatty Acids

Long-chain fatty acids (LCFAs), frequently called free fatty acids or nonesterified fatty acids, are straight-chain fatty acids containing 12 or more carbon atoms. Since LCFAs are usually synthesized in animals or plants from acetyl-CoA and are then degraded two carbons at a time via β-oxidation in animals, the LCFAs found most commonly in animals have an even number of carbon atoms. LCFAs having carbon chain lengths of 16 and 18 comprise the greatest bulk of fatty acids in animal tissues and most animal diets. The saturated 16-carbon LCFAs is palmitic acid, and the saturated 18-carbon LCFA is stearic acid. Unsaturated 18-carbon LCFA are common, with double bonds occurring at C_9-C_{10} (oleic acid), at C_9-C_{10} and C_{12}-C_{13} (linoleic acid), and at C_9-C_{10}, C_{12}-C_{13}, and C_{15}-C_{16} (linolenic acid). The double bonds found in fatty acids in nature are mostly of the *cis* configuration. Ruminant fat contains more *trans*-LCFAs than that of nonruminants because rumen microbes isomerize some plant *cis*-LCFAs to *trans* isomers. Unsaturated LCFAs have a lower melting point than saturated LCFAs with the same number of carbons and are more susceptible to spontaneous oxidation (Gurr and Harwood, 1991). The 20-carbon polyunsaturated fatty acids, arachidonic acid (double bonds at C_5-C_6, C_8-C_9, C_{11}-C_{12}, C_{14}-C_{15}) and eicosapentaenoic acid (also called timnodonic acid), which is arachidonic acid with an additional double bond at C_{17}-C_{18}, are the precursors of the eicosanoids (prostaglandins, leukotrienes, thromboxanes).

Long-chain fatty acids are relatively insoluble in water at physiological pH. They dissolve readily in highly alkaline solutions, forming soaps. LCFAs are amphiphilic, being quite polar (hydrophilic) at their carboxyl end and quite nonpolar (hydrophobic) at the methyl end. All LCFAs must bind to proteins in order to be transported for any significant distance, and albumin is the primary transport protein in plasma (Gurr and Harwood, 1991).

Plasma LCFA concentrations can be determined spectrophotometrically with either a procedure involving extraction and chemical reaction or a procedure involving direct enzymatic reaction. The extraction/chemical reaction method involves causing formation of cobalt or copper salts of LCFAs, which are extracted with organic solvents followed by colorimetric assay of cobalt or copper (Duncombe, 1964; Elphick, 1968; Demacker *et al.*, 1982). The enzymatic method involves direct reaction of plasma LCFA to form LCFA-CoA. Then, LCFA-CoA is oxidized using LCFA-CoA oxidase, which produces hydrogen peroxide. The hydrogen peroxide is used to produce a colored product under the catalysis of peroxidase (Shimizu *et al.*, 1980; Demacker *et al.*, 1982). Generally, the enzymatic method is more satisfactory because it is more rapid, requires less operator skill, and is available commercially as a kit. If a sample contains triacylglycerol and lipase, which is not uncommon, LCFA may be released if the sample is allowed to stand. Falsely high LCFAs may be avoided by centrifuging blood samples and freezing the plasma immediately after collection or by adding paraoxon, a lipase inhibitor (Degen and Van der Vies, 1985).

B. Synthesis of Long-Chain Fatty Acids

LCFAs can be synthesized in most tissues, but only liver, adipose, or mammary tissue do it on a large scale. Synthesis occurs in the cytosol from acetyl-CoA. The precursor of the acetyl-CoA used for LCFA synthesis is usually acetate or glucose, with the former being important in ruminants and the latter being important in nonruminant mammals. When acetate is the acetyl-CoA precursor, it is formed from plasma acetate in the cytosol, the same cellular location as the enzymatic machinery needed to manufacture the LCFAs. However, when glucose is the precursor, it must go through glycolysis, which has its terminal enzyme, pyruvate dehydrogenase, located in the mitochondria. Thus, the acetyl-CoA is produced in the mitochondria, which is a problem if it is to be used for LCFA synthesis because the inner mitochondrial membrane is relatively impermeable to acetyl-CoA (Goodridge, 1991).

This problem has been solved by a mechanism known as the *citrate shuttle*, which is shown in Fig. 4.1. Acetyl-CoA in the mitochondria combines with oxaloacetate under the catalysis of citrate synthase to form citrate. Citrate is translocated across the mitochondrial membrane where it is cleaved into acetyl-CoA and oxaloacetate by ATP-citrate lyase. Thus, acetyl-CoA has been effectively transported from mitochondrion to cytosol. What remains is for the oxaloacetate to reenter the mitochondria to complete the cycle. However, the inner mitochondrial membrane is also impermeable to oxaloacetate, so it is first converted to malate by malate dehydrogenase or aspartate by aspartate aminotransferase in the cytosol. The malate

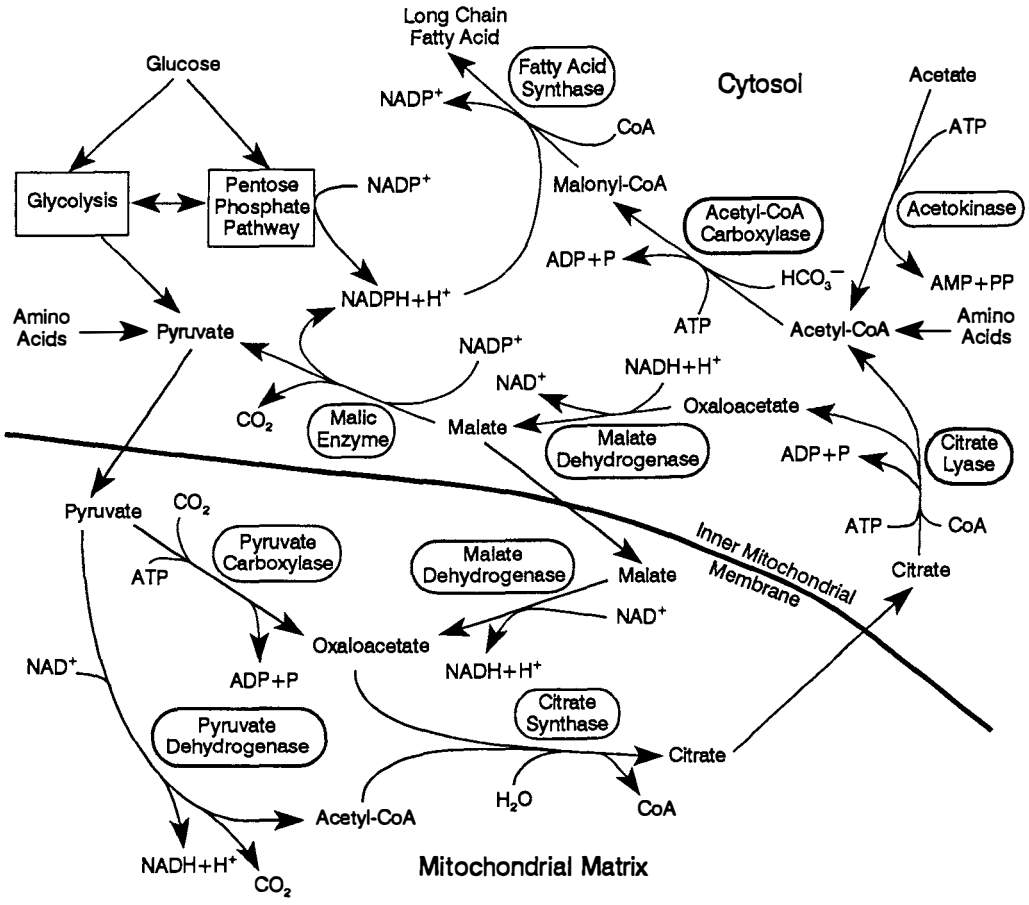

FIGURE 4.1 Fatty acid synthesis. Acetyl-CoA is generated in the mitochondria from pyruvate but cannot penetrate the mitochondrial membrane to reach fatty acid synthesizing enzymes in the cytosol. Citrate is formed from acetyl-CoA and oxaloacetate and migrates to the cytosol where it is cleaved to regenerate acetyl-CoA and oxaloacetate. The acetyl-CoA is converted into malonyl-CoA and used for fatty acid synthesis. The oxaloacetate cannot penetrate the mitochondrial membrane but must be converted to malate or pyruvate, which can penetrate the membrane and be converted back to oxaloacetate in the mitochondria. NADPH needed for fatty acid synthesis is generated by the pentose phosphate pathway and malic enzyme.

or aspartate are translocated into the mitochondrion where they can be converted back to oxaloacetate by reversal of the reactions that occurred in the cytosol. Alternately, malate in the cytosol can be converted to pyruvate by malic enzyme, and the pyruvate can enter the mitochondrion and be converted to oxaloacetate by pyruvate carboxylase (Goodridge, 1991).

Once acetyl-CoA reaches or has been formed in the cytosol, it must be carboxylated to produce malonyl-CoA via acetyl-CoA carboxylase if it is to be used for LCFA synthesis. This biotin-containing enzyme catalyzes the following reaction:

Acetyl-CoA carboxylase

$$CH_3CO\text{-}CoA + CO_2 + ATP \rightarrow {}^{-}OOCCH_2CO\text{-}CoA + H^+ + ADP + P_i.$$

Acetyl-CoA carboxylase is the main regulatory site in the synthesis of LCFA, which makes sense because the cell has little use for malonyl-CoA other than for the synthesis of LCFA. The enzyme is activated by citrate, which is again logical because citrate will be abundant only when there is a plentiful supply of mitochondrial acetyl-CoA. In addition, acetyl-CoA carboxylase is directly inhibited by LCFA-CoA, which can be derived from the synthetic process itself or from uptake and activation of plasma LCFAs. Acetyl-CoA carboxylase is also regulated by hormones via phosphorylation of the enzyme itself. Glucagon and LCFA-CoA stimulate phosphorylation, which inhibits the enzyme. Insulin activates the enzyme quickly, probably by stimulating dephosphorylation (Goodridge, 1991). These controls make sense in that a fasting or exercising animal will have its capacity for LCFA synthesis suppressed by increased plasma glucagon and LCFA levels, decreased plasma insulin, and increased intracellular LCFA-CoA. Conversely, in a

recently fed animal, these controls will all be reversed to promote LCFA synthesis.

Malonyl-CoA is used as the building block for LCFA in the cytosol by a large, complex, multiple-unit enzyme called *fatty acid synthase.* Fatty acid synthase uses malonyl-CoA to add two carbon units at a time to a growing LCFA chain that is attached to the enzyme itself, and uses NADPH to reduce the oxygen that was attached to what was the end carbon of the old LCFA chain. The reaction proceeds in a series of distinct steps, all of which occur on the same enzyme complex. The overall reaction is

$$CH_3\text{-}(CH_2)_n\text{-CO-enzyme} + {}^{-}OOCCH_2CO\text{-CoA} + 2\ NADPH + 3\ H^+ \rightarrow CH_3\text{-}(CH_2)_{n+2}\text{-CO-enzyme} + CO_2 + H_2O + 2\ NADPH^+.$$

The subscript n in the structural formula for the growing LCFA is an even number ranging from zero (i.e., the starting acetyl group) to usually no more than eight (stearate). The process begins when an acetyl group binds to the enzyme complex and usually ends when a palmityl (16-carbon) group has been formed on the enzyme, at which point the LCFA is detached from the enzyme. New carbons are added to the carboxyl end, not the methyl end, of the growing LCFA. The carbon atom in the carbon dioxide produced in the fatty acid synthase reaction is the same carbon atom in the carbon dioxide used to form malonyl-CoA from acetyl-CoA.

Cellular synthesis of the enzymes directly involved in LCFA synthesis (acetyl-CoA carboxylase and fatty acid synthase) and the enzymes involved in the generation of NADPH and acetyl-CoA translocation is stimulated by diets that are high in carbohydrate and low in fat and suppressed by fasting, high-fat/low-carbohydrate diets, and diabetes. These changes appear to be brought about, in part, by alterations in plasma insulin and glucagon that accompany diet changes or diabetes (Goodridge, 1991; Gurr and Harwood, 1991).

Fatty acid synthesis is expensive energetically. To add a single acetyl-CoA to a growing LCFA chain, one ATP is used directly and six more are used indirectly (each of the two NADPH is equivalent to three ATP). Because fatty acid synthesis occurs in the cytosol and requires NADPH, there must be a generous source of that cofactor when fatty acid synthesis is active. The main source of NADPH for fatty acid synthesis is the pentose phosphate (i.e., hexose monophosphate) pathway in the cytosol. This pathway utilizes plasma glucose in the case of adipose or mammary tissue, whereas in the liver, it can use plasma glucose, glycogen, or gluconeogenesis as the hexose source. Another source of NADPH in the cytosol is the malic enzyme reaction. These sources of NADPH are illustrated in Fig. 4.1.

Although the most common length for nascent LCFAs when they are released from fatty acid synthase is 16 carbons, they can be as long as 18 carbons or, in the case of fat synthesis in the mammary gland, as short as 4 carbons. When LCFAs are detached from fatty acid synthase, they are rapidly thioesterified to CoA by LCFA-CoA synthetase, an enzyme found in the endoplasmic reticulum and outer mitochondrial membrane. Most of the palmitate produced by fatty acid synthase will be elongated to produce stearate by fatty acid elongase, an enzyme found mainly in the endoplasmic reticulum but also in mitochondria. This enzyme adds two new carbons at the carboxyl end of the existing LCFA. Fatty acid elongase uses the same substrates (malonyl-CoA and NADPH) as fatty acid synthase, but is located in a different part of the cell and prefers palmityl-CoA as its substrate. However, fatty acid elongase can use longer LCFA-CoA as substrates to a limited degree to produce LCFA-CoA with a length of as great as 24 carbons (Cook, 1991).

Nonruminant mammals synthesize LCFA in liver, adipose, and mammary tissue. Ruminants synthesize LCFA primarily in adipose and mammary tissue with acetate being the most important precursor. Ruminants generally have a low capacity for LCFA synthesis in liver, but after eating large amounts of high starch diets, they may synthesize some LCFA in the liver from acetate and propionate (Hanson and Ballard, 1967; Ingle, 1972a, 1972b; Liepa *et al.*, 1978).

C. Catabolism of Long-Chain Fatty Acids

1. Desaturation

Most animals are capable of desaturating LCFAs only at the Δ^4, Δ^5, Δ^6, and Δ^9 positions (counting from the carboxyl end). Animals are able to desaturate palmityl-CoA and stearyl-CoA between C_9 and C_{10} by means of the Δ^9 desaturase system located in the endoplasmic reticulum to produce palmitoleyl-CoA and oleyl-CoA, respectively. However, animals are not able to create additional double bonds beyond C_9 in these products to any significant extent, so linoleic and linolenic acids must be absorbed from the intestinal tract (Cook, 1991). By a combination of the actions of the LCFA elongase and Δ^4, Δ^5, and Δ^6 desaturase systems, the livers of most mammals can synthesize arachidonic acid and eicosapentaenoic acid from linoleic and linolenic acids, respectively. However, the cat has very low levels of Δ^6 desaturase in its liver and must have arachidonic acid in its diet (MacDonald *et al.*, 1984).

2. β-Oxidation

The main catabolic route for LCFAs is β-oxidation. Most tissues can perform β-oxidation (erythrocytes are an exception), but those most adept at it are liver,

skeletal muscle, and heart. In addition, the liver can partially oxidize LCFAs to ketones, an important process that is discussed extensively later. Before LCFAs can be subjected to β-oxidation, they must be esterified to CoA, which is accomplished by the following reaction:

$$\text{LCFA} + \text{ATP} + \text{CoA} \leftrightarrow \text{LCFA-CoA} + \text{AMP} + \text{PP}.$$

The reaction is catalyzed by LCFA-CoA synthetase, an enzyme bound to the endoplasmic reticulum and the outer mitochondrial membrane. The pyrophosphate (PP) is rapidly hydrolyzed, so the reaction effectively consumes two ATP. The activation of LCFA is not rate limiting for β-oxidation (Pande, 1971).

In order for LCFA-CoA to be catabolized, it must pass into the mitochondrion, which presents a problem because the inner mitochondrial membrane is impermeable to it. The CoA must be exchanged for a carnitine moiety, a reaction catalyzed outside the mitochondrion by carnitine acyltransferase I (see Fig. 4.2), as follows:

$$\text{LCFA-CoA} + \text{carnitine} \leftrightarrow \text{LCFA-carnitine} + \text{CoA}.$$

LCFA-carnitine passes readily through the inner mitochondrial membrane and is acted on by carnitine acyltransferase II, which converts the LCFA-carnitine back to LCFA-CoA (Kopec and Fritz, 1973).

Carnitine acyltransferase I appears to be controlled by inhibition by malonyl-CoA (McGarry *et al.*, 1977), and it is logical that when lipogenesis is stimulated, the LCFAs that are produced should be prevented from entering the mitochondrion where they will be catabolized.

In the mitochondrion, the process of β-oxidation per se cleaves the LCFA into acetyl-CoA units. The reaction sequence is

$$\text{R-CH}_2\text{-CH}_2\text{-CO-CoA} + \text{FAD} \xrightarrow{\text{Acyl-CoA dehydrogenase}} \text{R-CH=CH-CO-CoA} + \text{FADH}_2,$$

$$\text{R-CH=CH-CO-CoA} + \text{H}_2\text{O} \xrightarrow{\Delta^2\text{-Enoyl-CoA hydratase}} \text{R-C(OH)H-CH}_2\text{-CO-CoA},$$

$$\text{R-C(OH)H-CH}_2\text{-CO-CoA} + \text{NAD}^+ \xrightarrow{\text{L(+)-3-Hydoxyacyl-CoA dehydrogenase}} \text{R-CO-CH}_2\text{-CO-CoA} + \text{NADH} + \text{H}^+,$$

$$\text{R-CO-CH}_2\text{-CO-CoA} + \text{CoA} \xrightarrow{\text{Thiolase}} \text{R-CO-CoA} + \text{CH}_3\text{-CO-CoA}.$$

The resulting acyl-CoA is two carbons shorter and can recycle through the pathway. Each trip of an acyl-CoA through the pathway generates one $FADH_2$ and one NADH + H^+, which can generate 5 ATP via oxidative phosphorylation. If the LCFA has an odd number of carbons, which is rare, the final product of β-oxidation will be propionyl-CoA. The double bond produced by the acyl-CoA dehydrogenase reaction has a *trans* configuration, not the *cis* configuration occurring in unsaturated LCFA found free or esterified to glycerol.

Unsaturated LCFA can proceed through β-oxidation to within three carbons of the double bond. As this point, Δ^2-enoyl-CoA hydratase cannot act because it requires a *trans*, rather than a *cis*, configuration in its substrates, and it requires that the double bond be between C_2 and C_3 rather than between C_3 and C_4. At this point, Δ^3, Δ^2-enoyl-CoA isomerase will convert the Δ^3-*cis* double bond to a Δ^2-*trans* double bond, which will allow β-oxidation to proceed (Kilponen *et al.*, 1991). Polyunsaturated LCFAs require an additional enzyme, 2,4-dienoyl-CoA reductase, because after enoyl-CoA isomerase acts, the new *trans* double bond will still have the second *cis* double bond in proximity, which will prevent Δ^2-enoyl-CoA hydratase from acting. 2,4-Dienoyl-CoA reductase effectively eliminates the second double bond by reducing it with NADPH (Roe *et al.*, 1990).

β-Oxidation in the mitochondria appears to be controlled mainly by substrate availability. The acetyl-CoA units can be oxidized in the citric acid cycle provided there is sufficient oxaloacetate to condense with them to form citrate. Alternatively, acetyl-CoA units can be recondensed to form ketones, which will occur when there is not sufficient oxaloacetate for citrate formation or when citrate synthase is inhibited by high levels of citrate. Although β-oxidation occurs mostly in mitochondria, the process occurs to a minor extent in peroxisomes as well (Wanders *et al.*, 1992).

Although the main catabolic route for LCFA is β-oxidation, there are two quantitatively minor alternatives. α-Oxidation, in which carbons are removed one at a time from the carboxyl end of the LCFA, is used by brain tissue to produce LCFAs of varying lengths for synthesis of complex lipids. ω-Oxidation, which is oxidation that occurs at the methyl, rather than at the carboxyl, end is conducted to a limited extent by the cytochrome P450 system in the endoplasmic reticulum of liver. The resulting dicarboxylic acid can then undergo β-oxidation to a chain length of six carbons (adipate) most of which will be excreted in the urine (Mortensen, 1990; Gurr and Harwood, 1991).

III. TRIACYLGLYCEROL

A. Structure, Properties, and Assay of Triacylglycerol

The main storage form of LCFAs is the triacylglycerols (also called triglycerides), in which three LCFAs are esterified to glycerol. Triacylglycerols are even less

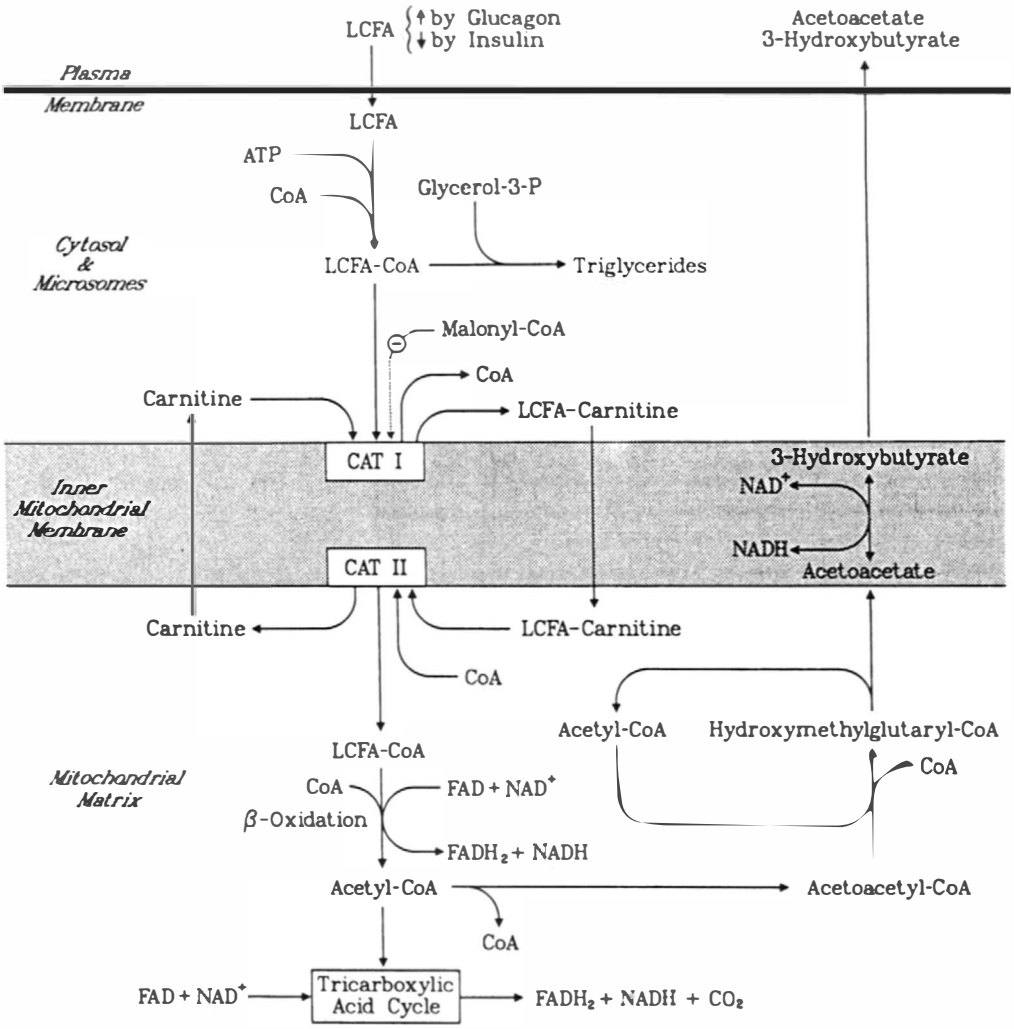

FIGURE 4.2 LCFA oxidation and ketogenesis in the liver. Abbreviations: CAT, carnitine acyltransferase.

soluble than LCFAs, and also must be bound to proteins in complexes called *lipoproteins* for transport through plasma.

Assay of triacylglycerol in plasma or serum is best accomplished by enzymatic hydrolysis using lipase followed by enzymatic determination of the released glycerol (McGowan *et al.*, 1983; Klotzsch and McNamara, 1990). If high plasma glycerol levels are likely, as can occur in animals that have not eaten lately, a plasma blank must be run. Older methods that use alkaline hydrolysis require caustic reagents, consume more time, and may assay phospholipids plus triacylglycerol. Glycerol, which has been used occasionally to lubricate stoppers of blood collection tubes, and soap, which may contain glycerol or triacylglycerols, contamination of samples will lead to falsely elevated values. If the sample contains lipase, which is not uncommon, triacylglycerol levels will decrease if the sample is allowed to stand. Prompt centrifugation of blood samples followed by rapid analysis or freezing of the plasma will prevent falsely low triacylglycerol levels.

B. Synthesis of Triacylglycerol

Although most cells can synthesize triacylglycerols, liver, adipose, mammary gland, and small intestine are particularly adept at it. The LCFA-CoA are the building blocks for triacylglycerol synthesis. There are two sources of LCFA-CoA for triacylglycerol synthesis: LCFAs in the plasma and LCFAs synthesized locally. Generally, physiological or pathological circumstances, such as starvation or diabetes, that promote high plasma levels of LCFAs suppress LCFA synthesis. Physiological circumstances that promote LCFA synthesis, such as eating a carbohydrate meal, also inhibit lipolysis in adipose, so plasma LCFA levels are not elevated.

To form triacylglycerols, the LCFA-CoA are esterified to glycerol-3-P. Glycerol-3-P can be produced in the liver from glycerol, which is absorbed from the plasma, and ATP in a reaction catalyzed by glycerol kinase as follows:

$$\text{Glycerol} + \text{ATP} \rightarrow \text{glycerol-3-P} + \text{ADP}.$$

Glycerol is normally plentiful in plasma only when there is active lipolysis occurring in adipose tissue.

When glucose is plentiful in the plasma and LCFAs are being synthesized from glucose via acetyl-CoA, glycerol-3-P is also synthesized from glucose in liver, mammary gland, and adipose. This process occurs via glycolysis to dihydroxyacetone-P followed by a reduction catalyzed by glycerol-3-P dehydrogenase:

$$\text{Dihydroxyacetone-P} + \text{NADH} + \text{H}^+ \leftrightarrow \text{glycerol-3-P} + \text{NAD}^+.$$

LCFA-CoA is esterified to glycerol-3-P by glycerol-P acyltransferase as follows:

$$\text{glycerol-3-P} + \text{LCFA-CoA} \rightarrow \text{1-acyl-glycerol-3-P} + \text{CoA}.$$

This reaction occurs in both mitochondria and smooth endoplasmic reticulum, but the smooth endoplasmic reticulum enzyme is more plentiful and most important in triacylglycerol synthesis. Next, another LCFA-CoA is esterified by the enzyme, acylglycerol-P acyltransferase, which is located in the smooth endoplasmic reticulum:

$$\text{1-Acyl-glycerol-3-P} + \text{LCFA-CoA} \rightarrow \text{phosphatidate} + \text{CoA}.$$

Phosphatidate (the ionized form of phosphatidic acid) is 1,2-diacyl-glycerol-3-P. Next, the phosphate is hydrolyzed from phosphatidate by phosphatidate phosphohydrolase to produce a diacylglycerol:

$$\text{Phosphatidate} \rightarrow \text{diacylglycerol} + \text{P}.$$

This reaction occurs in the smooth endoplasmic reticulum and cytosol. Finally, a last LCFA-CoA is esterified by the enzyme diacylglycerol acyltransferase, an enzyme located in the smooth endoplasmic reticulum (Brindley, 1991):

$$\text{Diacylglycerol} + \text{LCFA-CoA} \rightarrow \text{triacylglycerol} + \text{CoA}.$$

If the triacylglycerol has been synthesized in adipose, it will migrate into the large storage vesicle that each adipocyte possesses. Most of the triacylglycerol synthesized in liver will normally be incorporated into and exported from the liver as part of very low density lipoproteins (VLDLs). However, if triacylglycerol synthesis exceeds hepatic export capacity, triacylglycerol will accumulate in vesicles in hepatocytes, leading to fatty liver. If the triacylglycerol has been synthesized in mammary gland, the resulting triacylglycerols will accumulate in vesicles of secretory cells and the vesicles will be extruded into the lumina of the gland acini.

The regulation of triacylglycerol synthesis is not fully understood and differs among tissues. In small intestine, substrate availability is most important because triacylglycerol synthesis in that organ is an integral part of triacylglycerol absorption. In mammary gland, substrate availability and the hormones that support lactation regulate triacylglycerol synthesis.

In liver, the limiting enzyme in the pathway appears to be phosphatidate phosphohydrolase. This enzyme is subject to an interesting control mechanism in which it is switched between a less active and more active state by the enzyme itself being translocated between the cytosol and endoplasmic reticulum, respectively. Intracellular cAMP, which increases with high plasma glucagon or low plasma insulin levels (e.g., during fasting or with diabetes), inhibits binding of the enzyme to the endoplasmic reticulum, whereas LCFA or LCFA-CoA promote binding of the enzyme to the endoplasmic reticulum (Brindley, 1991; Gurr and Harwood, 1991). The role of LCFA and LCFA-CoA in promoting synthesis of triacylglycerols in the liver is important and explains how fat synthesis and fatty liver can occur in the fasting state when hormonal changes would oppose triacylglycerol synthesis.

In adipose tissue, the synthesis of triacylglycerol is very much regulated by hormones, especially glucagon, catecholamines, and insulin. The first two hormones increase intracellular cAMP and the latter tends to decrease it, although insulin probably has effects independent of cAMP. In conditions in which glucagon would be elevated and insulin would be decreased (e.g., during fasting), hormone sensitive lipase will be activated and lipolysis will occur. It is important that fat synthesis not be operative during lipolysis, so as not to waste energy. Low insulin and elevated catecholamine or glucagon levels decrease the level of lipoprotein lipase (LPL) in adipose tissue. Fat cells need LPL in order to hydrolyze plasma triacylglycerol so that the resulting LCFAs can be absorbed and used for triacylglycerol synthesis. Decreased plasma insulin levels will decrease entry of glucose into adipocytes, which will result in less glycerolphosphate being synthesized. Increased intracellular cAMP in adipose tissue decreases the activity of several key enzymes in fat synthesis, including fatty acyl-CoA synthetase, glycerolphosphate acyltransferase, phosphatidate transferase, and diacylglycerol acyltransferase; however, the mechanism of inhibition is uncertain (Saggerson, 1988).

C. Catabolism of Triacylglycerol

Catabolism of triacylglycerol involves the action of lipases, which are specialized esterases that hydrolyze glyceride bonds. The major lipases are pancreatic lipase, hepatic lipase, hormone sensitive lipase of adipose, LPL found on endothelial cells, and lysosomal lipases contained in most cells. Pancreatic lipase is the essential lipase for digestion of triacylglycerol in the GI tract and is discussed later. Hepatic lipase is synthesized in hepatocytes from where it migrates to the surface of hepatic endothelial cells. Hepatic lipase primarily attacks triacylglycerol in the plasma, which are part of VLDL remnants to produce low-density lipoproteins (LDLs), and it attacks triacylglycerol in high-density lipoproteins (HDLs) as well.

Lipoprotein lipase attacks triacylglycerol in chylomicrons and VLDL in plasma and is found on the endothelium of many organs and tissues, but is in greatest quantity in adipose, heart, skeletal muscle, and mammary gland. Lipoprotein lipase is synthesized by the underlying tissue and migrates to the capillary endothelium where is it anchored on the cell surfaces to glycoproteins, which have polysaccharide chains structurally similar to heparin. If heparin is injected into an animal, LPL can switch its attachment from cell surface glycoproteins to the free injected heparin and, thus, appears in the plasma. If the animal had a lipemia prior to injecting the heparin, the large amount of lipoprotein lipase released into the plasma will clear the lipemia. Phospholipids and apolipoprotein C-II must be present for lipoprotein lipase to have full activity (Fielding and Fielding, 1991).

IV. PHOSPHOLIPIDS

A. Structure and Properties of Phospholipids

Most of the phospholipids found in the body consist of a core of glycerol that has LCFA esterified to its 1 and 2 carbons and phosphate esterified to its 3 carbon, a compound called phosphatidate. In addition, the phosphate is often esterified to a hydroxyamino compound such as choline, ethanolamine, or serine to produce phosphatidylcholine (also called lecithin), phosphatidylethanolamine, and phosphatidylserine, respectively. Inositol may be esterified to the phosphate to produce phosphatidylinositol. Because of the phosphate group, phospholipids are very polar on one end, but nonpolar on the other end and still must be part of lipoproteins for transport through the plasma. Phospholipids are constituents of all cellular membranes, lipoproteins, and bile micelles. The fatty acid portion of the molecule is oriented toward the center of the membrane or micelle, and the phosphatidyl group is oriented toward the outer surface (i.e., toward the aqueous medium). In micellar structures, like lipoproteins and bile micelles, the surface coating of the polar ends of constituent phospholipids provides a surface charge that helps to keep the micelles in suspension.

B. Synthesis of Phospholipids

Phospholipids are synthesized either from phosphatidate (e.g., phosphatidylinositol) or diacylglycerol (e.g., phosphatidylcholine and phosphatidylethanolamine), both of which are intermediates in the synthesis of triacylglycerol. In all cases, cytidine triphosphate (CTP), a high-energy organophosphate that derives it phosphates from ATP, plays an important role. In the case of phosphatidylinositol, CTP reacts with phosphatidate to form CDP-diacylglycerol, which then reacts with inositol to form phosphatidylinositol and CMP. In the case of choline or ethanolamine, they must first be phosphorylated by reaction with ATP. Then the phosphocholine or phosphoethanolamine reacts with CTP to form CDP-choline or CDP-ethanolamine, respectively, which then react with diacylglycerol to produce phosphatidylcholine and phosphatidylethanolamine, respectively. Phosphatidylserine is formed by serine replacing ethanolamine in phosphatidylethanolamine. In the endoplasmic reticulum of the liver, a methyl group from S-adenosylmethionine can be transferred to phosphatidylethanolamine to produce phosphatidylcholine (Vance, 1991). Fig. 4.3 illustrates the synthesis of phospholipids.

The enzymes that synthesize CDP-choline and CDP-ethanolamine (cytidylyltransferases) appear to be rate limiting for the synthesis of phosphatidylcholine and phosphatidylethanolamine, respectively. Phosphocholine cytidylyltransferase is subject to regulation similar to that of phosphatidate phosphohydrolase, the control enzyme in triacylglycerol synthesis. When phosphocholine cytidylyltransferase is bound to the endoplasmic reticulum it is relatively active, but when it is free in the cytosol, it is relatively inactive. Factors that increase binding of the enzyme to the endoplasmic reticulum are decreased levels of phosphatidylcholine, increased levels of diacylglycerol or LCFA, and dephosphorylation of the enzyme. Opposite changes in these factors inhibit binding of the enzyme to the endoplasmic reticulum, forcing it to remain inactive (Vance, 1991).

C. Catabolism of Phospholipids

Phospholipids are hydrolyzed by phospholipases, which can be found in the lysosomes of most tissues and in pancreatic secretion. Mammalian phospholi-

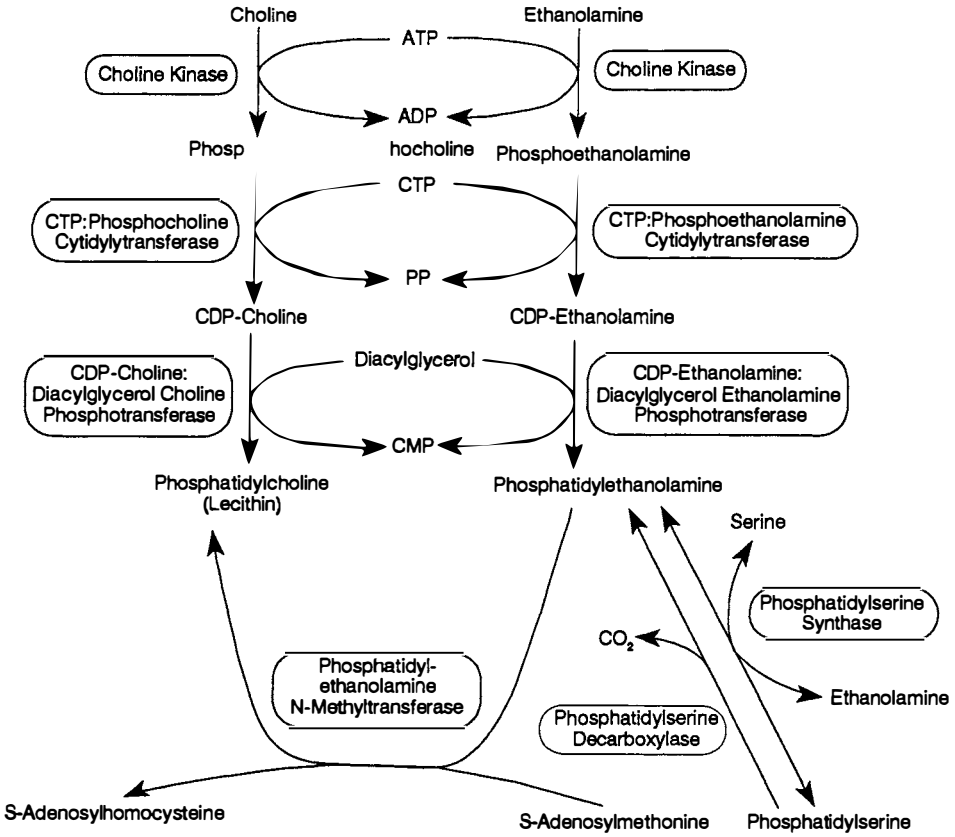

FIGURE 4.3 Synthesis of phospholipids. Diacylglycerol is the lipid to which organic bases and phosphate are transferred via CDP derivatives. Abbreviations: CTP, CDP, CMP, cytidine tri-, di-, and monophosphate, respectively.

pases are primarily of the A type, meaning that they hydrolyze the glycerol-LCFA ester bond at either position 1 (A_1 type) or 2 (A_2 type), but not both (Gurr and Harwood, 1991; Waite, 1991). Phospholipase types B, C, and D, which hydrolyze at other locations in the molecule, exist in mammalian tissues, but with lower activities.

V. CHOLESTEROL

A. Structure, Properties, and Assay of Cholesterol

Structurally, cholesterol is composed of a core of phenanthrene to which a cyclopentane ring is attached, and there is an eight-carbon side chain attached to the cyclopentane ring (see Fig. 4.4). Cholesterol is found only in animals and is not present in plants or microorganisms. Cholesterol is the precursor of steroid hormones, vitamin D, and the bile acids and is a constituent of cell membranes and bile micelles. Cholesterol can be obtained from the diet if it contains animal products or it can be synthesized. The chief synthetic and catabolic organ for cholesterol is the liver. Steroidogenic endocrine organs (adrenal cortex, testis, ovary, placenta) can synthesize small amounts of cholesterol; however, these organs utilize hepatically synthesized cholesterol for most of their steroid synthesis (Pedersen, 1988). Pure cholesterol and cholesterol esters are insoluble waxy white solids and must be transported through plasma as part of lipoproteins.

Enzymatic methods are used almost universally for assay of cholesterol (Stein and Meyers, 1994). Older nonenzymatic methods used harsh reagents and lack specificity. The key enzymes in the assay are cholesterol esterase, which hydrolyses cholesterol esters, and cholesterol oxidase. The latter enzyme is of microbial origin and has an action analogous to that of glucose oxidase, that is, it uses dissolved oxygen to oxidize cholesterol to produce cholest-4-ene-3-one and hydrogen peroxide. In the presence of added peroxidase, hydrogen peroxide will oxidize an added organic dye (e.g., dianisidine, ABTS, 4-aminoantipyrine plus phenol) to generate a colored product that can be quantified spectrophotometrically. If cholesterol esterase is included in the reagent, then total cholesterol will be determined. If cholesterol esterase is omitted from the reagent, then only nonesterified (i.e., free) cholesterol

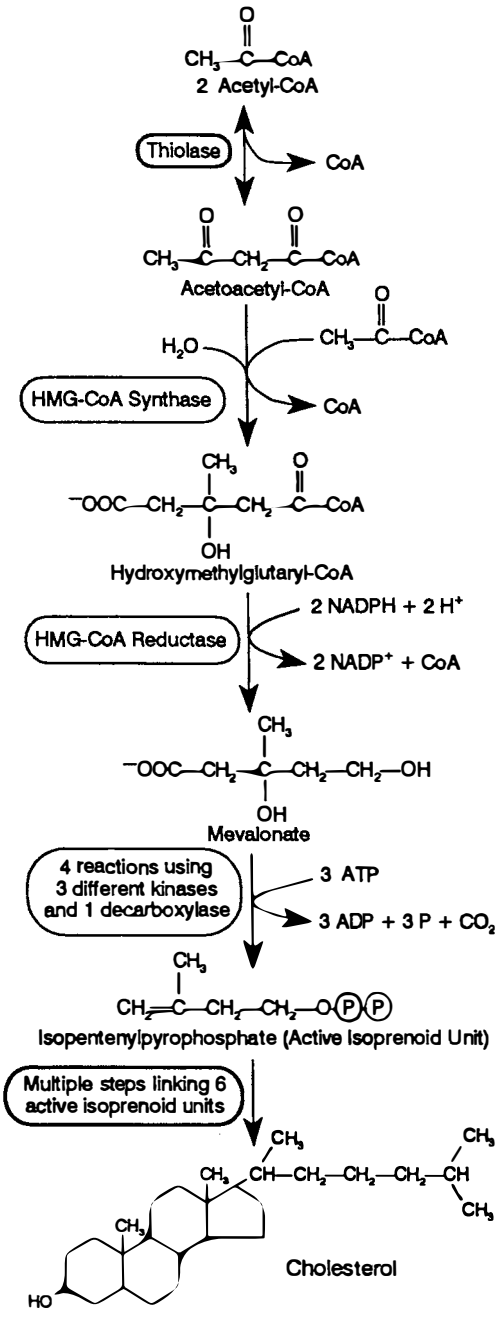

FIGURE 4.4 Synthesis of cholesterol. The first two reactions occur in the cytosol and the remainder in the smooth endoplasmic reticulum.

will be determined. If the assay is done with and without cholesterol esterase, then cholesterol ester concentration can be determined by subtraction.

Because virtually all of the cholesterol and cholesterol esters in plasma are part of lipoproteins, they must be liberated before they can be acted on by the enzymes of the reagent. This liberation can be accomplished by extracting cholesterol and its esters with an organic solvent prior to the assay or, more conveniently, by including small amounts of detergents (bile acids or artificial detergents) in the reagent (Stein and Meyers, 1994).

B. Metabolism of Cholesterol

As is the case for LCFA and ketones, the substrate for cholesterol synthesis is acetyl-CoA. The beginning site of cholesterol synthesis is in the cytosol, so acetyl-CoA, which is generated primarily in the mitochondria, must be transferred to the cytosol via the citrate shuttle mechanism discussed earlier. The process of cholesterol synthesis is shown diagrammatically in Fig. 4.4. In the cytosol, the first two steps of cholesterol synthesis are identical to the first two steps of ketone synthesis except that the process occurs in the cytosol rather than in the mitochondria. The enzymes that catalyze the first two steps are acetyl-CoA: acetoacetyl-CoA thiolase and hydroxymethylglutaryl-CoA (HMG-CoA) synthase:

$$2 \text{ Acetyl-CoA} \leftrightarrow \text{acetoacetyl-CoA} + \text{CoA},$$
$$\text{Acetoacetyl-CoA} + \text{acetyl-CoA} \rightarrow \text{HMG-CoA} + \text{CoA}.$$

The remaining enzymes of cholesterol synthesis are located in the endoplasmic reticulum, perhaps because of decreasing solubility of succeeding products formed in the pathway. Next, HMG-CoA is reduced to mevalonate under the catalysis of HMG-CoA reductase as follows:

$$\text{HMG-CoA} + 2 \text{ NADPH} + 2 \text{ H}^+ \rightarrow \text{mevalonate} + 2 \text{ NADP}^+ + \text{CoA}.$$

HMG-CoA reductase is the primary control point for cholesterol synthesis; its control mechanisms are discussed later. Next, via three steps, isopentenylpyrophosphate is formed. Six of these molecules, often called the active isoprenoid units, are linked to form cholesterol in a long and complex pathway that is only partially understood (Faust *et al.*, 1988; Edwards, 1991).

The control of HMG-CoA reductase is complex and not completely understood. Artificially increasing plasma cholesterol levels *in vivo* decreases the activity of the enzyme in liver. However, cholesterol does not inhibit the enzyme directly, but represses synthesis of the enzyme mRNA (Edwards, 1991). Thus, if the amount of cholesterol consumed in the diet increases, the amount synthesized by the liver will decrease. This reciprocal relationship between cholesterol consumed and hepatic synthesis limits the extent to which plasma cholesterol levels can be decreased by restricting the amount of cholesterol in the diet.

Hepatic HMG-CoA reductase is inhibited by phosphorylation of the enzyme and reactivated by dephos-

phorylation. The protein kinase system responsible for the phosphorylation of HMG-CoA reductase is stimulated by intracellular cAMP (Edwards, 1991). Hepatic intracellular cAMP levels are controlled in part by plasma glucagon, which increases it, and by insulin, which decreases it. Thus, conditions that increase insulin (e.g., eating) will increase cholesterol synthesis. Conditions that decrease insulin (e.g., diabetes) or increase glucagon (e.g., fasting) will decrease cholesterol synthesis. Other hormones that affect hepatic HMG-CoA reductase activity, but probably not by altering intracellular cAMP levels, are thyroid hormones (increase HMG-CoA reductase activity) and glucocorticoids (decrease HMG-CoA reductase activity). Some drugs, such as lovastatin and mevastatin, used in humans to decrease plasma cholesterol levels operate by inhibiting HMG-CoA reductase (Brown and Goldstein, 1990).

Once cholesterol has been synthesized in the hepatocyte, it can be secreted into the plasma as part of lipoproteins (mostly in VLDL), it can be secreted into the canaliculi and become part of bile micelles, it can be degraded to bile acids, or it can be esterified to a LCFA by acyl-CoA : cholesterol acyltransferase (ACAT), which is located in the smooth endoplasmic reticulum. Cholesterol esters are even less soluble than cholesterol and are found in membranes and micelles wherever cholesterol itself is found. Cholesterol ester can be exported as part of lipoproteins or it can be converted back to cholesterol plus LCFA by cholesterol ester hydrolases, which are found in the cytosol, endoplasmic reticulum, and lysosomes. Deesterification is mandatory before cholesterol can be catabolized to bile acids. Because enzymes for the final steps of cholesterol synthesis and the first steps of its degradation are colocated in the endoplasmic reticulum, it might seem that most of newly synthesized cholesterol would be immediately degraded. However, the negative feedback of bile acids on cholesterol degradation keeps this process in check.

HDL contains lecithin : cholesterol acyltransferase (LCAT), which esterifies cholesterol by transferring a LCFA moiety from lecithin (phosphatidylcholine). The cholesterol to be esterified by LCAT can be that secreted with HDL at the time of its synthesis or it can be cholesterol from other lipoproteins or cell membranes that come in contact with HDL at a later time.

VI. LIPOPROTEINS

A. Structure, Properties, and Assay of Lipoproteins

Lipoproteins are very large noncellular conglomerations (micelles) of lipids and proteins that are suspended in plasma or lymph. Their main function is to transport most lipids (steroid hormones and LCFAs being notable exceptions) among tissues. Another function of lipoproteins is the esterification of cholesterol. Lipoproteins have a micellar structure in which the least polar molecules (triacylglycerol and cholesterol) occupy the center and more polar molecules (proteins and phospholipids) coat the exterior. Lipoproteins are synthesized almost exclusively by liver and the small intestine.

The main classes of lipoprotein are defined by their density as determined by ultracentrifugation and are chylomicrons ($d < 0.94$ g/ml), VLDLs ($d =$ 0.94–1.006 g/ml), LDLs ($d =$ 1.006–1.063 g/ml), and HDLs ($d =$ 1.063–1.21 g/ml). Less commonly considered are very high density lipoproteins (VHDL, $d > 1.21$ g/ml), which are usually very low in concentration in plasma. It is common to designate the lighter LDL ($d =$ 1.006–1.019 g/ml) as intermediate-density lipoproteins (IDL), and some schemes subdivide the HDL into HDL_1, HDL_2, and HDL_3. (Chapman, 1986; Gotto *et al.*, 1986).

The lipid component of lipoproteins is less dense than the protein component, but the lipids have similar densities and the proteins have similar densities. Therefore, the density of a lipoprotein is almost entirely dependent on its ratio of lipid to protein, with the chylomicrons having the highest ratio and, on the other end of the spectrum, the HDL having the lowest ratio (see Table 4.1). More than one-half of the lipid in chylomicrons and VLDL is triacylglycerol, whereas in LDL and HDL the majority of the lipids are not triacylglycerol (see Table 4.1). In domestic species, HDL is normally the most abundant plasma lipoprotein in the fasting state.

Chylomicrons and VLDL particles are large enough to refract light significantly, so they make plasma appear turbid or creamy if in high enough concentration (lipemic plasma). The chylomicrons have a low enough density that they will rise to the top of an undisturbed refrigerated plasma sample in 6–12 hours. This phenomenon is the basis of the *chylomicron test*, in which a milky plasma sample is placed in the refrigerator overnight. If a "cream layer" has formed at the top, then hyperchylomicronemia is present, and if the bottom portion of the plasma is turbid, then elevated levels of VLDL are present.

Because of the expense, time, and complexity involved with ultracentrifugation, electrophoresis in an alkaline medium has been used as an alternative method of lipoprotein classification. A variety of electrophoretic supports, ranging from paper to acrylamide gels, have been used. The sample is applied at the cathode end of the support, voltage is applied for a variable time, and the proteins are fixed and stained

TABLE 4.1 Composition of Lipoproteins of Domestic Animals[a]

	Triacylglycerol (wt %)	Free cholesterol (wt %)	Cholesterol esters (wt %)	Phospholipid (wt %)	Protein (wt %)
Cattle:					
Chylomicrons	87	4	2	4	3
VLDL	60	5	4	25	6
LDL	1	5	35	36	23
HDL	4	4	30	20	42
Dogs:					
VLDL	68	6	2	10	14
LDL	27	5	25	22	21
HDL	1	5	23	33	38
Horses:					
VLDL	57	5	6	18	14
LDL	6	8	36	23	27
HDL	0	2	20	28	50

[a] References: Cattle: Ferreri and Elbein, 1982 (chylomicrons); Stead and Welch, 1975 (other lipoproteins). Dogs: Mahley and Weisgraber, 1974; Blomhoff *et al.*, 1978. Horses: Watson *et al.*, 1993; Le Goff *et al.*, 1989.

with a lipid stain such as oil red O. A densitometer is used to quantify the lipoprotein fractions on the stained electrophoretogram.

Typically, three to five bands of lipoproteins can be discerned; however, additional bands may be present depending on the species of animal, electrophoretic technique, and presence of abnormal lipoproteins. The fastest moving band is HDL, which is designated as α-lipoprotein. The next fastest moving band is VLDL, which is designated pre-β-lipoprotein followed by the LDL band, which is designated as β-lipoprotein. The slowest moving band, which is still at the origin and seen primarily in the postprandial period, is composed of chylomicrons. With some electrophoresis systems, a separate IDL band, designated as slow pre-β-lipoproteins, can be discerned between the VLDL and LDL bands, and sometimes subbands of the HDL can be discerned. The correlation of electrophoretic and ultracentrifuge fractions established for humans does not always apply to animals. For example, bovine LDL can appear as α or β bands on electrophoresis (Puppione, 1983). Usually, two HDL bands can be discerned for dog plasma (Rogers, 1977). Figure 4.5 illustrates the distribution of lipoproteins in dog plasma.

Although easier and cheaper to perform than ultracentrifugation, lipoprotein electrophoresis still requires considerable time and expense. Consequently, methods have been developed that involve precipitation of one or more lipoprotein classes followed by analysis of a particular lipid, usually cholesterol, in the remaining supernatant. For example, chylomicrons can be removed by low-speed centrifugation (they rise to the top), and then precipitation of VLDL and LDL in human plasma can be accomplished by treatment with magnesium and dextran sulfate. The main lipoprotein remaining in the supernatant will be HDL, and if cholesterol is determined, it will mostly be HDL cholesterol (Stein and Meyers, 1994). Such empirical methods may be species specific. For example, the preceding method, though valid for human plasma, does not work for dog plasma (Rhodes *et al.*, 1992).

B. Apolipoproteins

The protein components of lipoproteins are called *apolipoproteins*. Some apolipoproteins are found in only one class of lipoproteins, whereas others can be found in multiple classes. Although there are species variations in the amino acid sequences of apolipoproteins, individual apolipoproteins in the domestic species are quite similar. The main classes of apolipoproteins are designated with a letter (A through E), sometimes fol-

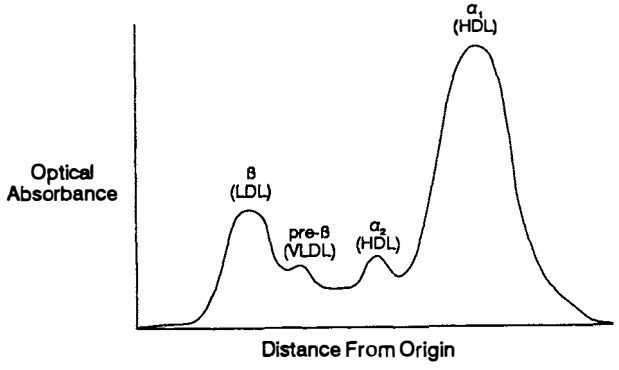

FIGURE 4.5 Densitometric scan of an electrophoretogram of canine plasma lipoproteins. The scan is typical of a fasted dog. In a fed dog, an additional peak due to chylomicrons would be present at the origin. Abbreviations: HDL, LDL, and VLDL, high, low, and very low density lipoproteins, respectively.

lowed by a number to indicate a distinct subclass. The main classes and subclasses of apolipoproteins found in domestic animals are A-I, A-II, A-IV, B_{48}, B_{100}, C-I, C-II, C-III, C-IV, and E. Characteristics of these apolipoproteins are listed in Table 4.2.

The B_{100} apolipoprotein, synthesized in the liver and part of VLDL, is one the largest polypeptide chains in mammals, having a molecular weight of 527,000 in horses (Watson *et al.*, 1991). The B_{48} apolipoprotein is about one-half the size of B_{100} and contains a subset of the B_{100} amino acid sequence (i.e., they are probably coded by the same gene); however, B_{48} is synthesized in the small intestine and is part of chylomicrons. The origin of the "48" and "100" designations stems from the fact that human B_{48} is exactly 48% of the mass of human B_{100}. Both B_{48} and B_{100} are glycoproteins and have a variety of carbohydrates attached to them (Chapman, 1986).

In addition to apolipoproteins, HDL contains an additional protein in the form of the enzyme LCAT, which esterifies cholesterol esters by transferring a LCFA moiety from phosphatidylcholine (lecithin) to cholesterol. LCAT is activated by lipoprotein A-I.

C. Digestion of Fat and Formation of Chylomicrons

The largest lipoproteins are the chylomicrons. To understand their formation, the digestion of triacylglycerol must be discussed. The main site of digestion and absorption of triacylglycerol is the small intestine, and the chief enzyme involved is pancreatic lipase. The pancreas not only supplies lipase to attack triacylglycerol, but also supplies cholesterol esterase to hydrolyze cholesterol esters and phospholipase A_2 to attack phospholipids. If any of these enzymes is to be effective, the lipids in food must first be emulsified with bile. Bile contains micelles composed mostly of bile acids, phospholipids, and cholesterol. Fats in food become part of these micelles, and then the enzymes can attack them on the outer surface of the micelles. The fatty acids, monoacylglycerols, and cholesterol resulting from the attack of the enzymes become part of the lipids of the brush border of the intestinal cells. The intestinal cells then use the monoacylglycerols and fatty acids to resynthesize triacylglycerol. Globules of triacylglycerol coated with protein are extruded from the basolateral membranes into the interstitium as chylomicrons. The lymphatic capillaries of the microvilli are called *lacteals* and have many large openings between the endothelial cells that line them. Consequently, the chylomicrons can enter the lymphatics, but not the blood capillaries. From the small intestine, the lymph flows to larger abdominal ducts to the thoracic duct and enters the right atrium. Thus, unlike most other nutrients, most of the absorbed fat bypasses the portal system and liver (Brindley, 1991).

The main apolipoproteins in chylomicrons are A series, B_{48}, C series, and E. The A series and B_{48} apolipoproteins are added by the small intestine, but the C series and E apolipoproteins, which are synthesized in the liver, appear to transfer from HDL to nascent chylomicrons soon after they are released into the circulation.

Chylomicrons are attacked by LPL, which resides on the surface of endothelial cells and hydrolyses tri-

TABLE 4.2 Apolipoproteins of Domestic Animals[a]

Apolipoprotein	Molecular weight	Major synthetic organ	Constituent of lipoprotein	Special properties
A-I	28 kDa (all species)	Small intestine	Chylomicrons, HDL	Activates lecithin: cholesterol acyltransferase
A-II (monomer)	8.5 kDa (cattle, dog) 6.5 kDa (horse)	Small intestine	Chylomicrons, HDL	Exists mostly as a dimer
A-IV	43 kDa (cattle, dog)	Small intestine	Nascent chylomicrons, HDL	Activates lecithin: cholesterol acyltransferase?
B_{48}	270 kDa (cattle, horse)	Small intestine	Chylomicrons	
B_{100}	534 kDa (cattle, horse) 325 kDa (swine)	Liver	VLDL, LDL	Binds to LDL receptor
C-I	8.0 kDa (cattle)	Liver	VLDL, LDL, HDL, chylomicrons	
C-II	9.5 kDa (cattle, pig) 14 kDa (horse)	Liver	VLDL, LDL, HDL, chylomicrons	Activator of lipoprotein lipase
C-III	8.0 kDa (cattle) 12 kDa (horse)	Liver	VLDL, LDL, HDL	
C-IV	10 kDa (cattle)	Liver	VLDL, LDL, HDL, chylomicrons	
E	37 kDa (all species)	Liver	VLDL, LDL, HDL, chylomicrons	Binds to LDL and chylomicron remnant receptor

[a] References: Chapman, 1986; Demacker *et al.*, 1987; Watson *et al.*, 1991; Bauchart, 1993; Watson and Barrie, 1993.

acylglycerol. Most of the resulting LCFA are absorbed by the tissue cells. As the chylomicron diminishes in size, some of the apolipoproteins, mostly A series and C series, transfer to HDL. Finally, a much diminished chylomicron remnant is left and will attach to an apolipoprotein E receptor on hepatocytes. The remnant will be absorbed, and its components hydrolyzed within the hepatocytes (Brindley, 1991; Schneider, 1991). The transport and metabolism of chylomicrons is illustrated in Fig. 4.6.

D. Very-Low-Density Lipoproteins: Synthesis, Export, and Metabolism

Secretion of VLDLs into the plasma is the main method by which hepatocytes export triacylglycerol. Its main apolipoproteins are B_{100}, C series, and E, but some A series is present as well. The A-series apolipoproteins, which are synthesized in the small intestine, transfer from HDL to VLDL soon after its secretion. Some C-series and E apolipoprotein may transfer from HDL to newly secreted VLDL as well. Like chylomicrons, the main lipid component of VLDL is triacylglycerol (see Table 4.1). VLDL and chylomicrons both serve as a means to distribute triacylglycerol to tissues. In the case of chylomicrons, the triacylglycerol is a product of fat digestion, whereas in the case of VLDL, the triacylglycerol is synthesized in the liver.

The assembly process for VLDL is complex (Fig. 4.7). Final steps in the synthesis of triacylglycerol, phospholipid, and cholesterol occur in the smooth endoplasmic reticulum. Microdroplets containing these three lipids and cholesterol esters move toward the confluence of the rough and smooth endoplasmic reticulums where they are joined by apolipoproteins synthesized on the rough endoplasmic reticulum to form the nascent VLDL.

The nascent VLDL particles move through microtubular membranes to the Golgi apparatus where the apolipoproteins are glycosylated. In the Golgi apparatus, the nascent VLDL particles reach final composition and are surrounded by membranes to form secretory granules. The secretory granules merge with the plasma membrane and spill their contents into the plasma (Alexander *et al.*, 1976; Davis, 1991).

The capacity of the liver to synthesize the protein components of VLDL is stimulated by a diet high in carbohydrate. It has been hypothesized that this stimu-

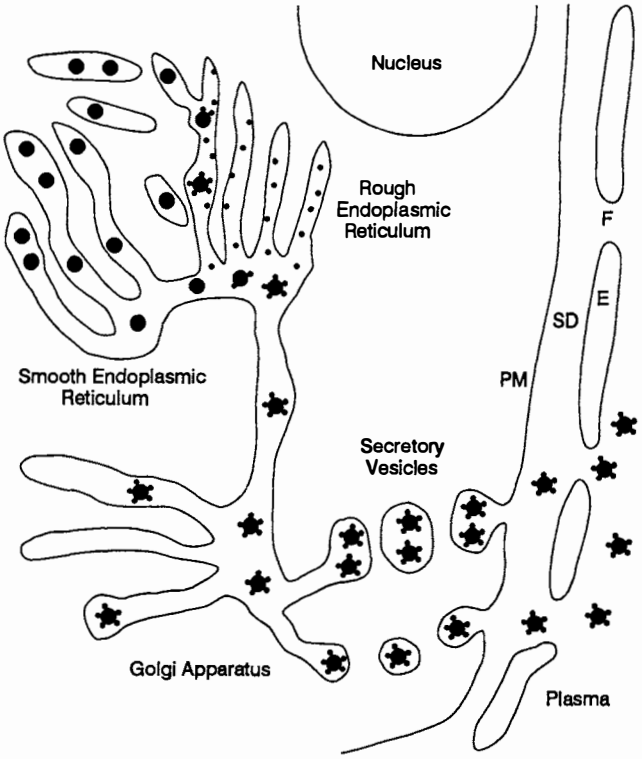

FIGURE 4.7 Synthesis of VLDL in liver. Triacylglycerol and phospholipid synthesis occurs in the smooth endoplasmic reticulum to generate lipid particles (large dots), which acquire small amounts of cholesterol and its esters as well. Apolipoproteins (small dots) are synthesized on the rough endoplasmic reticulum. Lipid particles acquire apolipoproteins at the convergence of the rough and smooth endoplasmic reticulum or by merging of sections of the two organelles. The nascent VLDL move though tubular membranes to the Golgi apparatus where apolipoproteins are glycosylated, and the nascent VLDL are collected in secretory vesicles. The secretory vesicles migrate to and merge with the plasm membrane (PM) and spill VLDL into the space of Dissé (SD). The VLDL migrate through the fenestrae (F) between endothelial cells (E) to enter the plasma in hepatic sinusoids.

lation is due to increased insulin and decreased glucagon levels in plasma. Most studies have shown that glucagon partially inhibits hepatic VLDL secretion, whereas insulin stimulates it (Gibbons, 1990). Estrogens (Crook and Seed, 1990; Sacks and Walsh, 1994; Haffner and Valdez, 1995) and glucocorticoids (Gibbons, 1990; Martin-Sanz *et al.*, 1990) stimulate VLDL secretion.

The inherent capacity of the liver to synthesize the lipid components exceeds its inherent capacity to synthesize the protein components, a fundamental factor in the development of fatty liver. In addition, phosphatidylcholine is essential for lipoprotein assembly, so animals having a deficiency of choline tend to develop fatty livers (Davis, 1991).

Triacylglycerol in plasma VLDL is hydrolyzed by LPL just like triacylglycerol of chylomicrons, and most of the released LCFAs are absorbed by the underlying tissue cells. As the VLDLs shrink some of the apolipoproteins (C series and E) transfer to HDL. Finally, the shrinking VLDL becomes an IDL and then a LDL. The LDL will attach to an apoprotein B_{100} or E receptor on hepatocytes or extrahepatic tissues and be taken into the cell where its component parts will be hydrolyzed. The transport and metabolism of VLDL are illustrated in Fig. 4.8.

E. Metabolism of High-Density Lipoproteins

HDLs are synthesized by both liver and small intestine. Nascent HDL produced in the small intestine has only A-series apolipoproteins and gains C-series and E apolipoproteins and LCAT, which are synthesized in the liver, from other lipoproteins after it enters the circulation. Nascent HDL produced in the liver gains its A-series apolipoprotein, which is synthesized in the small intestine, from other lipoproteins after it enters the circulation. HDL serves two main functions. It is a repository for A-series, C-series, and E apolipoproteins, and it transports cholesterol from peripheral tissues to liver. LCAT is important in this latter function. The conversion of cholesterol to cholesterol ester within HDL creates a favorable concentration gradient from tissue cell to HDL, which promotes migration of cholesterol from tissue cells to HDL (Fielding and Fielding, 1991; Gurr and Harwood, 1991).

HDL is removed from the circulation primarily by the liver, and its component parts can be metabolized within the hepatocyte or some of its lipid components can be incorporated into VLDL and enter the plasma again. Cholesterol can migrate from HDL into hepatocytes without the entire HDL being removed and, as mentioned earlier, apolipoproteins can migrate from HDL to chylomicrons, VLDL, and other HDL.

In summary, chylomicrons and VLDL distribute triacylglycerol, cholesterol and phospholipids from the small intestine and liver, respectively, to other tissues. IDL and LDL are effectively remnants of VLDL. HDL is a reservoir of some apolipoproteins and transports cholesterol from peripheral tissues to liver.

VII. HYPERLIPIDEMIA

A. Introduction

Hyperlipidemia refers to increased plasma levels of cholesterol (hypercholesterolemia) and triacylglycerols (hypertriacylglycerolemia or hypertriglyceridemia). Note that increased plasma levels of LCFA alone

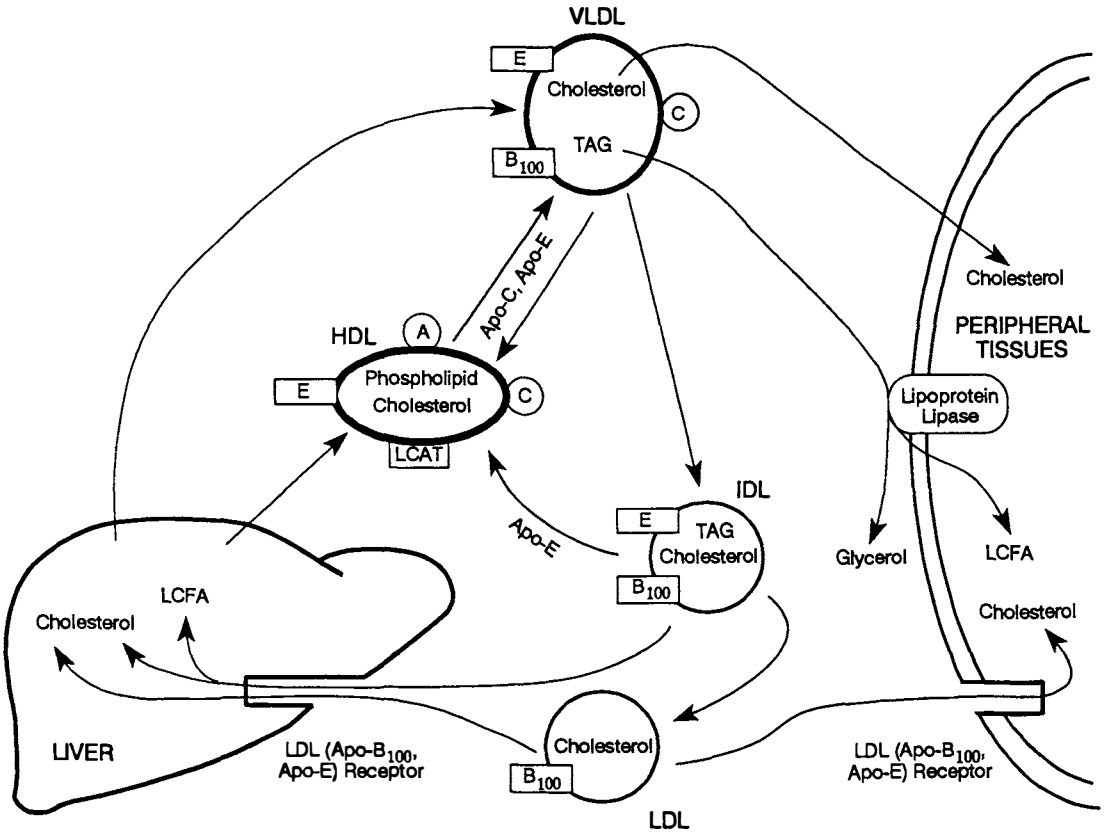

FIGURE 4.8 Metabolism and transport of VLDL. Abbreviations: A, B_{100}, C, E, apolipoproteins; HDL, IDL, and LDL, high-, intermediate-, and low-density lipoproteins, respectively; LCAT, lecithin:cholesterol acyltransferase; LCFA, long-chain fatty acid; TAG, triacylglycerol.

do not constitute hyperlipidemia. Because cholesterol and triacylglycerols must reside within lipoproteins in plasma, hyperlipidemia is synonymous with hyperlipoproteinemia. *Lipemia* is a term denoting that hyperlipidemia is severe enough that the plasma looks milky (i.e., lactescent). If lipemia is marked, whole blood may have a light red color or "tomato soup" appearance. The most common form of hyperlipidemia is postprandial hyperlipidemia, which is observed after an animal consumes a meal containing fat, and is primarily a result of increased chylomicron levels. For evaluation of possible abnormalities in lipid metabolism, it is important that blood samples be taken from fasting animals to avoid confusion caused by postprandial hyperlipidemia. One exception is adult ruminants, which are usually on a very low fat diet and, in addition, because of the volume of the rumen and fermentative nature of digestion there, have absorption spread over a considerable time period.

B. Canine Fasting Hyperlipidemias

Healthy dogs normally do not develop significant hyperlipidemia on fasting. Therefore, fasting hyperlipidemia in a dog usually is an abnormal sign with potential causes being hypothyroidism, diabetes, pancreatitis, hyperadrenocorticism, hepatic disease, nephrotic syndrome, and inherited defects in lipid metabolism. Hyperlipidemia is commonly observed in dogs with hypothyroidism, whether of congenital or acquired origin (Manning *et al.*, 1973; Liu *et al.*, 1986; DeBowes, 1987; Medaille *et al.*, 1988; Barrie *et al.*, 1993; Watson and Barrie, 1993). The main lipid that is increased is cholesterol, but triacylglycerol can be increased too. Most of the increased lipid is in LDL and HDL, but some animals have increased VLDL or chylomicron levels as well (Rogers, 1977; Whitney, 1992). The mechanism by which hypothyroidism causes hyperlipidemia in dogs is unknown; however, a similar phenomenon occurs in humans, and in that species, it appears that hypothyroidism decreases lipoprotein lipase and hepatic lipase activities (Valdemarsson *et al.*, 1983). The prolonged hypercholesterolemia associated with chronic hypothyroidism in dogs may lead to atherosclerosis (Patterson *et al.*, 1985; Liu *et al.*, 1986) although other factors may be involved as well.

Dogs with naturally occurring pancreatitis frequently have hyperlipidemia (Whitney *et al.*, 1987; Hardy, 1992). Because the pancreatitis in some of these

animals causes diabetes, the hyperlipidemia in those individuals may be a result of the diabetes. Plasma lipid levels of dogs with pancreatitis induced by injecting bile into or ligating the pancreatic duct are comparable to control dogs (Zieve, 1968; Bass *et al.*, 1976; Whitney *et al.*, 1987). In some cases, hyperlipidemia may play a role in the pathogenesis of pancreatitis rather than being a result of pancreatitis. This proposition is supported by the fact that humans with some forms of hyperlipidemia have increased risk of pancreatitis (Greenberger, 1973; Cameron *et al.*, 1974). One proposed mechanism is that increased lipids, especially chylomicrons, entering the pancreatic capillaries will be hydrolyzed by pancreatic lipase, and the resultant LCFA may injure endothelial or acinar cells (Havel, 1969). Once the initial damage occurs, there is a positive feedback in which more lipase enters the circulation and hydrolyses more triacylglycerol leading to more LCFA release and more damage. In support of this theory, when dog pancreata were perfused with a medium containing high levels of triacylglycerol or LCFA, they became edematous and hemorrhagic and released large amounts of amylase compared to pancreata perfused without these additions (Saharia *et al.*, 1977). In a related proposed mechanism, large amounts of chylomicrons or VLDL may impede the microcirculation of the pancreas, leading to partial stasis, which allows blood lipids and their hydrolysis products more contact with pancreatic cells (Hardy, 1992).

Dogs with uncontrolled diabetes frequently have hyperlipidemia (Rogers, 1977; Medaille *et al.*, 1988; Whitney, 1992). In naturally occurring cases, plasma triacylglycerol levels are increased with concomitant increases in VLDL levels and often hyperchylomicronemia is present as well (Rogers *et al.*, 1975b; Rogers, 1977; DeBowes, 1987; Ford, 1995). The increase in VLDL is due in part to increased mobilization of LCFA from adipose. The liver removes LCFA from plasma and reissues some of them to the plasma as triacylglycerol in VLDL. In addition, synthesis of lipoprotein lipase by peripheral tissues is partially dependent on insulin, so less of this enzyme is available to remove triacylglycerol from the circulation (Brown and Goldstein, 1994).

Hyperlipidemia with increases in plasma triacylglycerol and cholesterol levels has been noted in dogs with cholestasis (Meyer and Chiapella, 1985; Bauer *et al.*, 1989). The increase in cholesterol can be explained in part by the inability of the liver to remove and catabolize cholesterol. However, there is evidence of production of an abnormal LDL, called lipoprotein-X, which is rich in cholesterol (Danielsson *et al.*, 1977; Blomhoff *et al.*, 1978; Meyer and Chiapella, 1985; Bauer *et al.*, 1989).

Dogs with hyperadrenocorticism (Cushing's disease) often have hyperlipidemia with increased total plasma cholesterol levels (Ling *et al.*, 1979; Scott, 1979; Medaille *et al.*, 1988; Barrie *et al.*, 1993; Feldman, 1995). Most of the increased plasma cholesterol is associated with LDL, and although the mechanism of the hyperlipidemia is unclear, it may be related to a decrease in activity of hepatic LDL receptors (Barrie *et al.*, 1993).

Dogs with nephrotic syndrome often have hyperlipidemia (McCullagh, 1978; Lewis and Center, 1984; Medaille *et al.*, 1988; Ford, 1995). Hypercholesterolemia is present most commonly, but hypertriacylglycerolemia may also be present, especially in more severe cases (McCullagh, 1978). In humans with nephrotic syndrome, the hyperlipidemia appears to be related to the loss of albumin or regulatory factors in the urine, and infusion of albumin or dextran into afflicted patients lowers lipid levels (Glassock *et al.*, 1991). Albumin or regulatory factors may inhibit VLDL production by the liver; without this inhibition, more VLDL will be released to the plasma increasing VLDL and LDL levels (Glassock *et al.*, 1991).

Idiopathic hyperlipidemia, which is probably inherited, occurs in some miniature schnauzers (Rogers *et al.*, 1975a; Richardson, 1989; Ford, 1993). Animals present with abdominal pain, diarrhea, and vomiting, and sometimes with seizures and pancreatitis. Affected animals have hypertriacylglycerolemia, hypercholesterolemia, and increased chylomicron levels and often have increased levels of other lipoproteins as well. It has been proposed that these animals may have low levels of LPL or perhaps deficient apolipoprotein C-II, the activator of LPL. However, some dogs have shown clearing of the plasma following heparin injection, so the mechanism remains unknown. The primary treatment is to place the animal on a low-fat diet. A similar syndrome has been reported in mixed breed dogs (Baum *et al.*, 1969; Rogers *et al.*, 1975a) and in Brittany spaniels (Hubert *et al.*, 1987).

C. Feline Fasting Hyperlipidemias

Not surprisingly, some of the same diseases that are associated with hyperlipidemia in dogs are associated with hyperlipidemia in domestic cats, including diabetes and nephrotic syndrome (McCullagh, 1978; Watson and Barrie, 1993; Jones, 1995). Some cats, however, have a well-characterized familial hyperlipidemia due to LPL deficiency (Jones *et al.*, 1983; Brooks, 1989; Watson *et al.*, 1992b; Whitney, 1992; Jones, 1993, 1995). There is lipemia with hyperchylomicronemia and increases in plasma levels of cholesterol and triacylglycerol (Whitney, 1992; Jones, 1993, 1995). The high plasma levels of lipids lead to deposition in tissues (xanthoma formation) in the skin, nerve sheaths, and

other locations (Whitney, 1992; Jones, 1993). Pressure on spinal or other nerves from xanthomas or subsequent granulomas may lead to peripheral neuropathy (Jones *et al.*, 1986). The disease appears to be autosomal recessive, and homozygotes apparently manufacture a defective LPL and do not have a defective or missing apolipoprotein C-II activator (Peritz *et al.*, 1990; Watson *et al.*, 1992b).

D. Equine Fasting Hyperlipidemia

The phenomenon of equine hyperlipidemia was reported in horses with maxillary myositis (Hadlow, 1962) and equine infectious anemia (Gainer *et al.*, 1966). It is likely that the hyperlipidemia described in these early reports was due to anorexia, and it has been shown that fasting alone causes hyperlipidemia in horses and that pregnancy, lactation, and obesity accentuate the effect (Schotman and Kroneman, 1969; Schotman and Wagenaar, 1969; Eriksen and Simesen, 1970; Schotman and Wensing, 1977). Total plasma triacylglycerol may increase from a normal fed value of less than 500 mg/liter to more than 2000 mg/liter (Morris *et al.*, 1972; Naylor *et al.*, 1980) and, in severe cases, may exceed 10,000 mg/liter (Schotman and Wensing, 1977; Naylor *et al.*, 1980; Freestone *et al.*, 1991). Although most horses are susceptible to this effect of calorie deprivation, it is harmless for the majority and only becomes pathological for a few. Ponies are more susceptible to the pathological syndrome, which can be fatal. Survival rates are inversely proportional to plasma triacylglycerol concentrations (Schotman and Wagenaar, 1969), and severe fatty liver and increased plasma levels of liver enzymes have been reported (Schotman and Wagenaar, 1969). Like in other mammals, fasting increases the plasma levels of LCFA in horses and ponies (Baetz and Pearson, 1972; Naylor *et al.*, 1980; Watson *et al.*, 1992a), and the hyperlipidemia in horses and ponies is due to increased VLDL levels (Morris *et al.*, 1972; Bauer, 1983; Watson *et al.*, 1992a). Presumably, horse liver is removing LCFAs from plasma and reesterifying them into triacylglycerol, which is released to the plasma as VLDL. It appears that the liver of fasting horses has a high capacity for reesterification of LCFAs into triacylglycerol, which is exported as VLDL. Horses do have increased plasma ketone levels when fasting (Rose and Sampson, 1982), so some of the LCFAs removed from plasma by liver are converted to ketones, but additional LCFAs are reesterified to glycerol and are recycled to the plasma as triacylglycerol in VLDL.

The mechanism of fasting equine lipemia is uncertain; it could be increased secretion or decreased uptake of VLDL or a combination thereof. In one study, fasting horses were injected with Triton WR 1339, a compound shown to inhibit LPL in rats, and the rate of increase in plasma triacylglycerol levels was observed (Morris *et al.*, 1972) and compared with the preinjection level of triacylglycerol. The authors claimed that the rate of increase was not related to the level of triacylglycerol concentration. However, only four horses were used, which may not have been enough given the high variation in fasting triacylglycerol levels observed among them. On close examination of the data, it is apparent that three horses showed a perfect rank correlation of fasting triacylglycerol level and rate of triacylglycerol increase after Triton injection, with the fourth being a considerable outlier to the trend. In addition, the dose of Triton was such that all the horses developed anemia due to intravascular hemolysis. Thus, elucidation of the mechanism of fasting equine lipemia will have to await additional kinetic or enzyme studies. There are reports of apparent therapeutic success with intravenous glucose and oral carbohydrates (Watson and Love, 1994; Mogg and Palmer, 1995). This therapy makes sense in that increased plasma glucose levels should lead to increased insulin and decreased glucagon levels, which should inhibit lipolysis in adipose that is generating the plasma LCFAs used for triglyceride synthesis. In addition, the hormonal changes may stimulate LPL activity. Although supplemental insulin has been used with carbohydrate therapy, its efficacy and safety have not been adequately evaluated.

VIII. KETOGENESIS AND KETOSIS

A. Introduction

The ketones or ketone bodies, which are composed of acetoacetic acid, 3-hydroxybutyric acid (also known as β-hydroxybutyric acid), and acetone, are important compounds in the metabolism of birds and mammals. Ketosis simply means that ketones are present in body fluids in elevated concentrations. Ketones are important clinically and have a rather sinister reputation because of the ketoacidosis that is often present when their plasma levels are high. In recent years though, the survival value of ketogenesis has become clearer, and although increased levels of ketones in biological fluids will continue to be regarded as a pathological sign in many situations, perhaps the beneficial aspects of ketogenesis will be more widely appreciated.

B. Chemistry of Ketones

1. Structure and Properties

The ketones, acetone, 3-hydroxybutyric acid, and acetoacetic acid, are relatively simple chemical structures. Of the three, only 3-hydroxybutyric acid can

exist as stereoisomers, having L (+) and D (−) forms. Only the D (−) form is produced in a free state in intermediary metabolism. The L (+) form exists only as its CoA thioester produced and destroyed in β-oxidation (Newsholme and Leach, 1983). Acetone is relatively volatile, whereas the other two ketones are not. Acetone has a characteristic organic solvent odor, which may be detectable in the exhaled breath of animals with elevated blood ketone levels. Anecdotal evidence indicates that people vary greatly in their olfactory sensitivity for acetone.

Acetone does not ionize appreciably, whereas 3-hydroxybutyric acid and acetoacetic acid do readily ionize. Acetoacetic acid has a pK_a of 3.58, and 3-hydroxybutyric acid has a pK_a of 4.41 (Dean, 1985). Consequently, at normal plasma pH of 7.40, 99.9% of either compound exists in its ionized form. Therefore, the compounds will usually be referenced by the names of their ions whenever their metabolism is discussed. Acetoacetic and 3-hydroxybutyric acids are more powerful acids than the volatile fatty acids (VFAs; acetic, propionic and butyric acids), which have pK_a's of 4.76–4.87 (Dean, 1985). Acetoacetic acid is more powerful and 3-hydroxybutyric acid is less powerful as an acid than lactic acid, which has a pK_a of 3.86 (Dean, 1985).

Acetone and acetoacetic acid are miscible in water in all proportions, and 3-hydroxybutyric acid is exceedingly soluble, but not in all proportions (Dean, 1985). The common metallic salts of acetoacetic acid and 3-hydroxybutyric acid are soluble in water. Acetone and 3-hydroxybutyric acid and its salts are relatively stable compounds. Acetoacetic acid spontaneously decomposes to acetone and carbon dioxide. This reaction occurs readily without catalysis, and its rate is accelerated by increased temperature and hydrogen ion concentration. Apparently, some nonspecific catalysis of acetoacetate decarboxylation by cellular proteins can occur (Williamson, 1978). The lithium, sodium, and potassium salts of acetoacetic acid are relatively stable if stored in dry form below 0°C.

2. *Detection and Assay*

a. Qualitative

The most common qualitative test for ketones is the alkaline nitroprusside test, which is also known as the Rothera test (Rothera, 1908). This test has been used for decades in clinical practice and is still exceedingly useful today. The test relies on the reaction of nitroprusside with acetone or acetoacetate to produce a purple chromogen. The nitroprusside test has been used for virtually every body fluid imaginable including whole blood, serum, plasma, urine, and milk. The test is most sensitive for acetoacetate (0.5 mmol/liter can be detected), gives only a slight response to acetone, and is completely insensitive to 3-hydroxybutyrate.

The nitroprusside test is available commercially in the form of strips, tablets, and powders. The maximum sensitivity of all three forms is approximately 0.5 mmol/liter, although specific formulations may have a sensitivity less than this value. The strip form is commonly used for urine. The powder form and strips are both commonly used for milk. The tablet form is used for serum, plasma, and whole blood and can be used for milk and urine as well. The test is often used in a semiquantitative manner with the result expressed in adjectival form (negative, weak, strong) or as a series of pluses (−, +, ++, etc.).

A number of drugs or other substances may appear in urine and give a false positive with the nitroprusside test. Some compounds react with nitroprusside to yield a purple or near purple color. Included in this group are phenylketones, levodopa, methyldopa, acetaldehyde, paraldehyde (Caraway and Kammeyer, 1972), cysteine, cysteamine, penicillamine, and mesna (Csako, 1987). In general, substances with keto, aldehyde, or sulfhydryl groups have the potential for reacting with nitroprusside. Since the nitroprusside test is performed in an alkaline medium, some substances, like sulfobromophthalein and phenolsulfonphthalein, which may exist in urine and are otherwise colorless, may yield a purple or near purple color simply due to the alkaline pH (Caraway and Kammeyer, 1972).

b. Quantitative

Commonly used means of quantitative assay for ketone concentrations in biological fluids include microdiffusion methods, used primarily for assay of acetone, and enzymatic methods, used primarily for assay of acetoacetate and 3-hydroxybutyrate. Regardless of the method to be used for analysis, proper handling of the samples prior to analysis is crucial for obtaining representative results. In particular, the volatility of acetone and instability of acetoacetate must be respected.

Blood samples should be cooled immediately after collection. Ketones can be determined on whole blood or plasma. Serum is not recommended because of losses, particularly of acetoacetate, that may occur during the time required for clotting. Any of the common anticoagulants (heparin, fluoride, oxalate, citrate, or EDTA) may be used. If whole blood is to be used, it should be mixed with perchloric acid immediately after collection to precipitate proteins. The tube should be chilled on ice until centrifuged, which should be performed within a few hours. The supernatant should

be frozen until analyzed. If plasma is to be used, the red cells should be spun down within a few hours, and the plasma proteins precipitated with perchloric acid. The supernatant should be frozen until analyzed.

The microdiffusion method can be used to determine the concentration of acetone or acetone plus acetoacetate in any biological fluid. The reagents are relatively simple and inexpensive although rather corrosive. The diffusion step requires specialized, but inexpensive, apparatus and adds to the complexity and time to complete the assay. The method relies on the reaction of acetone with vanillin (Henry *et al.*, 1974) or salicylaldehyde (Nadeau, 1952) to produce a colored product that can be quantified in a spectrophotometer. In the author's experience, vanillin provides more sensitivity than salicylaldehyde, but variability in the purity of vanillin batches from commercial sources makes salicylaldehyde the reagent of choice. Salicaldehyde must be stored under nitrogen or argon to preserve its purity.

The method as described by Henry *et al.* (1974) was shown to determine acetone, and there was speculation that it would also detect acetoacetate simultaneously. In fact, the method as described by Henry *et al.* (1974) is specific for acetone. It has been found in the author's laboratory that to use the method for acetone plus acetoacetate, it is necessary to preincubate the sample with an equal volume of 10 *N* sulfuric acid for 4 hours at 50°C in a sealed container to decarboxylate all of the acetoacetate. The method can be adapted to measure 3-hydroxybutyrate as well by introducing a step in which 3-hydroxybutyrate is oxidized to acetoacetate with potassium dichromate (Procos, 1961). However, if the primary interest is the determination of acetoacetate or 3-hydroxybutyrate, rather than acetone, the enzymatic method described later should be used.

The enzymatic method for assay of acetoacetate or 3-hydroxybutyrate in biological fluids is accurate and precise (Williamson *et al.*, 1962) and is probably the most common method used for quantitative assay of ketone concentrations. The method has been successfully adapted to a variety of automated analysis systems (Ozand *et al.*, 1975; Työppönen and Kauppinen, 1980; Harano *et al.*, 1985) and is a relatively straightforward spectrophotometric or fluorometric method. For a detailed step-by-step practical description of the method, see Mellanby and Williamson (1974) and Williamson and Mellanby (1974).

The method relies on the reversible reaction catalyzed by 3-hydroxybutyrate dehydrogenase:

$$\text{3-Hydroxybutyrate} + \text{NAD}^+ \leftrightarrow \text{acetoacetate} + \text{NADH} + \text{H}^+.$$

The reaction is run in the forward direction by including an excess of NAD^+ in the reaction mixture to assay 3-hydroxybutyrate and in the backward direction by including an excess of NADH in the reaction mixture to assay acetoacetate. The equilibrium constant of the reaction is 1.42×10^{-9} and, therefore, is highly favorable toward the reduction of acetoacetate at pH 7.0 (Krebs *et al.*, 1962). To force the reaction to completion in the direction of oxidizing 3-hydroxybutyrate, hydrazine is used as a trapping agent to remove acetoacetate as it is formed, and the reaction mixture is buffered at an alkaline pH. The change in NADH concentration is measured by the change in absorbance at 340 nm in either case. Alternately, a fluorometer can be used to measure the change in NADH concentration. To avoid interference from lactate or pyruvate in the sample, the 3-hydroxybutyrate dehydrogenase should be free of lactate dehydrogenase; alternatively, the lactate dehydrogenase inhibitor, oxamic acid, can be added to the reaction mixture (Harano *et al.*, 1985).

Table 4.3 lists normal blood and plasma ketone concentrations for several domestic species. The values are for healthy fed animals. Plasma and blood ketone concentrations are assumed to be similar because of the generally high permeability of cell membranes to ketones and lack of protein binding of ketones; however, reports of definitive studies on this problem are not apparent in the literature. For clinical purposes, there is no lower normal limit for ketone concentrations.

C. Synthesis of Ketones

Ketones are primarily products of intermediary metabolism. Only under unusual circumstances would more than trace amounts be absorbed from the contents of the gastrointestinal tract. The real source of ketones is fatty acids including those with short (1–4 carbons), medium (5–11 carbons), and long (>11 carbons) chains. Of course, any compound (glucose, lactate, glycerol, amino acids, etc.) that can be converted to fatty acids can be considered as a source of ketones, but for the purposes of this discussion, the origin of ketones will be considered to be fatty acids, either esterified or nonesterified.

The predominant source of ketones in healthy animals is LCFAs released during lipolysis in adipose tissue. When plasma insulin levels decrease and plasma glucagon levels increase, cAMP levels in adipose cells increase. Increased cAMP levels lead to activation of hormone sensitive lipase, which hydrolyses triacylglycerols to LCFA and glycerol. The LCFAs bind to plasma albumin for transport to other tissues, whereas glycerol freely dissolves in plasma water (Spector and Fletcher, 1978; McGarry, 1979; Newsholme and Leach, 1983).

TABLE 4.3 Blood and Plasma Ketone Concentrations of Domestic Animals[a]

Species	3-Hydroxy-butyrate (mmol/liter)	Acetoacetate (mmol/liter)	Sample	References
Cow	0.41 ± 0.03	0.043 ± 0.00	Plasma	Hibbit *et al.*, 1969
(lactating)	0.95 ± 0.18	0.13 ± 0.03	Blood	Gröhn, 1985
Cow (nonlactating)	0.27 ± 0.04	0.011 ± 0.003	Plasma	Baird *et al.*, 1968
Dog	0.033 ± 0.015	0.018 ± 0.010	Blood	Balasse, 1970
	0.030 ± 0.006	—	Plasma	Lammerant *et al.*, 1985
Goose	0.042 ± 0.015	0.023 ± 0.003	Plasma	Maho *et al.*, 1981
Horse	0.11 ± 0.01	—	Blood	Snow and Mackenzie, 1977
	0.064 ± 0.006	0.029 ± 0.003	Plasma	Rose *et al.*, 1980
Sheep	0.27 ± 0.04	0.051 ± 0.005	Blood	Brockman, 1976
	0.55 ± 0.04	0.030 ± 0.002	Blood	Heitman *et al.*, 1986

[a] Values are means ± standard errors for healthy fed animals. Ketone concentrations were determined by the method of Williamson *et al.* (1962) or a modification thereof.

1. Ketogenesis by Liver

The liver has an enormous capacity to remove LCFAs from plasma. LCFAs unbind from albumin, diffuse through the hepatocyte plasma membrane, and bind to fatty acid binding protein in the cytosol (Burnett *et al.*, 1979). In the cytosol, LCFAs are converted to LCFA-CoA as discussed earlier. The LCFA-CoA can be used to synthesize triacylglycerol or can go through β-oxidation to acetyl-CoA in the mitochondrion, also discussed earlier. Mitochondrial acetyl-CoA can have a number of fates, but under circumstances that elevate plasma LCFA levels, the two main fates are combustion in the TCA cycle or conversion to ketones. Two acetyl-CoA units can be recondensed to form ketones, which will occur when there is insufficient oxaloacetate for citrate formation or when citrate synthase is inhibited by high levels of citrate.

Four enzymes are involved in ketogenesis from acetyl-CoA: acetoacetyl-CoA thiolase, hydroxymethylglutaryl-CoA (HMG-CoA) synthase, HMG-CoA lyase, and D-3-hydroxybutyrate dehydrogenase. These four enzymes catalyze the following four reactions, respectively:

$$2\ \text{Acetyl-CoA} \leftrightarrow \text{acetoacetyl-CoA} + \text{CoA},$$
$$\text{Acetoacetyl-CoA} + \text{acetyl-CoA} \rightarrow \text{HMG-CoA} + \text{CoA},$$
$$\text{HMG-CoA} \rightarrow \text{acetoacetate} + \text{acetyl-CoA},$$
$$\text{Acetoacetate} + \text{NADH} + \text{H}^+ \leftrightarrow \text{3-hydroxybutyrate} + \text{NAD}^+$$

Thiolase occurs in both cytosol and mitochondria, whereas the other three enzymes are mainly restricted to the mitochondrion. However, there is some HMG-CoA synthase in the cytosol that is involved with cholesterol synthesis. The first three enzymes are in the mitochondrial matrix, whereas 3-hydroxybutyrate dehydrogenase is in the inner membrane of the mitochondrion, and membrane lipids are required for full activity of the enzyme. Interestingly, livers of ruminants have lower apparent activities of 3-hydroxybutyrate dehydrogenase than the livers of other species (Nielsen and Fleischer, 1969; Watson and Lindsay, 1972), a situation that has not been explained adequately. Because ruminant liver is continuously presented with 3-hydroxybutyrate synthesized by the rumen epithelium, the low hepatic activity of 3-hydroxybutyrate dehydrogenase may be beneficial because more of the compound will reach peripheral tissues in an unoxidized state.

Acetoacetyl-CoA thiolase and 3-hydroxybutyrate dehydrogenase catalyze reactions that are at or near equilibrium; that is, the rates of these reactions are controlled by the concentrations of the substrates and products. HMG-CoA synthase and lyase catalyze reactions that are far removed from equilibrium, and these enzymes may be subject to regulatory controls other than the concentrations of substrates and products. The synthase is considered to be the rate-limiting enzyme and appears to be restricted almost exclusively to the liver (McGarry and Foster, 1969; Duee *et al.*, 1994; Valera *et al.*, 1994). Physiological controls of the enzyme are not completely understood; however, the concentration of enzyme molecules in the mitochondria is increased by cAMP, so fasting and diabetes increase it and refeeding decreases it (Serra *et al.*, 1993). In addition, succinyl-CoA inhibits the enzyme (Quant *et al.*, 1990). Glucagon usually decreases mitochondrial succinyl-CoA, whereas an abundance of glucose or glucose precursors, like propionate, increases it. A summary of ketogenesis in the liver is depicted diagrammatically in Fig. 4.2.

Ketogenesis can occur from VFAs and medium-chain fatty acids. Medium-chain fatty acids are normally in quite low concentration in the diet or in triacylglycerols of mammals and, therefore, are not usually

quantitatively important in ketogenesis. Except in unusual circumstances, nonherbivores do not absorb large quantities of VFAs from the gastrointestinal tract. Among the herbivores, the metabolism of VFAs has been studied most thoroughly in ruminants. Propionate is the major gluconeogenic precursor and is not an important precursor of ketones; in fact, propionate inhibits ketogenesis in ruminant liver (Faulkner and Pollock, 1991). The propionate inhibition probably is due to inhibition of carnitine acyltransferase I in ruminant liver by methylmalonyl-CoA, a metabolite of propionate (Brindle *et al.*, 1985). Without active carnitine acyltransferase I, LCFAs cannot enter mitochondria and be oxidized to ketones.

Butyrate is converted to 3-hydroxybutyrate by the rumen epithelium and is discussed later. Acetate must be covalently bound to CoA under the catalysis of acetokinase before it can be catabolized further. Acetokinase is found in the cytosol and mitochondria of most cells in most organs. In ruminants, the liver has a relatively low concentration of acetokinase, and most absorbed acetate passes through the liver and is removed from the plasma by other tissues, particularly heart, skeletal muscle, kidney, and mammary gland (Cook *et al.*, 1969; Bauman and Davis, 1975).

2. *Ketogenesis by the Alimentary Tract*

Butyrate produced during fermentation of feedstuffs in the rumen is readily absorbed by the rumen wall (Stevens, 1970). The rumen epithelial cells possess high activities of butyryl-CoA synthetase, which can convert butyrate to butyryl-CoA (Cook *et al.*, 1969). By β-oxidation, butyryl-CoA is converted to L-3-hydroxybutyryl-CoA, which is oxidized to acetoacetyl-CoA followed by cleavage of the CoA and reduction of the resulting acetoacetate to 3-hydroxybutyrate (Emmanuel, 1980). Rumen epithelium does have HMG-CoA synthase, HMG-CoA lyase, and 3-hydroxybutyrate dehydrogenase activities, although in lesser concentration than in liver (Baird *et al.*, 1970; Emmanuel, 1980). It is possible that rumen epithelium can cleave CoA from acetoacetyl-CoA directly because it contains acetoacetyl-CoA deacylase (Bush and Milligan, 1971). In addition, rumen epithelium possesses 3-ketoacid CoA-transferase, an enzyme to be discussed later when ketone oxidation is discussed (Bush and Milligan, 1971). This enzyme can catalyze the transfer of CoA from acetoacetyl-CoA to succinate, thus liberating acetoacetate. This latter route may be the predominant pathway in rumen epithelium (Bush and Milligan, 1971).

3-Hydroxybutyrate appears in portal blood (Stevens, 1970; Katz and Bergman, 1969). At least 50% of absorbed butyrate is oxidized to ketones in the rumen wall, and of the butyrate that does appear in portal blood, nearly all of it is removed on the first pass through the liver (Ramsey and Davis, 1965; Bergman *et al.*, 1965; Bergman and Wolfe, 1971; Fell and Weekes, 1975). Ruminal production of 3-hydroxybutyrate is probably the main reason why fed ruminants normally have a higher plasma concentration of this compound than fed nonruminants (see Table 4.3).

3. *Ketogenesis by Other Organs*

It has been claimed that mammary gland may synthesize appreciable ketones in ketotic dairy cows; however, the evidence is weak. Arteriovenous concentration differences and mammary blood flow have been used to estimate mammary ketone production and uptake in dairy cows (Kronfeld *et al.*, 1968). It was found that the mammary gland utilized small quantities of acetoacetate and larger quantities of 3-hydroxybutyrate in healthy cows, whereas the mammary gland of ketotic cows produced large quantities of acetoacetate. The increased uptake of 3-hydroxybutyrate by mammary in ketotic cows equaled almost exactly mammary production of acetoacetate. There was no significant difference in mammary uptake of acetate between healthy and ketotic cows.

In yet another study on ketotic cows (Schwalm *et al.*, 1969), arteriovenous (AV) concentration differences across the mammary glands of acetoacetate and 3-hydroxybutyrate were observed. A positive AV difference was noted for 3-hydroxybutyrate, which was almost equal in magnitude to the negative AV difference noted for acetoacetate. The foregoing results point toward mammary conversion of 3-hydroxybutyrate to acetoacetate, which increases in ketosis. This process cannot really be called ketogenesis; perhaps *ketoconversion* would be the appropriate term.

D. Catabolism of Ketones

1. *Reduction and Oxidation*

Reduction is a possibility for acetoacetate and, of course, the reduction product is 3-hydroxybutyrate. 3-Hydroxybutyrate is a metabolic cul de sac because it can be metabolized only by being reconverted to acetoacetate. In comparison to acetoacetate, 3-hydroxybutyrate should be viewed as a means by which the liver can export reducing power (hydrogen) to the peripheral tissues for combustion and energy generation there.

Both acetoacetate and 3-hydroxybutyrate can be reduced by being converted to LCFA. This fate is more likely to occur in mammary gland than in

adipose tissue. Plasma 3-hydroxybutyrate has been shown to be a milk fat precursor in cows (Palmquist *et al.*, 1969), goats (Linzell *et al.*, 1967), and rabbits (Jones and Parker, 1978). A substantial portion of 3-hydroxybutyrate used for milk fat synthesis in ruminants is incorporated as a four-carbon unit (Palmquist *et al.*, 1969; Kinsella, 1970).

Ultimately, the fate of most 3-hydroxybutyrate and acetoacetate is oxidation in the peripheral tissues. Once 3-hydroxybutyrate has been oxidized to acetoacetate, the acetoacetate is converted to acetoacetyl-CoA by the following reaction:

$$\text{Acetoacetate} + \text{succinyl-CoA} \leftrightarrow \text{acetoacetyl-CoA} + \text{succinate.}$$

This reaction is catalyzed by 3-ketoacid CoA-transferase and, viewed from the point of converting succinyl-CoA to succinate, it effectively bypasses the succinyl-CoA synthetase reaction of the citric acid cycle. Because the reaction catalyzed by succinyl-CoA synthetase produces one GTP from GDP, the 3-ketoacid CoA-transferase reaction effectively consumes 1 mol of ATP. The reaction also pushes succinyl-CoA toward oxaloacetate in the citric acid cycle, and oxaloacetate will be needed to form citrate from the acetyl-CoA derived from the acetoacetyl-CoA.

3-Ketoacid CoA-transferase is found in spleen, skeletal muscle, brain, adipose, heart, lung, and kidney of rodents and sheep although the activities are very low in sheep heart and brain (Williamson *et al.*, 1971). In general, though, the highest activities are in the heart and kidney. Activity of 3-ketoacid CoA-transferase is absent in liver (Williamson *et al.*, 1971). The absence of the enzyme from liver is logical because if there were a need for NADH for combustion in the liver, it could be obtained directly from acetyl-CoA in the citric acid cycle rather than shunting the acetyl-CoA units into ketones and back again.

Acetyl-CoA is produced from acetoacetyl-CoA via the acetoacetyl-CoA thiolase reaction, which was discussed under ketogenesis. All tissues have thiolase, and it is in greatest activity in heart, liver, and kidney (Williamson *et al.*, 1971). Heart and brain of sheep have significantly less thiolase than in rodents. The activities of 2-ketoacid CoA-transferase and acetoacetyl-CoA thiolase are relatively stable in fasting, fed state, high-fat diet, and diabetes except that in rodents, thiolase increases on feeding a high-fat diet (Williamson *et al.*, 1971). In general, it appears that the ketone utilizing capacity of the body is relatively constant and ketone availability controls ketone oxidation.

For many years, acetone was viewed as a metabolic dead-end, a substance destined to be excreted in the urine or exhaled in the breath. Although much acetone does indeed wind up in the breath and urine, evidence has accumulated that indicates that some acetone is metabolized (Luick *et al.*, 1967; Owen *et al.*, 1982; Vander Jagt *et al.*, 1992; Kalapos *et al.*, 1994). Furthermore, evidence for the catabolic pathway for acetone metabolism indicates that it is metabolized to pyruvate, apparently via hydroxyacetone and pyruvaldehyde (Vander Jagt *et al.*, 1992). Thus, by this mechanism, it is possible that small amounts of fat can be converted to glucose.

Labeling patterns of milk glutamate carbons following injection of 2-^{14}C-acetone into cows indicated that acetone was metabolized via pyruvate (Luick *et al.*, 1967; Black *et al.*, 1972). Labeling patterns of glucose in humans injected with radiolabeled acetone also indicate metabolism via pyruvate (Owen *et al.*, 1981). In rats, however, labeling patterns of glucose following radiolabeled acetone injection indicate that acetone can be metabolized via pyruvate and acetate, but that the latter pathway predominates (Kosugi *et al.*, 1986). Thus, there appear to be real species differences in acetone metabolism. In humans, at least, the fraction of acetone that is metabolized versus the amount excreted varies inversely with acetone concentration (Owen *et al.*, 1982), so it appears that the catabolizing pathways for acetone are not capable of handling large quantities.

2. *Renal Metabolism and Excretion*

The kidney cannot synthesize ketones to any appreciable extent (Lynen *et al.*, 1958; Weidman and Krebs, 1969), but is a voracious consumer of ketones as an energy source in ruminants (Kaufman and Bergman, 1971, 1974) and nonruminants (Weidman and Krebs, 1969; Baverel *et al.*, 1982). It is interesting though that in fasting sheep, the kidney removes from the plasma and catabolizes both acetoacetate and 3-hydroxybutyrate (Kaufman and Bergman, 1974), whereas in fasting humans, there is substantial removal of 3-hydroxybutyrate and a slight production of acetoacetate (Owen *et al.*, 1969).

Ketones are freely filterable in the glomerulus. There appears to be in humans and dogs, at least, a direct or indirect energy-consuming tubular transport system for acetoacetate and 3-hydroxybutyrate that approaches saturation at relatively low plasma concentrations of ketones such as those encountered in the fed state or after a one-day fast. Neither ketone is excreted at these lower concentrations, but they do begin to appear in the urine as plasma levels begin to rise (Visscher, 1945; Schwab and Lotspeich, 1954; Sapir and Owen, 1975; Wildenhoff, 1977). However, as the ketone concentrations increase in the glomerular filtrate, the primary mode of reabsorption is by diffusion down a

concentration gradient as water is reabsorbed from the tubular lumen. Acetone begins to appear in the urine as soon as it begins to appear in the plasma (Widmark, 1920); presumably, this effect is due to great lipid solubility of acetone, which allows it to penetrate cell membranes with relative ease.

Renal excretion and reabsorption of ketones is approximately proportional to their filtration rates (or plasma concentrations if glomerular filtration rate remains constant) at concentrations found after more than a 1-day fast in humans and in ruminants (Wildenhoff, 1977; Kaufman and Bergman, 1974). At least some parts of the nephron, probably beyond the proximal tubule, are less permeable to ketones than to water because when plasma ketone levels are substantially increased, the urinary concentration exceeds the plasma concentration.

The dual mode of ketone reabsorption has an advantage in that none of this valuable energy source is lost at lower plasma concentrations; however, there is no transport maximum for the kidney as a whole, so 80–90% of filtered ketones are reabsorbed regardless of how concentrated ketones become in the plasma during pathological conditions or prolonged starvation. Mammals presumably could have evolved a greater activity of the energy-consuming ketone transport system. However, the energy cost of continuously maintaining the system at a higher activity probably outweighed the survival value of having the system available during rare periods of prolonged starvation.

E. Pathophysiology of Ketonemia

As discussed earlier, the acetoacetate and 3-hydroxybutyrate are more powerful acids than the VFA and, in the case of acetoacetate, more powerful than lactic acid. Not surprisingly, then, a high concentration of ketones in the plasma results in a metabolic acidosis known as *ketoacidosis.* The most significant ketoacidoses commonly encountered in domestic animals are in diabetes mellitus and ovine pregnancy toxemia. The ketoacidosis encountered in these syndromes may cause plasma bicarbonate to be below 10 mmol/liter (Reid, 1968; Ling *et al.*, 1977) and is a chief contributor to mortality.

The ketoacidosis in diabetes of dogs and cats can be severe with blood pH being 7.2 or less (Schaer, 1976; Ling *et al.*, 1977; Edwards, 1982). Because plasma ketone concentrations in diabetic dogs have been reported to average 3.2 mmol/liter with some individuals having levels of 7–8 mmol/liter (Balasse *et al.*, 1985), the base deficit in extracellular fluids would be greater than that concentration for two reasons. First, the distribution space of the ketones is greater than that of extracellular fluid and, secondly, some acetoacetate and 3-hydroxybutyrate anions may have been lost in the urine without equal losses of hydrogen ion. (A mineral ion, such as sodium or potassium would have balanced the electrical charge.) Base deficits of more than 15 mmol/liter have been reported in spontaneously diabetic dogs (Ling *et al.*, 1977; Edwards, 1982).

As the metabolic acidosis of diabetes progresses in dogs, increased catabolism of muscle protein occurs (Balasse *et al.*, 1985). Much of the nitrogen from protein degradation is diverted into ammonia rather than urea, and it is ammonium ion that balances most of the electrical charge on excreted acetoacetate and 3-hydroxybutyrate.

Ketones are really an alternate form of lipid, comparable to triacylglycerols, LCFAs or VFAs, and should be considered as such in caloric balance (Williamson, 1971). VFAs and ketones are effectively water-soluble forms of lipids; however, only the ketones can be produced in large quantities in tissue metabolism.

In fed animals, only a nominal caloric production is derived from oxidation of ketones; however, in fasted animals or in some pathological conditions, ketone oxidation accounts for a substantial quantity of expended calories. For example, only 3–4% of expired carbon dioxide is derived from 3-hydroxybutyrate in fed cows (Palmquist *et al.*, 1969), whereas 30% of expired carbon dioxide is derived from ketones in fasted pregnant ewes (Pethick and Lindsay, 1982).

It has been demonstrated in canine perfused liver (Shaw and Wolfe, 1984) and *in vivo* in humans (Mebane and Madison, 1964; Binkiwicz *et al.*, 1974; Miles *et al.*, 1981) and dogs (Paul *et al.*, 1966; Balasse *et al.*, 1967) by infusing acetoacetate or 3-hydroxybutyrate that both ketones inhibit gluconeogenesis. In most of these experiments, evidence was seen of increased plasma insulin concentrations, which could account for the diminution in plasma glucose concentration. The survival value of having ketones inhibit gluconeogenesis is that in starvation, as ketones concentrations increase and become available for tissue energy needs, the rate at which body protein must be catabolized to supply glucose precursors can decrease.

Not surprisingly in view of the increased insulin levels usually observed, decreased levels of LCFAs were noted during ketone infusions in some of the experiments mentioned earlier. Thus, increased ketone levels may serve as a negative feedback on rate of lipolysis in adipose and, therefore, on the plasma levels of ketones themselves.

F. Fasting Ketosis

During fasting, hormonal changes occur that promote lipolysis. Most important, as less glucose is available from the gut or from gluconeogenesis in the liver,

plasma glucose concentrations will decrease. Responding to the hypoglycemia, pancreatic islet cells will release less insulin and more glucagon, so that plasma insulin concentrations will decrease and plasma glucagon concentrations will increase. These hormonal changes will increase cAMP concentrations in adipose cells, which leads to the activation of hormone sensitive lipase.

Through the action of hormone sensitive lipase, triacylglycerols are hydrolyzed with release of LCFAs and glycerol. LCFAs are utilized directly by tissues for energy but are also taken up by the liver in proportion to their plasma concentration. During fasting, hepatic concentrations of malonyl-CoA and methylmalonyl-CoA are relatively low, so carnitine acyltransferase I activity is relatively high, and LCFA-CoA are quickly converted to LCFA-carnitine, which is translocated into the mitochondrion (McGarry *et al.*, 1977). Once in the mitochondrion, LCFA-carnitine is converted to LCFA-CoA again.

Following β-oxidation of ketones, some acetyl-CoA is combusted in the citric acid cycle. However, during fasting, gluconeogenesis is quite active in the liver, and much of the mitochondrial oxaloacetate is used for that purpose and is unavailable for citrate formation with acetyl-CoA; consequently, large quantities of acetyl-CoA are shunted into ketogenesis.

Acetoacetate and 3-hydroxybutyrate can be utilized by most extrahepatic tissues. Because peripheral tissues can also use LCFAs, the utility of hepatic production of ketones from LCFAs was not clear originally. However, many tissues have as great or greater capacity for utilizing plasma ketones as for utilizing plasma LCFAs. Among these tissues are heart and kidney (Hall, 1961; Williamson and Krebs, 1961; Owen *et al.*, 1969; Little *et al.*, 1970). In some species, such as the rat (Hawkins *et al.*, 1971) and human (Owen *et al.*, 1967), ketones constitute a major energy source for the brain during fasting. In some other species though, it appears that the brain prefers glucose and utilizes only small quantities of ketones in the fed or fasted state in sheep (Jones *et al.*, 1975; Lindsay and Setchell, 1976; Pell and Bergman, 1983), dog (Wiener *et al.*, 1971), and pig (Tildon and Sevdalian, 1972). Resting skeletal muscle utilizes ketones preferentially as a fuel during short-term starvation (Owen and Reichard, 1971); however, LCFAs are preferred during long-term starvation (Owen and Reichard, 1971) or exercise (Hagenfeldt and Wahren, 1968a, 1968b).

Ketones are quite soluble, require no protein carrier, and diffuse (in their un-ionized form) or are transported rapidly through biological membranes including the blood–brain barrier (Hawkins *et al.*, 1971; Persson *et al.*, 1972). The liver has an advantage over other tissues regarding uptake of LCFAs from plasma albumin because of its unique sinusoidal vascular system. Therefore, the liver can be regarded as a machine that can rapidly remove LCFAs from plasma and convert them to a form, the ketones, that other tissues can utilize rapidly.

Because they must be bound to albumin if they are to be nontoxic, the maximum safe plasma concentration of LCFA is fixed by the albumin concentration. Furthermore, in prolonged fasting, albumin concentration decreases, which lessens the number of LCFA carriers. Generally, LCFA concentrations do not rise above 2 mmol/liter in fasting, whereas ketone concentrations can increase to 3-4 mmol/liter or more. Thus, ketones can have a greater concentration gradient to allow their entry into the cell.

Although the acid nature of ketones has received much attention in the clinical literature, less well recognized is the toxic potential of LCFAs. If LCFAs are released into the plasma in excess of hepatic uptake, albumin binding capacity will be exceeded (Spector and Fletcher, 1978). Unbound fatty acids may damage endothelial cells, perhaps due to detergent action, oxidation of unsaturated LCFAs or changes in cell metabolism (Ramasamy *et al.*, 1991). Such damage to endothelial cells has been proposed as a mechanism in the development of atherosclerotic plaque (Zilversmit, 1973). There is some evidence in humans and guinea pigs that high levels of LCFAs within the heart may predispose it to arrhythmias (Oliver *et al.*, 1968; Cowen and Vaughn-Williams, 1977). The possible role of LCFAs in causing some cases of pancreatitis was discussed earlier.

Ketogenesis in fasting should be viewed as an evolved mechanism with specific survival value for peripheral tissues and not a burden that the liver is placing on the rest of the body. It is important to remember that fasting animals should be expected to have a degree of ketonemia, ketonuria, and ketolactia. Thus, any disease condition that causes anorexia will usually be accompanied by increased ketone levels in body fluids that have no significance other than the fact that the animal has a subnormal caloric intake.

G. Diabetic Ketosis

Although diabetes mellitus is covered in more depth elsewhere in this book, no discussion of ketones would be complete without a mention of this disease. Diabetes is diagnosed more frequently in dogs and cats than other domestic species, and the ketoacidosis that occurs can be fatally severe and was discussed earlier under acid–base balance.

In experimental diabetes in dogs, plasma total ketone concentrations are 3.2 mmol/liter as compared with 0.1 mmol/liter in healthy dogs (Balasse *et al.*,

1985). Diabetes is accompanied by hyperglycemia, whereas most other ketotic syndromes occurring in domestic animals are usually accompanied by normoglycemia or hypoglycemia. The ketonemia in diabetes is due to increased lipolysis in adipose plus accelerated hepatic gluconeogenesis, both brought about by a lack of insulin. Thus, there are abundant plasma LCFAs as ketogenic substrates and metabolic conditions in the liver that favor ketone synthesis.

H. Ketosis Associated with Pregnancy and Lactation

These ketoses are most commonly observed in ruminants although they have been documented in dogs and humans. Before specific syndromes are discussed, a general picture of ketogenesis in pregnancy and lactation is presented.

Fetal demands for glucose are high, and the placenta can transport glucose from maternal to fetal plasma (Setchell *et al.*, 1972; Warnes *et al.*, 1977). When an imbalance occurs between the maternal ability to synthesize or absorb glucose and fetal consumption, hypoglycemia results. Under these circumstances, hypoglycemia will lead to lipolysis in adipose tissue and release of LCFAs as discussed earlier. The LCFAs will be taken up by the liver and converted to ketones with resulting ketosis.

Ketosis in lactation is somewhat more complex than ketosis occurring during pregnancy. The volume of milk produced is almost totally dependent on the rate of lactose synthesis by the mammary gland because milk volume formation is an osmotic phenomenon, and lactose is the predominant molecular species in milk (Peaker, 1977). There is virtually only one precursor of lactose and that precursor is plasma glucose (Kleiber *et al.*, 1955; Bickerstaffe *et al.*, 1974). Therefore, a female that is in heavy lactation will have a heavy drain on plasma glucose. The two sources of plasma glucose are absorption from the gut and gluconeogenesis.

In ruminants, little glucose is absorbed from the gut, so the overwhelming bulk of it is synthesized (Lindsay, 1959; Otchere *et al.*, 1974). Most (approximately 90%) of this synthesis occurs in the liver with the remainder occurring in the kidney (Bergman, 1982). The chief substrates are propionate and amino acids, with the former being most important in animals on a high-grain diet. Other precursors are branched-chain VFAs and lactate absorbed from the rumen and glycerol released during lipolysis (Bergman, 1975). If there is a mismatch between mammary drain of glucose for lactose synthesis and gluconeogenesis in the liver, hypoglycemia will result. Under these circumstances, hypoglycemia will lead to ketosis as explained in the discussion on fasting ketosis.

1. Bovine Ketosis

Bovine ketosis is actually at least three different syndromes that occur in cows during lactation (Kronfeld, 1980; Kronfeld *et al.*, 1983). The syndromes are characterized by anorexia, depression (usually), ketonemia, ketolactia, ketonuria, hypoglycemia, and decreased milk production. The three syndromes are underfeeding ketosis, alimentary ketosis, and spontaneous ketosis.

Underfeeding ketosis occurs when a dairy cow receives insufficient calories to meet lactational demands plus body maintenance. This version of ketosis can be conveniently divided into nutritional underfeeding ketosis and secondary (or complicated) ketosis. The former occurs when the cow has a normal appetite but is given an insufficient quantity of feed or a diet with low metabolic energy density. The latter occurs when a cow has some other disease, such as hypocalcemia, mastitis, or metritis, which suppresses appetite and causes the cow to consume insufficient nutrients. In most respects, underfeeding ketosis resembles starvation ketosis as explained earlier, except that there is the additional caloric and glycemic burden of milk production.

Alimentary ketosis occurs when cattle have been fed spoiled silage that contains excessive amounts of butyric acid (Brouwer and Kijkstra, 1938; Adler *et al.*, 1958). As discussed previously, the rumen epithelium has a high capacity to activate butyrate to acetoacetate and 3-hydroxybutyrate. Under conditions where excessive butyrate is presented to the rumen epithelium, large amounts of 3-hydroxybutyrate will be produced and released to the circulation with resulting ketosis. Alimentary ketosis then is really butyrate toxicosis.

Spontaneous ketosis is probably the most common, the most researched, the most controversial, and the least understood form of bovine ketosis. It occurs in high-producing dairy cows that are near the peak of lactation, that have access to abundant high-quality feed, and that have no other disease (Kronfeld, 1980; Baird, 1982). The disease is not accompanied by severe acidosis (Sykes *et al.*, 1941) and spontaneous recovery is common although there is a large decrease in milk production (Kronfeld, 1980; Baird, 1982). Several schemes have been proposed for the molecular pathogenesis of the syndrome. As these schemes are discussed, we will see that they are not necessarily mutually exclusive, and more than one of them may be correct and present simultaneously in the same animal.

The most widely accepted theory of bovine ketosis is the hypoglycemia theory (Baird, 1982). In this theory, hypoglycemia is the driving force in the syndrome and ultimately causes the ketonemia. Dairy cows are selected for remaining in the herd more for milk production than for any other factor. Thus, dairy cows have been selected for many generations to have a metabolically aggressive mammary gland. This selection criterion has dictated that the mammary produce a maximum amount of milk with secondary regard for the metabolic consequences for the rest of the animal. It is not surprising, therefore, that occasionally the mammary gland might withdraw glucose from the plasma more rapidly than the liver can resupply it, which leads to hypoglycemia even in a well-fed animal. The hypoglycemia will lead to ketonemia by mechanisms discussed earlier and below. The hypoglycemia and ketonemia may cause the cow to be ill enough that she will decrease her feed intake. At this point, the syndrome will resemble underfeeding ketosis.

As explained earlier, high milk production equates to a high rate of plasma glucose utilization by the mammary gland, which equates to a high rate of hepatic gluconeogenesis. In a lactating cow, plasma glucose concentration represents the balance point between hepatic glucose production and peripheral glucose utilization, with the mammary gland being the chief user. If peripheral glucose utilization should leap ahead of hepatic glucose production, hypoglycemia will result. In theory, hypoglycemia under these circumstances should lead to a decrease in plasma insulin and an increase in plasma glucagon levels. Lower plasma insulin and higher plasma glucagon should increase the activity of hormone sensitive lipase in adipose tissue, which will lead to increased plasma levels of LCFAs. Consequently, more LCFAs will reach the liver and exceed its capacity to oxidize them completely or to reesterify them, and increased ketogenesis will result.

What evidence supports this theory? First, the vast majority of cows with clinical spontaneous ketosis are indeed hypoglycemic (Baird *et al.*, 1968; Schwalm and Schultz, 1976; Gröhn *et al.*, 1983). Second, cows with spontaneous ketosis usually are hypoinsulinemic (Hove, 1974; Schwalm and Schultz, 1976). Third, compared to the prelactation period, postparturient dairy cows have been found to have elevated levels of plasma immunoreactive glucagon (Manns, 1972; De Boer *et al.*, 1985), which is even greater in cows with ketosis (Sakai *et al.*, 1993). Fourth, ketotic cows have elevated levels of plasma LCFAs (Baird *et al.*, 1968; Ballard *et al.*, 1968; Schwalm and Schultz, 1976).

Some investigation of molecular mechanisms of ketogenesis in the liver ketotic cows has been performed (Baird *et al.*, 1968; Ballard *et al.*, 1968). In particular, there has been interest in hepatic mitochondrial oxaloacetate levels. In the discussion of ketogenesis presented earlier, it was noted that when increased levels of plasma LCFAs occur, the liver can reesterify them or can oxidize them to acetyl-CoA. The acetyl-CoA can be oxidized to carbon dioxide provided there is sufficient oxaloacetate to permit entry into the citric acid cycle as citrate. In order for the citric acid cycle to operate, there must also be a sufficient amount of ADP available for phosphorylation as well or accumulation of NADH will slow the cycle. If acetyl-CoA accumulates, the excess will be diverted into ketogenesis.

Two studies have attempted to investigate oxaloacetate concentrations in the livers of ketotic cows (Baird *et al.*, 1968; Ballard *et al.*, 1968). Different methodologies were used to estimate oxaloacetate concentrations, and one study (Ballard *et al.*, 1968) concluded that there was no change in oxaloacetate concentration during ketosis, and the other concluded that oxaloacetate concentrations were lower in ketotic than in healthy cows (Baird *et al.*, 1968). Actually, both studies measured total hepatic oxaloacetate rather than mitochondrial oxaloacetate, which may be critical in ketogenic control. However, there has been no evidence to indicate that the ruminant liver should be any different from the nonruminant liver with regard to the concept that if the liver is presented with sufficient LCFA, ketogenesis will result. Research on the control of lipolysis in adipose in ruminants is insufficient. In particular, research has been insufficient in differences in plasma levels of lipogenic and lipolytic hormones and sensitivity of adipose to these hormones in cow populations that are susceptible and nonsusceptible to ketosis. No matter how low mitochondrial oxaloacetate levels might be in the liver, ketogenesis will not occur at a significant rate without sufficient precursor in the form of LCFAs and, conversely, ketogenesis could occur with normal oxaloacetate levels if the liver were presented with a sufficiently high concentration of LCFA.

Dairy cattle, however, can become ketonemic without the presence of significant hypoglycemia (Ballard *et al.*, 1968; Gröhn *et al.*, 1983). This is often the case with subclinical ketosis in which ketonemia exists without other signs of ketosis. It has been postulated that there is a lipolytic signal of unknown identity for lipolysis to meet mammary demand for LCFAs that is independent of plasma glucose concentration (Kronfeld, 1982; Kronfeld *et al.*, 1983). The increased plasma LCFAs lead directly to increased hepatic ketogenesis.

When it was first observed that glucocorticoids appeared to be an effective treatment for spontaneous ketosis, the hypothesis was made that the disease was due to adrenal cortical insufficiency (Shaw, 1956). This

theory has fallen into disfavor because ketotic cows have been shown to have higher plasma levels of glucocorticoids than healthy cows (Robertson *et al.*, 1957). Glucocorticoids are efficacious and probably have their effect by stimulating proteolysis and inhibiting glucose use in muscle, thereby providing gluconeogenic precursors and glucose (Ryan and Carver, 1963; Bassett *et al.*, 1966; Robertson, 1966; Braun *et al.*, 1970; Reilly and Black, 1973).

The efficacy of glucose or glucose precursors as ketosis treatments favors the hypoglycemic theory. Parenteral glucose provides nearly immediate relief although relapses are common (Kronfeld, 1980). Gluconeogenic precursors, such as propylene glycol, glycerol, and sodium propionate, have been shown to be efficacious (Schultz, 1952; Simesen, 1956; Emery *et al.*, 1964; Kauppinen and Gröhn, 1984). Treatment of cows with bovine somatotropin in one lactation appears to decrease the likelihood of ketosis in the next lactation (Lean *et al.*, 1994). Cows treated with somatotropin appear to have less body fat and more skeletal muscle, so after calving, there is less fat to mobilize to LCFAs and more protein to mobilize as glucose precursor. Therefore, hypoglycemia and subsequent fatty acidemia and ketonemia are less likely to occur.

2. *Ovine Pregnancy Toxemia*

This syndrome occurs in pregnant ewes that are carrying more than one fetus and that have been subjected to caloric deprivation or stress. Because of intense genetic selection for twinning, the syndrome is, to a large extent, a man-made disease. Susceptibility increases as ewes approach term because fetal glucose demands increase with increasing body size. The ovine placenta is capable of extracting glucose from maternal plasma at concentrations below 1 mmol/liter and readily does so. It might seem biologically useless for the fetuses to cause a fatal hypoglycemia in the ewe, which will also lead to their own demise, but the fetuses are highly dependent on glucose as a caloric and synthetic source and would expire without it anyway.

Fetal lambs normally maintain a very low plasma glucose concentration of approximately 0.6 mmol/liter compared to 2.7 mmol/liter in a ewe (Warnes *et al.*, 1977). Thus, the transplacental glucose gradient greatly favors movement from dam to fetus. Curiously, the most concentrated carbohydrate in fetal sheep plasma is fructose (5.1 mmol/liter), which is synthesized from glucose in the placenta by reducing glucose to sorbitol followed by oxidation to fructose (Hers, 1960; Warnes *et al.*, 1977). Despite the abundance of fructose in the plasma of the fetal sheep, glucose constitutes its primary energy supply (Warnes *et al.*, 1977; Lindsay and Pethick, 1983), and the fetuses normally consumed 60–70% of maternal glucose production (Setchell *et al.*, 1972; Prior and Christenson, 1978).

The ovine placenta appears to have a low permeability for acetoacetate. When acetoacetate loads have been infused into pregnant sheep, the concentrations in fetal blood have remained low. Further, *in vitro* experiments with perfused sheep placenta have also demonstrated a low permeability for acetoacetate (Alexander *et al.*, 1966, 1969). Thus, it appears that maternal acetoacetate, and perhaps 3-hydroxybutyrate, cannot be a major energy source for the ovine fetus.

The disease is characterized by depression and weakness in the ewes, which is associated with hypoglycemia, ketonemia, and ketonuria (Reid, 1968). The ketonemia is severe enough to cause acidosis, which can be severe (Holm, 1958; Reid, 1968). There is also considerable fatty deposition in the liver to the extent that it may interfere with liver function (Snook, 1939; Cornelius *et al.*, 1958). Eventually, the ewes are unable to rise, become comatose, and die if untreated.

Mild cases respond to intravenous glucose, glucocorticoids, glucose precursors such propylene glycol, or glycerol coupled with removal of stress and improved nutrition (McClymont and Setchell, 1955a, 1955b; Thompson, 1956). Severe cases, in which the ewes are unable to rise, usually respond only to delivery of the lambs and even then a high mortality will occur (Holm, 1958; Reid, 1968).

3. *Syndromes in Other Species*

Ketosis associated with lactation can occur in dairy goats (Morand-Fehr *et al.*, 1984). The syndrome has also been reported in beef cows with caloric deprivation and nursing two calves (Khan *et al.*, 1986). Pregnancy toxemia has been reported in goats carrying multiple fetuses (Rindsig, 1980; East, 1983; Thedford, 1983; Morand-Fehr *et al.*, 1984). The syndrome can be produced with calorie deprivation, particularly if coupled with stress, and almost always occurs in does carrying more that one fetus. Obesity also may be a predisposing factor in does (Thedford, 1983; Morand-Fehr *et al.*, 1984). Generally, the syndrome in does appears entirely similar to that in ewes.

Pregnancy toxemia has been reported in beef cows in the last two months of gestation (Sampson *et al.*, 1945; Kingrey *et al.*, 1957; Caple *et al.*, 1977; Tyler *et al.*, 1994). The disease occurs predominantly in cows that are carrying twins. The cows may be in good or even obese body condition, but sudden food deprivation or decrease in quality or imposition of stress such as water deprivation may precipitate the syndrome. The disease resembles pregnancy toxemia in sheep in most re-

spects. Pregnancy toxemia has been reported in pregnant bitches (Irvine, 1964; Jackson *et al.*, 1980) and appears similar to the disease in sheep. Hypoglycemia is severe in canine cases, and the animals respond readily to intravenous glucose. If the animals will eat a carbohydrate-containing diet, a relapse is unlikely; otherwise; removal of the fetuses is required for a cure. Pregnancy toxemia occurs in pregnant guinea pigs and, like in pregnant ewes, the syndrome can be precipitated by inadequate calories and stress (Bergman and Sellers, 1960; Wagner, 1976). The syndrome in guinea pigs is quite similar to that in sheep. There is marked ketonemia and acidosis, and the animals become weak and depressed with eventual coma (Wagner, 1976).

I. Postexercise Ketosis

Postexercise ketosis, which was first documented in 1909 (Forssner, 1909), has been investigated most extensively in humans and rats. Neither trained nor untrained humans or rats show much increase in ketones during exercise, but only untrained individuals exhibit a significant ketonemia and ketonuria after exercise (Johnson *et al.*, 1969; Winder *et al.*, 1975; Koeslag, 1982). The experiments of Winder *et al.* (1975) demonstrated a greater enzymatic capacity of muscles of trained rats to catabolize ketones. It also appears that trained athletes have a greater capacity to oxidize LCFAs in muscle than nonathletes (Johnson *et al.*, 1969). A high-carbohydrate diet in conjunction with training also decreases the magnitude of postexercise ketosis (Koeslag *et al.*, 1980).

From the foregoing, it appears that a number of factors are involved in postexercise ketosis. During exercise all forms of fuel, including LCFAs, ketones, and glucose, are oxidized. Postexercise there is a diminution of LCFA release, although plasma LCFA concentrations decrease little at first because of an even greater diminution in LCFA oxidation, and more LCFA may be converted to ketones. Ketone oxidation by muscle is decreased postexercise, which will allow ketones to accumulate. In the postexercise period, there is gluconeogenesis as lactate is cycled back into glucose and glycogen, which may lead to decreased mitochondrial oxaloacetate levels and increased ketogenesis. Finally, compared to the exercise period, in the postexercise period, relatively more of the cardiac output will flow through the portal system, and the rate at which LCFAs are presented to the liver may increase.

Postexercise ketosis undoubtedly occurs in most mammalian species but, among the domestic species, has been best documented in dogs and horses. Postexercise increases in plasma levels of ketones have been observed in racing sled dogs (Hammel *et al.*, 1977). Postexercise ketosis has been reported several times in the horse (Dybdal *et al.*, 1980; Lucke and Hall, 1980; Rose and Sampson, 1982). In these studies, horses were subjected to endurance rides of 80 to 160 km. Plasma 3-hydroxybutyrate concentrations increased two- to threefold 5 to 60 minutes postexercise compared to preexercise levels. Plasma LCFA concentrations increase fivefold or more in horses during exercise (Lucke and Hall, 1980; Rose and Sampson, 1982) and decrease little during 30 to 60 minutes postexercise. Thus, abundant LCFAs are available to the liver postexercise when muscle utilization of LCFAs and ketones is decreased, a situation that results in ketonemia.

CHAPTER

5

Serum Proteins and the Dysproteinemias

J. JERRY KANEKO

I. INTRODUCTION

The nitrogenous compounds of blood plasma encompass all those organic and inorganic nitrogen-containing compounds of blood. These include the organic macromolecular compounds such as the proteins and nucleic acids; the smaller molecular weight compounds such as glutathione, urea, and creatinine; and the inorganic compounds such as nitrate and ammonia. The nonprotein nitrogen (NPN) compounds are those grouped together as the fraction of the N-containing compounds of plasma that are not removed by the common protein precipitating agents such as trichloracetic acid (TCA). The principal components of the NPN fraction are urea (50%) and amino acids (25%), which total about 35.7 mmol N/liter (50 mg N/dl) plasma in contrast to protein nitrogen, which totals more than 714 mmol N/liter (1 g N/dl) plasma (or 6.25 g protein/dl). This chapter deals primarily with this latter fraction, which is classed collectively as the plasma or serum proteins. The diagnostic and interpretive aspects of the various individual fractions of this pool of proteins are the focus of this chapter.

II. CLASSIFICATION OF PROTEINS

A. Structural Classification

Proteins are most frequently classified according to their form and composition:

Primary structure: the amino acid structure of a single polypeptide chain.
Secondary structure: the helical structure of the chain (α-helix).

Tertiary structure: the folding of the helices into different shapes; globular (myoglobin), linear (fibrinogen), etc. These are monomers.
Quaternary structure: the combination of two or more monomers; dimers (creatine kinase), tetramers (hemoglobin), etc.

B. Chemical Classification

Proteins are also classed according to their chemical composition:

1. Simple proteins contain the basic elements of the amino acids: carbon, hydrogen, oxygen, nitrogen, sulfur.
2. Conjugated proteins are those bound to elements, prosthetic groups, or to other compounds:
   a. Metalloproteins—ferritin (iron)
   b. Phosphoproteins—casein (phosphate)
   c. Lipoproteins—high-density lipoproteins (triglyceride, cholesterol, cholesterol ester)
   d. Glycoproteins—glycohemoglobin, fructosamine
   e. Nucleoproteins—ribosomal proteins.

C. Physical Classification

Proteins have also been classified by their physical behavior: (1) water and salt solubility, (2) density, and (3) molecular weight.

III. METABOLISM OF PROTEINS

A. General

The intake of nitrogenous compounds and the maintenance of nitrogen balance in animals essentially evolve about the intake and metabolism of the amino acids of the ingested proteins. Very few free amino acids and little ammonia are present in the diet. In the adult, excretory losses are balanced by intake so that a nitrogen equilibrium is maintained. Major routes of loss are lactation, illness with cell breakdown, and urinary or gut losses, all of which can result in a negative balance unless nitrogen intake is increased. Positive nitrogen balance occurs during pregnancy, growth, and recovery from disease.

B. Synthesis of Proteins

The fundamental units of protein structure in nature are the 20 natural amino acids. The essential amino acids of this group are those not synthesized by animals and hence must be supplied in the diet (Table 5.1). The nonessential amino acids are those that are synthesized through transamination reactions from the carbon skeletons shown in the figures of Chapter 3. Thus, α-keto-glutarate of the TCA cycle is transaminated to become glutamic acid by accepting the α-amino group from alanine, which then becomes pyruvate. The enzyme catalyzing this reaction is widely used in clinical biochemistry as an index of liver function. The enzyme is named alanine amino transferase (ALT; EC 2.6.1.2) formerly known as glutamic-pyruvate transaminase (GPT).

The α-amino acids are linked together by peptide bonds by the protein synthesizing mechanisms within cells on the rough endoplasmic reticulum (rER). The intricacies of the process by which genetic information for replication is transmitted (transcription) and the mechanism by which this information is expressed in protein structure (translation) are summarized in the genetic code and the mechanisms of protein synthesis. Briefly, in the nucleus, a precise sequence of nucleotides of DNA (chromosomal material) forms a template on which a complementary messenger RNA (mRNA) is replicated (transcription). This transcription is catalyzed by DNA-directed RNA polymerases. The newly formed mRNAs now move to the cytoplasm to become bound with the ribosomes. Meanwhile, transfer RNAs (tRNA) or triplet nucleotides have bound to their specific amino acids also in the cytoplasm. The tRNA (the anticodon) with its amino acid next moves to its complementary triplet segment (the codon) of the mRNA. Succeeding amino acids are brought to the mRNA and sequential peptide linkages are formed until a terminator sequence on the mRNA is reached, at which time the completed polypeptide chain is released. This is the molecular basis of the inheritance of protein structure as represented by DNA transcription and RNA translation into a protein identical in structure to its progenitor. Many replicates of the protein molecule can be synthesized on a single mRNA. When a cell divides, the genetic information is again transmitted from mother to daughter cells via DNA so that identi-

TABLE 5.1 Natural Amino Acids

Essential amino acids:		
Histidine	Lysine	Threonine
Isoleucine	Methionine	Tryptophan
Leucine	Phenylalanine	Valine
Nonessential amino acids:		
Alanine	Cysteine	Proline
Arginine	Glycine	Serine
Asparagine	Glutamate	Tyrosine
Aspartate	Glutamine	

cal proteins are synthesized by succeeding generations of cells. In certain disease states, a single cell or a family of genetically homogenous cells (clone) might exhibit uncontrolled proliferation, for example, plasma cells in multiple myeloma, and excessively produce a single discreet species of protein, immunoglobulin M.

C. Catabolism of Proteins

1. Turnover of Proteins

Tissue and plasma proteins are constantly being degraded to their constituent amino acids and the amino acids in turn are sources of energy as well as sources of carbohydrate and fat carbon. The interrelationships linking these major foodstuffs were discussed in Chapter 3. Generally, amino acid carbons, after conversion to fat (lipogenesis) or to carbohydrate intermediates or glucose (gluconeogenesis), become sources of energy after their oxidation to CO_2 and H_2O. Carnivores derive as much as 40–50% of their energy requirements from dietary proteins and their amino acids, whereas omnivores and herbivores derive from less than 10% to about 20%.

The rate of degradation of the plasma proteins is expressed as their turnover, fractional clearance, or as their half-times. Clearance half-times may range from a few hours (some enzyme proteins) to as long as 160 days for hemoglobin in cow red cells (Kaneko, 1983). The clearance half-times of most plasma protein range between 1 to 3 weeks.

2. The Urea Cycle

Proteins, as the major dietary source of nitrogen, are hydrolyzed in the gut to their constituent amino acids and absorbed by the intestinal mucosal cells. Gut bacteria may also degrade the amino acids so that ammonia itself may be absorbed. This is an important consideration in the management of liver disease. Sterilization of the gut by the use of antibiotics is one of the management strategies designed to reduce the NH_3 load in liver diseases. The amino acids and ammonia are transported to the liver via the portal circulation and then on to other protein metabolizing tissues.

About 75% of the amino acids or ammonia is transported across the liver cell membrane to be taken up by the liver cell and on into the mitochondria. In the mitochondria, a number of mechanisms of deamination to generate ammonium ion are present, such as glutamate dehydrogenase and glutaminase. In the mitochondria, ammonium ion from any source, bicarbonate, and ornithine form citrulline. Citrulline moves to the cytoplasm where arginine and then ornithine are formed with the release of urea. This cyclical process is known as the Krebs–Henseleit or urea cycle and is given in Fig. 5.1. The compartmentalization between mitochondria and cytosol coordinates the deamination reactions within the mitochondria with the aspartate and TCA cycle within the cytosol. Urea excretion by the kidney tubules is the major route of nitrogen excretion and most others routes, for example, uric acid and nucleic acids, are relatively minor.

All animals are quite intolerant of free ammonia in their cell or body fluids and it is the free ammonia form that is highly toxic. Fortunately, at the pH of blood, 99% of the total ammonia is in the form of ammonium ion:

$$NH_3 + H^+ \rightarrow NH_4^+.$$

The ammonium ion does not readily transfer across cell membranes whereas the NH_3 form readily moves across cell membranes into cells where it is reconverted to the NH_4^+ form. Ammonia is particularly toxic to brain cells where it is thought to reduce their metabolic activity by reducing Krebs cycle activity. Glutamate is often increased and α-ketoglutarate decreased in the presence of increased ammonia. Also, ammonia itself may be toxic by decreasing neurotransmitters. Ammonia is clearly associated with hepatic encephalopathy of humans, dogs (Strombeck *et al.*, 1975), and horses (Divers *et al.*, 1983) but the mechanism is still unknown. It is often found in portasystemic shunts of young dogs.

Disposal of ammonia by the kidney tubules is a second important route of nitrogen excretion. In the

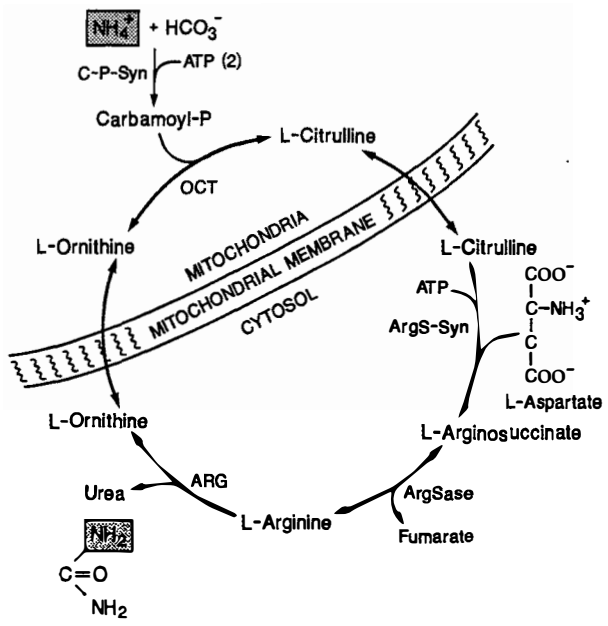

FIGURE 5.1 The Krebs–Henseleit urea cycle. Note the partitioning of the reactions of the cycle between the cytosolic and the mitochondrial compartments.

tubules, glutamine is deaminated to glutamate and ammonia by glutaminase. Ammonia in the tubular lumen is converted to ammonium by binding to H^+ and is therefore an equally important mechanism for removal of excess H^+ for the maintenance of acid–base balance.

IV. THE PLASMA PROTEINS

A. Sites of Synthesis

The major site of synthesis of the plasma proteins is the liver. The second major site is the immune system consisting of the monocyte–macrophage system, lymphoid, and plasma cells. Structural, functional, and enzyme proteins that are synthesized in all body cells and tissues are present in plasma in minor quantities as a result of cell turnover. In general, plasma contains about 5–7% (50–70 g/liter or 5–7 g/dl) protein. If hemoglobin is included, whole blood is composed of about 20% or more of protein.

B. Functions of the Plasma Proteins

The functions of proteins in the body are innumerable. They form the basis of structure of cells, organs, and tissues; they maintain colloid osmotic pressure; they are catalysts (enzymes) in biochemical reactions; they are buffers to maintain acid–base balance, they are regulators (hormones); they function in blood coagulation and in body defenses (antibodies); they are nutritive; and they are transport and carrier compounds for most of the constituents of plasma. The biological activity of proteins and polypeptides for these various functions depends on their structure, from the primary amino acid sequence of the polypeptide hormones to the macromolecular fibers of the fibrin polymers that participate in clot formation.

C. Factors Influencing the Plasma Proteins

1. Age

At birth, plasma proteins of most animals are quite low due to the minimal quantities of immunoglobulins and low albumin. As the newborn animal ingests colostrum, a rapid rise in the immunoglobulins occurs as a result of the absorbed maternal immunoglobulins. As the maternal antibodies decline due to normal turnover, the neonatal animal rapidly gains immunocompetence and begins to synthesize its own immunoglobulins. Upon reaching young adulthood, adult levels of the albumins and globulins are reached.

With increasing age, the plasma proteins are seen to increase above the normal adult levels as a result of a small decrease in albumin and a progressive increase in the globulins.

2. Hormones, Pregnancy, and Lactation

During gestation, total plasma protein decreases due to an albumin decrease even though there is a slight increase in the globulins. Near term, there is a sharp rise in the γ-globulins and a corresponding rise in total plasma protein. In lactation the total plasma protein again decreases due to an albumin decrease.

Some hormones (testosterone, estrogens, growth hormones) effect an increase in total plasma protein due to their anabolic effects, whereas others (thyroxine, cortisol) tend to decrease the total plasma protein due to their catabolic effects.

D. Handling and Identification of Proteins

The process of protein denaturation is the net effect of the alteration of the biological, chemical, and physical properties of the protein by disruption of its structure. It is, therefore, of great importance that proteins be handled in a way to prevent this structural change. Heat, ultraviolet light, surfactant detergents, and chemicals all have some effect on protein structure. If this effect is significant, the protein is denatured, its biological and physical activity is irreversibly lost, and it cannot be accurately measured. A corollary to measurement of any protein is, therefore, the avoidance of denaturation by gentle handling and careful preservation at the appropriate temperature. Assuming proper collection, timely centrifugation, and proper handling of the serum or plasma, Thoresen *et al.* (1995) report that the reliability of the total protein assay is unaffected by storage for up to 240 days either at −20°C or −70°C. Proper handling and storage is of particular importance when enzyme activity needs to be determined because it cannot be assayed if its activity is lost.

Albumin is a water-soluble, globular protein that is usually identifiable as a single discreet molecular species. The globulins are also globular proteins but precipitate in water so they require some salt to maintain their solubility. In contrast to albumin, a major feature of globulins is that they are not a single discreet species of protein but rather a mix of proteins of various types. By virtue of their structure, they migrate in groups in an electric field or precipitate together as rather large families of proteins that are identifiable as

the α-, β-, or γ-globulins. The use of cellulose acetate or agarose gel as the support medium for the electrophoretic separation of the various protein fractions is a common first step in the investigation of protein dyscrasias. Agarose gel or "high resolution" is gradually replacing cellulose acetate as the medium of choice. Serum protein electrophoresis has evolved into an extremely useful technique because aberrations are observed in many disease states. There are, however, only a few diseases for which the electrophoretic pattern can be considered pathognomonic.

V. METHODOLOGY

A. Total Serum Protein

A number of methods are available for the determination of total protein in the serum or other body fluids. Classically, the N in the protein has been determined by the Kjeldahl analysis and multiplied by the factor 6.25 (16% N in protein). The technique is rather cumbersome and, for many reasons, is not amenable for use in the clinical laboratory. Other chemical or physical techniques are used.

1. Chemical Methods

a. Biuret

This method continues to be the most widely used colorimetric method for the determination of total protein in serum. The biuret reaction is highly specific for protein and is based on the formation of the blue peptide–Cu complex in alkaline solution.

The method is highly accurate for the range of total protein likely to be found in serum (10–100 g/liter; 1–10 g/dl), but it is not sensitive enough for the very low levels found normally in other body fluids, for example, cerebrospinal fluid (CSF). It is the chemical method of choice for total serum or plasma protein in the clinical laboratory because of its simplicity, accuracy, and precision. It is widely adapted for automated chemical analyzers as well as for point-of-care chemical analyzers.

b. Phenol–Folin–Ciocalteau

The Phenol–Folin–Ciocalteau method is very sensitive (Lowry *et al.*, 1951) and is the method of choice for the dilute solutions such as CSF. It is based on the reaction of the phenolic groups of tryptophan and tyrosine of proteins with the reagent to form a blue color. Automated as well as manual techniques are available.

c. Bicinchoninic Acid

The bicinchoninic acid (BCA) method is a relatively new modification of the Lowry method and is more sensitive than the original Lowry method. It is often the method of choice for dilute solutions (Smith *et al.*, 1985).

d. Precipitation Methods

Depending on their charges, proteins can be brought to their isoelectric points, where they will precipitate, by the addition of either anions or cations. Anionic precipitants such as TCA, sulfosalicylic acid, and tungstic acid combine with cationic proteins to cause precipitation. Barium and zinc ions are common cationic precipitants. These reagents are more generally used to prepare protein-free filtrates in the clinical laboratory but have been used for total protein, for example, the sulfosalicylic acid method for urine protein.

2. Physical Methods

a. Refractometric

Proteins in solution cause a change in refractive index of the solution that is proportional to the concentration of the protein. Properly controlled and used, this method can be quite accurate at the levels of total protein found in serum or plasma. It is currently in widespread use as a screening method, for the rapid determination of protein in serum, plasma, or other body fluids. Because of its rapidity and simplicity, it is well suited for the office, point-of-care, or emergency clinical laboratory. Due to its dependence on the transmission of light, it is important that the method be used only for clear, nonturbid, and nonlipemic sera and fluids. A moderate degree of hemolysis or icterus does not interfere. The calibration of the refractometer should be frequently checked because this has been found to be a frequent source of error (Booij, 1972). The hand-held Goldberg refractometer is the most useful and versatile refractometer for the veterinary clinical biochemical laboratory because it is scaled to read both total serum protein and urine specific gravity, its scale has finer divisions, and it is temperature controlled.

b. Fibrinogen

Fibrinogen (Fbn) is a large protein of 340,000 Da, which constitutes about 5% of the total proteins of plasma. It is most simply and rapidly estimated by the heat precipitation–refractometer method (Kaneko and Smith, 1967), which takes advantage of the fact that Fbn precipitates on heating to 56°C. The total protein in a sample of plasma is first determined by the refractometer. A sample of the plasma in a microhematocrit

tube is heated at 56°C for 3 minutes in a waterbath. The tube is then centrifuged and the total protein in the clear supernate (serum) is determined. The difference between the serum and the plasma protein gives an estimation of the plasma Fbn. In a variation of this method, the height of the precipitated Fbn column can be measured or the amount of precipitate formed can be weighed. The heat precipitation method is now extensively used as a routine screening method but, for more accurate results, fibrinogen is determined as the protein content of the clot (Davey *et al.*, 1972) or as the thrombin time (see the chapter on hemostasis).

B. Fractionation of the Serum Proteins

To determine the amounts of albumins and globulins that make up the total serum protein, various fractionation techniques have been designed to separate and quantitate the serum proteins. All quantitative fractionation techniques first require the determination of the total serum protein, after which the concentrations of the individual fractions are determined by calculations depending on the fractionation method. In its simplest form, if either the albumin or globulin were determined, the other can be obtained by subtraction from the total serum protein. Ultimately, the accuracy of any of the clinical chemical methods is based on comparisons with serum protein electrophoresis, the "gold" standard of reference for serum protein fractionations.

1. Salt Fractionation

Salts added to protein solutions dehydrate the proteins, causing them to precipitate and the solution to become turbid. The most commonly used salts are those of sodium or ammonium sulfate. The salt fractionation technique is based on the differences in solubility of the various protein fractions at different salt concentrations. Albumin is soluble in water and the various globulins precipitate independently in different concentrations of salt. The principle of the technique has been applied for many years in clinical biochemistry in the form of the serum flocculation tests for liver function. Numerous tests have been devised and include the zinc sulfate, sodium sulfate, and ammonium sulfate turbidity tests. These are turbidimetric tests in which the amounts of salts used are adjusted for the normal concentrations of γ-globulins in human sera. In the presence of increased amounts of γ-globulins, flocculation occurs. Because the concentrations of globulins differ in animals, these tests are not directly applicable to animal sera. They can, however, be adapted to animal sera if the concentrations of salt are adjusted to the normal concentrations of γ-globulins in a particular species. This has been done in the calf (Pfeiffer *et al.*, 1977) and foal (Rumbaugh *et al.*, 1978a), where detection of suckling was evaluated using $ZnSO_4$ turbidity. The test successfully detected colostral immunoglobulin transfer to newborn foals when compared to electrophoresis and was deemed better than other rapid tests such as the sodium sulfite precipitation test. Another precipitation test for detection of hypogammaglobulinemia in calves is the glutaraldehyde coagulation test, which also appears to have practical value in identifying hypogammaglobulinemic calves (Tennant *et al.*, 1979).

2. Dye Binding

The acid dye, 2-(4'-hydroxyazobenzene)-benzoic acid (HABA), was widely used in the past for the determination of serum albumin because of its adaptation for automated systems. However, the dye binds so poorly to the albumins of domestic animals that the method is unacceptable. The HABA dye method has now been replaced by bromcresol green (BCG). The BCG method, in comparison with electrophoresis, is quite accurate for albumin within the reference ranges of albumin concentration in animals. However, its accuracy becomes progressively less outside the reference ranges and is usually unacceptable at very low or very high levels. This discrepancy between the BCG and electrophoresis is a common finding in hypoalbuminemic sera. A dye binding method for albumin with properties similar to BCG is the bromcresol purple (BCP) method.

The Coomassie blue dye binding method (Bradford, 1976) for albumin is another innovation that is sensitive at low concentrations of proteins but suffers from variability.

3. Colorimetric Determination of Globulin

The reaction of glyoxylic acid with globulins forms a purple color complex, which is proportional to the amount globulin. The test has not gained acceptance in clinical biochemistry because of its variability and is infrequently used.

C. Electrophoretic Fractionation of the Serum Proteins

The electrophoretic technique is the current standard of reference for the fractionation of the serum proteins (SPE) in clinical biochemistry. The marked advances in technology of the past decade have made this previously elaborate technique into a widely used, routine clinical biochemical test procedure. Its current

widespread use is commensurate with its reflection of a variety of changes in serum protein patterns in disease. Although only a few changes in pattern can be considered as diagnostic of a specific disease, the results of electrophoresis, properly interpreted, can be one of the most useful diagnostic aids available to the clinician. There are a large number of methods for serum protein electrophoresis that basically differ only in the type of support media used. Cellulose acetate (CA) continues to be used as a support medium but it is being supplanted by agarose gel (AG) as the medium of choice in clinical laboratories.

1. *Principle*

The principle of the electrophoretic separation of serum proteins is based on the migration of charged protein particles in an electric field. The direction and rate of migration of the particles is based on the type of charge (+ or −) on the protein, size of the protein, intensity of the electric field, and the support medium through which the protein particles are induced to migrate. It follows that it is of importance that the support medium, pH, buffer, and the electric current be described fully in order to be able to compare results of SPE.

When a support medium is used for electrophoresis, the process is called *zone electrophoresis* (as compared to free). Historically, the most commonly used support medium was CA but AG is now widely used in clinical biochemistry for SPE. Many other support media such as agar gel, starch gel, or polyacrylamide gel are also available. Many of the latter yield greater separability of the serum proteins than does CA or AG, but in the clinical laboratory CA and AG are the most useful methods. Recall that the globulins are comprised of a myriad of separate protein moieties—enzymes, carriers, antibodies, clotting factors—and that a specific serum protein can only be identified by additional special techniques.

2. *Cellulose Acetate Electrophoresis*

Depending on factors already noted, particularly the charge and the medium, the protein particles move toward the anode or the cathode of the electric field. Most serum proteins are negatively charged and, on CA in barbital buffer, pH 8.6, they migrate toward the anode. Albumin, with the strongest negativity, migrates farthest toward the anode. The globulins, with weaker negativities, migrate more slowly toward the anode, while some γ-globulins may not move or may even move toward the cathode. The globulins move in groups classed as the α-, β-, and γ-globulins. Depending on the species, there may normally be one or two α, one or two β, and one or two γ fractions (Figs. 5.2 and 5.3).

After the CA membrane is stained for protein, the CA membrane can be cleared and the staining densities of the individual proteins determined using a recording densitometer. The recording provides a visual display of the relative amounts of each protein class in the serum and is the electrophoretogram. When combined with an integrating unit, the intensities of staining of the different classes or bands on the electrophoretogram are translated into a percentage of the total staining intensities. Modern densitometers incorporate a computer that automatically multiplies this percentage times the total serum protein concentration and the amount of each of the separate protein fractions is obtained. This arithmetic calculation can be done manually as well.

A frequent difficulty in dealing with the sera of domestic animals is the difference in the normal pattern between the species. This has created some confusion in the identification of a particular fraction of the electrophoretogram as α, β, or γ. As a first step toward standardization, a useful resolution is to identify the midpoint of the electrophoretogram, which lies between or very nearly between the α_2 and β_1 peaks (Fig. 5.2). This plus the knowledge of the normal number of peaks in a particular species usually suffices to identify the individual peaks with confidence.

3. *Gel Electrophoresis*

Agarose gel electrophoresis (AGE), while retaining most of the limitations of cellulose acetate electrophoresis (CAE), has the same ease of performance and is capable of resolving proteins of serum, CSF, or urine into from 9 to 15 fractions depending on the species. Hence, AGE has been called *high-resolution protein electrophoresis* (HRPE). Because there are so many fractions, it is difficult to quantitate the individual fractions so most often the electrophoretogram is interpreted subjectively by visual examination. Kristensen and Barsanti (1977) using AGE were able to separate cat sera into 10 fractions. Keay (1982) reported similar results in cats, and Keay and Doxey (1982) separated dog, horse, sheep, and cow serum proteins into 7, 8, 9, and 10 fractions, respectively.

Polyacrylamide gel electrophoresis (PAGE) has not been used extensively for the study of animal serum proteins. Furukawa and Sugiyama (1986), using immunoelectrophoresis (IEP), were able to identify 21 feline plasma proteins.

Of the almost infinite number of proteins in serum, only about 200 have been studied; of these, clinical information relative to their interpretation in disease

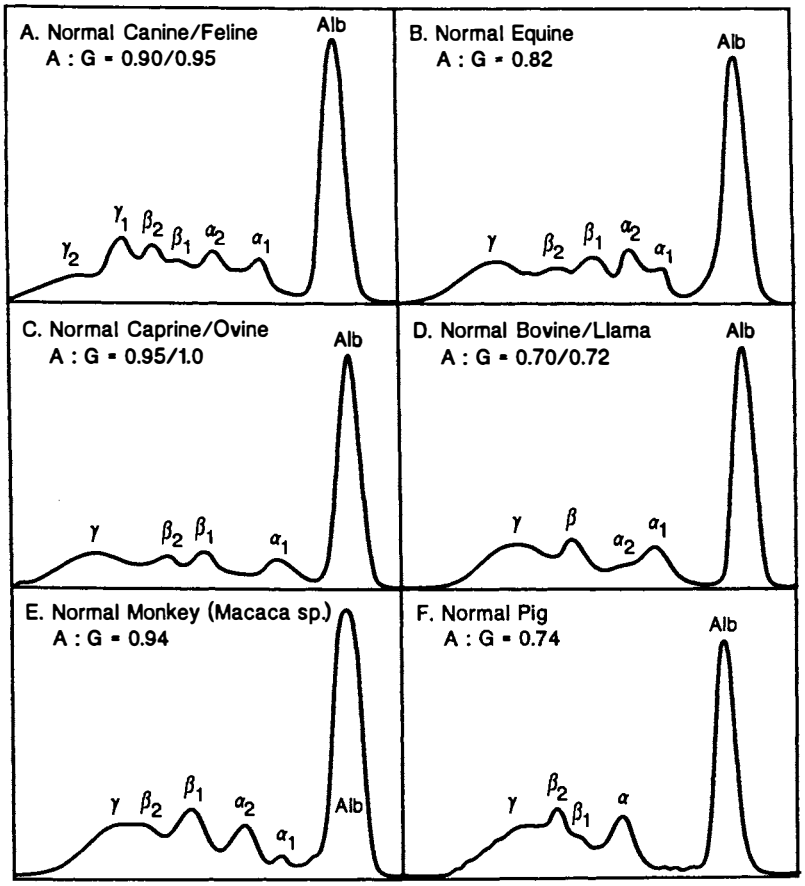

FIGURE 5.2 Cellulose acetate electrophoretograms of serum proteins of some normal mature animals. The albumin-to-globulin (A : G) ratios are within the normal ranges for these animals.

is available in only about 50. Furthermore, present clinically effective separation methods can only resolve a maximum of about 12.

Interpretation of a 5-7 band CAE scanned and quantitated by densitometry remains a very useful technique. Most densitometric methods, however, are unable to resolve fully all of the visible protein bands because of limitations of instrument sensitivity and variations in staining. Thus, it is best to use the densitometric results in conjunction with a visual examinination of the electrophoretogram.

4. Immunoelectrophoresis

IEP technique combines electrophoresis in one dimension with immune diffusion in a second dimension to obtain a more precise identification of the various serum proteins. Quantitation of the specific immunoglobulins G, M, A, and E has also been performed in those species of animals in which specific antisera have been available. This field of immunology has experienced unprecedented growth in the last two decades and the scope of its importance continues to increase. This is a highly specialized area and is more fully described in the chapter on clinical immunology.

VI. NORMAL SERUM PROTEINS

More than 200 plasma proteins have been described and quantitated in man and animals. Many of these plasma proteins change markedly in disease and many change only subtley or not at all. Because the proteins of an individual or of a species are synthesized under genetic control, it is to be expected that variations in proteins would occur between individuals and between species. These variations are reflected in the species differences of the normal SPE patterns. Thus,

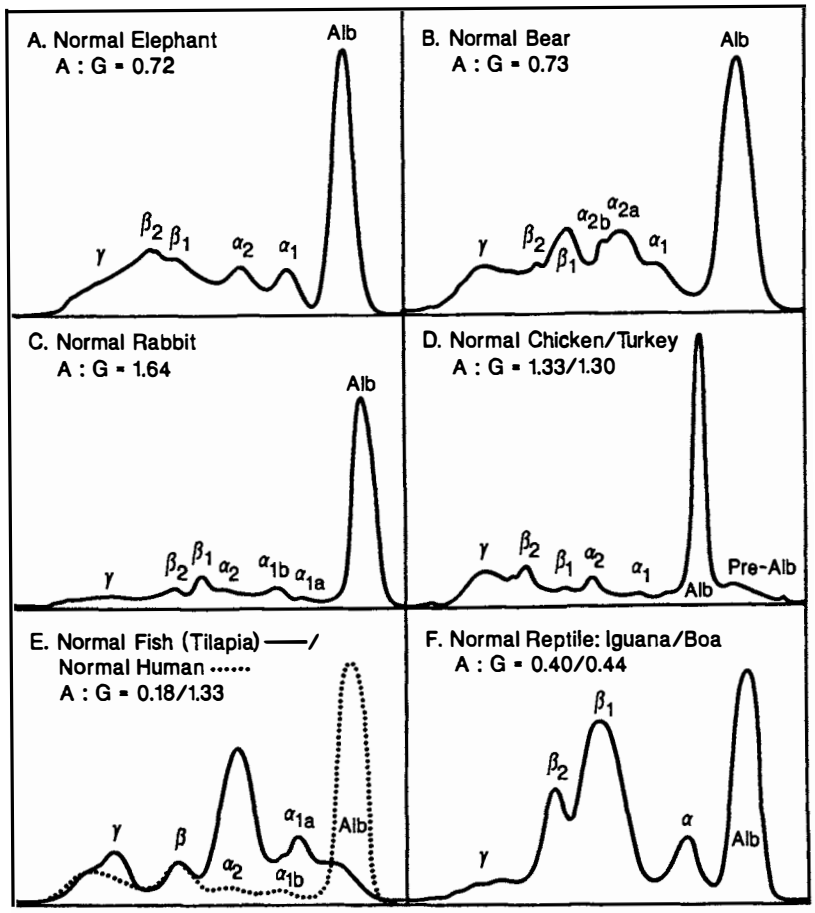

FIGURE 5.3 Cellulose acetate electrophoretograms of serum proteins of some normal mature animals of different genera. E is redrawn from Kaneko (1983).

in ruminants such as the cow, the normal SPE pattern has an albumin, one α, one β, and one γ fraction. Table 5.2 lists some of the important serum proteins with their principal functions and conditions under which alterations may be found. Because there are significant differences in fractionation depending on the method used, reference is made here only to CAE. Reference values for total serum protein and its fractions are given in Appendixes VIII, IX, X, and XI.

A. Prealbumin

Prealbumin is the most rapidly migrating fraction in human serum, is usually not visualized, and may not exist in any domestic animal, but does exist in some birds. However, a protein with the characteristics of prealbumin migrates in the α_2-globulin region of the SPE of dogs (Fex *et al.*, 1977). The only known function of prealbumin is thyroxine binding and transport (Oppenheimer *et al.*, 1965).

B. Albumin

1. Structure

Albumin is the most prominent of the serum proteins on SPE and in animals constitutes 35–50% of the total serum proteins in contrast to humans and nonhuman primates in which albumin accounts for 60–67% of the total. Its tertiary structure is globoid or ellipsoid and it is the most homogenous fraction discernible on SPE. It is the only discreet protein species that can be detected by SPE. However, other methods such as starch gel allow for the separation and detection of genetic polymorphisms of albumin.

It is also important to observe the sharpness of the albumin peak as a measure of the quality of the SPE

TABLE 5.2 Common Serum Proteins, Their Function, and Changes in Disease

Protein	M_r (Da)	Function	Change in disease
Prealbumin	54,400	Thyroxine transport	Increase: nephrotic syndrome Decrease: liver disease, protein deficiency
Albumin	69,000	Osmotic pressure regulation, general transport	Increase: dehydration Decrease: liver, kidney, gastrointestinal disease, malnutrition, blood and plasma loss
α-Globulins (α_1 and α_2)			
Thyroxine-binding globulin (TBG)	54,000	Thyroxine transport	Increase: pregnancy
α_1-Fetoprotein	65,000	Unknown	Increase: hepatoma, pregnancy
α_1-Antitrypsin	45,000	Trypsin inhibitor	Increase: acute inflammatory disease Decrease: liver disease, chronic pulmonary disease
α_1-Antichymotrypsin	68,000	Chymotrypsin inhibitor	Increase: acute inflammatory disease
α_1-Acid glycoprotein (orosomucoid, seromucoid)	44,000	Unknown	Increase: acute inflammatory disease Decrease: liver disease, nephrotic syndrome, malnutrition
α_1-Antithrombin III	65,000	Thrombin inhibitor	Increase: disseminated intravascular coagulation, liver disease
α_1-Lipoprotein (HDL, α-lipoprotein)	200,000	Lipid transport	
α_2-Lipoprotein (VLDL, pre-β lipoprotein)	1,000,000	Lipid transport	Increase: nephrotic syndrome, diabetes mellitus, hypothyroidism, steroid therapy
α_2-Macroglobulin	820,000	Insulin binding, trypsin inhibitor	Increase: nephrotic syndrome, chronic active liver disease, acute inflammatory disease
α_2-Globulin	54,000	Thyroxine transport in dogs	
Ceruloplasmin	151,000	Copper transport, ferrioxidase	Increase: acute inflammatory disease
Haptoglobin	100,000	Hemoglobin binding	Increase: acute inflammatory disease
Protein C	62,000	Protease, anticoagulant	Increase: acute inflammatory disease
β-Globulins (β_1 and β_2)			
β_2-Lipoprotein (LDL, β-lipoprotein)	2,750,000	Lipid transport	Increase: nephrotic syndrome, hypothyroidism, hepatocanalicular disease
Transferrin	76,000	Iron transport	Increase: anemias, iron deficiency, pregnancy, acute liver disease, nephrotic syndrome Decrease: iron storage disease, chronic liver disease, acute inflammatory disease
Ferritin	465,000	Iron transport	Increase: iron storage disease, acute inflammatory disease Decrease: iron deficiency
Hemopexin	80,000	Heme transport	Decrease: hemolytic anemia, chronic active liver disease
C3 complement	75,000	Complement C3 factor	Increase: acute inflammatory disease, atopic dermatitis Decrease: autoimmune disease
C-Reactive protein	140,000	Activates complement	Increase: acute inflammatory disease
C4 complement		Complement C4 factor	Increase: acute inflammatory disease Decrease: autoimmune disease
Plasminogen		Proenzyme of plasmin, fibrinolysis	Increase: disseminated intravascular coagulation
Fibrinogen	340,000	Fibrin precursor, coagulation	Increase: acute inflammatory disease Decrease: disseminated intravascular coagulation, afibrinogenemia
γ-Globulins (γ_1 and γ_2)			
Immunoglobulin G (IgG)	150,000	Major antibody formed in response to infectious agents, toxins	Increase: infectious disease, connective tissue disease, liver disease, myelomas and other tumors of the reticuloendothelial system Decrease: fetuses, newborn animals before intake of colostrum, immune deficiency diseases, agammaglobulinemia
Immunoglobulin A (IgA)	150,000	Secretory antibodies in the fluids of the respiratory, gastrointestinal, and the genitourinary tracts	Increase: infectious disease, connective tissue disease, liver disease, myelomas and other tumors of the reticuloendothelial system Decrease: fetuses, newborn animals before intake of colostrum, immune deficiency diseases, agammaglobulinemia

(continues)

TABLE 5.2 (*continued*)

Protein	M_r^a (Da)	Function	Change in disease
Immunoglobulin E, IgE	200,000	Antibodies in allergy	Increase: allergies, anaphylaxis Decrease: aglobulinemia
Immunoglobulin M, IgM	900,000	Cold agglutinin, initiator	Increase: chronic disease, primary cell reactions macroglobulinemia (Waldenstrom's)
Immunoglobulin D, IgD	160,000	Unknown, not seen in animals	
Light chains (Bence-Jones protein)	30,000	Part of the immunoglobulin molecule	Increase: myeloma

[a] M_r, Relative molecular mass.

fractionation. This sharpness or slope of the albumin peak is a useful guide for differentiating the sharp monoclonal globulin peaks from the polyclonal peaks. Additionally, the horse frequently exhibits a minor postalbumin fraction, which appears as a shoulder on the cathodal side of the albumin peak. This shoulder becomes progressively more prominent with the severity of the hypoalbuminemia or with acute inflammatory disease. It is consistently observed in chronic liver disease in horses. A thyroxine binding function of this postalbumin fraction has also been observed in horses.

2. *Function*

Albumin is synthesized by the liver as are all plasma proteins except for the immunoglobulins and it is catabolized by all metabolically active tissues. Its rate of metabolism varies among species and this is reflected in the half-times for clearance (Table 5.3). There appears to be a direct correlation between albumin turnover and body size because clinically significant hypoalbuminemic edemas occur only in the larger animals. This would suggest that edema develops in large animals because of slow replacement of albumin. Hypoalbuminemic edemas do occur in small animals but usually in the presence of posterior vena caval hypertension.

TABLE 5.3 Albumin Turnover in Animals

Species	$T_{1/2}$ (days)	Reference
Mouse	1.90	Allison (1960)
Rat	2.50	Allison (1960)
Guinea pig	2.80	Allison (1960)
Rabbit	5.70	Dixon *et al.* (1953)
Pig	8.20	Dick and Nielsen (1963)
Dog	8.20	Dixon *et al.* (1953)
Sheep	14.28	Campbell *et al.* (1961)
Human	15.00	Dixon *et al.* (1953)
Baboon	16.00	Cohen (1956)
Cow	16.50	Cornelius *et al.* (1962)
Horse	19.40	Mattheeuws *et al.* (1966)

Albumin is a major labile storage reservoir of proteins and as well as being a transporter of its constituent amino acids. It is the most osmotically active plasma protein due to its abundance and small size and accounts for about 75% of the osmotic activity of plasma. A major metabolic function of albumin is its role as a general binding and transport protein. Virtually all constituents of plasma not bound and transported by a specific transport protein and even many that are (e.g., thyroxine) are transported by albumin. Albumin binding solubilizes substances in plasma that are otherwise lipid soluble or only sparingly soluble. Albumin binding permits the effective transport of these substances in the aqueous plasma. Binding to albumin also prevents the loss of plasma chemical constituents through the kidneys. The binding of unconjugated bilirubin or of fatty acids by albumin is an example of this function.

C. Globulins

1. *α-Globulins*

The α fraction is the most rapidly migrating of all the globulins and, in most species except the ruminant, it migrates as an α_1 (fast) and an α_2 (slow) fraction. Most of the globulins of this fraction are synthesized by the liver, except for the α_1-fetoprotein, which is synthesized by fetal liver cells. In general, the α_1-globulins are smaller than the α_2, but there appears to be no functional separation between the two fractions. Important proteins of this fraction are the α-lipoproteins (HDL), which migrate as α_1, and the pre-β-lipoproteins (VLDL), which migrate in the α_2 position.

The β-lipoprotein (LDL), so named because it migrates in the β region on paper, also migrates in the α_2 region on CA. These latter two lipoproteins together with α_2-macroglobulin account for the increase in α_2-globulins seen in the nephrotic syndrome. The α_2-macroglobulin, haptoglobin, ceruloplasmin, and amy-

loid A (SAA) are also diagnostically important acute phase proteins (Table 5.4).

2. *β-Globulins*

β-Globulins trail the β_2 and similarly migrate as β_1 (fast) and β_2 (slow) fractions in most domestic animals except ruminants. Important proteins of this fraction are complement (C_3, C_4), hemopexin, transferrin, ferritin, and C-reactive protein (CRP). Fibrinogen slightly trails the β_2 and is another important acute phase protein. CRP and SAA are now considered the most diagnostically important of the acute phase proteins in humans (Maurey, 1985) and a recent study (Caspi *et al.*, 1987) indicates it may be equally valuable in dogs. Some immunoglobulins, IgM and IgA, extend from the β_2 to the γ_2 regions. Therefore, in response to the antigenic stimulus of infectious agents, or in plasma cell malignancies, immunoglobulin can rise in the β_2 zone as well as in the γ_1 and γ_2 zones.

3. *γ-Globulins*

In most animals, the γ fraction is also observed as two fractions, a γ_1 (fast) and a γ_2 (slow). Of the immunoglobulins observed in animals, IgA, IgM, and IgE are found primarily in the γ_1 region and IgG is found primarily in the γ_2 region. The specific identification and quantitation of the immunoglobulins require the use of immunochemical techniques (Iammarino, 1972; Mancini *et al.*, 1965). Immunochemical assays are widely used in protein research and now in the clinical laboratory. A brief description of immunological principles is given here as a basis for understanding the interpretation of dysproteinemias visualized on SPE. More thorough coverage is given in the chapter on clinical immunology.

TABLE 5.4 Acute Phase Proteins: Markers of Acute Inflammatory Disease

Positive Acute Phase Proteins:
α_1-Globulins
α_1-Antitrypsin
α_1-Acid glycoprotein (orosomucoid, seromucoid)
α_2-Globulins
α_2-Macroglobulin
Ceruloplasmin

Albumin
Transferrin

a. Source

Antigens employed in the immunochemical tests are of two types. complete antigens, which induce formation of specific antibodies and incomplete antigens (haptens), which, though they react with antibodies, do not elicit an immune response. Complete antigens usually have a molecular weight greater than 5000 Da and are proteins, glycoproteins, complex carbohydrates, or nucleic acids that are recognized as foreign by the host and elicit an immunologic response from the host. Haptens are low-molecular-weight compounds that, if coupled to a larger molecular weight compound such as a protein, elicit an antibody response. Most antibodies used in radioimmunoassay (RIA) are produced in response to haptens coupled to albumin, for example, T_4 antibody for T_4 RIA.

Antibodies produced in response to antigens are highly specific if only one antigenic determinant is involved. In nature, however, multiple antigenic determinants are usually involved. Natural haptens are usually multiple and elicit antibodies with multiple specificities or cross reactivities.

The lymphocytic cell line is now known to play the central role in the immune system. There are two subpopulations, the B lymphocytes (bursa) and the T lymphocytes (thymus), which can be identified by special immunologic means.

The T cells are found in blood and in lymph nodes in the deep cortical areas and paracortical sinuses. They are associated with cell-mediated immunity. The B cells were originally identified in the bursa of Fabricius of the chicken and are now thought to be differentiated in fetal liver cells. In the adult, they are found in the blood and in the germinal centers of lymph nodes. The B cells respond to antigenic stimuli with the proliferation of plasma cells that produce the specific antibody or immunoglobulin. Of the five known immunoglobulins, IgG, IgA, IgM, IgD, and IgE, four have been identified in dogs (IgG, IgA, IgM, and IgA), cats (Gorham, 1971), and horses (McGuire *et al.*, 1975a). Under certain conditions, an excess of a portion of the immunoglobulin molecule, that is, light chains, might also be produced. These light-chain fragments appear in the plasma and because of their small size appear in the urine as the Bence–Jones protein.

A specific plasma cell population of defined genetic origin—a clone—produces a specific immunoglobulin. Uncontrolled growth of a single B-cell clone (malignancy) results in the overproduction of a single chemi-

cal species of immunoglobulin, which appears as a sharp "monoclonal" spike or monoclonal gammopathy on an electrophoretogram. Occasionally, a "biclonal" or "triclonal" gammopathy can be identified. A group of clones, each of a different genetic origin, can also overproduce a heterogenous mix of immunoglobulins, which appears as a diffuse or broad hyperglobulinemic region on the electrophoretogram. This region is described as a "polyclonal" gammopathy.

b. Immunoglobulins

The immunoglobulins are glycoproteins whose basic structure is a monomer comprised of two heavy (H) and two light (L) chains linked by disulfide bridges. Each H chain consists of 446 amino acids and each L chain consists of 214 amino acids (Edelman, 1973). The structure of the H chain governs the class of immunoglobulin and is named by corresponding Greek letters: γ = G, μ = M, α = A, Σ = E, and δ = D. The structure of the L chain is either kappa (κ) or lambda (λ) and denotes type. Structural variations in the variable regions of H or L chains provide a basis for further subdivision into subtypes and subclasses. To date, four subclasses of IgG have been identified: IgG_1, IgG_2, IgG_3, IgG_4, and two subclasses of IgA: IgA_1 and IgA_2.

IgG, IgD, and IgE are monomers; IgA is a dimer; and IgM is a pentamer. Most viral, bacterial, and toxin antibodies are of the IgG type and are present in all animals. IgD has been reported only in humans, where its function is unknown. IgE is involved in allergic and anaphylactic reactions and is present in dogs. IgA is a dimer of two basic units joined by a secretory piece. IgA is found in the secretions of the respiratory, genitourinary, and gastrointestinal tracts. IgM is a cyclic pentamer of five basic units that forms a high-molecular-weight unit. These are the macroglobulins or "M" components.

The Bence–Jones proteins are light-chain units and their presence reflects the asynchronous synthesis of H chains so that excess L chains appear. When they appear in urine, they are called Bence–Jones proteins. They are not detected on SPE, but when immunochemical techniques are used, they are often found to accompany gammopathies (Solomon, 1976), especially multiple myelomas.

VII. INTERPRETATION OF SERUM PROTEIN PROFILES

The determination of serum proteins and of their SPE profiles have evolved into important diagnostic aids in clinical biochemistry. This has occurred even though a specific diagnosis can seldom be made with SPE. Abnormal serum protein profiles can be identified with general types of disease processes and in this way provide the rationale for further definitive studies of the patient. A variety of electrophoretograms illustrating some common types of disease in different species are given in Figs. 5.2 through 5.6. Groulade (1985) gives a series of similar SPE profiles in chronic diseases of the dog. Foulon *et al.* (1992), in their study of feline retroviral diseases, observed both an increase in β-globulins and a decrease in γ-globulins in FeLV but only a decrease in γ-globulins in FIV. They suggest that the SPE can be used to differentiate between FeLV and FIV. An added impetus for the use of SPE has been the inclusion of total protein and albumin in automated systems, thereby providing the albumin-to-globulin ratio (A : G). A change in the A : G ratio is often the first signal of a protein dyscrasia, which leads to the further study of the proteins by SPE. Appendixes VIII, IX, X, and XI give reference values for total serum protein and its fractions in animals and birds.

A. Physiological Influences

Abnormalities of SPE must be interpreted in light of the many influences unassociated with disease. Normal physiological variations within an individual are relatively constant over a considerable period of time, therefore even minor changes in the SPE profile can be of significance and warrant close scrutiny.

1. Influence of Age and Development

In the fetus, the concentration of total protein and albumin progressively increases with little change in globulins and an absence of γ. However, γ-globulin was detected in 25% of bovine fetal serum samples (Kniazeff *et al.*, 1967), which they attributed to transplacental transfer. After nursing and up to 24 hours, baby pigs had large amounts of γ-globulin, which progressively decreased to 5% of the total serum protein by 4 weeks of age (Rutqvist, 1958; Rook *et al.*, 1951). In the calf, precolostral serum normally contains no γ-globulin (Pierce, 1955), but within a few hours after ingestion of colostrum, γ-globulin appears in serum and absorption continues for up to 48 hours after birth (Ebel, 1953), after which gut permeability ceases. In colostrum-deprived calves, immunoglobulin increases only minimally. In the developing foal from birth to 12 months of age, progressive increases in albumin, globulins, and total proteins are seen (Sato *et al.*, 1979; Rumbaugh and Adamson, 1983; Bauer *et al.*, 1985).

In all animals, there is a general increase in total protein, a decrease in albumin, and an increase in globulins with advancing age (Forstner, 1968; Tumbleson

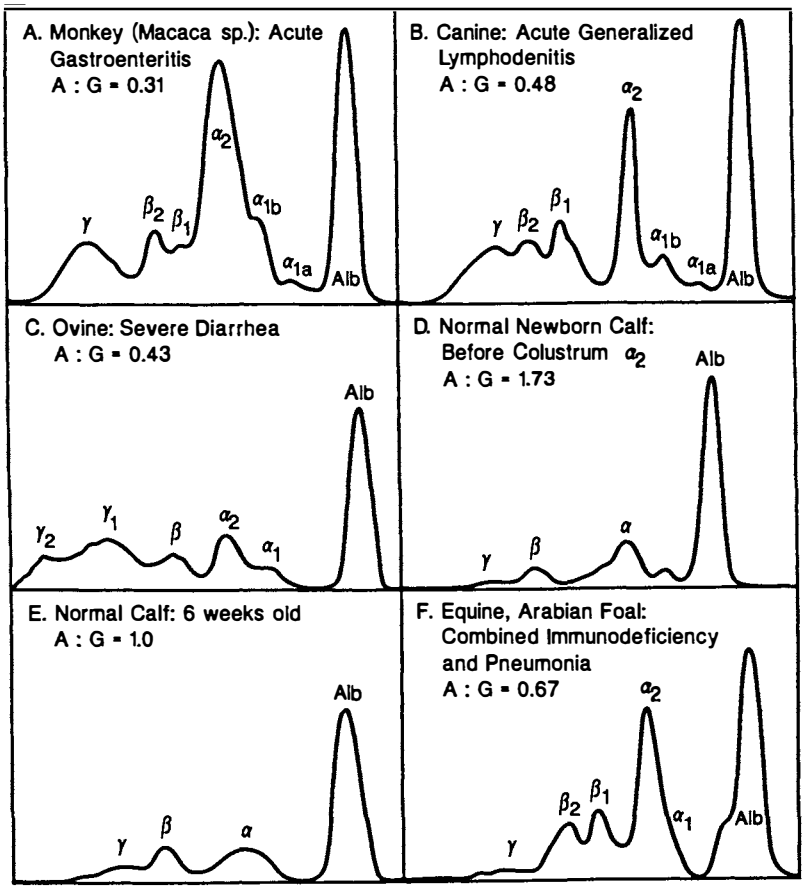

FIGURE 5.4 Cellulose acetate serum protein electrophoretograms in (A, B, F) acute inflammatory disease with acute phase protein increases, (C) gastrointestinal loss of albumin, (D, E) newborn and neonatal calves, and (F) immunodeficiency in a foal.

et al., 1972); and in the very old, the total proteins again decline. Similar changes due to age have also been clearly shown in chickens by Tanaka and Aoki (1963), who periodically followed serum protein changes up to 210 days of age. Thus, age is an important consideration in the interpretation of the SPE.

2. *Hormonal and Sexual Influences*

Hormonal effects on serum protein can be either anabolic or catabolic. Testosterone and estrogens are generally anabolic in all species. Diethylstilbestrol (DES) given to male calves and to chickens (Perk and Loebl, 1960) was found to increase total protein, decrease albumin, and increase globulins. Growth hormone is another well-known anabolic hormone with similar effects. On the other hand, thyroxine decreases total serum protein, most likely due to its catabolic effect (Sturkie, 1951). The glucocorticoids are characterized by gluconeogenic activity, but their effects on serum protein are not marked, because only small decreases in γ-globulin have been observed (Bjorneboe *et al.*, 1952). Thus, in general, hormonal effects of serum proteins are slight even though their effects on weight gains or body composition may be quite marked.

3. *Pregnancy and Lactation*

During gestation, albumins decrease and the globulins increase. In ewes, albumin decreases to a minimum at midgestation and returns to near normal at term. Globulins and the total serum protein progressively decrease throughout gestation (Dunlap and Dickson, 1955). In cows, the total serum protein, γ_1- and β_2-globulins begin to increase at 2 months before term, reach a maximum at 1 month, and then rapidly decline toward term (Larson and Kendall, 1957). These data indicate that the immunoglobulins rapidly leave the plasma during the last month of gestation when colostrum is being formed in the mammary gland. Lactation

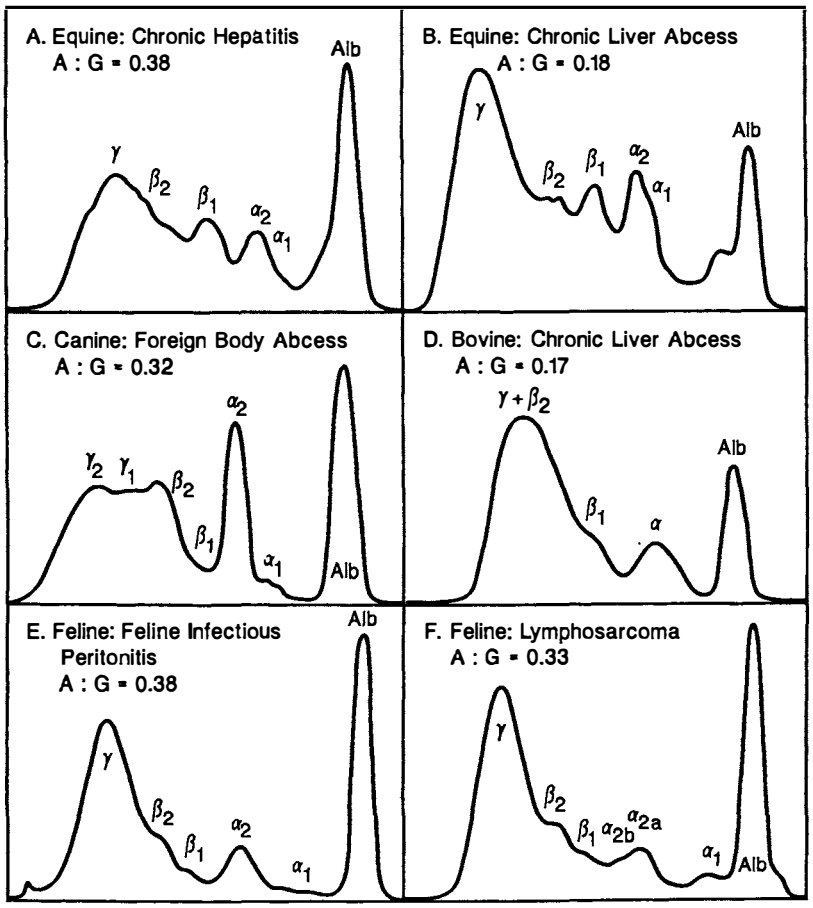

FIGURE 5.5 Cellulose acetate serum protein electrophoretograms of some polyclonal gammopathies in animals. Note that the major globulin peaks are broader and wider than the albumin peaks.

and egg production impose further stresses on protein reserves and metabolism and changes similar to pregnancy also occur.

4. Nutritional Influences

The plasma proteins are sensitive to nutritional influences but the changes are often subtle and difficult to detect and interpret. A direct relationship between vitamin A and lowered albumin has been observed in cows (Erwin *et al.*, 1959), which was corrected by the administration of carotene. Severe dietary protein deficiency induces a hypoproteinemia and hypoalbuminemia in rats (Weimer, 1961), chickens (Leveille and Sauberlich, 1961), and dogs (Allison, 1957). In humans, kwashiorkor and marasmus, diseases of severe protein-calorie malnutrition, are also characterized by hypoproteinemia and hypoalbuminemia. Dietary protein deficiency results in a decreased turnover of serum albumin in rats (Jeffay and Winzler, 1958). Immunoglobulins are affected only on severe protein restriction (Benditt *et al.*, 1949), but the effects are reversible on protein repletion (Wissler *et al.*, 1946).

5. Stress and Fluid Loss

Temperature stress, either febrile or hypothermia, is associated with nitrogen loss, increased adrenal activity, and increased protein turnover. These stresses cause a decrease in total serum protein, decrease in albumin, and often an increase in α_2-globulin. Similar findings are observed in crushing injuries, bone fractures, and extensive surgery. Tissue repair calls on protein reserves, and the increased protein turnover results in decreased albumin and increased α_2-globulin (Hoch-Ligeti *et al.*, 1953). In the inflammatory process, fluids and proteins move into the tissue fluids, inducing edema and contributing to a decrease in albumin. Hemorrhage or massive exudation with large external losses of plasma is followed by a rapid movement

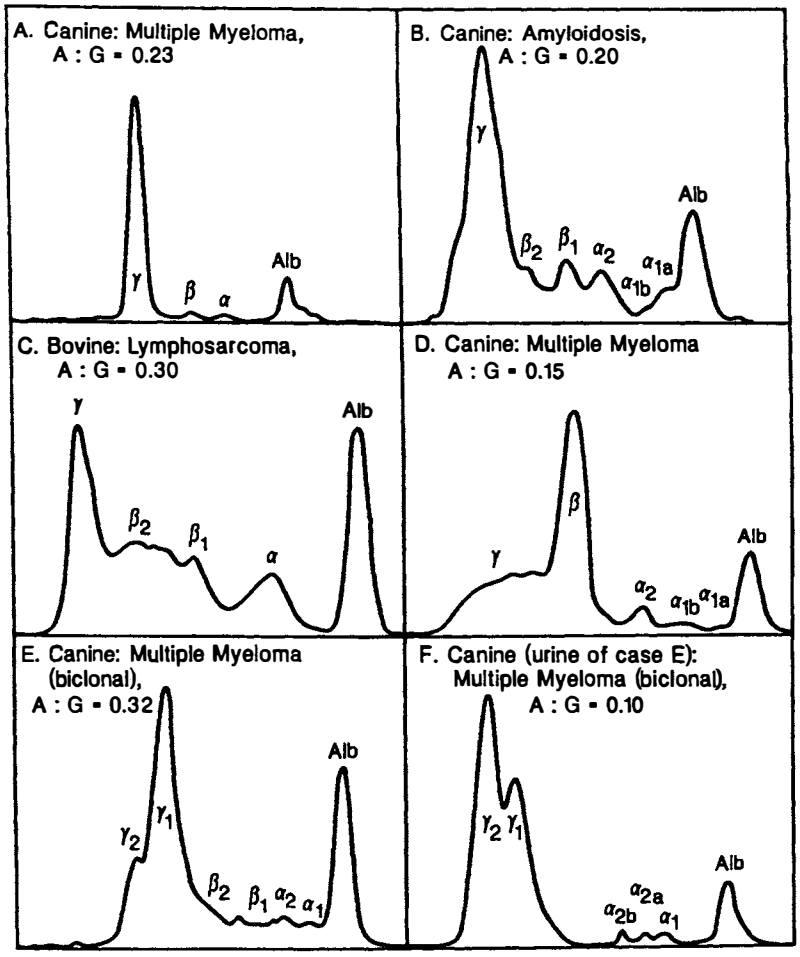

FIGURE 5.6 Cellulose acetate serum protein electrophoretograms of some monoclonal gammopathies in animals. Note that the major globulin peaks are narrow and as sharp or sharper than the albumin peaks. Biclonal gammopathies (E, F) are occasionally seen.

of interstitial fluid (without protein) into the plasma compartment to induce an acute hypoproteinemia. Conversely, dehydration leads to hemoconcentration through reduction in fluid volume and consequent hyperproteinemia. During splenic contraction in the horse, a large mass of erythrocytes moves into the circulation with little or no change in the serum protein.

B. Effects of Inflammation

It has long been known that changes in a select group of constitutive plasma proteins occur in the early stages of the inflammatory process in all animals. In recognition of this phenomenon, this group has been classified as the acute phase proteins (APPs) and the response of the APPs to inflammation is currently the subject of heightened interest. This interest is generated by the potential for use of APPs to provide an early and reliable signal to the clinician of the presence of any form of inflammatory disease or inflammation, including malignancies.

1. Mechanism of the Response

The inflammatory response to tissue injury is a fundamental mechanism by which the host mounts a defense against further injury and initiates a series of chemical events to begin the healing process. This series of events is mediated by the release of cytokines from the leukocytes that gather at the site of injury. The cytokines are polypeptides that may act locally to compound the leukocyte response or distantly to induce a febrile response. Interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor-α (TNF-α) are important cytokines in that they are released into the

circulation to reach the liver where they induce the synthesis and release of the APPs. Most of the APPs are globulins but very few are normally in high enough concentrations as to be readily determined. Their rates of release and their clearance half-times are also important factors in their seum levels in response to inflammation and, of course, their clinical diagnostic usefulness. A very important factor in their clinical usefulness is the magnitude of the response, which is minimal in some instances and can be several 100-fold in others. Further, some of the APPs may be reduced (e.g., albumin and transferrin) and these are the negative APPs. All of these factors are known to operate differently in different species so that significant species differences are seen and must be considered.

2. *Functions*

For many years, fibrinogen (Fbn) was the only well known and readily assayable APP. Fibrinogen, as part of the hemostatic process generates fibrin and the accumulation of fibrin is vital to localizing the injury and initiating healing. Haptoglobin (Hp), another important APP, binds to hemoglobin (Hb) and in this way may limit the scope of the injury by conserving the Hb released by local hemolysis, conserve its iron, or make iron unavailable to microorganisms. CRP binds to many products, including phosphorylcholine, lipoproteins, complement, or bacteria, and may play a similar protective role. SAA is a high-density lipoprotein (HDL) apolipoprotein and increased amounts of SAA may serve to increase HDL transport out of the plasma. In general, these are all defensive and healing responses to injury.

Other hepatic protein responses, notably Alb and Tf synthesis, are downregulated in inflammation. The common function of these negative APPs is transport of metabolites and among these Alb is a particularly well-known general metabolic transport protein. Therefore, any decrease in Alb may well enhance the protective and healing function of inflammation by focusing the animals' metabolic activities toward synthesis of protective proteins and away from catabolism of metabolites.

3. *Species Differences*

Species variations in the APPs occur because of inherent variations in synthesis and in rates of entry and exit of these APPs from the circulation as is true of any other plasma proteins such as the enzyme proteins, transport proteins, or coagulation factors. These variations may take the form of increased synthesis, release, or catabolism as expressed in their clearance half-times, but little is known of the impact of these variations on the species-specific response. As a result, widespread differences occur in the major APP responses among the various animal species. Fibrinogen, previously the most widely used APP for clinical purposes because of its ease and historical use, is a low to moderate responder in most species (Hayes, 1994). Although it has been very useful as a screening tool, it is not a major responder in any of the species studied. Therefore, current interest lies with other APPs. In dogs, the CRP is the major responder and there is intense interest in this APP (Yamamoto *et al.*, 1993, Burton *et al.*, 1994). Additionally, Hp (Conner *et al.*, 1988) and α-1-acid-glycoprotein (AGP) (Ohwada and Tamura, 1995) have been studied in the dog as a potentially useful APP. In rabbits, CRP is also the major responder (Kushner and Feldman, 1978). AGP was also increased in hemolymphatic tumors of dogs (Ogilvie *et al.*, 1993). In cats, TNF-α is a cytokine that responds to feline leukemia virus infection (Khan *et al.*, 1992). In ruminants, mainly cattle, Hp is the major APP responder (Skinner *et al.*, 1991) and, frequently, Hp or even Fbn is the better predictor of inflammation than the leukogram. In the horse, SAA is the major responder (Hayes, 1994). These are the species in which most information is available and important APPs in other species are given in Tables 5.4 and 5.5.

4. *Methodology*

A method based on heat precipitation of Fbn and the use of refractometric measurement of the total plasma proteins before and after heating has been widely used as a screening method for Fbn (see Section V.A.2.b). The common method for Hp is based on its hemoglobin binding property (Skinner *et al.*, 1991) as well as on single radial immunodiffusion (RID) (Morimatsu *et al.*, 1992). The AGP is assayed on the basis of its solubility (Ohwada and Tamura, 1995; Tamura *et al.*, 1989). A variety of methods have been used for CRP; RID (Conner *et al.*, 1988), enzyme-linked imunosorbent assay (ELISA) (Eckersall *et al.*, 1989), immunoturbidometry

TABLE 5.5 Acute Phase Protein: Major Responders in Various Animal Species

Species	Major APP
Cat	TNF-α
Cow	Hp, SAA
Dog	CRP, SAA
Horse	SAA
Mouse	SAA, AGP
Pig	CRP
Rabbit	CRP
Rat	α_2-Macroglobulin, AGP

(Eckersall *et al.*, 1991), and latex agglutination (Yamamoto *et al.*, 1993). The major APP in the horse, SAA, has been assayed based on the lipid binding properties of this lipoprotein (Pepys *et al.*, 1989).

C. The Dysproteinemias

The first approach and method of choice for the overall evaluation of protein status is by the use of SPE. The SPE profile and the absolute values of the individual fractions provide an excellent basis for presumptive diagnoses and for additional studies of the patient. The A:G ratio derived from chemistry panels or from the SPE is the basis on which the SPE can be interpreted.

A classification of the SPE profile in conjunction with the A:G provides for a sytematic approach to the interpretation of protein dyscrasias. Table 5.6 gives just such a classification of the SPE based on the A:G ratio and the nature of the profile. This table provides a useful vehicle for alerting the clinical biochemist and the clinician to the underlying significance of the specific dysproteinemia.

1. Normal A:G—Normal Profile

a. Hyperproteinemia

Simple dehydration with water loss is essentially the only instance when a simple hyperproteinemia without change in profile or A:G occurs. In this case, all protein fractions increase proportionately, including albumin, because only water has been removed from the system.

b. Hypoproteinemia

Overhydration through vigorous fluid therapy or excess water intake is a common cause of simple hypoproteinemia. This is simply a dilution of the system. In other instances, for example, after acute blood loss, interstitial fluid moves rapidly into the plasma compartment, thus diluting the system. This dilution may be further intensified by the ingestion of water to satisfy the thirst commonly seen in acute blood loss. Similarly, after acute plasma loss, whether internal or external, by exudation or extravasation, simple hypoproteinemia occurs because the water losses are rapidly replaced by movement of interstitial water into the plasma compartment.

2. Decreased A:G—Abnormal Profile

a. Decreased Albumin

Decreases in albumin are a common form of dysproteinemia. Fundamentally, the decreases can be attributed to either albumin loss or failure of albumin synthesis. Depending on the stage of the disease, it can be associated with either slight hyperproteinemia (acute stage), normoproteinemia (progressive stage), or, in its advanced stages, hypoproteinemia. Therefore, the total serum protein is rarely a reliable index of albumin status and albumin must be determined.

Due to its small size and osmotic sensitivity to fluid movements, albumin is selectively lost in renal disease (Osborne and Vernier, 1973), gut disease (Meuten *et al.*, 1978; Kaneko *et al.*, 1965), and in intestinal parasitism (Dobson, 1965). The hypoalbuminemia of intestinal parasitism is aggravated by increased albumin catabolism (Cornelius *et al.*, 1962; Holliday *et al.*, 1968; Holmes *et al.*, 1968). Furthermore, due to the sensitivity of albumin synthesis to protein and nitrogen loss such as that occurring in any form of diarrhea, albumin loss impairs albumin synthesis and further compounds the hypoalbuminemia. Due to this same sensitivity of albumin synthesis to protein and nitrogen availability, decreased albumin precedes the development of generalized hypoproteinemia in dietary protein deficiencies. Classic human protein-calorie malnutrition, kwashiorkor, is characterized by hypoalbuminemia and hypoproteinemia (see Section VII.A.4).

The liver is the only site of albumin synthesis and hypoalbuminemia is an important feature of chronic liver disease (Figs. 5.4, 5.5, and 5.6). In the horse, a unique postalbumin shoulder (Fig. 5.5) with or without a hypoalbuminemia is virtually pathognomonic of liver disease. Additionally, albumin is a negative APP (Table 5.4) and extensive inflammation accompanying any of the aforementioned conditions may compound the hypoalbuminemia.

b. Increased Globulins

i. α-Globulins α_1-Globulin but mainly α_2-globulin increases are commonly found and are of diagnostic significance (Fig. 5.4). Many APPs migrate in the α_1- and α_2-globulin regions (Table 5.3) so that increases in these globulins are a common finding in acute inflammatory diseases. A rise in α_2-macroglobulin is also seen in acute inflammatory diseases. The specific APPs that account for the γ-globulin increase, however, must be specifically identified by other means (see Section VII.B.4). In the nephrotic syndrome, α_2-globulins increase due in part to the α_2-macroglobulin and the lipoproteins. The triad of azotemia, hypoalbuminemia, and cholesterolemia is a characteristic of the nephrotic syndrome.

ii. β-Globulins Increases in β-globulins alone are infrequent and found in association only with active liver disease, suppurative dermatopathies, and in the nephrotic syndrome. Transferrin appears to be the major component that rises in active liver disease together

TABLE 5.6 Classification of the Dysproteinemias Based on the Albumin-to-Globulin Ratio and the Serum Protein Electrophoretic Profile

A. Normal A:G—normal SPE profile
  1. Hyperproteinemia: dehydration
  2. Hypoproteinemia
    a. Overhydration
    b. Acute blood loss
    c. External plasma loss: extravasation from burns, abrasions, exudative lesions, exudative dermatopathies, external parasites; gastrointestinal disease, diarrhea
    d. Internal plasma loss: gastrointestinal disease, internal parasites

B. Decreased A:G—abnormal SPE profile
  1. Decreased albumin
    a. Selective loss of albumin: glomerulonephritis, nephrosis, nephrotic syndrome, gastrointestinal disease, internal parasites
    b. Decreased synthesis of albumin: chronic liver disease, malnutrition, chronic inflammatory disease
  2. Increased globulins
    a. Increased α_1-globulin
      i. Acute inflammatory disease: $\alpha_1$pantitrypsin, α_1-acid glycoprotein (orosomucoid, seromucoid)
    b. Increased α_2-globulin
      i. Acute inflammatory disease: α_2-macroglobulin, ceruloplasmin, haptoglobin
      ii. Severe active hepatitis: α_2-macroglobulin
      iii. Acute nephritis: α_2-macroglobulin
      iv. Nephrotic syndrome: α_2-macroglobulin, α_2-lipoprotein (VLDL)
    c. Increased β-globulin
      i. Acute hepatitis: transferrin, hemopexin
      ii. Nephrotic syndrome: β_2-lipoprotein (LDL), transferrin
      iii. Suppurative dermatopathies: IgM, C3
    d. β-γ Bridging
      i. Chronic active hepatitis: IgA, IgM
    e. Increased γ-globulin (broad increases)—polyclonal gammopathies: IgG, IgM, IgA
      i. Chronic inflammatory disease, infectious disease, collagen disease
      ii. Chronic hepatitis
      iii. Hepatic abscess
      iv. Suppurative disease: feline infectious dermatitis, suppurative dermatitis, tuberculosis
      v. Immune-mediated disease: autoimmune hemolytic anemia, autoimmune thrombocytopenia, Aleutian disease of mink, equine infectious anemia, systemic lupus erythematosus, autoimmune polyarthritis, autoimmune glomerulonephritis, autoimmune dermatitis, allergies
      vi. Tumors of the reticuloendothelial system (RES): lymphosarcoma
    f. Increased γ-globulin (sharp increases)—monoclonal gammopathies: IgG, IgM, IgA
      i. Tumors of the reticuloendothelial system (RES): lymphosarcoma
      ii. Plasma cell dyscrasias: multiple myeloma, Aleutian disease of mink
      iii. Macroglobulinemia
      iv. Canine ehrlichiosis
      v. Benign

C. Increased A:G—abnormal profile
  1. Increased albumin: does not occur except in dehydration
  2. Decreased globulins
    a. Fetal serum
    b. Precolostral neonate
    c. Combined immunodeficiency of Arabian foals
    d. Aglobulinemia

with hemopexin and complement. IgM can also rise in active liver disease in response to the antigenic stimulus of infectious agents. In the suppurative dermatopathies, a similar antigenic stimulus is thought to account for the IgM and complement increases in the β fraction. In the nephrotic syndrome, increases in β-globulins are associated with increases in Tf. Most increases in β-globulins are polyclonal, and only occasionally the sharp monoclonal spikes of multiple myeloma, Waldenstrom's macroglobulinemia, or lymphosarcoma are seen (Hurvitz *et al.*, 1977; MacEwen *et al.*, 1977).

iii. β-γ Bridging The phenomenon of β-γ bridging is virtually pathognomonic of chronic active hepatitis (Fig. 5.5). In this case, there is no clear separation be-

tween the β_2 and γ_1 fraction, which results from an increase of IgA, IgM, or both. Rarely does a low-grade gammopathy of lymphosarcoma result in a β-γ bridge.

iv. Increased γ-Globulin (Broad Increase): Polyclonal Gammopathy The diffuse or broad increases in the γ-globulins that characterize polyclonal gammopathies (Fig. 5.5) are a result of the heterogeneity of the clones of plasma cells, which produce a heterogenous mix of immunoglobulins. Any one or all of the immunoglobulins IgM, IgG, or IgA can be present, but a preponderance of one is usually seen.

The chronic inflammatory disease profile may be manifested by a variety of disease states such as chronic infections, collagen diseases, and malignancies in general. There is a concomitant decrease in albumin as a result of decreased synthesis.

Chronic hepatitis, hepatic abscesses, and suppurative disease processes also exhibit changes characteristic of chronic disease (Rumbaugh *et al.*, 1978b). In these cases, the polyclonal increase is more marked and the hypoalbuminemia more severe than in chronic inflammatory disease. This phenomenon may be a reflection of the severity of the disease process and the more intense antigenic response generated.

Immunologically mediated disease processes are also characterized by polyclonal increases. These may be immune processes directed against "self," that is, autoimmune disease, or against external antigenic stimuli. In either case, a multiple immunologic response is elicited, one or more organs may be affected, and polyclonal increases are observed on the electrophoretogram. Immune complexes trapped in the glomeruli and reacting with antigens are thought to be involved in the glomerulonephritis often seen with heartworms, pyometra, and systemic lupus erythematosus (SLE). SLE is a multifaceted disease in the dog often found in association with autoimmune hemolytic anemia (AIHA), thrombocytopenia (AITP), glomerulonephritis (GN), and rheumatoid polyarthritis. The basic defect in SLE is the LE factor, an anti-DNA antibody, and the widespread dissemination of the DNA–anti DNA complex throughout highly vascular structures. The LE cell is a granulocyte that has phagocytized the DNA–anti DNA complex.

AIHA is characterized by acute erythrocyte destruction, accelerated bone marrow response to the anemia, and the presence of autoantibodies against the patient's own erythrocytes. The antibodies may be of the warm or cold type but usually are warm. A prevailing view holds that the erythrocyte membrane proteins or prosthetic groups of these proteins are altered or mutated to become a "foreign" antigen, which the body's immune mechanism now does not recognize as "self." Anti-erythrocyte antibodies are formed, coat the erythrocytes, and in the presence of complement, hemolysis, fragmentation, or phagocytosis occurs. Diagnosis of AIHA is made by demonstrating a positive direct Coombs' test.

AITP is another form of autoimmune disease in which the platelets have either absorbed viral or drug antigens on their surfaces and become coated with antibody or have adsorbed antigen–antibody complexes directly. These antibody-coated platelets are rapidly removed from the circulation (Wilkins *et al.*, 1973). Definitive diagnosis is made by use of the PF-3 test (Karpatkin and Siskind, 1969).

Rheumatoid arthritis (RA) is characterized by the development of rheumatoid factor (RF), an autoantibody against IgG, and the immune complexes formed in the joints induce the chronic inflammatory lesion.

Tumors of the monocyte–macrophage system exemplified by lymphosarcoma can elicit either a poly- or monoclonal response. The hyperglobulinemic peaks can occur anywhere between the β_1 to γ_2 regions and range from very broad, diffuse peaks to very sharp, monoclonal spikes. The polyclonal peaks of lymphosarcoma are thought to be the result of a tumorous group of distantly related clones in contrast to the single discreet clones, which give rise to the monoclonal spikes.

v. Increased γ-Globulin (Sharp Increases): Monoclonal Gammopathy The monoclonal forms are characterized by sharp spikes of immunoglobulin and are frequently limited to the γ region (Fig. 5.6). A useful guideline for interpretation is to compare visually the sharpness of these spikes to the albumin peak. One or the other slope of the monoclonal spike is as steep or steeper than one of the slopes of the albumin peak. The monoclonal spike is the result of a single clone producing a single class of immunoglobulin, usually abnormal in nature. Thus, the monoclonal immunoglobulins are of identical structure and move as one on the SPE. These immunoglobulins have been described as "paraproteins" or as the "M" components because of the frequent occurrence of IgM. Waldenstrom's type macroglobulinemia with hyperviscosity and IgM monoclonal spikes have been reported in dogs (Hurvitz *et al.*, 1970; MacEwen *et al.*, 1977). In multiple myelomas, Bence–Jones proteins (light chains) are detected in approximately 50% of the cases in humans (Civantos *et al.*, 1973; Ritzmann *et al.*, 1972), but infrequently in dogs (Hurvitz, 1975). The characteristic monoclonal spike in the γ region, Bence–Jones proteinuria, and plasma cell tumors have been general findings in multiple myelomas reported in the horse (Cornelius *et al.*, 1959), dog (Osborne *et al.*, 1968; Shepard *et al.*, 1972), cat (Farrow and Penny, 1971), and rabbit (Pascal, 1961). Aleutian disease (AD) of mink, a valu-

able model of immunologic disease, is also characterized by plasma cell infiltration, hypoalbuminemia, hyperproteinemia, and hyper-γ-globuinemia, frequently with a monoclonal spike (Leader *et al.*, 1963; Thompson and Aliferis, 1964). Light-chain disease, in which the M component was identified as L chains (Bence–Jones proteins) in the plasma and urine, has been observed in dogs (Hurvitz *et al.*, 1971). An IgA monoclonal gammopathy in a dog without Bence–Jones proteinuria or plasma cell infiltration has also been observed (Dewhirst *et al.*, 1977).

Tumors of the monocyte–macrophage system (e.g., lymphosarcoma) frequently present with monoclonal spikes depending on the degree of cloning of the tumor cells. The dominant M component was identified as IgM in a case of lymphocytic leukemia in a dog (Braund *et al.*, 1978). A biclonal gammopathy has been observed in a dog with a combined myeloma and cutaneous lymphoma (Jacobs *et al.*, 1986) (Fig. 5.6). Even a triclonal gammopathy can be observed.

Monoclonal gammopathies are also seen in canine amyloidosis (Schwartzman, 1984) (Fig. 5.6) and in canine ehrlichiosis in association with large numbers of reactive plasma cells in the bone marrow (Breitschwerdt *et al.*, 1987).

Generally, the clinical characteristics of the monoclonal gammopathies are referable to the magnitude of plasma cell proliferation, the extent of organ infiltration and production of abnormal protein. Thus, immunologically associated diseases tend to be multifaceted and can present with bleeding tendencies, glomerulonephritis, polyarthritis, arteritis, hepatitis, and SLE. Treatment by cytotoxic drugs is largely ineffective, but symptomatic treatment by plasmapheresis is often followed by a brief period of clinical improvement. Infection is a common sequela and a frequent cause of death because of the immunosuppression. All monoclonal gammopathies are not necessarily pathologic, however, because they can be benign. In consequence, care must be exercised in the final evaluation of the monoclonal gammopathy.

3. *Increased A:G—Abnormal Profile*

a. Increased Albumin

True overproduction of albumin does not occur in any animal. Therefore, any rise in albumin is only a relative hyperalbuminemia due to hemoconcentration as a result of water loss and dehydration.

b. Decreased Globulins

The absence of γ-globulins in fetal serum or in serum from precolostral or colostrum-deprived neonatal animals can be readily demonstrated on SPE (Fig. 5.1). Hypo-γ-globulinemia occurred in about 15% of foals less than 2 weeks of age and was attributed to failure of colostral transfer even though most had nursed (McGuire *et al.*, 1975b). Combined immunodeficiency of Arabian foals is thought to be an inherited autosomal recessive disease. The disease is characterized by lymphopenia failure to synthesize IgG, IgM, and IgA and early death (McGuire *et al.*, 1975a). A selective IgM deficiency has been reported (Perryman *et al.*, 1977).

CHAPTER

6

Clinical Immunology

LAUREL J. GERSHWIN

I. INTRODUCTION

A healthy immune system is critical to survival. Clinical immunology is directed at evaluation of the immune system of patients and the ability of the immune system to respond to antigenic stimuli. Assays developed to target specific parts of the immune system enable the clinician not only to determine if a patient has normal immune responsiveness, but also to target those parts of the immune system that are suspect of inadequate function. Serology has historically been used to determine retrospectively if a patient was infected with a particular disease agent; antibody titers continue to have importance in diagnostics. In the fourth edition of this book, it was stated that veterinary clinical immunology is a rapidly growing field that has lagged somewhat behind its human counterpart due to a lack of specific assays and reagents. In the past six years the field of veterinary immunology has seen immense growth. The widespread use of molecular cloning techniques and the polymerase chain reaction have provided tools for development of probes and expressed genes that allow veterinary immunologists to measure cytokines, adhesion molecules, and a variety of other cell surface molecules. Awareness on

the part of practicing veterinarians of some less common immunological diseases has increased and some diseases with unknown etiology have been found to have a significant immune component.

II. THE IMMUNE RESPONSE

A. Innate Immune Responses

Several inherited defects of innate immunity have emerged during the inevitable inbreeding inherent in certain animal breeding programs. These defects demonstrate the importance of the particular function of the defective component. For example, a recently described absence of adhesion molecules on bovine neutrophils was manifested in severe bacterial infections in the presence of ever increasing neutrophil counts. Holstein calves lacking the CD18 glycoprotein on neutrophil cell membranes were unable to deal with normally easily stopped bacterial infections because the neutrophils were unable to marginate along blood vessels. They were thus unable to undergo diapedesis and migrate to the site of a bacterial infection. This syndrome, called *bovine leukocyte adhesion deficiency* (BLAD) can be detected by use of a polymerase chain reaction (PCR) to detect the presence of the defective gene (Kehrli *et al.*, 1990).

Several other inherited defects of innate immunity focus on slightly different functions of the neutrophil. For example, in canine granulopathy syndrome the neutrophils are able to marginate and undergo diapedesis, but their ability to kill organisms once they have arrived at the site of infection is severely compromised (Renshaw and Davis, 1979). This is also true for the Chediak–Higaski syndrome seen in Persian cats. Assays are described later in this chapter for the evaluation of neutrophil function.

B. Acquired Immune Responses: Antigens

The ability of a patient to develop an immune response to a specific antigen depends on the presence of B lymphocytes, helper T lymphocytes, and generally an antigen presenting cell, such as a macrophage. The first exposure to antigen elicits primarily an IgM response, but subsequent exposures trigger the production of IgG. Mucosal sites have a preference for production of secretory immune responses, such as IgA production. IgE production is elicited by certain antigens, *allergens*, in individuals that are genetically high responders, *atopic*, and by parasite antigens.

This chapter addresses the various components of the immune system and how to evaluate whether or not their function is normal. Information is included on the variety of immunological tests that are available for detecting immune response to certain pathogens. Some have importance in the historical development of serological techniques, whereas others are quite newly developed.

An antigen is broadly defined as something foreign. Indeed foreignness is the most important characteristic of an antigen. As an illustration, consider a simple serum protein such as albumin. If bovine serum albumin is injected into a rabbit, the rabbit's immune system recognizes it as foreign and develops an immune response to it. If, however, that same bovine serum albumin is injected into a cow, it will not be recognized as foreign and no immune response will occur. Another important characteristic of an antigen is its size. Most effective antigens are greater than 10,000 Da. Other factors such as chemical complexity and molecular rigidity are important determinants of antigenicity.

A complete antigen is a substance that is able to induce an immune response and can then react with the products of that response, namely, antibodies and sensitized T lymphocytes. An incomplete antigen, also known as a hapten, cannot induce an immune response by itself, but requires prior binding to a carrier molecule, usually a protein. The hapten can then bind to the induced antibodies without attachment to a carrier. There are several examples of drug moieties, such as penicillinoyl, that act as haptens and bind to host proteins or cells to induce an immune response. Once induced, these antibodies can induce immunological disease.

Although an individual protein can be an antigen, in reality the immune response is not directed to the entire molecule, but rather to one or more antigenic determinants or epitopes present on the protein. In a normal (polyclonal) immune response, some antibodies are produced specific for each of these epitopes. This is the basis for the phenomenon of cross reactivity. Related but different antigens will usually react with antibodies induced by immunization with each other. This occurs because they share at least one epitope. Cross reactivity is important because it is essential to have specific antisera as reagents for use in diagnostic assays. One way to obtain such reagents is to absorb with the offending organism antisera that cross react, thereby removing those antibodies that recognize the cross-reactive epitopes and leaving only those that are specific for the immunogen used to prepare the antiserum. Another way to prepare specific antisera is to

develop monoclonal antibodies against the agent, as described later in this chapter.

III. ANTIBODIES

Electrophoretic separation of serum proteins creates four broad categories: albumin, α-globulins, β-globulins, and γ-globulins. The antibody activity is present in the γ-globulin fraction, with a slight amount in the β fraction. These immunoglobulins are heterogeneous, having different molecular weights and functional properties.

The five classes (isotypes) of immunoglobulins are IgG, IgM, IgA, IgE, and IgD. They share a basic structure, which consists of four polypeptide chains bound by disulfide bonds. Two of these chains are called light chains, because with a molecular weight of about 22,000 Da each. They are lighter than the other two heavy chains (approximately 55,000 Da each). At the nitrogen terminal of the polypeptide chains on all four chains is a portion of variable amino acid sequences. This is the antigen binding end of the immunoglobulin. The hinge region of the immunoglobulin provides for flexibility of the molecule, so that the two "arms" containing the antigen binding portion can move apart. Treatment of an IgG molecule with papain causes it to break into three pieces, two that contain the antigen binding sites (Fab), and a third consisting solely of heavy chain, and called the Fc (for crystallizable) fragment. Sometimes antibody reagents are described as being *Fc specific*, which means that there is no cross reactivity between isotypes due to recognition of light chains.

A. Immunoglobulin G

In the serum IgG is the antibody class with the greatest concentration, approximately 1–2 g/100 ml, with some species differences (Tizard, 1992). Subclasses of IgG are recognized in most species. IgG has a four polypeptide chain structure with a total molecular weight of 180,000 Da. The heavy chains in IgG are called gamma chains and are unique to IgG. Immunoglobulin G is important in host defense because it can exit the vascular system and distribute throughout the extravascular tissue fluid where it has many protective functions. For example, IgG can agglutinate bacteria, causing them to clump; it can opsonize bacteria, by binding to the bacteria by the Fab fragment and to the phagocyte by receptors for the Fc fragment, thereby facilitating engulfment of the bacteria by the phagocyte. Complement (a series of serum proteins to be discussed later in this chapter) can be fixed by IgG molecules and target cells can be lysed by this mechanism. In addition, IgG can participate with lymphocytes called null cells in antibody-dependent cellular cytotoxicity. This mechanism allows destruction of virus-infected cells after recognition by the antibody bound to the null cell. IgG can neutralize toxins, such as those produced by *Clostridium tetani.*

B. Immunoglobulin M

Immunoglobulin M (IgM) is the first antibody to be synthesized in response to an immunogenic stimulus and is the first antibody seen in ontogeny. In serum IgM is present in the second greatest concentration, generally between 100 and 400 mg/100 ml (species dependent). The structure of IgM consists of five of the basic four polypeptide units held together by a J chain. The large size of IgM (900,000 Da) keeps it confined to the intravascular space. There are a total of 10 potential antigen binding sites on IgM. Even though in reality, due to steric hindrance, only five to seven of the antigen binding sites are functionally active, this large capacity to bind antigen makes IgM a very efficient antibody at agglutination, precipitation, opsonization, complement fixation, and virus neutralization.

C. Immunoglobulin A

Immunoglobulin A exists primarily in two forms, as a monomer (160,000 Da) in the blood-vascular compartment, and in a dimeric secretory form (390,000 Da). Less commonly, polymers of greater number occur. The dimeric form consists of two monomers, each containing a heavy chain (alpha) and a light chain. These are held together by a J chain and include an additional component called the *secretory piece.* The secretory piece is produced by mucosal epithelial cells and functions to assist in transport of IgA dimers from the lamina propria of the intestine through to the lumen where it then protects the IgA dimer from proteolysis by intestinal enzymes. In domestic animals IgA is important as a secretory antibody both within the intestinal tract and the lung. It is capable of neutralizing virus and preventing adherence of bacterial pathogens to target tissues. It does not function as an opsonin and is unable to fix complement.

D. Immunoglobulin E

Immunoglobulin E is recognized and characterized in dogs, cattle, sheep, pigs, and horses and is functionally recognized in cats. The existence of IgE in chickens

is still undocumented. IgE occurs normally in very small amounts in the serum (nanogram quantities). In allergic or parasitized individuals the serum concentration of IgE is greatly increased. The basic four polypeptide chain structure of IgE, with epsilon heavy chains that contain one additional domain, has a molecular weight of 196,000 Da. Functions of IgE are mediated through its ability to bind via the Fc portion to receptors on tissue mast cells and blood basophils. When antigen cross-links these cell-bound antibodies the cell degranulates, releasing vasoactive amines, stimulating leukotriene synthesis, and resulting in potent pharmacologic effects.

E. Immunoglobulin D

A complete discussion of immunoglobulin isotypes should include IgD, the antibody that has been demonstrated on lymphocyte surfaces. In mouse and human it has been shown to be an important antigen receptor during the differentiation of B lymphocytes. Although IgD has been demonstrated in pigs and in chickens, information is lacking in other domestic animal species. IgD exists in the four polypeptide chain configuration (heavy chains are called delta) with a molecular weight of 180,000 Da.

F. Epitopes and Specificity of Immunoglobulins

Most antigens contain several different antigenic determinants or epitopes. Larger molecules usually have more epitopes than small molecules. Consider, for example, the protein bovine serum albumin, with a molecular weight of about 60,000 Da. Ten to 12 different epitopes could easily be present on such a molecule. When we immunize an animal with an antigen and then analyze the antibody response, we measure the sum of the immune responses to each of these epitopes. This is called a *polyclonal response.* Each immature B lymphocyte with specificity for the antigen recognizes only one epitope. Consequently, the progeny of that cell, the resulting clone, produces antibody that reacts with a single epitope. However, within the animal are many such cells and the resultant antibodies are mixed together in the serum (a polyclonal antiserum). Recent advances in biotechnology have created a new type of antibody reagent, monoclonal antibodies, produced by hybridomas. Monoclonal antibodies are a characteristic of patients with multiple myeloma. These plasma cell tumors originate from single antibody forming cells. Neoplastic proliferation of these cells results in a high level of circulating antibody all specific for a single epitope and all with identical isotype. Kohler and Milstein (1975) took advantage of this type of tumor and produced a hybrid cell, between a mouse spleen-derived B lymphocyte and a mouse myeloma cell line. These hybrids have the antigenic specificity of the B cell and the ability to grow continuously in the tissue culture from the myeloma cell line. This technique of fusing spleen cells from immunized mice with myeloma cells is now a commonly used technique to produce antibody reagents that have specificity for a single epitope. Additional advantages of these reagents include their ability to grow *in vitro* thus guaranteeing availability of large amounts of standardized antibody reagents for use in different laboratories.

IV. COMPONENTS OF THE IMMUNE RESPONSE

Antibody formation in response to antigen requires the cooperation of several cell types. The B lymphocyte is the most important cell in humoral immunity because it possesses the receptors for antigen recognition and ultimately gives rise to the antibody producing cell. However, the role of the T helper lymphocyte is critical for a response to most antigens. Antigen must also be presented to the T cells, and while B cells can present antigen in some cases, the majority of external antigens, such as bacterial pathogens, first require some processing by a macrophage, which acts as the presenting cell to T helper cells.

A. B Lymphocytes

Although lymphocytes are indistinguishable from each other when observed with a microscope and a simple Wright's or Giemsa stain, there are actually several very distinct populations. B lymphocytes are the cells that differentiate into antibody forming plasma cells following exposure to antigen. B cells develop in the bone marrow of mammals or bursa of Fabricius in fowl. They then seed specific areas of the secondary lymphoid organs, such as germinal centers in lymph nodes. Antigen receptors, present on the B-cell membrane, are actually immunoglobulin molecules, with an additional piece of polypeptide chain that anchors the Fc fragment into the cell membrane. Each B-cell receptor has a unique variable region that allows it to react with the appropriate antigen. The specificity of the antibodies that result from antigenic stimulation of a B-cell clone is identical to that of the antigen receptors on the original B cell that was stimulated. During development of a B-cell clone it displays first IgM on the cell surface. This isotype is then joined by IgD, and finally other isotype receptors, such as

IgG or IgA, are displayed. The final differentiation step creates the antibody forming cell, the plasma cell.

B. Antigen Presenting Cells

As stated earlier, antigen is presented to T cells on a cell membrane surface, frequently a macrophage, dendritic cell, Langerhans' cell, or other cell carrying major histocompatibility complex (MHC) antigen class II. The presence of this molecule is imperative for T helper presentation because the cell surface MHC class II glycoprotein cradles the processed antigen within a specific groove and displays it in such a way that the T-cell receptor can recognize it. Great detail on this phenomenon is available in several reference texts listed at the end of this chapter.

C. T Cells and Cytokines

Progress in the area of antigen-specific T-cell activation and cytokine production has been immense in recent years. Recognition of a variety of chemokines, interleukins and other cell-stimulatory factors has allowed for a better understanding of how the immune response is regulated. For example, the profile of cytokines secreted by a T cell after antigen recognition is dependent on the type of T cell. A subset of T cells, referred to as T helper type 1 cells, which secrete gamma interferon and interleukin 2 (IL-2), promotes delayed-type hypersensitivity reactions; whereas a different subset, T helper type 2 cells, directs B cells to produce antibodies, and thus predisposes for a humoral response (Salgame *et al.*, 1991). The major cytokine involved in this response is interleukin 4 (IL-4), produced by CD4+ T cells. Besides stimulation of B-cell proliferation and differentiation (especially into IgE producing cells), IL-4 also increases expression of MHC class II antigens and CD23 (low affinity IgE receptor) expression on appropriate cells. The discovery of interleukin 13 (IL-13) has added another cytokine with similar activity as IL-4. Interleukin 13 also induces CD23 expression on B cells and upregulates MHC class II expression. Unlike IL-4, IL-13 is produced by activated cells of both the CD4+ and CD8+ phenotypes. Production of IL-13 occurs earlier after cell stimulation than IL-4 and its effect lasts longer. The effects of IL-4 on production of gamma interferon are downregulatory, whereas the effects of IL-13 are stimulatory for gamma interferon production. Although IL-13 behaves like IL-4 and induces a B-cell switch to production of IgG4 and IgE in humans, thus facilitating an allergic response, the same does not appear to be true in mice. Thus there will most likely be some species-specific differences noted among the domestic animals.

Along with the recognition of T-cell subsets that produce different cytokine patterns, a series of disease paradigms has developed: activation of T helper type 2 cells causes the production of IL-4, IL-5, IL-6, and IL-10, which leads to the selective differentiation of B cells into plasma cells that produce IgE, IgA, and some classes of IgG. Activation of T helper type 1 cells causes production of IL-2, gamma interferon, and tumor necrosis factor (TNF), with some selective IgM and IgG induction as well (Mosmann and Coffman, 1989; Romagnani, 1991). This type of response facilitates the delayed-type hypersensitivity reaction. Certain diseases, such as leprosy in humans, can exist in several forms, which can be directly linked to a particular T-cell profile. When immunity is focused on production of a cellular response, there is greater healing as compared to the humoral response, which results in disease exacerbation.

Another group of cytokines is of particular importance in response to disease; these are the inflammatory cytokines, TNF, IL-1, IL-6, and IL-8. The inflammatory cytokines are produced early in disease and their production is independent of antigen. Bacterial lipopolysaccharide derived from gram-negative bacteria is a potent inducer of these cytokines. Chemotaxis of neutrophils is stimulated by IL-8 (Arai *et al.*, 1990).

V. PRIMARY AND SECONDARY IMMUNE RESPONSES

The primary immune response occurs after the animal's immune system is exposed to an antigen for the first time. In the case of young animals with high levels of maternal immunoglobulin specific for the antigen, the primary immune response may be delayed until there are sufficiently low levels of maternal antibody for persistence of antigen to stimulate immune cells in the animal. In the absence of passive antibody, the antigen will stimulate the B and T cells, as described earlier, resulting in the production of IgM antibody for a short period of time. The IgM response takes 10–14 days to develop and is sometimes followed with low levels of IgG, which do not persist long in the circulation.

Subsequent exposures to antigen result in a secondary immune response, a quicker and greater magnitude response than that seen with initial exposure. Also of note is the preponderance of IgG in the secondary response. The concentration of antibody is greater and the titer stays high longer. Further exposure to antigens in the future results in increasing amounts (greater titer) of antibody. This information is extremely useful in determining the result of serological assays for infec-

tious agents. For example, if a horse has a pectoral abscess, which resembles a *Corynebacterium pseudotuberculosis* lesion, and a blood sample obtained for testing has a titer of 16, the result on its own is relatively meaningless. However, if a second sample taken 3 weeks later shows an increase in titer to 128, then the response can be attributed to infection with the *C. pseudotuberculosis* organism.

To illustrate how the isotype-specific immune response can be used in diagnostics, an example can be cited: In the clinical immunology laboratory, serological tests for infection with canine distemper virus can be very confusing, primarily because the presence of maternal antibody and the frequency of vaccination generally create dogs with some level of antibody. However, performance of a serological test that determines an IgM titer separately from an IgG titer is often helpful in determining the likelihood of recent exposure to the virus.

VI. EVALUATION OF IMMUNE RESPONSES: DETECTION OF ANTIGENS AND ANTIBODIES

A. General Principles

Immunological tests to detect antigens or antibodies are based on several properties of antigen–antibody reactions. An antibody binds specifically with the antigen that induced its formation. Antibodies of the IgG and IgM isotypes precipitate with soluble antigen or agglutinate particulate antigen. These reactions can be used to secondary and/or qualitatively observe an antigen–antibody reaction. Antibody to a virus can neutralize its infectivity and antibody to a toxin can neutralize its toxigenic effect. These properties have been used in assays to measure the antibody response. Regardless of what type of assay is performed, if it is based on an antigen–antibody reaction it is important that there are not any cross-reacting antigens or antibodies that could give an erroneous result. Specificity of an immunological test is best achieved with well-defined reagents. Detection of antibody isotypes that do not precipitate with antigen, such as IgE, require either *in vivo* assays that make use of the mast cell degranulation function, such as intradermal skin tests, or assays that use a second labeled antibody to indicate the presence of antigen-bound IgE, such as the radioallergosorbent test (RAST) or enzyme-linked immunosorbent test (ELISA).

A second important concept to remember when evaluating immunological tests is the sensitivity of the test. The most sensitive tests, that is, those that detect the smallest amount of protein, are referred to as primary binding assays, radioimmunoassay, and ELISA. These can detect nanogram amounts of protein. Virus neutralization is also very sensitive. Other techniques such as agar gel diffusion (a precipitin test) are much less sensitive, requiring greater than 10 μg/ml before protein antigen is detectable. In immunological tests in which serum is diluted serially, the results are usually expressed as a titer. The titer by convention is the inverse of the last dilution that produces a positive reaction (end point). In studies involving infectious disease, it is desirable to obtain two serum samples, one during the acute phase of the illness and another after convalescence. A rise in titer, as illustrated earlier, of two doubling dilutions or more is suggestive of a positive role for the particular pathogen in the disease process.

B. Serological Tests

1. Precipitin Reactions

Soluble antigen reacts with specific antibody to form immune complexes. These immune complexes can be small or large depending on the proportion of antigen to antibody within the complex. When there is either antigen or antibody excess, complexes are soluble. However when there is an optimal proportion of antigen to antibody, complexes are insoluble and form a visible precipitate. Initially the solution containing the complexes becomes cloudy, then after some time they settle out. This is because a lattice structure is formed between the multivalent antigen and the bivalent antibody. Precipitation is the basis for several immunological assays. There are several ways to perform secondary precipitin reactions. Tube precipitin tests can quantitatively determine the amount of antigen that reacts with a given antiserum at equivalence and thus provide an estimation of the "strength" of a particular antiserum. Laser nephelometry can be used to detect immune complexes in solution. This technique is receiving some application in the clinical immunology laboratory for rapid quantitation of immunoglobulins. Precipitin reactions can be performed in a semisolid matrix, such as agar gel. When the reactants reach the point of optimum proportion, a line of precipitation develops. Ouchterlony double diffusion in gel makes use of this principle. Wells are cut in an agarose slab and are filled with either antigen or antibody. After incubation for 24–48 hours, visible lines are present between antigen and antibody wells, indicating the presence of immune complexes. In this technique several types of reactions are identifiable: identity, nonidentity, and partial identity. Unknown reactants can be identified by this test by demonstration of an arc of identity with a known antigen. When two separate

antigens in adjacent wells react with different antibodies in the same antibody well, the precipitin lines cross each other and the reaction is termed *nonidentity*. Partial identity occurs when two adjacent wells contain antigen with a cross-reacting determinant. Partial identity is recognizable as a spur. These principles are useful in several diagnostic tests. The agar gel diffusion test for diagnosis of equine infectious anemia (Coggin's test) is an Ouchterlony double immunodiffusion test in which viral antigen is placed in a central well and positive control sera are alternated with test sera in the peripheral wells. A line of identity between positive and test serum is indicative of a positive test (Fig. 6.1). A similar principle is used in the bovine leukemia test.

Another type of agar gel immunodiffusion test is widely used to quantitate secondary levels of specific immunoglobulin isotypes. In single radial diffusion, antiserum specific for the reactant being measured is incorporated into the agar. Wells are punched and filled with serum to be assayed. During incubation the antigens in the serum diffuse radially into the agarose and cause formation of a precipitate ring around the well at the point where an optimal proportion of antigen to antibody exists for lattice formation. The sizes of the precipitate rings are proportional to the amount of antigen present in the wells. Wells containing known standards are used to draw a standard curve from which quantitative values for the unknown serums are obtained. Total serum IgG, IgM, or IgA is readily measured for most species using this method. Test kits are available from several commercial companies. These kits provide agarose plates containing the appropriate antibody and a set of standards (Fig. 6.2).

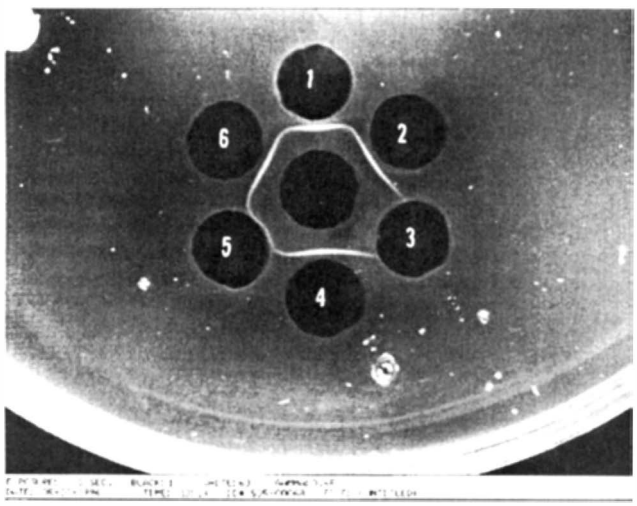

FIGURE 6.1 Coggin's test for equine infectious anemia. Viral antigen is in the center well. Lines of identity between the positive controls are in wells 2, 4, and 6. The sample in well 1 shows positive, the sample in well 5 is weakly positive, and well 3 is negative.

Immunoelectrophoresis is another technique that utilizes the principle of precipitation and provides a useful test in the clinical immunology laboratory (Caron and Penn, 1992). In this test antigens, usually proteins in the patient's serum, are separated by electrical charge in an agarose gel. After protein separation is complete, a trough is removed from the agarose and antiserum specific for components in the serum is added. Wherever antigen and antibody meet at optimal proportions, precipitin arcs develop. In the clinical immunology laboratory a patient's serum is compared with a control serum on opposite sides of each antiserum trough. This technique is a useful adjunct to the diagnosis of hypogammaglobulinemia, paraproteinemia, and isotype-specific immunoglobulin deficiency (Fig. 6.3).

2. *Agglutination*

Agglutination reactions have important applications in diagnostic immunology. Although a relatively quick and easy assay, agglutination has greater sensitivity than precipitin-type reactions. The process of agglutination occurs when particulate antigens such as bacterial cells or erythrocytes are incubated with a source of antibody that recognizes determinants on these cell surfaces. This type of assay has traditionally been performed to detect serum agglutinating antibodies specific for *Salmonella* H and O antigens (Olitzki, 1972). A slide test is performed by mixing a drop of specific antiserum with a drop of suspended bacteria. Rapid development of clumping indicates a positive test. This process was used to define bacterial serotypes. Agglutination tests have found use in test kits, some of which utilize the concept of passive agglutination, in which an antigen is chemically fixed to a solid particle, such as a latex bead or an erythrocyte. The patient's serum is mixed with the solid substrate and observed for agglutination. It provides a quick positive or negative result when performed in this manner. A commonly used test kit for rheumatoid factor in canine serum is based on this principle. A more sensitive and quantitative assay is the passive agglutination test used to determine antibody to *Toxoplasma gondii*. This test kit provides latex beads coated with *Toxoplasma* antigen. The beads are mixed with serial dilutions of serum and are plated into 96-well microtitration plates. After incubation wells are read for agglutination of the beads and a titer is obtained.

3. *Coombs' (Antiglobulin) Test*

The antiglobulin test is performed to detect the presence of incomplete antibody bound to erythrocyte membranes. Its use in the diagnosis of autoimmune

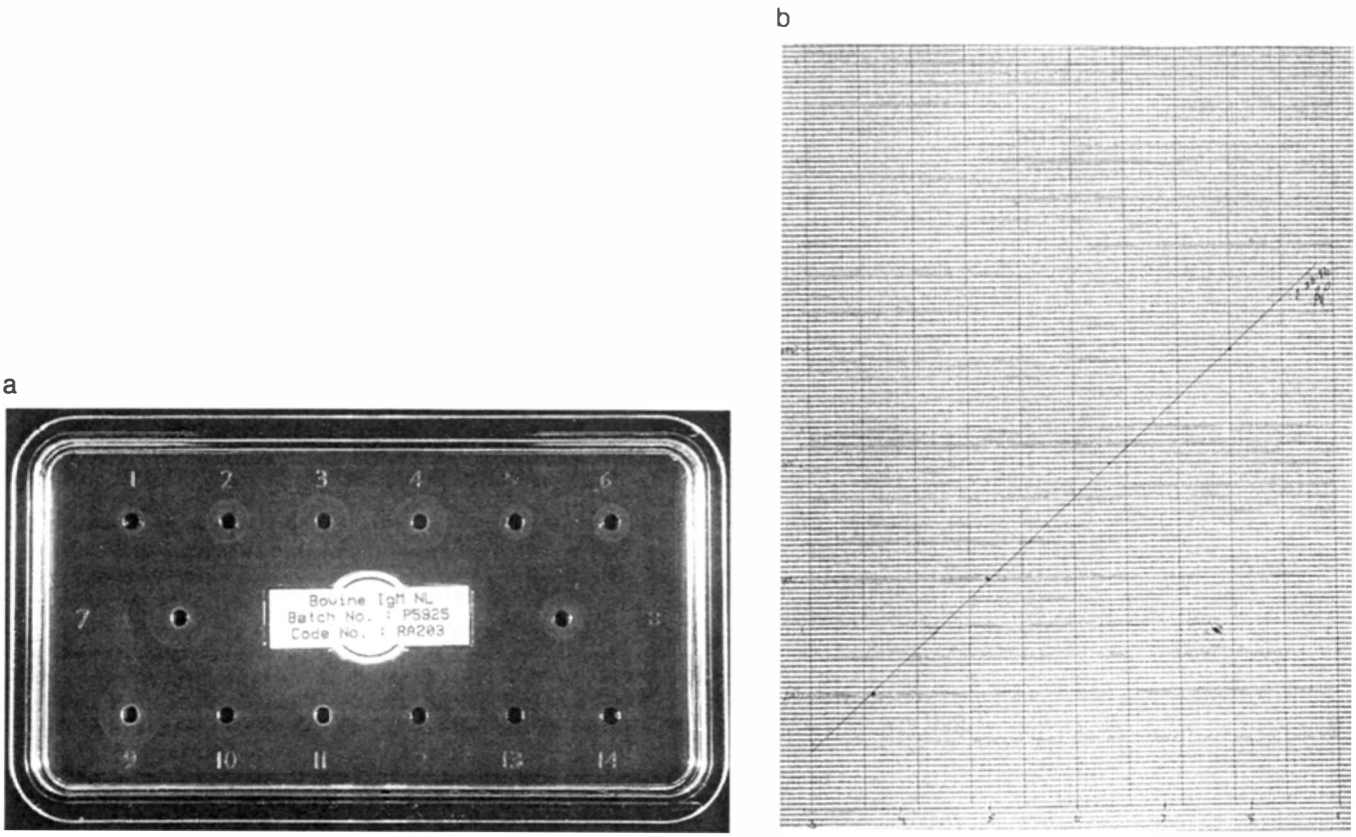

FIGURE 6.2 Single radial immunodiffusion test for measuring the concentrations of bovine IgM. The diameters of the standards (a) are used to plot a curve (b) from which sample concentrations are determined. The Y axis is the amount of IgM and the X axis is the diameter of the diffusion reaction.

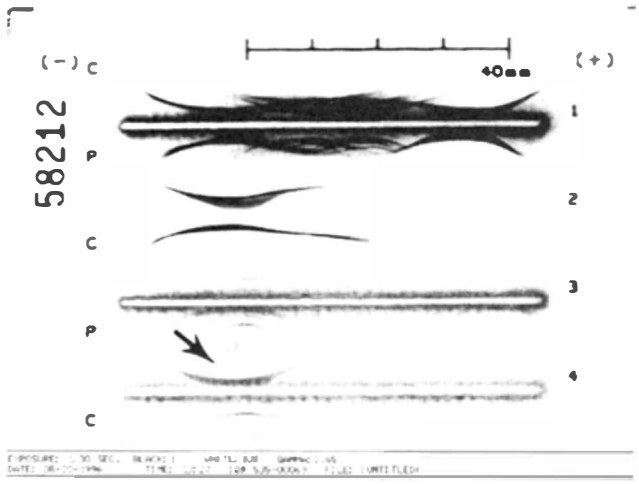

FIGURE 6.3 This immunoelectrophoresis profile is indicative of the presence of an IgA myeloma protein (*arrow*). Trough contents: (1) anti-canine serum; (2) anti-canine IgG (h and l); (3) anti-canine IgM; (4) anti-canine IgA. Well contents: (C) normal control dog; (P) patient.

hemolytic anemia is described later in this chapter. The basis of the test is agglutination.

4. Hemagglutination and Hemagglutination Inhibition

Some viruses have receptors for erythrocytes and when incubated in their presence cause them to agglutinate. This phenomenon is called *hemagglutination.* The specifics of the erythrocyte source, mammalian or avian, and optimum temperature and time for reaction vary depending on the virus of interest. Myxoviruses, paramyxoviruses, enteroviruses, and adenoviruses are several virus groups with members of veterinary interest that are capable of hemagglutination (Davis *et al.*, 1990). The hemagglutination procedure is itself of little immunological interest. However, the ability of antiserum to inhibit the hemagglutination caused by virus receptors for erythrocytes has been utilized to develop a serological test called *hemagglutination inhibition* (HI). The antibodies bind to receptor sites for erythrocytes and thus block the hemagglutination reaction. The test

is used to measure antibody titers to the virus. Alternatively, with a known source of antiserum, one can use the HI test as a preliminary viral identification step.

To perform the HI test, serial twofold dilutions of heat-inactivated serum are prepared in saline. A 0.25-ml aliquot of each dilution is then mixed with a similar amount of viral suspension that contains four hemagglutinating units. These are mixed and incubated. Next 0.25 ml of a 1% erythrocyte suspension is added and the tubes are mixed again and incubated at the appropriate temperature and time for the virus of interest. The agglutination or absence thereof is read and the HI titer of the serum is assigned as the reciprocal of the highest serum dilution that completely prevents hemagglutination. Alternatively, one can perform the test by making serial dilutions of the virus suspension and using a standard amount of serum. Test sera are then compared with known negative and positive sera. The former HI test is called the α procedure and the latter, the β procedure. Appropriate controls must be included in either procedure, particularly to prevent false-positive results from the presence of hemagglutinating substances in test sera.

5. Virus Neutralization Assays

Detection of antibodies specific for viral epitopes is an important indicator of exposure to the virus. However, antibodies detected by precipitin tests or primary binding tests are not necessarily protective. It is therefore often worthwhile to measure the titer of functional antibody (i.e., antibody capable of neutralizing the infectivity of a virus), and which is specific for epitopes responsible for virus adherence to and entry into cells. The two types of virus neutralization are the α and the β procedures. In the α procedure, the virus concentration is varied and the serum dilution is held constant, whereas in the β procedure the serum is diluted and the virus concentration is held constant. The β procedure provides a more quantitative test and wastes less serum. This procedure is performed by incubation of serum dilutions with virus and then observing whether or not the virus is still able to infect cells and produce cytopathic effect (CPE). It is therefore necessary to know the dose of virus that produces CPE in 50% of the cells ($TCID_{50}$). After mixing serum dilutions with virus, the virus is used to inoculate the cell culture. After the appropriate incubation period, the cultures are read to determine the end point: A reduction in CPE is expected for each dilution until the last dilution of serum that produces CPE in 50% of the cells is determined. The inverse of that dilution is the titer (Rovozzo and Burke, 1973).

6. Complement Fixation Tests

No discussion on veterinary immunological tests would be complete without the mention of the complement fixation (CF) test. Once used as a primary means of diagnosis for several important infectious diseases, the CF test has been replaced in many laboratories by more modern primary binding assays, such as ELISA. The principle of the CF test is simple. Dilutions of the patient's serum are mixed with antigen and then a measured amount of complement is added. If antibodies are present in the patient's serum specific for the antigen, then the complement will be fixed. If no antibodies are present, the complement remains to react with an indicator system (erythrocytes sensitized with anti-erythrocyte serum). Fixation of complement by the indicator system results in hemolysis. Hence, an absence of hemolysis is indicative of the presence of antibody in the patient's serum. Titers are obtained by observing tubes for the presence or absence of hemolysis. It is obvious that the performance of the CF test requires very accurate titration of each reactant. Protocols are available for setting up the CF test in the referenced texts (Rovozzo and Burke, 1973).

C. Primary Binding Assays

Each of the assays discussed earlier requires more than antigen–antibody binding for a result to be achieved. A secondary phase of the reaction is required: forming an insoluble lattice (precipitin), settling out of cross-linked particulate antigen (agglutination), or binding to complement (CF test). Generally these kinds of assays are less sensitive than those that require simply the binding of antigen to antibody.

1. Immunofluorescence-Based Assays

The coupling of an antibody to a fluoresceinated compound has been a popular method for detecting antigen or antibody for a number of years. The technique was originally used on tissue sections to demonstrate the presence of antigens and/or antibodies. However, recent advances in technology have given rise to a number of other uses, such as detection of individual cells in suspension using a fluorescence-activated cell sorter. Fluorochromes are compounds that absorb light of one wavelength, and when stimulated with the appropriate wavelength of light, give off light in the fluorescent spectrum. Using specialized optical systems, one can then visualize the fluorescence. When the fluorochrome is coupled to an antibody or antigen, it can effectively demonstrate the location of that antibody or antigen. Fluorescein iso-

thiocyanate, a common fluorochrome conjugate, gives off an apple-green color. It has an absorption/emission spectrum of 495 nm/517 nm (Goldman, 1986). Another fluorochrome, rhodomine isothiocyanate, fluoresces with a reddish-orange color; its absorption emission spectra are 550 nm/580 nm. It is possible to combine two or more fluorochromes to perform localization of two substances in one single tissue section or other sample.

Examples of indirect immunofluorescence tests used in the clinical immunology laboratory are the antinuclear antibody test (described later in this chapter), canine distemper antibody titer, feline infectious peritonitis antibody titer, and feline immunodeficiency virus titer. Characteristic of the indirect FA test is that the patient's serum serves as the primary antibody, which is first incubated with the antigen-containing cells. After incubation and washing steps a fluorescein-conjugated secondary antibody is added (e.g., for canine serum a rabbit anti-canine IgG-FITC would be added). These tests are performed on cells that are grown in Lab-Tek slides and fixed *in situ*. Canine distemper antibody assays use a mink kidney cell line infected with canine distemper virus as antigen on slides. Slides are fixed in acetone to allow the cell membrane to become permeable to antibody. A positive serum sample reveals intracellular fluorescence where virus antigen has been bound by antibody. Similarly cat serum is evaluated for antibodies to feline infectious peritonitis (FIP) virus using cells infected with FIP virus using an indirect fluorescent antibody test (Fig. 6.4).

Direct immunofluorescence is used for detection of antigen in tissue sections or in cells obtained from patients. For example, kidney biopsy samples, preserved for frozen section, are incubated with fluorescein-conjugated anti-immunoglobulin serum for the detection of immune complex deposition in glomeruli. Conjunctival smears from distemper suspect dogs are fixed and stained with conjugated antisera specific for distemper virus to demonstrate the presence of distemper virus in infected dogs that have viral antigen in the conjunctiva (Fig. 6.5).

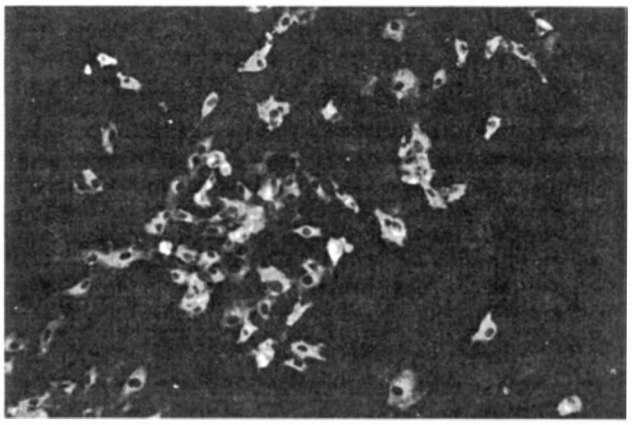

FIGURE 6.4 Positive feline serum reacting with feline infectious peritonitis virus in feline cells as indicated by indirect immunofluorescence.

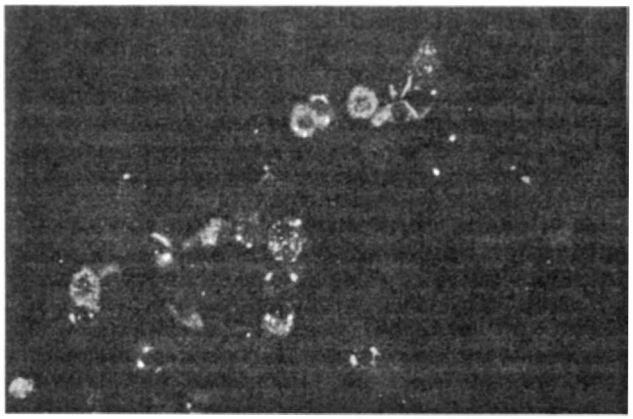

FIGURE 6.5 Canine distemper virus is demonstrated in conjunctival cells by direct immunofluorescence.

2. *Enzyme-Linked Immunosorbent Assay (ELISA)*

The ELISA is a highly sensitive assay that can be used to detect either antigen or antibody. Applications of ELISA include diagnostics for noninfectious diseases involving hormones, drugs, serum components, oncofetal proteins, or autoimmune diseases as well as diagnostics for infectious diseases caused by bacterial, viral, mycotic, or parasitic diseases (Voller *et al.*, 1981). Similarities between the ELISA, fluorescent antibody assays, and radioimmunoassays (RIAs) are notable. All three types of assay take advantage of an indicator that is attached to antibody (sometimes antigen), allowing bound antibodies to be detected by presence of the indicator (i.e., enzymatic digestion of a chromogenic substrate, fluorescence, or radioactivity respectively). ELISA is as sensitive as RIA, but has the advantage that it does not require the use of isotopes with the accompanying concerns for containment and monitoring.

To perform ELISA, antigen or antibody is attached to a solid phase. This makes it possible for reactants that bind immunologically to be separated from the unbound substances during washing procedures. Tubes, beads, and disks can be used, but most commonly 96-well microtitration plates made from polystyrene are used. The plastic will bind noncovalently, but very strongly, protein that is added in an alkaline

buffer solution (e.g., carbonate buffer pH 9.6). The amount of antigen that is used to sensitize the plates must be predetermined by checkerboard titration using reference reagents. Generally small amounts of protein antigen are required for optimum sensitivity, 1–10 μg/ml. Sensitization can be achieved using one of several protocols; overnight at 4°C or several hours at 37°C is commonly used. In some systems it is necessary to block any sites on the plastic that have not adsorbed antigen. This is accomplished using a solution of unrelated protein, such as bovine or rabbit serum albumin or gelatin. Washing steps and sample dilution are usually performed using phosphate buffered saline solution to which is added the detergent Tween 20. This assists in prevention of nonspecific binding. When assaying for antibodies, a single solution of test serum can be used to assay and compare to a standard curve. Enzyme is conjugated to antibody using a coupling agent such as glutaraldehyde or sodium periodate. Horseradish peroxidase and alkaline phosphatase are the most frequently used enzymes, but others such as β-galactosidase can also be used. The substrate used is usually colorless and develops into a colored reaction product after enzymatic activation. The colored reaction product is then read visually for a positive/negative assessment or the absorbance value is read on a spectrophotometer for quantitative results. Specially designed ELISA readers are available for this purpose. Direct connection to a computer system allows for easy data manipulation and standard curve development.

Several methods are used for setting up the ELISA, depending on whether antigen or antibody is to be measured. These are similar to the strategies described for fluorescence immunoassay, that is, indirect, double antibody sandwich, and competitive. Commercial kits have become available for use by veterinary practitioners. These take a variety of forms: Some contain presensitized plastic wells accompanied by appropriate positive and negative controls, often utilizing one monoclonal antibody specific for a virus protein as sensitizing antibody and a monoclonal specific for another determinant as conjugate. Test wells are read visually for color development and are compared with positive and negative controls. Other test kits have wandlike devices that are dipped into a succession of reagents to achieve a colored result. Still other tests have evolved as a "dot blot" type of assay in which the patient's serum sample is compared to positive and negative control dots on a membrane-type apparatus. Aside from these test kits, an immense variety of ELISAs is available, both commercially and in research laboratories, for the detection and/or quantitation of antibodies/antigens important in numerous diseases. This technique is both sensitive and quantitative.

Enzyme immunoassay has an additional application in immunohistochemistry. Enzyme conjugates can be used to stain specific antigens in fixed tissue sections just as fluorescent-labeled antibodies are used. Enzyme techniques have several advantages: The test can be performed on paraffin-embedded tissue and the slides can be permanently retained (Mason and Woolston, 1982), and there is no requirement for special adaptation of the microscope for illumination and viewing as there is for fluorescence. This technique has had wide application for diagnosis of infectious and autoimmune disease.

3. Western Blot

The technique of Western blotting has developed to allow further differentiation of antibody reactivity than a simple solid-phase ELISA or other antibody assay will provide. In this technique the antigen preparation, which is composed of a number of different proteins, is subjected to electrophoretic separation using SDS-polyacrylamide gel (Heegaard and Bjerrum, 1988). Proteins separated by size are then transferred to a nylon membrane. The membrane is reacted with a source of antibody (such as patient serum), washed, and then reacted with an antibody reagent conjugated to an indicator, either an enzyme or an isotope. The membrane is ultimately developed with substrate or by autoradiography (if a radioactive indicator was used) and the proteins to which antibody bound are visualized as bands on the membrane. This can be compared with an unblotted protein stained gel of the antigen so that the size and number of proteins to which antibody is directed can be determined. This type of assay is very sensitive and can be useful in differentiating antibody titers obtained by vaccination from those obtained by infection if there are differences in the number of proteins present in the vaccine and field isolates of the organism. This is particularly effective when subunit vaccines are used. Western blot is used in diagnosis of equine protozoal myelitis.

D. Detection and Quantitation of Lymphocyte Populations Using Monoclonal Antibodies Specific for Cell Surface Markers and Fluorescence Analysis

The increase in availability of monoclonal antibodies recognizing specific determinants characterizing subpopulations of lymphocytes has enabled researchers to enumerate B-cell, T-cell, and CD4+ helper T-cell subsets, CD8+ cytotoxic cell subpopulations, gamma/

delta T cells, MHC class II expression, interleukin-2 (IL-2) receptor expression, and expression of other markers for memory B cells. A standard protocol for cell purification, staining, and analysis is as follows.

Evaluation of cell populations using monoclonal antibodies and fluorescence analysis can be done on samples from peripheral blood, lymph, bronchoalveolar lavage fluid, and single cell suspensions from tissue. The lymphocytes are purified by centrifugation through a Ficoll–hypaque gradient. Cells are allocated into tubes at 10^7 cells per tube. These cells are resuspended in the primary antiserum and incubated for 30 minutes on ice. They are then washed and resuspended in 100 μl of fluoresceinated antibody and incubated for another 30 minutes on ice. Finally, cells are pelleted, resuspended, and washed twice more in phosphate buffered saline solution. Cells are resuspended and are assayed for fluorescence using a fluorescence-activated cell scanner (FACS) or FACSTAR within 24 hours. Analysis on FACS provides information on the percentage of the cell population that stains with the particular antibody of interest. Normal data on several species are becoming available. Analysis of cell populations by FACS utilizes size and fluorescence intensity as the parameters for selection of the population to be examined. There are several ways to present data obtained by FACS, including the contour graph and the histogram (Fig. 6.6). Ultimately the percentage of positive cells is of greatest interest. One direct application of such data is the calculation of a ratio between CD4+ and CD8+ T lymphocytes.

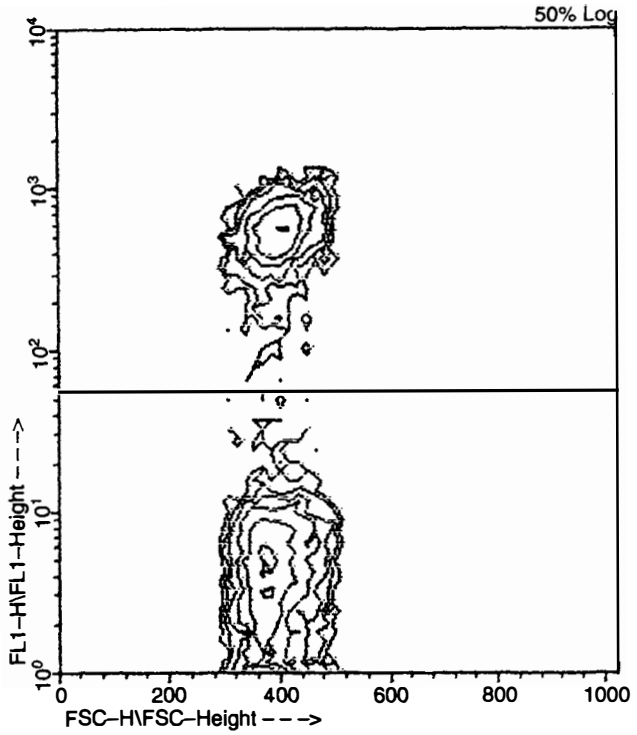

FIGURE 6.6 Contour plot demonstrating CD4+ T cells (*top*) and unstained CD4- T cells (*bottom*) using the fluorescence-activated cell scanner (Becton–Dickinson).

E. Detection and Quantification of Cytokines

In species for which genes coding for individual cytokines have been cloned and expressed, antibodies are available for use in ELISA or other primary binding assays to detect cytokines in serum or secretions. For those species in which there are no immunoassays for cytokine quantitation, detection of the mRNA is one method that is frequently used. Performance of reverse transcriptase–polymerase chain reaction (RT-PCR) on RNA derived from cells is used with appropriate primers and the product is then viewed on an agarose gel and its density is compared to a standard "housekeeping gene" such as actin. The RT-PCR involves steps that first convert the RNA into cDNA. Using a thermal cycler, the DNA is heated so that the two strands separate. Next a set of primers (small sequences of DNA that are complementary to sites on the desired gene) is added and the primers bind in an appropriate spot on the cDNA at the annealing temperature. Addition of nucleotides to the primers occurs with the help of the DNA polymerase enzyme, which is thermostable and able to resist the temperature changes that occur in the thermal cycler. This extends the new DNA strands. Once extended, the strands are again broken apart at a high temperature and the cycle starts once again. After multiple cycles a segment of the desired cDNA has been amplified sufficiently for visualization on an agarose gel.

The third type of assay commonly used to detect cytokines is the functional assay. This type of assay usually involves *in vitro* cell stimulation followed by harvesting of the cell supernatants and using them to stimulate a cell line, which is responsive to the particular cytokine. For example, IL-2 concentration in cell supernatant can be assayed using an IL-2–dependent cell line (see later discussion).

1. Gamma Interferon

There is a commercially available test (Idexx) for the detection of bovine gamma interferon. The test is marketed as a kit for diagnosis of *Mycobacterium paratuberculosis* infection. A facultative intracellular bacteria, the presence of *M. paratuberculosis* is best demonstrated by a cell-mediated immune response. Production of gamma interferon is such an indicator. The

test can be adapted for use with other antigen/infectious agent systems in which the presence of gamma interferon is thought to be important. The assay itself is an ELISA, based on an antibody to gamma interferon, but the test sample consists of supernatant obtained from culturing the patient's lymphocytes with the antigen.

2. *Interleukin-2*

Interleukin-2 has been measured in several species using a biological assay long before the gene was cloned in several species. Generally IL-2–dependent cell lines are incubated in the presence of supernatant thought to contain IL-2. The presence of IL-2 is then demonstrated by the ability or lack thereof to sustain growth of the dependent cell line. For example, bovine IL-2 stimulates proliferation of BT-2T-lymphoblast cells and murine IL-2 is able to support growth of CTLL 2 cells. Protocols are available for these biological assays (Coligan *et al.*, 1991).

3. *Interleukin-4*

With the exception of murine and human species there is currently no readily available ELISA to measure IL-4. Biological assays, as described earlier, and RT-PCR are the current methodologies used for detection and semiquantitation of this cytokine.

F. Testing for Autoimmune Disease

1. *Antinuclear Antibodies*

Generally a diagnosis of autoimmune disease is indicated by the presence of autoantibodies, such as antinuclear antibodies. In domestic animals the generalized autoimmune disease systemic lupus erythematosus (SLE), occurs and is accompanied by the presence of a positive ANA test. The ANA test, an indirect immunofluorescence test performed using a human cell line (HEP-2), indicates the presence of antibodies that react with DNA, RNA, or nuclear proteins. To perform the ANA test, a slide containing wells with fixed cells is incubated with serial dilutions of test serum and positive and negative control sera. After incubation and washing, an appropriate dilution of fluorescein-conjugated antiserum (species specific) is applied. The slide is incubated again, washed, and observed under the fluorescence-equipped microscope. Several patterns of fluorescence are described, including speckled, peripheral, homogeneous. A titer as well as a pattern are reported when the sample shows positive fluorescence (Fig. 6.7). Adaptations of the test for veterinary species are detailed by Lewis and Picut (1989).

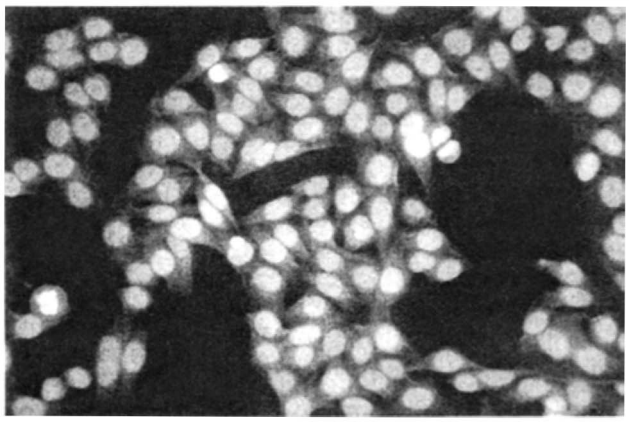

FIGURE 6.7 A positive anti-nuclear antibody test demonstrating a homogeneous pattern of fluorescence.

In addition to the ANA test, which measures a variety of antibodies reactive with nuclear components, some laboratories perform a test for native DNA. This test uses a protozoan parasite, *Crithidia lucia,* which has a structural body called a kinetoplast that contains only native DNA. Staining of the kinetoplast is indicative of antibodies reactive with native DNA (Ballou, 1992).

The presence of LE cells is pathognomonic for SLE. Although seen infrequently in SLE cases, these characteristic neutrophils, containing large homogeneous eosinophilic nuclei and a flattened cellular nucleus, indicate that nuclear material is being opsonized with antinuclear antibodies prior to engulfment by the neutrophil.

2. *Organ-Specific Autoantibody Detection*

Tissue or organ-specific autoimmune diseases are characterized by the presence of particular antibodies reactive with antigens present only in the affected organ. The variety of organ systems involved include the hematopoietic system (autoimmune hemolytic anemia, autoimmune thrombocytopenia), the endocrine system (thyroid, pancreas, adrenal gland), and the neuromuscular system (myasthenia gravis). Assays that detect these are referable to the body system involved. For example, for signs referable to hemolytic anemia of autoimmune etiology, the Coombs' test for the presence of anti-erythrocyte antibodies is performed. In this test the patient's cells are incubated with anti-γ-globulin (species specific). If there is autoantibody on the red blood cell surface, then the added antibodies will bind to those already on the cell surface and cause agglutination. Absence of antibodies on the erythrocyte surface will result in no agglutination. The assay, as described earlier, is a direct Coombs' test. Also per-

formed is the indirect Coombs' test in which the patient's serum is examined for the presence of anti-erythrocyte antibodies by incubation with normal erythrocytes. Agglutination of the cells after addition of the antiglobulin reagent indicates that the patient's serum contains anti-erythrocyte antibodies.

Other antigen–antibody systems involved in autoimmune disease include thrombocytes/megakaryocytes in autoimmune thrombocytopenia, anti-thyroglobulin antibodies in autoimmune thyroiditis, anti-pancreatic islet cell antibodies in autoimmune diabetes mellitus, and anti-acetylcholinesterase antibodies in myasthenia gravis. Many of these autoantibodies are detectable using direct or indirect immunofluorescence on the appropriate tissue section. The IFA test for autoimmune thrombocytopenia is performed on a bone marrow aspirate. The slide is incubated with a fluorescein-conjugated anti-IgG antibody specific for the same species as the patient. The presence of fluorescence on megakaryocytes is indicative of autoantibody on the cells, whereas a lack of fluorescence means that there is no autoantibody present.

Among the several skin diseases that have autoimmune etiology, pemphigus complex shows antibody bound to intercellular cement substance within the epidermis. Systemic lupus erythematosus or discoid lupus show antibody bound to the basement membrane at the dermal–epidermal junction. Direct immunofluorescence is a useful technique to demonstrate both of these lesions in frozen tissue sections taken by biopsy. Isotype specificity of the autoantibody is determined by using isotype-specific fluoresceinated antibodies in the test; use of antiserum specific for the third component of complement (C3) will demonstrate complement deposition in tissue if it has occurred. Preservation of biopsy material is possible for frozen section/FA by placing the sample in Mischel's media, which contains NH_4SO_4 and prevents solubilization of deposited complexes. The fluorescent antibody technique for detection of antibody and/or C3 in tissues is detailed by Valenzuela and Deodhar (1992) as originally developed for human patients. Adaptations for veterinary species are detailed by Lewis and Picut (1989).

VII. DETECTION OF IMMUNE DEFICIENCY

Evaluation of the immune system requires that each element of the immune system be considered separately: humoral, cellular, innate, and complement. Generally elements of the clinical history, age, and breed/species of the animal and the type of agent causing infections will be helpful in formulating a tentative diagnosis. For example, a Holstein heifer 3 weeks of age with recurrent apurulent bacterial infections is a likely candidate for bovine adhesion deficiency (a defect in innate immunity), whereas a 3-month-old Arabian foal with adenovirus pneumonia may have severe combined immunodeficiency.

A. Humoral Immunity

Diagnosis of defects in humoral immunity is accomplished using some of the previously described assays such as the radial immunodiffusion test for antibody. This agar gel test is isotype specific and is quantitative. The exception for this choice is when it is necessary to evaluate a neonate for colostrum consumption within the first day after birth. Although less accurate than SRD the quick tests for IgG will provide a faster result than the SRD test, thereby allowing colostrum supplementation to be performed prior to intestinal closure. Of the available tests, the zinc sulfate test is acceptable, and the more expensive CITE tests are also popular and trustworthy if done according to instructions. Diagnosis of severe combined immunodeficiency generally requires that two measurements be made: lymphocyte count (absolute and percentage) and IgM concentration. Both will be negligible if the foal has severe combined immunodeficiency (SCID).

Selective immunoglobulin deficiencies are present as inherited defects in several species. Those currently recognized are reviewed (Tizard, 1992). For example, in dogs several breeds have inherited IgA deficiencies. For these breeds (Shar-pei, German shepherd, Dalmatian), agar gel diffusion (SRD) is the preferable method to quantitate the amounts of a specific isotype such as IgA in serum. In these breeds, one usually sees levels less than normal, rather than total absence of the antibody. Thus only the truly quantitative method is acceptable.

B. *In Vitro* Assays for Cell-Mediated Immune Responses

1. Lymphocyte Stimulation

Unlike serology, there are not many methods available for *in vitro* evaluation of cellular immune responses. The most commonly used assay is one referred to as *lymphocyte stimulation/lymphocyte transformation;* it has been used extensively in several species (Fletcher *et al.,* 1992). Lymphocyte stimulation is performed by incubation of peripheral blood lymphocytes with plant mitogen in 96-well microliter plates. Concanavalin A and phytohemagglutinin are the commonly used T-cell mitogen, while pokeweed mitogen stimulates both T and B lymphocytes. From 2 to 3 days after stimulation, tritiated thymidine is added to the cultures and allowed to incorporate into the DNA of dividing

cells. At about 18 hours later the cells are harvested onto filter paper disks, which are read for radioactivity in a scintillation counter. Calculation of the stimulation index by dividing the counts per minute from stimulated wells by the values from the unstimulated controls provides a number indicative of the cellular responsiveness. When performing this test a normal species-matched control is always tested in parallel. It is possible to measure antigen-specific responsiveness by stimulating with antigen instead of or in addition to the mitogen. Stimulation indices are always much lower for antigen-specific systems, because only a small percentage of cells is responsible to an individual antigen, whereas all T cells respond to antigen.

2. *Innate Immunity: Neutrophil Function*

Evaluation of neutrophil function is particularly important in cases of recurrent or persistent bacterial infection with organisms that are generally avirulent or mildly pathogenic. Infection of mucosal surfaces, including the lung and skin, are particularly common in animals with decreased neutrophil function. To evaluate fully the function of neutrophils it is necessary to be aware of each step required for a neutrophil to kill an organism. First, having a sufficient supply of neutrophils is mandatory. In cyclic neutropenia of gray collies, for example, at cyclic periods the bone marrow shuts down its production of neutrophils, creating a peripheral neutropenia. During these times the dogs are at increased risk for developing bacterial infections (Jones *et al.*, 1975). Assuming there are a sufficient number of neutrophils in the peripheral blood, response to an invasion with bacteria requires that the cells be able to marginate (adhere to vascular endothelial cells), undergo diapedesis, and move out of the blood vessel. In BLAD and canine leukocyte adhesion deficiency, the cells are unable to exit the blood–vascular system because they lack an adhesion molecule (CD11b/CD18) necessary for margination to occur; affected individuals are unable to make pus. Once out of the blood–vascular system the neutrophils must be able to locate and travel toward the bacteria. This requires chemotactic ability. Defective chemotaxis can result in a depressed neutrophil response to infection, as seen in Pelger–Huet anomaly in several dog breeds. When the neutrophil reaches the bacteria, it must then engulf by phagocytosis the organism and then kill it using an oxidative and nonoxidative enzyme system. This requires fusion of the phagosome with the lysosomes so that the enzymes used in killing can be combined with the organisms in the phagosome. Inability to kill can occur by several mechanisms, including abnormal lysosomes, as seen in the Chediak–Higashi syndrome in certain breeds of cattle, mink, and Persian cats (Padgett *et al.*, 1964).

Assays to examine each of these neutrophil functions are available. A simple leukocyte count and differential will provide information on the number of circulating neutrophils. In cyclic neutropenia of gray collie dogs, numbers will be very low (Jones *et al.*, 1975). In cattle it is now possible to determine if the genetic defect responsible for BLAD is present by using the PCR. Chemotaxis can be evaluated using one of several assays (Coates *et al.*, 1992). Phagocytic ability can be evaluated by calculation of the phagocytic index; this test requires incubation of the patient's cells with bacteria and observation of the numbers of organisms engulfed during a finite period of time. To evaluate the enzymes of the respiratory burst a nitroblue tetrazolium blue test can be performed, and finally to evaluate overall killing ability the bactericidal test is superior (Quie and Herron, 1992).

3. *Evaluation of Complement*

Proteins that comprise the complement system are important accessory molecules in the immune system. Complement-mediated killing of bacteria, viruses, and parasites is important in innate and acquired immune responses. The absence or subnormal concentration of one or more components of complement may affect the phagocytosis (opsonins), chemotaxis (chemotactic factors), and killing (lysis by C6–C9). While absence of C1, C4, and C2 can have subclinical effect, a relative or absolute absence of C3 will have major implications on the ability of the patient's immune system to eliminate pathogens. In domestic animal species it is most common to test for overall complement function by performing a test called hemolytic complement/50 (Wolfe and Halliwell, 1980; Barta and Oyekan, 1981). In this assay, the ability of the patient's plasma to serve as a lytic complement source is tested for and is compared with that of plasma from a normal animal of the same breed. To analyze individual components of complement, single radial immunodiffusion can be used providing there is a species-specific source of antisera specific for the complement component of interest available (Ruddy, 1992).

VIII. TYPING FOR MAJOR HISTOCOMPATIBILITY ANTIGENS

The major histocompatibility complex (MHC) is a segment of DNA that codes for the histocompatibility antigens, polymorphic cell surface proteins that are inherited in a codominant manner. Class I MHC anti-

gens are present on all nucleated cells, whereas class II antigens are present on only a select population of cells, primarily B cells, macrophages, and dendritic cells. Both class I and class II antigens play important roles in the immune response.

A. Class I MHC Antigens: Microcytotoxicity

Class I antigens are detected with typing antisera, using a test called the *microcytotoxicity test*. Typing sera, specific for the various class I determinants, are added to cells from the patient to be typed in microliter well plates. Complement is added and then trypan blue dye. Cells are observed to determine if they remain uncolored or if they have taken up the blue dye. Cells that have the surface MHC antigen for which the antibody is specific bind antibody and are permeabilized when the complement is fixed. Wells in which antisera that is not specific for the MHC determinants on the cells remain viable and do not take up the blue dye. By observing which wells contain blue cells and which contain unstained cells, one can determine which MHC determinants are present on the patient's cells.

B. Class II MHC Antigens: Mixed Lymphocyte Reaction

The mixed lymphocyte reaction (MLR) is designed for typing of MHC class II molecules on the surface of lymphocytes for the purpose of tissue transplantation. In this assay typing cells with known MHC specificities are rendered metabolically paralyzed and then are mixed with the patient's cells. If, however, it sees foreign determinants, then it will react with blastogenesis. Blastogenesis, as mentioned earlier, can be measured by incorporation of radioactive nucleotides. Mixed lymphocyte reactions have been used to assist in characterization of MHC class II specificities in several species. If the patient shares specificities with the typing cells, it will not react.

C. Restriction Fragment Length Polymorphisms and Southern Blotting

Differences in the MHC genes can be detected by digestion of DNA with restriction endonucleases and then comparing the fragments by polyacrylamide gel electrophoresis. When the gel is blotted onto nylon (as in the Western blot) and probed with a labeled piece of DNA from a particular MHC allele, the size of the fragment can be determined. Some class II specificities have been identified using restriction fragment length polymorphisms (Davies *et al.*, 1992).

IX. SUMMARY

Advances in molecular biology and immunology are gradually being incorporated into the clinical veterinary immunology laboratory. Since the last edition of this book, use of the fluorescence-activated cell scanner to determine cell populations based on markers recognized by monoclonal antibodies has moved from a purely research-based endeavor to diagnostic applications. Similarly the ability to measure cytokines and/or their message has received some application to diagnostics; the gamma interferon assay for diagnosis of Johne's disease is a prime example. In the near future we expect to see increasing movement of methodology from the research laboratory to the clinical laboratory.

CHAPTER

7

The Erythrocyte: Physiology, Metabolism, and Biochemical Disorders

JOHN W. HARVEY

I. INTRODUCTION

Mammalian erythrocytes or red blood cells (RBCs)[1] are anucleate cells that normally circulate for several months in blood despite limited synthetic capacities and repeated exposures to mechanical and metabolic insults. Their primary purpose is to carry hemoglobin

[1] Abbreviations used in tables, figures, and text: EMP, Embden–Meyerhof pathway; PPP, pentose phosphate pathway; HK, hexokinase; GPI, glucose phosphate isomerase; PFK, phosphofructokinase; Aldo, aldolase; TPI, triosephosphate isomerase; GAPD, glyceraldehyde-3-phosphate dehydrogenase; PGK, phosphoglycerate kinase: MPGM, monophosphoglycerate mutase; DPGM, diphosphoglycerate mutase; DPGP, diphosphoglycerate phosphatase; Enol, enolase; PK, pyruvate kinase; G6PD, glucose-6-phosphate dehydrogenase; 6PGD, 6-phosphogluconate dehydrogenase; LDH, lactate dehydrogenase; GOT, glutamic oxaloacetic transaminase; GR, glutathione reductase; GPx, glutathione peroxidase; GST, glutathione S-transferase; MR, methemoglobin reductase; Diaph, diaphorase; TK, transketolase; TA, transaldolase; GSSG, oxidized glutathione; PNP, purine nucleoside phosphorylase; ATPase, adenosine triphosphatase; AST, aspartate aminotransferase; Gluc, glucose; G6P, glucose 6-phosphate; F6P, fructose 6-phosphate; FDP, fructose 1,6-diphosphate; DHAP, dihydroxyacetone phosphate; GAP, glyceraldehyde 3-phosphate; 1,3DPG, 1,3-diphosphoglycerate; 2,3DPG, 2,3-diphosphoglycerate; 3PG, 3-phosphoglycerate; 2PG, 2-phosphoglycerate; PEP, phosphoenolpyruvate; Pyr, pyruvate; Lac,

(Hb), a heme-containing protein that accounts for 95% of the total protein in RBCs. The benefits of having Hb contained within cells, as opposed to free in plasma, include the much slower turnover in blood (free Hb has a half-life of only a few hours), the metabolic capability of RBCs to maintain iron in Hb in the functional ferrous state, and the ability to control Hb oxygen affinity by altering the concentrations of organic phosphates (especially 2,3DPG). In addition, the presence of free Hb in plasma in concentrations normally found in whole blood would exert an osmotic pressure several times greater than that normally exerted by plasma proteins, profoundly affecting the movement of fluid between the vascular system and tissues.

A. Species Differences in Erythrocyte Shape

Most RBCs in normal dogs, cats, horses, cattle, and sheep occur in the shape of biconcave disks (discocytes). The degree of biconcavity is most pronounced in dogs and less so in cats and horses (Jain, 1986). RBCs from goats generally have a flat surface with little surface depression; a variety of irregularly shaped RBCs (poikilocytes) may be present in clinically normal goats (Jain, 1986). The apparent benefit of the biconcave shape is that it gives RBCs high surface area to volume ratios and allows for deformations that must take place as they circulate.

Marked acanthocytosis is reported to occur in young goats (Holman and Drew, 1964) and some young cattle (McGillivray *et al.*, 1985; Sato and Mizuno, 1982). Acanthocytosis of young goats occurs as a result of the presence of HbC at this stage of development (Jain *et al.*, 1980). Normal adult angora goats (Jain and Kono, 1977; Jain *et al.*, 1980) and some breeds of British sheep (Evans, 1968) have variable numbers of fusiform or spindle-shaped RBCs that resemble sickle cells (drepanocytes) in normal deer and people with sickle cell anemia (Taylor, 1983). Drepanocyte formation in deer depends on the Hb types present. It is an *in vitro* phenomenon that occurs when oxygen tension is high and pH is between 7.6 and 7.8 (Taylor, 1983). The proportion of fusiform cells in angora goats varies depending on the individual and *in vitro* alterations in temperature, pH, and oxygenation, but the tendency to form fusiform cells could not be attributed to differences in Hb type (Jain and Kono, 1977). Echinocytosis is a consistent artifact in stained blood films from pigs (Jain, 1986).

B. Functions of Erythrocytes

The RBC functions of oxygen transport, carbon dioxide transport, and hydrogen ion buffering are interrelated. Each Hb tetramer can bind four molecules of oxygen when fully saturated. Assuming a normal arterial pO_2 of 100 mm Hg and a Hb concentration of 15 g/dl in blood, the presence of Hb-containing RBCs increases the oxygen carrying capacity of blood to approximately 70 times more than that which could be transported dissolved in plasma (West, 1985).

Approximately 10% of CO_2 is transported dissolved in blood, 30% is transported bound to amine groups of blood proteins, and 60% is transported in the form of bicarbonate in normal individuals (West, 1985). Carbonic acid is formed when dissolved CO_2 combines with water. This reaction occurs nonenzymatically but is accelerated by the presence of the carbonic anhydrase (CA, carbonate dehydratase) enzyme in RBCs. Bicarbonate is formed by the rapid spontaneous dissociation of carbonic acid as shown:

$$H_2O + CO_2 \overset{CA}{\rightleftharpoons} H_2CO_3 \rightleftharpoons H^+ + HCO_3^-.$$

Hb potentiates the formation of bicarbonate by buffering hydrogen ions and shifting the equilibrium of the reaction to the right. Carbamino groups are formed by the combination of CO_2 with the terminal groups of proteins. The globin of Hb is the most important blood protein in this regard. The reaction can be represented as follows:

$$\text{Hb-NH}_2 + CO_2 \rightleftharpoons \text{Hb-NHCOOH} \rightleftharpoons \text{Hb-NHCOO}^- + H^+.$$

The transportation of CO_2 from the tissues to the lungs as carbamino groups is potentiated because DeoxyHb binds twice as much CO_2 as OxyHb.

Hb is the most important protein buffer in blood because it occurs in high concentration, has a relatively low molecular weight, and has a large number of histidine residues with pK_a values sufficiently close to 7.4 to function as effective buffers. It has about six times the buffering capacity of the plasma proteins. An addi-

lactate; AMP, adenosine monophosphate; ADP, adenosine diphosphate; ATP, adenosine triphosphate; NAD, nicotinamide adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced nicotinamide adenine dinucleotide phosphate; Hb, hemoglobin; GSH, reduced glutathione; P_i, inorganic phosphate; RBC, red blood cell; MetHb, methemoglobin; Ep, erythropoietin; ALA, delta-aminolevulinic acid; MB, methylene blue; LMB, leukomethylene blue; BFU-E, burst-forming unit-erythroid; CFU-E, colony-forming unit–erythroid; SOD, superoxide dismutase; Cb_5R, cytochrome-b_5-reductase; OxyHb, oxyhemoglobin; DeoxyHb, deoxyhemoglobin; HzB, Heinz body or bodies; PCV, packed cell volume; MCV, mean cell volume; GCS, gamma-glutamylcysteine synthetase; MCHC, mean cell hemoglobin concentration; HK^+, high potassium; LK^+, low potassium.

tional factor of importance that contributes to the effectiveness of Hb as a blood buffer is the fact that DeoxyHb is a weaker acid than OxyHb. As a result, most of the H^+ produced in the tissues under normal conditions is buffered as a direct result of the H^+ uptake by DeoxyHb owing to an increase in the effective pK_a of Hb following release of oxygen to the tissues (West, 1985).

II. ERYTHROPOIESIS

A. Stem Cells and Progenitor Cells

Throughout life, mammalian blood cells are produced continuously from primitive stem cells within extravascular spaces of the bone marrow. Stem cells are capable of proliferation, self-renewal, and differentiation. They are mononuclear cells that cannot be distinguished morphologically from lymphocytes. The most primitive hematopoietic stem cell can give rise to lymphoid stem cells as well as a pluripotent myeloid stem cell that supports the production of all nonlymphoid blood cells. The myeloid stem cell gives rise to a series of progressively more differentiated progenitor cells with little or no self-renewal capabilities (Quesenberry, 1995). When measured in an *in vitro* cell culture assay, these progenitor cells are referred to as colony forming units (CFUs). The colony-forming unit–granulocyte, erythrocyte, macrophage, megakaryocyte (CFU-GEMM) is an oligopotential progenitor cell that can give rise to multiple cell lines.

The CFU-GEMM, and possibly other oligopotential progenitor cells, produce the burst-forming unit–erythroid (BFU-E), the earliest unipotential progenitor cell committed to the erythroid cell line. The BFU-E gives rise in culture to multiple subcolonies of a more differentiated progenitor cell, the colony-forming unit–erythroid (CFU-E). The CFU-E gives rise to the first morphologically recognizable erythroid cell, the rubriblast (Quesenberry, 1995). Although discussed earlier as discrete cell compartments, the transition from one cell type to another is gradual; consequently, considerable heterogeneity exists within stem cell and progenitor cell compartments.

B. Hematopoietic Microenvironment

Blood cell production occurs in bone marrow of adult animals because of the unique microenvironment present there. The hematopoietic microenvironment is a complex meshwork composed of various stromal cells, accessory cells, glycoprotein growth factors, and extracellular matrix that profoundly affects stem cell and progenitor cell survival, proliferation, and differentiation (Campbell and Wicha, 1988). Stromal cells (endothelial cells, fibroblast-like reticular cells, and macrophages) and accessory cells (subsets of lymphocytes and natural killer cells) produce a variety of positive and negative growth factors (Moore, 1991; Pantel and Nakeff, 1993). Stromal cells also produce components of the extracellular matrix (Long, 1992; Tavassoli and Hardy, 1990).

The extracellular matrix (ECM) consists of broad categories of macromolecules: collagen, proteoglycans, and glycoproteins. In addition to providing structural support (collagen) the ECM is important in the binding of hematopoietic cells and soluble growth factors to stromal cells so that optimal proliferation and differentiation can occur. Adhesion molecules (primarily integrins) on progenitor cells bind to ECM glycoproteins such as hemonectin, fibronectin, thrombospondin, and vascular cell adhesion molecule-1 (Campbell, 1992; Long and Dixit, 1990; Papayannopoulou and Brice, 1992; Yanai *et al.*, 1994). The spectrum of expression of adhesion molecules varies with the type and maturity of hematopoietic cells. Proteoglycans with their glycosaminoglycan moieties such as chondroitin sulfate and heparan sulfate bind growth factors and at least strengthen the bond between progenitor cells and stromal cells (Minguell, 1993; Tavassoli and Hardy, 1990). Growth factors such as stem cell factor (KIT ligand) may also be involved in the adhesion of hematopoietic cells by binding to both the extracellular matrix and to specific receptors on hematopoietic cells (Sieff, 1991).

Proliferation of stem cells and progenitor cells cannot occur spontaneously, but requires the presence of specific hematopoietic growth factors (HGFs). Hematopoietic cells coexpress receptors for more than one HGF on their surface, with the number of each receptor type present depending on the stage of cell differentiation (Metcalf, 1993). Binding of an HGF to its receptor can stimulate proliferation and/or modulation of HGF receptors on the surface of the cell that is acted on. The binding of an HGF generally results in downmodulation of its own receptor and upmodulation (transactivation) of receptors for distal HGFs that act primarily on more differentiated cell types (Testa *et al.*, 1993).

Stem cell factor (KIT ligand) can maintain survival of stem cells, but the presence of additional factors such as interleukin-3 (IL-3), interleukin-6 (IL-6) and granulocyte macrophage colony-stimulating factor (GM-CSF) are needed for proliferation to occur (Hoffman *et al.*, 1993; Shull *et al.*, 1992). CFU-GEMM cells are stimulated to proliferate and differentiate into BFU-E by IL-3 and GM-CSF in the presence of erythropoietin

(EPO). BFU-E proliferation and differentiation into CFU-E results from the presence of these same factors and may be further potentiated by additional factors such as interleukin-9. EPO is the primary growth factor involved in the proliferation and differentiation of CFU-E into rubriblasts (Erickson and Quesenberry, 1992; Metcalf, 1993).

Marrow macrophages appear to be an important component of the hematopoietic microenvironment involved with erythropoiesis. Both early and late stages of erythroid development occur with intimate membrane apposition to central macrophages in so-called erythroblastic islands (Bernard, 1991). These central macrophages may regulate RBC development by producing both positive factors such as burst-promoting activity and EPO (Rich, 1986, 1991; Vogt *et al.*, 1989) and negative factors such as IL-1α, TNFα, interferon and transforming growth factor β (Khan *et al.*, 1992; Wang *et al.*, 1992). Macrophages may be important in the local or basal regulation of erythropoiesis, but humoral regulation is also important, with EPO production primarily occurring in the kidney and various inhibitory cytokines being produced during inflammation throughout the body. In addition to negative factors already listed, leukotrienes B_4 and C_4 are reported to inhibit BFU-E and CFU-E growth (Estrov *et al.*, 1988).

C. Erythropoietin

EPO is a 34-kDa glycoprotein hormone that exhibits a high degree of sequence homology among mammals (Wen *et al.*, 1993). It is the principal HGF that promotes the viability, proliferation, and differentiation of erythroid progenitor cells that express specific cell surface EPO receptors (EPO-Rs). Early BFU-E cells do not express EPO-Rs, but more mature BFU-E cells express EPO-Rs and are weakly responsive to EPO. EPO-R copies on cell surfaces increase to maximum values in CFU-E cells and then decline in rubriblasts and are lost in later stages of development (Porter and Goldberg, 1993; Youssoufian *et al.*, 1993). Because of their EPO-R density, CFU-E cells readily respond to EPO. After binding to its receptor, EPO is internalized and promotes the proliferation, differentiation, and transformation of CFU-E cells into rubriblasts, the first morphologically recognizable erythroid cell type.

EPO stimulation promotes increased heme synthetic enzyme activities and represses heme degradation enzyme activity. The resultant increase in intracellular heme may promote erythroid differentiation. In addition, increased heme may be important in stimulating erythropoiesis by the upmodulation of EPO receptors (Abraham, 1991; Mayeux *et al.*, 1986)

High titers of EPO may accelerate rubriblast entry into the first mitotic division, shortening the marrow transit time and resulting in the early release of stress reticulocytes (Erslev and Beutler, 1995). Although EPO has been assumed to act as a mitogen because of its capacity to amplify RBC production, other studies have suggested it acts primarily as a survival factor preventing apoptosis and permitting cells to proceed with programmed proliferation and maturation (Erslev and Beutler, 1995; Koury and Bondurant, 1988).

In the presence of EPO, other hormones including androgens, thyroid hormones, and growth hormone can enhance the growth of erythroid precursor cells *in vitro* (Fisher *et al.*, 1971; Peschle, 1988; Popovic *et al.*, 1977). These substances apparently increase the number of erythroid colonies formed *in vitro* at suboptimal EPO concentrations, possibly by modulating the fraction of CFU-E cells that will enter terminal differentiation at a given EPO concentration. Both positive and negative effects of glucocorticosteriods have been reported. Hydrocortisone promotes BFU-E growth in culture, but inhibits T-lymphocyte production of HGFs that stimulate BFU-E proliferation (Morra *et al.*, 1989).

The kidney is the major site of EPO production in adult mammals, at least when anemia is present (Oishi *et al.*, 1995). Most studies indicate that EPO is produced by peritubular interstitial cells located within the inner cortex and outer medulla of the kidney (Erslev, 1990; Porter and Goldberg, 1993). The liver is an extrarenal source of EPO in adults and the major site of EPO production in the mammalian fetus. Bone marrow macrophages have also been shown to produce EPO, suggesting the possibility of short-range regulation of erythropoiesis (Rich, 1991).

EPO production is stimulated by tissue hypoxia. The oxygen sensor has not been defined, but there is evidence that a heme protein may be involved (Porter and Goldberg, 1993) Tissue oxygen tension is determined by the oxygen consumption by the tissues and the oxygen-delivering capacity of the blood. Oxygen-delivering capacity depends on cardiovascular integrity, oxygen content in arterial blood, and Hb oxygen affinity. Low oxygen content in the blood can result from low partial pressure of oxygen (pO_2) in blood, such as that occurring with high altitudes or with congenital heart defects where some of the blood flow bypasses the pulmonary circulation. Low oxygen content in blood can also occur with normal pO_2, such as that occurring with anemia and methemoglobinemia. An increased oxygen affinity of Hb within RBCs results

in a decreased tendency to release oxygen to the tissues (Erslev, 1990).

III. DEVELOPING ERYTHROID CELLS

A. Morphologic and Metabolic Changes

Rubriblasts are continuously generated from progenitor cells in the extravascular space of the bone marrow. The division of a rubriblast initiates a series of approximately four divisions over a period of 3 or 4 days to produce 16 metarubricytes that are no longer capable of division. These divisions are called *maturational divisions* because there is a progressive maturation of the nucleus and cytoplasm concomitant with the divisions. Each division yields a smaller cell with greater nuclear condensation and increased Hb synthesis. An immature RBC, termed a reticulocyte, is formed following extrusion of the nucleus.

Early precursors have intensely blue cytoplasm, when stained with Romanowsky-type blood stains, owing to the presence of many basophilic ribosomes and polyribosomes that are actively synthesizing globin chains and smaller amounts of other proteins. Because the cells are nonsecretory, rough endoplasmic reticulum is scant and limited to early erythroid precursors (Bessis, 1973). Hb progressively accumulates in these cells, imparting a red coloration to the cytoplasm. Cells with both red and blue coloration are described as having polychromatophilic cytoplasm. Kinetics of erythroid cells and changes in biochemical and metabolic pathways are depicted in Fig. 7.1; time intervals were determined for cattle (Rudolph and Kaneko, 1971).

B. Iron Metabolism

1. Transferrin

Developing erythroid cells generally extract 70–95% of the iron circulating in plasma (Bush *et al.*, 1956; Gillis and Mitchell, 1974; Kaneko and Mattheeuws, 1966; Obara and Nakajima, 1961; Weissman *et al.*, 1960). Plasma iron is bound to transferrin, a β-globulin that can maximally bind two atoms of ferric iron per molecule. Transferrin molecules transport iron to erythroid cells and bind to transferrin receptors on cell surfaces. Transferrin-iron-receptor complexes are internalized in a clathrin-coated vesicle, which matures into an ATP-dependent proton-pumping endosome. Ferric iron is released following acidification and leaves the endosome by an undefined mechanism that appears to require its reduction to the ferrous state (Aisen, 1994). Following iron release, apotransferrin-receptor complexes are returned to the surface where at neutral pH apotransferrin is released and returns to plasma.

The proportion of apo-, mono-, and diferric forms of transferrin present in serum depends on the percent saturation of transferrin with iron. Diferric transferrin is more efficient than monoferric transferrin in delivering iron to cells, because it binds with higher affinity to receptors and can deliver twice the iron per molecule of transferrin incorporated (Huebers *et al.*, 1985).

2. Intracellular Iron Transport

Within the cytoplasm iron appears to be complexed to ATP (Weaver and Pollack, 1989) and possibly other low-molecular-weight compounds for transport to mitochondria, the site of iron incorporation into protoporphyrin to form heme. Entry of iron into mitochondria is not well characterized but is energy dependent and involves the reduction of ferric iron to the ferrous state during transport into mitochondria (Romslo, 1980).

3. Ferritin

Iron not required for heme synthesis is stored as ferritin. Each ferritin molecule is composed of a protein shell of 24 apoferritin subunits surrounding a central core of up to 4500 iron atoms as ferric oxyhydroxide (Leibold and Guo, 1992). Individual ferritin molecules can be visualized by electron microscopy, and large aggregates of ferritin molecules can be visualized by light microscopy when stained for iron. When membrane bound, ferritin aggregates have been called siderosomes (Bessis, 1973).

4. Iron Regulation of Transferrin Receptor and Ferritin Expression

Transferrin receptor and ferritin expression are regulated in response to iron availability and demand for heme synthesis. When increased iron is needed, as occurs in iron-deficient states, transferrin receptor synthesis is increased and ferritin synthesis is decreased. These effects are accomplished by changes in the structure of an iron regulatory factor (IRF) protein, which binds with high affinity to iron responsive elements (IREs) of transferrin receptor mRNA and ferritin mRNA (Melefors and Hentze, 1993).

Free iron is toxic because it forms reactive hydroxyls that can cause oxidation of cellular components. When excess iron is present, transferrin receptor synthesis is decreased and ferritin synthesis is increased, minimizing free iron concentration. These effects occur when IRF binding to IREs on mRNAs is reduced (Melefors and Hentze, 1993).

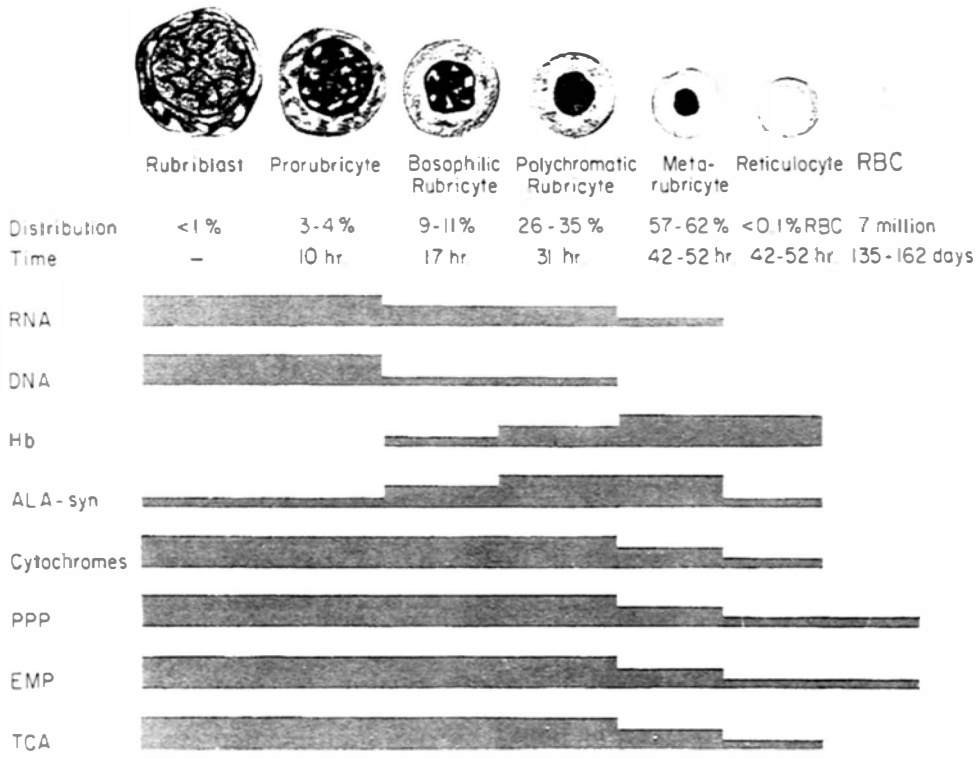

FIGURE 7.1 Summary of metabolic activities of the erythroid series. Maturation progresses from left to right. The time intervals indicated are for cattle. From Kaneko (1980) with permission.

5. Siderocytes and Sideroblasts

Nucleated erythroid cells with iron-staining inclusions are called *sideroblasts*, and anucleated cells are called *siderocytes*. The inclusions occur in erythroid precursors in bone marrow of normal people (Cartwright and Deiss, 1975), dogs (Feldman *et al.*, 1981), and pigs (Deiss *et al.*, 1966). Siderotic inclusions are rare or absent in circulating RBCs of normal animals, but may occur with lead poisoning (George and Duncan, 1979; Goodman and Dallman, 1969), hemolytic anemia, dyserythropoiesis, myeloproliferative diseases (Jain, 1986), chloramphenicol therapy (Harvey *et al.*, 1985), and in pigs fed a pyridoxine-deficient diet (Deiss *et al.*, 1966).

Siderotic inclusions in normal animals and people are composed of ferritin. Mitochondria can accumulate iron during certain pathologic states to a point at which they can be visualized as siderotic inclusions by light microscopy (Cartwright and Deiss, 1975). Mitochondrial iron overload appears when heme synthesis is impaired (Cartwright and Deiss, 1975). Pathologic sideroblasts and siderocytes with iron-loaded mitochondria have been demonstrated in a dog treated with chloramphenicol (Harvey *et al.*, 1985), a dog with dyserythropoiesis of unknown etiology (Canfield *et al.*, 1987), and in pigs fed a pyridoxine-deficient diet (Hammond *et al.*, 1969). Congenital sideroblastic anemias have been reported in people, but not in animals (Bottomley, 1991).

C. Hemoglobin Synthesis

Hb is a tetrameric protein consisting of four polypeptide globin chains, each of which contains a heme prosthetic group within a hydrophobic pocket. In adults the molecule consists of two identical alpha and two non-alpha chains that are generally classified as beta chains.

1. Heme Synthesis and Metabolism

Heme is a planar molecule composed of the tetrapyrrole protoporphyrin IX, containing a central ferrous molecule. The initial rate-controlling step in heme synthesis, the delta-aminolevulinic acid (ALA) synthetase (5-aminolevulinate synthase) reaction, occurs within mitochondria (see Chapter 8). Glycine and the Krebs cycle intermediate succinyl-CoA are utilized as substrates, and vitamin B_6, as pyridoxal phosphate, is required as a cofactor. The ALA formed is transported to the cytoplasm where a series of reactions results in

the formation of coproporphyrinogen III, which must enter the mitochondria for the final steps in heme synthesis. The final reaction, heme synthetase, involves the insertion of ferrous iron into protoporphyrin IX.

Following synthesis, heme must be transferred from mitochondria to the cytoplasm for combination with globin chains to complete the synthesis of Hb. Free heme is poorly soluble in water and can bind to and damage cellular components (Hebbel and Eaton, 1989). It apparently is bound to cytosolic proteins for transport to sites of globin chain synthesis (Harvey and Beutler, 1982). Sometime after its synthesis, the iron moiety of heme is oxidized (presumably spontaneously) to the ferric state and is then more specifically called *ferriheme* (Schulman *et al.*, 1974).

Heme affects erythroid cell metabolism in different ways depending on the stage of maturation. It stimulates iron uptake, ferritin synthesis, and heme synthesis in early erythroid cells, but it inhibits iron uptake and heme synthesis in reticulocytes (Abraham, 1991; Battistini *et al.*, 1991). Excess heme accumulation presumably does not occur in early erythroid cells because of the presence of heme oxygenase activity, which decreases during maturation (Abraham, 1991).

2. *Globin Synthesis*

The synthesis of polypeptide globin monomers occurs in association with ribosomes and polyribosomes in the cytoplasm. Ferriheme is inserted into each globin chain, either during translation or shortly thereafter. Following synthesis, a ferriheme-containing alpha chain spontaneously combines with a ferriheme-containing beta chain to form a stable alpha-beta dimer. Two like alpha-beta dimers combine in a readily reversible manner to form the Hb tetramers (Bunn, 1987). Because it is ferriheme that combines with globin, newly synthesized Hb is in the form of MetHb (Schulman *et al.*, 1974).

3. *Control of Hemoglobin Synthesis*

The synthesis of heme and globin chains are coordinated such that minimal amounts of free heme or globin monomers exist in the cytoplasm (Bunn, 1987). Heme plays a central role because it governs the initiation step of translation in globin chain synthesis (Traugh, 1989). Increased amounts of free heme increase globin synthesis, and the lack of free heme inhibits globin synthesis. In addition, α and β chain synthesis is coordinated; surplus α chains inhibit their own synthesis but stimulate β chain synthesis, and surplus β chains inhibit their own synthesis (Jandl, 1987).

4. *Hemoglobin Types in Animals*

Hemoglobin types are different in animal and human embryos than in fetuses or in adults. Embryonal Hbs are composed of either one or two pairs of peptide chains not found in adult Hbs (Kitchen and Brett, 1974). In ruminants and humans, embryonal Hbs are replaced by fetal Hbs composed of two α and two γ chains. Most fetal Hb is replaced by adult Hb types in ruminants during the first month(s) after birth (Aufderheide *et al.*, 1980; Blunt, 1972; Huisman *et al.*, 1969; Kitchen and Brett, 1974; Lee *et al.*, 1971). This switch from production of fetal Hb to the production of adult Hb appears to result from an inherent programming of hematopoietic stem cells (Wood *et al.*, 1985). In cats, dogs, horses, and pigs, embryonal Hbs are replaced by adult Hb types during the fetal period. Hb types present in fetuses are identical to those found in adults (Bunn and Kitchen, 1973; Kitchen and Brett, 1974).

Considerable heterogeneity of Hb types occurs in adult animals. With the possible exception of pigs, two or more types are reported to occur in domestic animal species (Braend, 1988; Kitchen, 1969). Most polymorphism of animal Hbs is determined genetically and usually caused by multiple amino acid interchanges (Kitchen, 1974). Nongenetic alterations in Hb structure can also contribute to apparent Hb heterogeneity. Examples include the *N*-acetylation of β chains in cat HbB (Taketa *et al.*, 1972) and glycosylation of Hb, a function of intracellular glucose concentration and RBC lifespan (Higgins *et al.*, 1982; Rendell *et al.*, 1985). Increased glycosylation of Hb has been reported in diabetic dogs (Mahaffey and Cornelius, 1982; Wood and Smith, 1980).

A unique occurrence in sheep and goats is the synthesis of HbC in response to anemia (Huisman and Kitchen, 1968). This Hb switching from synthesis of HbA in sheep and HbA and HbB in goats to HbC is mediated by EPO (Barker *et al.*, 1980). Carbon dioxide decreases oxygen affinity for HbC more than it does for normal adult Hbs (Huisman and Kitchen, 1968; Winslow *et al.*, 1989).

D. Reticulocytes

1. *Formation*

Although reticulocytes may be formed by denucleation as metarubricytes pass through endothelial cells into vascular sinuses of bone marrow, most are formed within the extravascular space of the bone marrow by a process of nuclear extrusion that requires functional microtubules (Chasis *et al.*, 1989) and is likened to mitosis (Bessis, 1973; Simpson and Kling, 1967). Extruded nuclei are bound and phagocytosed by a novel receptor

on the surface of bone marrow macrophages (Qui *et al.*, 1995). Early reticulocytes have polylobulated surfaces. Their cytoplasm contains ribosomes, polyribosomes, and mitochondria necessary for the completion of Hb synthesis. Reticulocytes derive their name from a network or reticulum that appears when stained with basic dyes such as methylene blue and brilliant cresyl green. That network is not preexisting but is an artifact formed by the precipitation of ribosomal ribonucleic acids and proteins. As reticulocytes mature, the amount of ribosomal material decreases until only a few basophilic specks can be visualized with reticulocyte staining procedures. These mature reticulocytes have been referred to as type IV (Houwen, 1992) or punctate reticulocytes (Alsaker *et al.*, 1977; Perkins and Grindem, 1995). To reduce the chance that a staining artifact would result in misclassifying a mature RBC as a punctate reticulocyte using a reticulocyte stain, the cell in question should have two or more discreet blue granules that are visible without requiring fine focus adjustment of the cell being evaluated to be classified as a punctate reticulocyte.

2. *Metabolism*

Reticulocyte metabolism and maturation have been reviewed by Rapoport (1986) and are summarized here. Immature reticulocytes continue to synthesize protein (primarily globin chains) with residual mRNA, tRNA, and rRNA formed prior to denucleation. Synthesis of fatty acids is minimal, but phospholipids are synthesized from preformed fatty acids. Substrates for protein and lipid synthesis and for energy metabolism are provided from endogenous sources (breakdown of mitochondria and ribosomes) as well as from plasma. The reticulocyte can synthesize adenine and guanine nucleotides *de novo*.

Most ATP is generated in reticulocytes by oxidative phosphorylation in mitochondria. Glucose is the major substrate, but amino acids and fatty acids can also be utilized for energy (Rapoport, 1986).

3. *Maturation into Erythrocytes*

Reticulocyte maturation into mature RBCs is a gradual process that requires a variable number of days depending on the species involved. Consequently the morphologic and physiologic properties of reticulocytes vary with the stage of maturation. The cell surface undergoes extensive remodeling with loss of membrane material and ultimately the formation of the biconcave shape of mature RBCs (Bessis, 1973). The loss of membrane protein and lipid components appears to require ATP (Weigensberg and Blostein, 1983) and involve formation of intracellular multivesicular bodies that fuse with the plasma membrane releasing vesicles (exosomes) extracellularly (Johnstone, 1992). This is a highly selective process where some proteins (e.g., transferrin receptor and fibronectin receptor) are lost and cytoskeletal proteins (e.g., spectrin) and firmly bound transmembrane proteins (e.g., the anion transporter and glycophorin A) are retained and concentrated (Johnstone, 1992; Rapoport, 1986).

Some membrane proteins such as the nucleoside transporter, glucose transporter, Na,K-ATPase, insulin receptor and adrenergic receptors decrease to variable degrees depending on the species involved (Chasis *et al.*, 1989; Johnstone, 1992). Examples where reticulocytes from a species exhibit a complete or nearly complete loss of a protein, which is retained in mature RBCs from other species, include the adenosine transporter in sheep (Jarvis and Young, 1982), the glucose transporter in pigs (Zeidler and Kim, 1982), and Na,K-ATPase in dogs (Maede and Inaba, 1985).

Although loss of membrane components accounts for much of the change in membrane protein composition during reticulocyte maturation, certain proteins such as protein 4.1 and glycophorin C increase because they are still being synthesized in reticulocytes (Chasis *et al.*, 1989).

Mitochondria undergo degenerative changes owing to lipoxygenase attack and subsequent ATP-dependent proteolysis (Rapoport, 1986). Degenerating mitochondria are either digested or extruded following entrapment in structures resembling autophagic vacuoles (Simpson and Kling, 1968). The polysomes separate into monosomes and decrease in number and disappear as reticulocytes mature into RBCs. The degradation of ribosomes appears to be energy dependent; it presumably involves proteases and RNAases (Rapoport, 1986).

4. *Species Differences in Marrow Release*

Reticulocyte maturation begins in the bone marrow and is completed in the peripheral blood and spleen in dogs, cats, and pigs. As reticulocytes mature, they lose the surface receptors needed to adhere to fibronectin and thrombospondin components of the extracellular matrix, thereby facilitating their release from the bone marrow (Long and Dixit, 1990; Patel *et al.*, 1985; Vuillet-Gaugler *et al.*, 1990). Residual adhesion molecule receptors on newly released reticulocytes may explain their tendency to concentrate in the reticular meshwork of the spleen (Patel *et al.*, 1985).

Reticulocytes become progressively more deformable as they mature, a characteristic that also facilitates their release from the marrow (Waugh, 1991). To exit the extravascular space of the marrow, reticulocytes press against the abluminal surfaces of endothelial cells that make up the sinus wall. Cytoplasm thins and small

pores (0.5–2 μm) develop in endothelial cells that allow reticulocytes to be pushed through by a small pressure gradient across the sinus wall (Lichtman and Santillo, 1986; Waugh, 1991). Pores apparently close after cell passage.

Relatively immature aggregate-type reticulocytes are released from canine bone marrow; consequently, most of these cells appear polychromatophilic when viewed following routine blood film staining procedures (Laber *et al.*, 1974). Absolute reticulocyte counts oscillate with a periodicity of approximately 14 days in some dogs, suggesting that canine erythropoiesis may have a homeostatically controlled physiologic rhythm (Morley and Stohlman, 1969). Reticulocytes are normally not released from feline bone marrow until they mature to punctate-type reticulocytes; consequently, few or no aggregate reticulocytes (<0.4%), but up to 10% punctate reticulocytes, are found in blood from normal adult cats (Cramer and Lewis, 1972). The high percentage of punctate reticulocytes results from a long maturation time (Fan *et al.*, 1978) with delayed degradation of organelles. Reticulocytes are generally absent in peripheral blood of healthy adult cattle and goats, but a small number of punctate types (0.5%) may occur in adult sheep (Jain, 1986). Equine reticulocytes are absent from blood normally and are not released in response to anemia.

5. *"Stress" Reticulocytes*

Except for horses, increased numbers of reticulocytes are released in response to anemia, with better responses to hemolytic anemias than to hemorrhage. When the degree of anemia is severe, basophilic macroreticulocytes or so-called stress reticulocytes may be released into blood. It is proposed that a generation in the maturation sequence is skipped, and immature reticulocytes that are twice the normal size are released (Rapoport, 1986). Increased EPO results in a diminution in the adventitial cell and endothelial cell barrier separating marrow hematopoietic cells from the sinus, thereby potentiating the premature release of stress reticulocytes from the marrow (Chamberlain *et al.*, 1975). Although a portion of these macroreticulocytes apparently is rapidly removed from the circulation (Noble *et al.*, 1990), it is clear from studies in cats that some can mature into macrocytic RBCs with relatively normal lifespans (Weiser and Kociba, 1982).

E. Abnormalities in Erythroid Development

1. *Ineffective Erythropoiesis*

Ineffective erythropoiesis is used to describe the destruction of developing erythroid cells in marrow. Normally, minimal cells die within the marrow (Odartchenko *et al.*, 1971), but ineffective erythropoiesis is prominent in disorders of nucleic acid, heme, or globin synthesis. Examples include folate deficiency, iron deficiency, vitamin B_6 deficiency, lead poisoning, and thalassemia in humans (Jandl, 1987). Ineffective erythropoiesis also occurs in association with myeloproliferative and myelodysplastic disorders (Durando *et al.*, 1994; Jain, 1986) and congenital dyserythropoiesis (Holland *et al.*, 1991; Steffen *et al.*, 1992).

2. *Vitamin and Mineral Deficiencies*

Folate is required for normal DNA synthesis. Folate deficiency impairs the activity of the folate-requiring enzyme thymidylate synthase (Jandl, 1987). Not only is deoxythymidylate triphosphate (dTTP) synthesis decreased, but deoxyuridylate triphosphate (dUTP) accumulates secondarily in the cell such that some becomes incorporated into DNA in place of dTTP. Cycles of excision and attempts to repair these copy errors, with limited thymidine available, result in chromosomal breaks and malformations and slowing of the S phase in the cell cycle. Consequently, erythroid precursors are often large with deranged appearing nuclear chromatin; such cells are classified as megaloblastic cells. Folate deficiency in people causes macrocytic anemia because fewer divisions occur as a result of retarded nucleic acid synthesis in the presence of normal protein synthesis (Jandl, 1987). Possible causes of folate deficiency include dietary deficiency, impaired absorption, and drugs that interfere with folate metabolism.

Macrocytic anemias resulting from folate deficiency are rarely reported in animals. A possible case was reported in a dog on anticonvulsant therapy (Lewis and Rebar; 1979), but serum folate was not measured. Megaloblastic precursors are present in bone marrow of cats with experimental dietary folate deficiency, but packed cell volumes (PCVs) and mean cell volumes (MCVs) remained normal (Thenen and Rasmussen, 1978). Macrocytic anemia occurs in folate-deficient pigs (Bush *et al.*, 1956) but not lambs (Stokstad, 1968).

Vitamin B_{12} (cobalamin) deficiency in people causes hematologic abnormalities similar to folate deficiency because vitamin B_{12} is necessary for normal folate metabolism in humans (Chanarin *et al.*, 1985). In contrast, vitamin B_{12} deficiency does not cause macrocytic anemia in any animal species (Chanarin *et al.*, 1985). Anemia has been reported in some experimental animal studies, but RBCs were of normal size (Stokstad, 1968; Underwood, 1977), although slight increases in MCV have been reported in B_{12}-deficient goats fed diets deficient in cobalt (Mgongo *et al.*, 1981). Cobalamin deficiency has been reported secondary to an inherited malabsorption of cobalamin in giant schnauzer dogs (Fyfe *et al.*, 1989, 1991). Affected animals have normo-

cytic, nonregenerative anemia with increased anisocytosis and poikilocytosis, neutropenia with hypersegmented neutrophils and giant platelets. Megaloblastic changes in the bone marrow were particularly evident in the myeloid cell line. The malabsorption of cobalamin in these dogs apparently results from the absence of an intrinsic factor-cobalamin receptor in the apical brush border of the ileum (Fyfe *et al.*, 1991). No blood or bone marrow abnormalities were recognized in kittens fed a B_{12}-deficient diet for several months (Morris, 1977), but a normocytic nonregenerative anemia was present in a cobalamin-deficient cat that probably had an inherited disorder of cobalamin absorption (Vaden *et al.*, 1992).

A number of disorders exhibit macrocytic anemias with megaloblastic abnormalities in the marrow that mimic findings in human folate or B_{12} deficiency, but have had normal serum levels of these vitamins when measured. Examples include cats infected with the feline leukemia virus (Dunn *et al.*, 1984; Hirsch and Dunn, 1983; Weiser and Kociba, 1983a), cattle with congenital dyserythropoiesis (Steffen *et al.*, 1992), and myelodysplastic syndrome in a horse (Durando *et al.*, 1994). In addition, some miniature and toy poodles exhibit macrocytosis without anemia and variable megaloblastic abnormalities in the bone marrow with normal serum folate and B_{12} values (Canfield and Watson, 1989; Schalm, 1976).

Abnormalities in heme or globin synthesis can result in the formation of microcytic hypochromic RBCs. Cellular division is normal, but Hb synthesis is delayed; consequently, one or more extra divisions occur in RBC development, resulting in smaller cells than normal.

Pyridoxine, vitamin B_6, is required for the first step in heme synthesis. Although natural cases of pyridoxine deficiency have not been documented in domestic animals, microcytic anemias with high serum iron values have been produced experimentally in dogs (McKibbin *et al.*, 1942), cats (Bai *et al.*, 1989; Carvalho da Silva *et al.*, 1959), and pigs (Deiss *et al.*, 1966) with dietary pyridoxine deficiency.

With the exception of young growing animals, iron deficiency in domestic animals usually results from blood loss. Milk contains little iron; consequently, nursing animals can easily deplete body iron store as they grow (Furugouri, 1972; Harvey *et al.*, 1987; Holter *et al.*, 1991; Siimes *et al.*, 1980). Microcytic RBCs are produced in response to iron deficiency (Holman and Drew, 1964, 1966; Holter *et al.*, 1991; Reece *et al.*, 1984) but a low MCV may not develop postnatally in species where the MCV is above adult values at birth (Weiser and Kociba, 1983b). The potential for development of severe iron deficiency in young animals appears to be less in species that begin to eat food at an early age.

Chronic iron deficiency anemia with microcytic RBCs is common in adult dogs in areas where hookworm and flea infestations are severe (Harvey *et al.*, 1982; Weiser and O'Grady, 1983). Severe iron deficiency appears to be rare in adult cats (French *et al.*, 1987; Fulton *et al.*, 1988) and horses (Smith *et al.*, 1986), but it occurs frequently in ruminants that are heavily parasitized with blood-sucking parasites such as *Haemonchus contortus*.

Prolonged copper deficiency generally results in anemia in mammals (Brewer, 1987; Lahey *et al.*, 1952), although it was not a feature of experimental copper deficiency in the cat (Doong *et al.*, 1983). The anemia is generally microcytic hypochromic; however, normocytic anemia has been reported in experimental studies in dogs, and normocytic or macrocytic anemias have been reported in cattle and adult sheep (Brewer, 1987). Copper deficiency results in impaired iron metabolism in at least two ways. In experimental studies in pigs, serum iron concentration is low in early copper deficiency when iron stores are normal (Lahey *et al.*, 1952). Functional iron deficiency results from inadequate iron absorption and mobilization of iron stores caused by a decreased concentration of circulating ceruloplasmin (Lee *et al.*, 1968). Ceruloplasmin is the major copper-containing protein in plasma, and its ferroxidase activity appears to be important in the oxidation of ferrous iron (released from ferritin stores) to the ferric state for binding to transferrin (Frieden, 1983).

If experimental copper deficiency is prolonged, hyperferremia occurs and bone marrow sideroblasts increase (Lee *et al.*, 1968). Reticulocyte mitochondria from copper-deficient pigs are unable to synthesize heme at the normal rate using ferric iron (Williams *et al.*, 1976). A deficiency in copper-containing cytochrome oxidase within mitochondria may slow the reduction of ferric to ferrous iron within mitochondria. That would, in turn, limit heme synthesis, which requires iron in the ferrous state (Porra and Jones, 1963).

3. *Deficiencies in Globin Synthesis*

Hereditary deficiencies in synthesis of the globin α chain (α-thalassemia) and β chain (β-thalassemia) cause microcytic hypochromic anemias in humans with variable degrees of poikilocytosis (Jandl, 1987). Both α- and β-thalassemia occur in mice, but hereditary hemoglobinopathies have not been reported in domestic animals (Kaneko, 1987).

4. *Aplastic Anemia*

Aplastic anemia is generally used to describe anemias where granulocytic, megakaryocytic, and erythrocytic cell lines are markedly reduced in the bone

marrow. When only the erythroid cell line is reduced or absent, terms such as *pure red cell aplasia* or *selective erythroid aplasia* or *hypoplasia* are used. These anemias can result from insufficient numbers of stem cells, abnormalities in the hematopoietic microenvironment, or abnormal humoral or cellular control of hematopoiesis (Appelbaum and Fefer, 1981; Juneja and Gardner, 1985). The factors mentioned are interrelated and the exact defect in a given disorder is usually unknown.

Drug-induced causes of aplastic anemia or generalized marrow hypoplasia in animals include estrogen toxicity in dogs (Crafts, 1948; Gaunt and Pierce, 1986; Sherding *et al.*, 1981) and ferrets (Bernard *et al.*, 1983; Kociba and Caputo, 1981), phenylbutazone toxicity in dogs (Schalm, 1979; Watson *et al.*, 1980; Weiss and Klausner, 1990), trimethoprim-sulfadiazine administration in dogs (Fox *et al.*, 1993; Weiss and Klausner, 1990), bracken fern poisoning in cattle and sheep (Parker and McCrea, 1965; Sippel, 1952; Tustin *et al.*, 1968), trichloroethylene-extracted soybean meal in cattle (Strafuss and Sautter, 1967), and various cancer chemotherapeutic agents. Thiacetarsamide, meclofenamic acid, and quinidine (Watson, 1979; Weiss and Klausner, 1990) have also been incriminated as potential causes of aplastic anemia in dogs, as has griseofulvin in a cat (Rottman *et al.*, 1991).

Human parvovirus, hepatitis viruses, Epstein–Barr virus, dengue, cytomegalovirus, and human immunodeficiency virus 1 have, in low percentages of infections, resulted in aplastic anemia in people (Rosenfeld and Young, 1991). Parvovirus infections can cause severe erythroid hypoplasia, as well as myeloid hypoplasia in canine pups (Robinson *et al.*, 1980), but animals usually do not become anemic because of the long lifespans of RBCs. Either affected pups die acutely or the bone marrow returns rapidly to normal before anemia can develop. In contrast to its effects in pups, parvovirus is reported to have a minimal effect on erythroid progenitors in adult dogs (Brock *et al.*, 1989). Parvovirus inhibits colony formation of both myeloid and erythroid progenitor cells in feline bone marrow cultures (Kurtzman *et al.*, 1989), but only myeloid hypoplasia was reported during histologic examination of bone marrow from viremic cats (Larsen *et al.*, 1976).

Although some degree of marrow hypoplasia and/or dysplasia often occurs in cats with feline leukemia virus (FeLV) infections, true aplastic anemia is not a well-documented sequela (Rojko and Olsen, 1984). Anemia is a common finding in ill cats infected with feline immunodeficiency virus (FIV). It does not appear to result from a direct action(s) of the virus on erythroid progenitor cells, but generally occurs secondary to inflammation, dysplasia, or neoplasia (Linenberger *et al.*, 1991; Shelton *et al.*, 1990). Dogs that enter the chronic stage of ehrlichiosis generally have some degree of marrow hypoplasia and in severe cases can develop aplastic anemias (Buhles, *et al.*, 1975).

Idiopathic aplastic anemias have also been reported in dogs (Eldor *et al.*, 1978; Weiss and Christopher, 1985) and horses (Berggren, 1981; Lavoie *et al.*, 1987). CFU-Es were not detected in bone marrow culture from a dog with an idiopathic aplastic anemia (Weiss and Christopher, 1985). One case of erythroid and myeloid aplasia, with normal megakaryocyte numbers, has been reported in a horse, the etiology of which was unknown (Ward *et al.*, 1980).

5. Selective Erythroid Aplasia

Selective erythroid aplasia (pure red cell aplasia) occurs as either a congenital or acquired disorder in people (Dessypris, 1991). Acquired erythroid aplasia is often associated with abnormalities of the immune system. Erythroid aplasia may also occur secondary to disorders including infections, malignancy, and drug or chemical toxicities.

Acquired erythroid hypoplasia or aplasia occurs in dogs (Weiss, 1986; Weiss *et al.*, 1982). Some cases have immune-mediated etiologies based on positive responses to immunosuppressive therapy and the presence of antibodies that inhibit CFU-E development in marrow cultures (Weiss, 1986). Erythroid hypoplasia or dysplasia is reported to be a rare sequela to vaccination against parvovirus in dogs (Dodds, 1983). High doses of chloramphenicol cause reversible erythroid hypoplasia in some dogs (Watson, 1977) and erythroid aplasia in cats (Watson and Middleton, 1978). A dog has been reported to have congenital erythroid aplasia based on histopathologic examination of bone marrow at necropsy, but the M:E ratio was normal when aspirate smears were examined several days prior to euthanasia (Hotston Moore *et al.*, 1993).

Selective erythroid aplasia occurs in cats infected with subgroup C FeLV, but not in cats infected only with subgroups A or B (Onions *et al.*, 1982; Riedel *et al.*, 1986). Although both myeloid and erythroid progenitor cells are infected with virus, only erythroid progenitor cell numbers are decreased in cat marrow. Recent studies suggest that CFU-E numbers are markedly decreased because the envelope glycoprotein gp70 of subgroup C FeLV is uniquely cytopathic for BFU-E or impairs differentiation of BFU-E into CFU-E (Abkowitz, 1991; Dean *et al.*, 1992; Dornsife *et al.*, 1989).

IV. THE MATURE ERYTHROCYTE

Values for RBC glucose utilization, ion concentrations, and survival times in normal animals are given in Table 7.1. Enzyme activities are given in Tables 7.2 and 7.3, and chemical constituents in RBCs are given in Tables 7.4 and 7.5. These are not, however, comprehensive lists. Other values are provided by Friedemann and Rapoport (1974) and in various chapters of a reference book edited by Agar and Board (1983a). Anemia induced by phlebotomy or by hemolytic drugs produces changes in many of the given values owing to the influx of young RBCs into the circulation in response to the anemia (Agar and Board, 1983a). Methods for enzyme assays vary considerably; consequently, each laboratory will need to establish its own normal ranges if enzyme studies are to be done.

A. Membrane Structure

The RBC membrane is composed of a hydrophobic lipid bilayer with a protein skeletal meshwork attached to its inner surface by binding to integral (transmembrane) proteins (Fig. 7.2). Membrane proteins from RBCs have been numbered by their migration location (Smith, 1987) on sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE); some have also been given one or more names. Electrophoretic patterns of membrane proteins on SDS–PAGE are species variable (Gillis and Anastassiadis, 1985; Smith *et al.*, 1983a; Kobylka *et al.*, 1972; Whitfield *et al.*, 1983).

1. Lipids

The lipid bilayer and associated transmembrane proteins chemically isolate and regulate the cell interior. The bilayer consists of phospholipids arranged with hydrophobic hydrocarbon chains of fatty acids to the center of the bilayer and the polar ends of the molecules in contact with both intracellular and extracellular aqueous environments. Molecules of unesterified cholesterol are intercalated between fatty acid chains in molar concentrations approximately equal to the sum of the molar concentrations of phospholipids. Phospholipids are asymmetrically arranged, with anionic amino-containing phospholipids (phosphatidylserine and most of the phosphatidylethanolamine) located in the inner layer of the bilaminar membrane. These phospholipids are shuttled across the membrane by an ATP-dependent aminophospholipid-specific transporter (Zwaal *et al.*, 1993). Most of the cationic choline-containing phospholipids, phosphatidylcholine (lecithin) and sphingomyelin, are located in the outer layer (Kuypers *et al.*, 1993). These choline-containing phospholipids are readily exchangeable with plasma phospholipids, whereas the aminophospholipids are not (Reed, 1968). Species vary in RBC membrane phospholipid compositions (Engen and Clark, 1990; Garnier *et al.*, 1984; Nelson, 1967; Wessels and Veerkamp, 1973).

TABLE 7.1 Erythrocyte Glucose Utilization, Ion Concentrations, and Survival Times of Various Mammals[a]

Species	RBC glucose utilization (μmol/hr/ml)	RBC Na^+ (mmol/liter)	RBC K^+ (mmol/liter)	RBC survival (days)
Human	1.48 ± 0.11 (1)	6.2 ± 0.8 (7)	102 ± 3.9 (7)	120 (11)
Dog	1.33 ± 0.12 (1)	92.8 ± 11.1 (8)	5.7 ± 1.0 (8)	100 (11)
Cat	0.94 ± 0.09 (1)	105.8 ± 14.4 (8)	5.9 ± 1.9 (8)	72 (11)
Horse	0.64 ± 0.10 (1)	10.4 ± 1.8 (9)	120 ± 11.1 (9)	143 (11)
Cattle	0.56 ± 0.05 (2)	79.1 ± 14.6 (8)	22.0 ± 4.5 (8)	130 (11)
Sheep	0.69 ± 0.19 (3)	HK^+, 17.1 (10) LK^+, 73.7 (10)	HK^+, 98.7 (10) LK^+, 39.4 (10)	135 (11)
Goat	1.94 (4)	13.4 (4)	76.1 (4)	115 (11)
Pig	0.09 (5)	15.6 ± 1.8 (8)	105.9 ± 12.7 (8)	67 (11)
Rabbit	2.26 ± 0.30 (2)	16.8 ± 6.3 (8)	110.1 ± 6.0 (8)	57 (11)
Guinea pig	1.44 (6)	24.4 ± 5.4 (8)	107.2 ± 10.1 (8)	80 (11)
Mouse	2.85 ± 0.20 (2)			43 (11)
Hamster		17.2 (12)	92.0 (12)	50 (11)
Rat	2.38 ± 0.20 (2)	33.5 ± 3.5 (8)	104.7 ± 15.4 (8)	56 (11)

[a] Mean values have been recalculated at times to permit direct comparisons between species. Standard deviation values are given where indicated. Figures in parentheses are the references cited below. Abbreviations used are given in the footnote at the beginning of the chapter. Early studies indicated that ruminant RBCs lack phosphatidylcholine, a finding at odds with a more recent study (Engen and Clark, 1990). Although RBC cholesterol/phospholipid ratios remain relatively constant, differences occur in membrane phospholipid composition between neonate and adult RBCs (Marin *et al.*, 1990).

A small amount of glycolipid is also located in the outer layer. Species differ in the dominant glycolipids of RBCs (Eberlein and Gercken, 1971; Yamakawa, 1983). Based on studies of human blood group antigens, it is assumed that many animal blood group antigens are also glycolipids and that specificity resides in the carbohydrate moieties.

2. *Integral Membrane Proteins*

Integral membrane proteins penetrate the lipid bilayer. These glycoproteins express carbohydrate residues on the outside surface of the cell. They contribute negative charge to the cell surface, function as receptors or transport proteins and carry RBC antigens (Chasis and Mohandas, 1992; Mohandas and Chasis, 1993; Schrier, 1985). Band 3 (protein 3) is the major integral protein accounting for approximately one-fourth of the total membrane protein (Schrier, 1985). It is important as an anion transporter and provides a site for binding of the cytoskeleton internally. Additional transmembrane glycoproteins called *glycophorins* also help anchor and stabilize the cytoskeleton (Chasis and Mohandas, 1992).

3. *Membrane Skeletal Proteins*

The membrane skeleton appears as a dense sweater-like meshwork bound to the inner surface of the lipid bilayer. It is a major determining factor of membrane shape, deformability, and durability (Mohandas and Chasis, 1993). Major skeletal proteins include spectrin, actin, protein 4.1, ankyrin, and adducin (Fig. 7.2). Spectrin is a heterodimer of long, flexible α and β chains twisted around one another. Heterodimers are bound together by self-association at their head ends to form tetramers. Multiple spectrin tail ends (average 6) are joined by binding to common short filaments of actin to form an anastomosed meshwork of polygons (Fig.

7.3). These junctional complexes with actin are stabilized by other proteins including protein 4.1 and adducin. The meshwork is bound to transmembrane protein 3 by ankyrin in regions of spectrin self-association (Mohandas and Chasis, 1993). Protein 4.1 also binds the meshwork to one or more integral membrane glycophorins (Chasis and Mohandas, 1992).

The cytoskeletal meshwork assumes a condensed configuration in nondeformed discocytes, with spectrin tetramer fibers existing in folded or coiled states (Fig. 7.3). When fully extended (accomplished by removal of lipid from the membrane), the cytoskeleton meshwork extends over an area several times the normal RBC surface area (Liu and Derick, 1992; Palek and Sahr, 1992). Because of the spectrin structure, membrane skeletons have extensional elasticity and can be stretched more than twice the normal RBC diameter without rupture.

B. Shape and Deformability

The normal biconcave shape of most mammalian RBCs (discocytes) represents the resting unstressed geometry of the cell. The biconcave shape results in a large surface area-to-volume ratio compared to that of a sphere, allowing RBCs to undergo marked deformation while maintaining a constant surface area (Lenard, 1974). This is important because an increase of 3–4% of surface area results in cell lysis (Mohandas and Chasis, 1993).

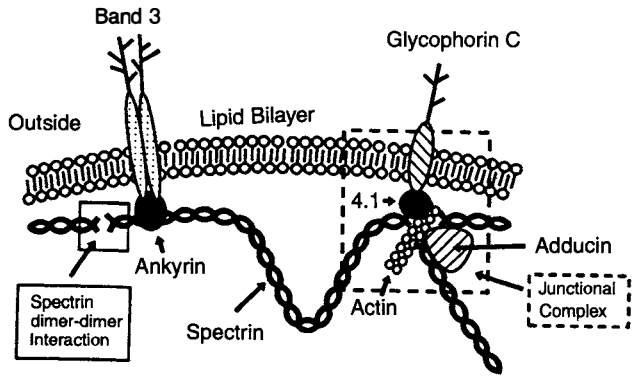

FIGURE 7.2 Schematic model of the organization of the RBC membrane skeleton.

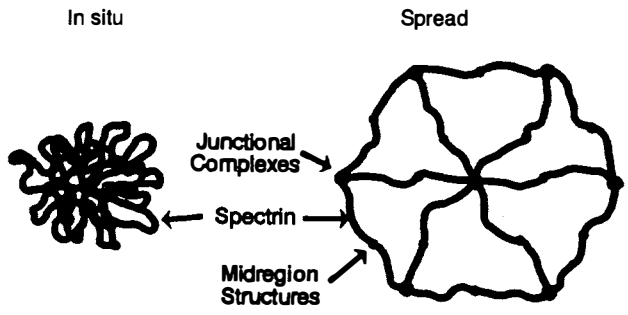

FIGURE 7.3 Schematic model of a hexagon of condensed and fully extended (spread) cytoskeletal meshwork. Spectrin dimer–dimer interactions and binding to band 3 occur in the midregions. See Figure 7.2 for components of junctional complexes.

The RBC spends little time in a discoid shape in the microcirculation. Except for goats, RBCs from domestic animals have diameters (Jain, 1986) greater than those of capillaries (approximately 4 μm) (Henquell *et al.*, 1976; Sobin and Tremer, 1972); consequently, they must be deformable to flow through capillaries. RBCs must pass through even smaller spaces in the sinus wall of the spleen (Chen and Weiss, 1973). The biconcave shape is generally more pronounced in species with larger RBCs (Jain, 1986), presumably because the degree of deformation required to flow through capillaries is greater. RBC deformability also reduces the bulk viscosity of blood in large vessels (Smith, 1991).

RBC deformability is a function of surface-to-volume ratio, viscosity of intracellular contents (determined primarily by intracellular Hb concentration), and viscoelastic properties of the membrane (Mohandas and Chasis, 1993). RBC shape and viscoelastic properties result from interactions between the fluid lipid bilayer and the underlying cytoskeleton, which stabilizes the lipid bilayer and provides both rigid support and elasticity. Membrane lipid fluidity varies with cholesterol composition, concentration of phospholipids present, and degree of saturation of fatty acids and length of acyl chains (Yawata *et al.*, 1984). Comparisons of RBC deformability among various animal species using ektacytometry have been reported (Smith *et al.*, 1979). Large RBCs are generally more deformable than small ones. RBCs from species in the family Camelidae are flat, thin, and not deformable; they apparently flow through vessels by orienting to the direction of flow.

In addition to mechanically-induced deformations, a wide variety of chemical perturbations, genetic defects, and oxidative injury can result in shape changes (Mohandas and Chasis, 1993; Smith, 1987). Small changes in the surface areas of the inner or outer lipid monolayers can result in transformations of discocytes into echinocytes or stomatocytes. Echinocytes are spiculated RBCs in which the spicules are relatively evenly spaced and of similar size. They form when the surface area of the outer lipid monolayer increases relative to the inner monolayer. Echinocytic transformation occurs in the presence of fatty acids, lysophospholipids, and amphiphatic drugs that distribute preferentially in the outer half of the lipid bilayer (Mohandas and Chasis, 1993; Smith, 1987). Transient echinocytosis occurs in dogs following coral snake (Marks *et al.*, 1990) and rattlesnake (Brown *et al.*, 1994a) envenomation, presumably secondary to the action of phospholipases present in venom. Echinocytes also form when RBCs are dehydrated (Weiss and Geor, 1993), pH is increased, RBC ATP is depleted (Jacob *et al.*, 1973), and intracellular calcium is increased (Smith, 1987). Echinocytes and other shape abnormalities have been recognized in dogs with RBC pyruvate kinase deficiency, which results in a decreased ability to generate ATP (Chandler *et al.*, 1975; Schaer *et al.*, 1992; Muller-Soyano *et al.*, 1986). Echinocytosis occurs in horses where total body depletion of cations has occurred. Increased numbers have been reported in horses during endurance exercise (Boucher *et al.*, 1981), following furosemide-induced electrolyte depletion (Weiss *et al.*, 1992), and in ill horses with systemic electrolyte depletion and hyponatremia (Geor *et al.*, 1993).

Although the mechanism(s) is unknown, ATP appears to be required in some manner for maintenance of normal shape and deformability of RBCs (Jacob *et al.*, 1973). Because ATP concentrations must be depleted for a number of hours to demonstrate changes in shape and deformability *in vitro*, its concentration does not directly control these properties; rather, the shapes of cells are altered by processes occurring secondary to ATP depletion (Feo and Mohandas, 1977).

ATP is required for a number of reactions involving the RBC membrane (Cohen and Gascard, 1992). It is used as the phosphoryl donor in a wide variety of phosphorylation reactions involving membrane proteins and for the phosphorylation of membrane phosphoinositides. It provides the energy needed to pump Ca^{2+} out of cells. Increased Ca^{2+} activates neutral proteases (calpains), which can degrade membrane skeletal proteins, and phospholipase C, which cleaves phosphoinositides. ATP is required for the transport of aminophospholipids to the inner half of the lipid bilayer, presumably assisting in the maintenance of the asymmetry of membrane phospholipids. The relative importance of each of these ATP-dependent reactions to the maintenance of RBC shape and deformability remains to be determined (Cohen and Gascard, 1992).

Cup-shaped stomatocytes form when amphiphatic drugs are present that distribute preferentially in the inner half of the lipid bilayer (Smith, 1987). Stomatocytes also form when RBC water content is increased as occurs in hereditary stomatocytosis in dogs (Giger *et al.*, 1988a; Pinkerton *et al.*, 1974).

Acanthocytes are RBCs with irregularly spaced, variably sized spicules. They form when RBC membranes contain excess cholesterol compared to phospholipids. If cholesterol and phospholipids are increased to a similar degree, codocyte formation is more likely than acanthocyte formation (Cooper *et al.*, 1972). Alterations in RBC membrane lipids can result from increasd blood cholesterol content (Cooper *et al.*, 1980) or the presence of abnormal plasma lipoprotein composition (Ulibarrena *et al.*, 1994). Another possible contributing factor is the defective repair (acylation of lysophospholipids) of oxidant-damaged RBC phospholipids reported in human patients with cirrhosis

and acanthocytosis (Allen and Manning, 1994). Acanthocytes have been recognized in animals with liver disease, possibly due to alterations in plasma lipid composition that can alter RBC lipid composition (Christopher and Lee, 1994; Shull *et al.*, 1978). They have also been reported in dogs with disorders such as hemangiosarcoma and disseminated intravascular coagulation that result in RBC fragmentation (Weiss *et al.*, 1993).

Poikilocytes can form when oxidant injury results in Heinz body formation and/or membrane injury. One or more blunt RBC surface projections may form as the membrane adheres to Heinz bodies bound to its internal surface. Eccentrocytes are RBCs in which the Hb is localized to part of the cell, leaving a Hb-poor area visible in the remaining part of the cell. Other terms used to refer to eccentrocytes include hemighosts, irregularly contracted cells, double-colored cells, and cross-bonded RBCs (Arese and De Flora, 1990; Chan *et al.*, 1982). They are formed by the adhesion of opposing areas of the cytoplasmic face of the RBC membrane (Fischer *et al.*, 1985; Fischer, 1986, 1988). Denatured spectrin is believed to be of primary importance in the cross bonding of membranes (Fischer, 1988; Arese and De Flora, 1990). Eccentrocytes have been seen in animals ingesting or receiving oxidants (Harvey and Rackear, 1985; Harvey *et al.*, 1986; Reagan *et al.*, 1994) and in a horse with G6PD deficiency (Stockham *et al.*, 1994).

Genetic defects in a variety of membrane proteins result in spherocyte or elliptocyte formation in people (Palek and Sahr, 1992). Hereditary elliptocytosis has been reported in a dog with protein 4.1 deficiency (Smith *et al.*, 1983a).

C. Blood Group Isoantigens

Large numbers of protein and complex carbohydrate antigens occur on the external surface of RBCs. Some antigens are present on RBCs from all members of a species and others (including blood group isoantigens) segregate genetically, appearing in some but not all members of a species. Blood group isoantigens are detected serologically on the surface of RBCs using agglutination and/or hemolysis tests. With detailed genetic studies, these isoantigens can be placed into blood groups (RBC isoantigen systems). Blood groups have individual chromosomal loci and each loci has from two to many allelic genes. Most blood groups (such as the ABO system in man) derive their antigenicity from the carbohydrate composition of membrane-associated glycolipids and glycoproteins. The amino acid sequence of membrane proteins accounts for the antigenic determinants in other blood groups, such as the complex Rh system in man (Agre and Cartron, 1991). Most isoantigens are produced by erythroid cells but some, such as the J group in cattle, the DEA-7 (Tr) group in dogs, the R group in sheep, and the A group in pigs (Tizard, 1992), are produced by other tissues and absorbed from plasma.

Blood groups in domestic animals have been reviewed (Bell, 1983; Smith, 1991; Tizard, 1992). They have been most extensively characterized in horses and cattle, where blood typing is routinely used for animal identification and parentage testing. Cattle have 11 blood groups with multiple alleles per group. Based on all the different combinations of factors that can occur, greater than 2 trillion distinctly different blood type profiles are possible in cattle.

1. Blood Group Isoantigens of Clinical Significance

Isoantigens vary in their potential to cause transfusion reactions when mismatched blood is given. Many isoantigens are weak (do not induce antibodies of high titer) or induce antibodies that do not act at normal body temperature. Fortunately only a few isoantigens appear to be important in producing hemolytic disease in animals. Although dogs have at least 12 blood groups, only the DEA-1.1 isoantigen regularly generates hemolysins in high enough titer to cause significant transfusion reactions (Giger *et al.*, 1995a; Stormont, 1982).

Incompatibilities in the AB blood group of cats have been recognized to cause transfusion reactions and neonatal isoerythrolysis (Auer and Bell, 1983; Giger and Bücheler, 1991; Giger and Akol, 1990; Hubler *et al.*, 1987). It has been proposed that the A and B isoantigens (blood types) result from the action of two different alleles at the same gene locus and that A is dominant over B (Giger *et al.*, 1991a). Type A cat RBCs have glycolipids with terminal *N*-glycolyneuraminic acid (NeuGc) on their surface, whereas type B cat RBCs have glycolipids with terminal *N*-acetylneuraminic acid (NeuAc) on their surface (Andrews *et al.*, 1992). Because the enzyme CMP-*N*-acetylneuraminic hydroxylase converts NeuAc to NeuGc, it has been proposed that type B cats lack this enzyme. The frequency of blood types varies with location and breed of cat. Fewer than 1% of domestic short- and long-hair cats in the United States are type B, but 15–59% of purebred cats in some breeds are type B (Giger *et al.*, 1991a).

Horse RBC isoantigens are recognized to occur at 7 blood group loci. The frequency of expression of RBC isoantigens varies by breed of horse (Bowling and Clark, 1985). Aa and Qa isoantigens are responsible for most cases of neonatal isoerythrolysis in horses, where mares negative for these factors develop anti-

bodies against them and transfer these antibodies to their foals through colostrum (Bailey, 1982). Neonatal isoerythrolysis has been reported in mule foals because of an RBC antigen not found in horses, but present in some donkeys and mules (McClure *et al.*, 1994).

Pig RBC isoantigens are recognized to occur in 15 blood groups numbered A to O. A-negative pigs exhibit intravascular hemolysis when transfused with A-positive blood and neonatal isoerythrolysis has been recognized in pigs, with antibodies usually directed against isoantigens of the E blood group (Tizard, 1992).

Naturally occurring neonatal isoerythrolysis has not been reported in cattle, but it occurs in some calves born to cows previously vaccinated for anaplasmosis or other bovine origin vaccines containing RBC membranes (Dimmock and Bell, 1970; Luther *et al.*, 1985). Several blood group isoantigens have been incriminated, but the most important blood group isoantigens involved in this disorder are uncertain (Dimmock and Bell, 1970). Based on experimentally produced disease, the B isoantigen group appears to generate potent hemolysins (Dimmock *et al.*, 1976).

2. *Natural Antibodies*

Some blood group systems, such as the ABO group in man, the AB group in cats, and the A group in pigs, are characterized by "naturally occurring" antibodies; that is, antibodies occur in plasma in the absence of prior exposure to blood from another individual (Tizard, 1992; Bücheler and Giger, 1993). In other blood groups, such as the Rh system in man and most blood groups in animals, antibody formation results from prior exposure to different RBC isoantigens via transfusion, pregnancy, or vaccination with products containing blood group antigens (Stormont, 1982). Fortunately, naturally occurring antibodies of clinical significance seldom occur in animals; consequently, adverse transfusion reactions to unmatched RBCs generally do not occur at the time of the first blood transfusion. However, exceptions may occur as in the case of the AB group in cats where B-positive cats have naturally occurring anti-A antibodies with high hemolytic titer (Bücheler and Giger, 1993).

D. Membrane Transport

The lipid bilayer is impermeable to most molecules. Consequently, various membrane protein transport systems are utilized for movement of molecules into and out of RBCs.

1. *Anions and Water*

Band 3 appears to function as an aqueous pore or channel for the movement of anions (e.g., bicarbonate and chloride), water, certain nonelectrolytes, and probably cations to some extent (Solomon *et al.*, 1983). Gruber and Deuticke (1973) studied phosphate as a model for anion exchange in RBCs from several species. There was a positive correlation between phosphate influx and the proportion of phosphatidylcholine in membrane phospholipids (Gruber and Deuticke, 1973).

2. *Sodium and Potassium*

Major interspecies, and in some cases intraspecies, differences occur in cation transport and subsequently in intracellular Na^+ and K^+ concentrations (Ellory and Tucker, 1983). There is a strong positive correlation between the intracellular K^+/Na^+ ratio and ATP concentration when RBCs of different species are compared. The cause of this relationship is unknown, but it is not related to differences in glucose utilization (Miseta *et al.*, 1993).

Like man, those animal species with high intracellular K^+ concentrations, horse, pig, and some ruminants, have an active Na^+, K^+-pump that exchanges intracellular Na^+ for extracellular K^+ with the hydrolysis of ATP. This Na^+, K^+-activated ATPase activity is often used as a measure of Na^+, K^+-pump activity. In addition to individuals with high potassium (HK^+) RBCs, some sheep, goats, buffalo, and most cattle have relatively low potassium (LK) and, consequently, high sodium RBCs. These LK^+ RBCs have low Na^+, K^+-pump activity and high passive K^+ permeability (Tosteson and Hoffman, 1960). Studies in sheep and goats have demonstrated the HK^+/LK^+ polymorphism is determined by a single autosomal genetic locus with two alleles, the LK^+ allele being dominant (Tunon *et al.*, 1987; Xu *et al.*, 1994). In sheep, this polymorphism is associated with an M and L blood group antigen polymorphism. The HK^+ cells exhibit M antigens and the homozygous LK^+ cells exhibit L antigens, with heterozygous LK_+ sheep exhibiting M and L antigens. The L_p-antigen in LK^+ RBCs appears to be an endogenous inhibitor of the Na^+, K^+-pump (Xu *et al.*, 1993).

RBCs from cats and most dogs do not have Na^+, K^+-pump activity and have Na^+ and K^+ concentrations near, but not at, those predicted for the Donnan equilibrium with plasma (Parker, 1977). Some clinically normal Japanese Akita dogs (Degen, 1987) and mongrel dogs from Japan (Inaba and Maede, 1984) have HK^+ RBCs. RBCs from these mongrel dogs have substantial Na^+, K^+-ATPase activity and altered amino acid metabolism, as discussed later. Dog, ferret, and bear RBCs have a unique Na^+-Ca^{++} countertransport system that can remove sodium (Parker, 1992). The calcium that enters the cell is subsequently pumped out by an ATP-dependent calcium pump.

Other pathways of sodium and potassium transport occur to variable degrees in certain species. These pathways include passive diffusion, Na^+, K^+, Cl^- cotransport, $Na^+ \times Na^+$ countertransport, band 3 anion transport as $NaCO_3^-$, Na^+-dependent amino acid transport, K^+, Cl^- cotransport, Na^+, H^+ exchange, and a calcium-dependent K^+ channel (Contreras *et al.*, 1986; Ellory and Tucker, 1983; Haas, 1989). A negative linear correlation between internal sodium concentration and membrane protein to lipid ratio was found by comparison of RBC values from nine mammalian species, the significance of which is unknown (Garnier *et al.*, 1984).

RBC volumes influence cation fluxes. Sodium flux increases when cells are shrunken, and potassium flux increases when cells are swollen. The Na^+, K^+, Cl^- cotransport and Na^+-H^+ exchange are activated by cell shrinkage and K^+-Cl^- cotransport is activated by cell swelling (Haas, 1989). Volume changes are believed to be detected from alterations in cytoplasmic macromolecules (Parker, 1992).

Early nucleated erythroid precursors in dog bone marrow have HK^+ content, whereas mature RBCs are of the LK^+ type. The switch from HK^+ to LK^+ content occurs during the maturation from early to late nucleated erythroid cells (Kirk *et al.*, 1983). When erythropoiesis is dramatically stimulated in response to a hemolytic anemia, much of the HK^+ to LK^+ transition does not occur until after denucleation. Consequently, stress reticulocytes, produced in response to anemia, have potassium contents much higher than reticulocytes normally released into blood. The high potassium concentration in canine stress reticulocytes results from membrane Na^+, K^+-ATPase activity that is lost during maturation into RBCs, possibly by ATP-dependent proteolysis (Inaba and Maede, 1986). Stress reticulocytes produced by LK^+-type ruminants (Israel *et al.*, 1972; Tucker and Ellory, 1971; Kim *et al.*, 1980) also have high potassium concentrations as a result of high Na^+, K^+-ATPase activities (Blostein and Grafova, 1990). The decline in the number of Na^+, K^+ pumps on LK^+ sheep reticulocytes during maturation is modulated by the L_p antigen (Xu *et al.*, 1994). Fetal and neonatal RBCs examined from mammals with LK^+ RBCs have higher potassium concentrations than adult RBCs, but the difference in dogs was not as dramatic as that in ruminants (Coulter and Small, 1973; Ellory and Tucker, 1983).

3. *Calcium*

Excessive intracellular Ca^{2+} is deleterious to RBCs; consequently, they actively extrude Ca^{2+} using a calcium pump having Ca^{2+}-activated, Mg^{2+}-dependent ATPase activity. The calcium pump is activated by a calcium-binding protein called calmodulin (Bababunmi *et al.*, 1991; Hinds and Vincenzi, 1986). This pump working in conjunction with a Na^+-Ca^{++} countertransport system appears to be important in RBC volume regulation in dogs (Parker, 1992).

4. *Amino Acids*

Amino acid transport in RBCs provides amino acids for synthesis of reduced glutathione (GSH). In addition, amino acid transporters may be responsible for efflux of amino acids during reticulocyte maturation (Tunnicliff, 1994).

Eight different amino acid transport systems have been recognized in mammalian RBCs, each with its own characteristic species distribution, ion requirements, and substrate specificity (Young, 1983; Fincham *et al.*, 1987). In addition, the band 3 anion transporter can transport glycine and some other amino acids (Fincham *et al.*, 1987). Amino acid transport in sheep appears to be mediated largely by the Na^+-independent C amino acid transporter, a carrier whose optimal substrates are small neutral amino acids and dibasic amino acids (Young, 1983). Sheep deficient in this transporter have low RBC GSH, because of impaired cysteine transport (Tucker *et al.*, 1981). A similar asc transport system occurs in most equine RBCs and deficient horses are predisposed to GSH deficiency (Fincham *et al.*, 1987; Fincham *et al.*, 1988). Dog and cat RBCs have a Na^+-dependent acidic amino acid transporter that optimally transports glutamate and aspartate. The transport of 1 glutamate into dog RBCs is accompanied by 2 Na^+ and by the counter transport of 1 K^+ and 1 anion (Sato *et al.*, 1994). Cat RBCs have an Ly^+ system for the transport of dibasic amino acids (Young, 1983).

5. *Glucose*

Species vary in their permeability to glucose, with human RBCs being very permeable and pig RBCs being poorly permeable (McManus, 1967). RBCs of other domestic animals appear to be intermediate between these extremes (Arai *et al.*, 1992; Bolis, 1973; Widdas, 1955). Glucose is transported into RBCs by passive diffusion. Both band 3 (Bosman and Kay, 1990; Langdon and Holman, 1988) and an integral membrane protein that migrates in the band 4.5 region on SDS–PAGE (Craik *et al.*, 1988) are believed to be involved in glucose transportation. Glucose movement into RBCs is not regulated by insulin (Baldwin, 1993). RBCs from adult pigs lack a functional glucose transporter (Craik *et al.*, 1988) and, therefore, have limited ability to utilize glucose for energy (Kim and McManus, 1971; Magnani *et al.*, 1983). In contrast, RBCs from neonatal piglets and pig reticulocytes have the transporter

(Craik *et al.*, 1988) and, consequently, exhibit substantial glucose transport (Kim and Luthra, 1977). With the exception of cats, fetal and neonatal RBCs studied from man and animals have higher glucose transport than RBCs from adults (Mooney and Young, 1978; Widdas, 1955).

6. Adenine, Adenosine, and Inosine

RBC membranes from most animal species have a nucleoside transporter (Young, 1983). The adenosine transporter from human and pig RBCs migrates in the band 4.5 region on SDS-PAGE (Kwong *et al.*, 1986). Rabbit, pig, and human RBCs exhibit substantially more adenosine uptake than those of other species studied (Van Belle, 1969). RBCs from dogs exhibit more adenosine uptake than cats, goats, or cattle, and RBCs from horses and most sheep appear to be nearly impermeable to adenosine. A low percentage of sheep have RBCs with a high affinity nucleoside transport system with a broad specificity for both purine and pyrimidine nucleosides (Young, 1983). While dog RBCs are permeable to adenosine, they are impermeable to inosine (Duhm, 1974). Dog and cat RBCs exhibit adenine uptake and incorporation into nucleotides, but values are much lower than those of human, rabbit, or rodent RBCs (Lalanne and Willemot, 1980).

E. Metabolism of Adenine Nucleotides

Adenine nucleotides in RBCs contain adenine, ribose, and one or more phosphate groups. Mature RBCs cannot synthesize adenine nucleotides *de novo* but can produce these compounds utilizing so-called salvage pathways (Brewer, 1974; Eaton and Brewer, 1974). AMP can be synthesized from adenine or from adenosine, both of which may be supplied to RBCs as they pass through the liver. One molecule of ATP interacts with one molecule of AMP to generate two molecules of ADP in the adenylate kinase reaction. ATP is generated from ADP in glycolysis (see later discussion).

AMP is synthesized from adenine and phosphoribosyl pyrophosphate (PRPP), utilizing the adenine phosphoribosyltransferase enzyme. Adenine is converted to ATP at a slower rate in dog and cat RBCs than in those of man, rodents, or rabbits (Lalanne and Willemot, 1980). AMP degradation to inosine monophosphate and ammonia is catalyzed by AMP-deaminase. The activity of this enzyme is generally lower in mammalian RBCs compared to nucleated RBCs from birds, reptiles, amphibians, and fish (Kruckeberg and Chilson, 1973).

Adenosine can be phosphorylated to AMP using ATP in the adenosine kinase reaction. A competing reaction, adenosine deaminase, converts adenosine to inosine, which cannot be incorporated into AMP. The uptake and/or deamination of adenosine varies considerably by species (Van Belle, 1969). Not only are dog, cat, and cattle RBCs poorly permeable to inosine, but inosine produced by adenosine deamination cannot be readily used for energy in these species because of low purine nucleoside phosphorylase activity, which converts inosine to ribose 1-phosphate and hypoxanthine (Duhm, 1974).

NAD and NADP can apparently be synthesized from nicotinate by way of a series of reactions in RBCs (Eaton and Brewer, 1974). In addition to ATP, PRPP and NH^3, or glutamine, are required. Comparative studies of the synthesis of these compounds in domestic animals have not been reported.

F. Carbohydrate Metabolism

RBCs require energy in the form of ATP for maintenance of shape and deformability, phosphorylation of membrane phospholipids and proteins, active membrane transport of various molecules, partial synthesis of purine and pyrimidine nucleotides, and synthesis of GSH (Nakao, 1974; Reimann *et al.*, 1981). Reducing potential in the form of NADH and NADPH is needed to counteract oxidative processes (see later discussion). Although substrates such as ribose, fructose, mannose, galactose, dihydroxyacetone, glyceraldehyde, adenosine, and inosine may be metabolized to some extent, depending on the species, glucose is the primary substrate for energy needs of RBCs from all species except the pig (Agar and Board, 1983b; Kim, 1983).

RBCs from adult pigs utilize glucose at lower rates than other species (Magnani *et al.*, 1983) because they lack a functional glucose transporter (Craik *et al.*, 1988; Zeidler and Kim, 1982). Inosine appears to be the major substrate for pig RBCs; its production by the liver is sufficient to meet their energy requirements (Young *et al.*, 1985; Zeidler *et al.*, 1985). Inosine can be used because nucleoside phosphorylase converts it to ribose 1-phosphate and hypoxanthine (Sandberg *et al.*, 1955). Ribose 1-phosphate is converted to ribose 5-phosphate, an intermediate of the pentose phosphate pathway (PPP), by phosphoribomutase (Brewer, 1974).

Glucose utilization rates of RBCs vary by species (Table 7.1). Factors such as pH, phosphate concentration, temperature, and leukocyte and platelet contamination of RBC incubations can have substantial effects on glucose utilization rates measured *in vitro*. Consequently, species comparisons of values determined in different laboratories may be misleading. Harvey and Kaneko (1976a) approximated physiologic conditions *in vitro* and measured mean glycolytic rates of 0.64,

0.94, 1.33, and 1.48 μmol/ml RBC for horse, cat, dog, and man, respectively. Once glucose enters the cell, it is phosphorylated to glucose 6-phosphate (G6P) utilizing the hexokinase (HK) enzyme. The G6P is then metabolized through either the Embden–Meyerhof pathway (EMP) or the pentose phosphate pathway (PPP) as shown (in Fig. 7.4).

G. Embden–Meyerhof Pathway

Most of the species variations in glucose utilization appear to result from variations in EMP metabolism, with PPP metabolism being relatively constant when not stimulated by oxidants (Harvey and Kaneko, 1976a). In addition to the phosphorylation of glucose, one molecule of ATP is used to phosphorylate fructose 6-phosphate, and one molecule of ATP is generated for each three-carbon molecule metabolized through the phosphoglycerate kinase (PGK) and pyruvate kinase (PK) reactions (Fig. 7.4). Consequently a net of two molecules of ATP is produced for each molecule of glucose metabolized to two molecules of lactate in the EMP. Since mature RBCs lack mitochondria, the EMP is the only source of ATP production in these cells.

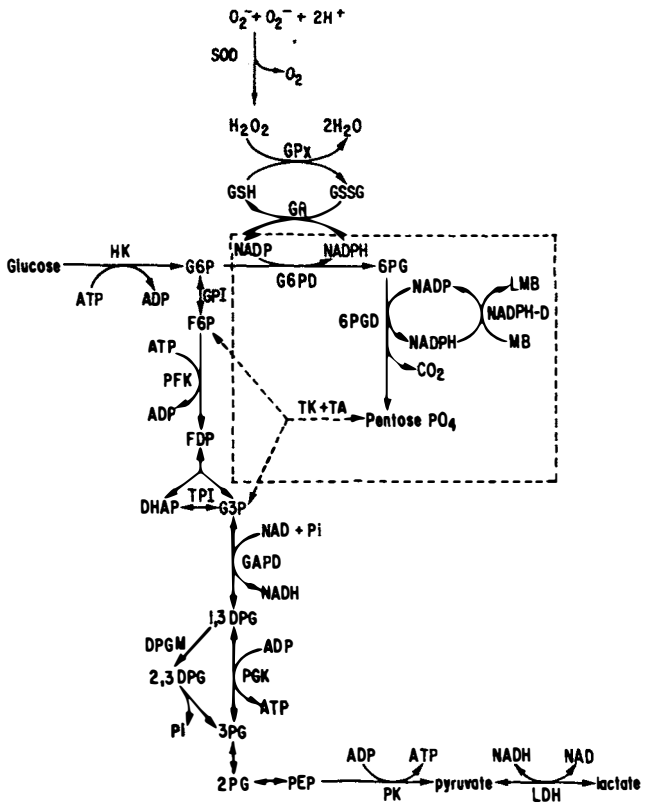

FIGURE 7.4 Metabolic pathways of the mature RBC. For abbreviations see footnote at beginning of chapter.

In human RBCs, reactions catalyzed by HK, phosphofructokinase (PFK), and PK appear to be rate-limiting steps in glycolysis, because these reactions are far displaced from equilibrium (Minakami and Yoshikawa, 1966). Under physiologic steady-state conditions, the PFK enzyme reaction controls glycolysis through the EMP (Rapoport, 1968). Its activity is influenced by a variety of effectors, with ATP being the most important inhibitor and AMP and inorganic phosphate (P_i) being the most influential activators. ADP is a less potent activator (Jacobasch *et al.*, 1974). Most of the adenine nucleotide pool in RBCs is maintained as ATP under normal conditions, with less as ADP and even less as AMP (Tables 7.4 and 7.5). Glycolysis is ultimately controlled by the demand for production of ATP. As ATP is utilized, concentrations of ADP, AMP, and P_i increase. These changes result in the activation of PFK and increased EMP metabolism. Other potential activators of PFK include ammonium ions (Debski and Rynca, 1985; Shimizu *et al.*, 1988), glucose 1,6-bisphosphate (Harvey *et al.*, 1992b; Accorsi *et al.*, 1985), and fructose 2,6-bisphosphate (Gallego and Carreras, 1990; Sobrino *et al.*, 1987; Harvey *et al.*, 1992b).

When PFK is activated, HK is activated secondarily because the concentration of G6P is reduced, and G6P competitively inhibits HK (Rapoport *et al.*, 1976). Although the HK reaction is normally not a rate-controlling step in glycolysis of human RBCs, conceivably it is more important in animal species with lower HK activity (Rapoport, 1968). The glycolytic rate is correlated with HK activity when RBCs of various species are compared at pH values above 8.0. Comparisons may be less reliable when measurements are made at pH 7.4 (Harvey and Kaneko, 1975a, 1976a). In human RBCs, the PK reaction becomes limiting when the PFK reaction is markedly stimulated, that is, at pH values greater than 7.6 (Jacobasch *et al.*, 1974). The pH values listed earlier are external values. The pH within RBCs is generally about 0.2 units lower than the external pH (Waddell and Bates, 1969).

In addition to ATP/ADP and ADP/AMP ratios, various other factors influence EMP metabolism. Alterations in pH of plasma or *in vitro* buffers affect glycolysis. As pH is increased above 7.2, PFK is activated and glucose utilization and EMP metabolism increase (Burr, 1972; Rapoport, 1968).

At physiologic pH values, high concentrations of P_i stimulate glycolysis through the EMP by reducing the ATP inhibition of PFK. Conversely, glycolysis is inhibited by short-term phosphate deficiency, primarily by decreasing intracellular P_i for glyceraldehyde phosphate dehydrogenase (GAPD) (Jacobasch *et al.*, 1974; Ogawa *et al.*, 1989; Wang *et al.*, 1985). Decreased glycolytic rates result in decreased RBC ATP concentrations

and hemolytic anemia in experimental dogs made severely hypophosphatemic by hyperalimentation (Yawata *et al.*, 1974; Jacob *et al.*, 1973). Hemolytic anemia associated with hypophosphatemia has also been reported in diabetic cats and a diabetic dog following insulin therapy (Adams *et al.*, 1993; Perman and Schall, 1983; Willard *et al.*, 1987), in a cat with hepatic lipidosis (Adams *et al.*, 1993), and in postparturient cattle in which decreased RBC ATP concentrations have been measured (Ogawa *et al.*, 1987, 1989). In addition to low ATP concentrations, dog RBCs might hemolyze as a result of decreased RBC 2,3DPG concentration, because dog RBCs with low 2,3DPG are more alkaline fragile than those of normal dogs and may hemolyze at physiologic pH values (Harvey *et al.*, 1988).

Several glycolytic enzymes including PFK, GAPD, and aldolase bind to the highly acidic region of the cytoplasmic domain of band 3 (Harris and Winzor, 1990). These enzymes are inhibited by binding to band 3. It is suggested that tyrosine phosphorylation of band 3 by protein tyrosine kinases may enhance glycolysis by preventing the binding and inhibition of one or more glycolytic enzymes (Harrison *et al.*, 1991).

There is a strong positive correlation between intracellular Mg^{2+} and ATP concentrations in RBCs from various species due to the presence of the Mg^{2+}–ATP complex within cells (Miseta *et al.*, 1993). RBCs of rats and dogs with short-term magnesium deficiency have lowered glycolytic rates, because adenine nucleotide substrates in four glycolytic kinase reactions (HK, PFK, PGK, and PK) must be complexed with Mg^{2+} (Rapoport, 1968). Dogs and rats on magnesium-deficient diets become anemic (Elin and Alling, 1978; Kruse *et al.*, 1933), owing to shortened RBC life spans.

The saturation of Hb with oxygen has an effect on glucose utilization. Human RBCs utilize more glucose when incubated anaerobically under nitrogen than under aerobic conditions (Asakura *et al.*, 1966). OxyHb is a stronger acid than DeoxyHb; consequently, the intracellular pH of human RBCs is lower in oxygenated blood than in deoxygenated blood (Takano *et al.*, 1976). The PFK reaction is inhibited as blood is oxygenated, due to the pH effect. In human RBCs, 2,3DPG is bound to DeoxyHb and released on oxygenation. Based on studies of glycolytic intermediates, the increased unbound 2,3DPG in oxygenated RBCs may have additional inhibitory effects on glycolysis (Hamasaki *et al.*, 1970). The effect of oxygenation on glycolysis of RBCs from domestic animals remains to be determined. It may not be important in ruminants because oxygenation results in insignificant decreases in intracellular pH values (Takano *et al.*, 1976).

2,3DPG inhibits glycolysis in part because of its reduction of intracellular pH as a consequence of the Donnan effect of this nonpenetrating anion (Duhm, 1975). 2,3DPG also inhibits glycolysis by inhibiting HK, PFK, and PK in a manner different from its pH effect on these enzymes (Duhm, 1975; Jacobasch *et al.*, 1974). In addition, 2,3DPG inhibits 6-phosphofructokinase-2-kinase, the enzyme responsible for the synthesis of the positive PFK effector fructose-2,6-bisphosphate (Sobrino *et al.*, 1987).

Glycolysis increases in human RBCs with increasing temperature to a maximum at 45°C, with a Q_{10} of 2 (Rapoport, 1968). Based on measurements of glycolytic intermediates, the major effect of temperature appears to be on the PFK reaction (Jacobasch *et al.*, 1974).

H. Diphosphoglycerate Pathway

Molecules of 1,3-diphosphoglycerate (1,3DPG), produced by the GAPD reaction, may be utilized by the PGK reaction in the EMP or may be converted to 2,3DPG by the diphosphoglycerate mutase (DPGM) reaction (Fig. 7.4). 2,3DPG degradation to 3-phosphoglycerate (3PG) is catalyzed by diphosphoglycerate phosphatase activity (DPGP). A single protein is responsible for both the DPGM and DPGP activities (Sasaki *et al.*, 1977). The DPG pathway or shunt (Rapoport–Luebering cycle) bypasses the ATP-generating PGK step in glycolysis; consequently, no net ATP is generated when glucose is metabolized through this pathway (Brewer, 1974).

Normally, from 10 to 30% of triose phosphate metabolism in human RBCs is shunted through this pathway (Jacobasch *et al.*, 1974; Oxley *et al.*, 1984). The proportion of 1,3DPG metabolized by PGK and DPGM is determined mostly by the concentration of ADP (Rapoport, 1968). ATP and 2,3DPG influence the relative amount of flow through each route by product inhibition of their own synthesis.

The absolute flow is also determined by the overall glycolytic rate. 2,3DPG inhibits HK, PFK, and GAPD in human RBCs (Srivastava and Beutler, 1972). The formation of 2,3DPG is stimulated by increased P_i concentration and increased pH, which stimulate glycolysis by activating PFK greater than PK (Jacobasch *et al.*, 1974).

The concentration of 2,3DPG can be affected by a decrease in PK activity. When PK activity is reduced relative to PFK activity, phosphorylated intermediates between the PK and GAPD reactions increase in concentration (Mueggler and Black, 1982). The synthesis of 2,3DPG is increased as a result of the increased concentration of the 1,3DPG substrate. Thyroid hormones can increase 2,3DPG in human (Snyder *et al.*, 1970) and sheep (Studzinski *et al.*, 1982) RBCs, possibly by a direct effect on the DPGM enzyme.

RBCs of dogs, horses, pigs, and man normally contain high concentrations of 2,3DPG, whereas those of cats and domestic ruminants have low concentrations (Tables 7.4 and 7.5). Based on results from a large number of mammalian species, only cats, hyenas and civets among carnivores, and deer, giraffe, antelope, and the cattle family among artiodactyls have low RBC 2,3DPG concentrations (Bunn, 1981; Bunn *et al.*, 1974). Low concentrations of 2,3DPG in cat, goat, and sheep RBCs result primarily from low RBC DPGM activities, whereas RBCs of cattle have relatively high DPGP activity in association with moderately low DPGM activity (Chemtob *et al.*, 1980; Pons *et al.*, 1985; Harkness *et al.*, 1969).

I. Hemoglobin Oxygen Affinity

1. *Oxygen Dissociation Curve*

The initial binding of a molecule of O_2 to a monomer of tetrameric, deoxygenated Hb facilitates further binding of O_2 to the Hb molecule. Since the O_2 binding of one heme group influences the affinity of other heme groups for O_2, this characteristic has been called the *heme–heme interaction.* The changing oxygen affinity of Hb with oxygenation results in a sigmoid oxygen dissociation curve (Fig. 7.5) when the percent saturation of Hb with oxygen is plotted against the partial pressure of oxygen (pO_2). The pO_2 at which Hb is 50% saturated is the P_{50}. The steepness of the middle portion of the curve is of great physiologic significance because it covers the range of oxygen tensions present in tissues. Consequently, relatively small decreases in oxygen tension result in substantial oxygen release from Hb (Benesch *et al.*, 1975).

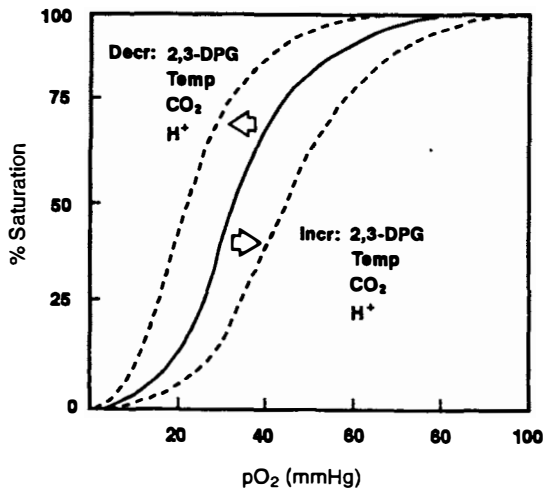

FIGURE 7.5 The hemoglobin–oxygen dissociation curve and factors influencing the position of the curve.

2. *Effects of H^+, CO_2, and Temperature*

The oxygen affinity of Hb is influenced by H^+ in a manner termed the Bohr effect. In capillaries of metabolizing tissues, CO_2 enters RBCs where it is rapidly converted to H_2CO_3 by carbonic anhydrase (carbonate dehydratase). This carbonic acid spontaneously ionizes to H^+ and HCO_3^-. The increased H^+ concentration decreases the oxygen affinity of Hb and facilitates oxygen delivery to the tissues. DeoxyHb is a weaker acid than OxyHb; therefore, DeoxyHb binds the excess H^+ and limits the decrease in pH. The increased HCO_3^- diffuses out of the cell down a concentration gradient and Cl^- moves in (chloride shift) to maintain electrical neutrality. These processes are reversed at the lungs.

The addition of H^+ to a suspension of RBCs results in an increase in P_{50} and a shift of the oxygen dissociation curve to the right (Fig. 7.5). The magnitude of the Bohr effect is defined numerically $\Delta \log P_{50}/\Delta$ pH. The relationship between the magnitude of the Bohr effect and average body size of various animal species is an inverse one (Riggs, 1960). The direct binding of CO_2 to Hb in carbamino groups also lowers oxygen affinity, but this effect is considered to be minor. Increased temperature decreases the oxygen affinity of Hb, a response that appears physiologically appropriate considering that increased heat production accompanies increased oxygen consumption in tissues (Benesch *et al.*, 1975).

The P_{50} for greyhound RBCs in whole blood is lower than that for mongrel dogs, yet the groups have similar 2,3DPG concentrations (Sullivan *et al.*, 1994). The cause of this difference remains to be determined, but it is suggested that the higher PCV found in greyhound dogs may represent a compensatory response to a higher oxygen affinity of Hb in this species.

3. *Effects of 2,3DPG*

In RBCs from most mammalian species, 2,3DPG decreases the oxygen affinity of Hb, resulting in an increase in P_{50} (Bunn *et al.*, 1974). 2,3DPG reacts with Hb in a ratio of one molecule per Hb tetramer. Negatively charged groups of 2,3DPG bind to specific positively charged groups in the N-terminal region of Hb beta chains. There is a marked preference for binding to DeoxyHb as compared to OxyHb due to differences in the conformation of the molecules. The interaction of 2,3DPG with Hb is represented as follows:

$$HbDPG + O_2 \leftrightharpoons HbO_2 + DPG.$$

When 2,3DPG is increased, the reaction is displaced to the left, and when pO_2 is increased, the reaction is displaced to the right. ATP has a similar effect on Hb oxygen affinity, but is generally much less important

than 2,3DPG, because it usually occurs in lower concentration and is complexed with Mg^{2+} (Bunn, 1971).

When the oxygen affinity of Hb is studied in hemolysates dialyzed to remove 2,3DPG and ATP, the "stripped" Hbs from species with low 2,3DPG RBCs have considerably lower oxygen affinities than stripped Hb from species with high 2,3DPG RBCs (Bunn, 1971; Bunn *et al.*, 1974). Furthermore, the oxygen affinity of stripped Hb from these low 2,3DPG RBCs is minimally affected by added 2,3DPG, because alterations are present in the β-chain-binding area that prevent or diminish 2,3DPG binding (Bunn, 1981). However, the Hb oxygen affinity in cattle RBCs (a low 2,3DPG species) is modulated by chloride ions and to a lesser extent phosphate ions (Fronticelli, 1990; Gustin *et al.*, 1994). Because stripped Hbs from species with high 2,3DPG RBCs have high oxygen affinities, 2,3DPG is needed within RBCs of these species to maintain Hb oxygen affinity within a physiologically useful range (Benesch *et al.*, 1975).

When blood from many mammalian species is studied, an inverse linear correlation is recognized between the P_{50} of whole blood and the log of body weight (Scott *et al.*, 1977). The relationship between metabolic rate (oxygen consumption per gram of tissue) and body weight (Kleiber, 1961) is an inverse one. Consequently, the higher P_{50} in smaller animals should be beneficial in meeting tissue oxygen requirements associated with their higher metabolic rates. Oxygen affinity of stripped Hb from various mammals does not correlate with body weight (Nakashima *et al.*, 1985). The maintenance of 2,3DPG is energetically expensive because the ATP-generating PGK reaction is bypassed. 2,3DPG apparently allows for an evolutionary adaption of blood Hb oxygen affinity to metabolic rate.

Potentially, animals with high 2,3DPG RBCs can alter their Hb oxygen affinity to meet metabolic needs. The significance of (and in some cases the appropriateness of) alterations in 2,3DPG in disease states is not always clear. RBC 2,3DPG increases in some anemic animals (Agar *et al.*, 1977; King *et al.*, 1992; Studzinski *et al.*, 1978). In the case of anemias the resultant increase in P_{50} would seem to be beneficial, but in the case of severe hypoxic hypoxemia the change might be detrimental, because Hb could not be fully saturated. Various studies in dogs indicate that cardiac output and microcirculation adjustments are much more important than changes in Hb oxygen affinity in adapting to hypoxia (Liard and Kunert, 1993; Schumacker *et al.*, 1985; Zachara *et al.*, 1981). However, a reduction in Hb oxygen affinity secondary to increased 2,3DPG can be beneficial, because it is far less energy demanding than is an increase in cardiac output (Liard and Kunert, 1993; Mairbäurl, 1994; Teisseire *et al.*, 1985). RBC 2,3DPG increases in hibernating mammals, but the effect of the decrease in body temperature, associated with hibernation, on Hb oxygen affinity *in vivo* would more than offset the effect of increased 2,3DPG (Bunn, 1981). Because pH has a substantial effect on Hb oxygen affinity, changes in RBC 2,3DPG concentration, in response to acidosis and alkalosis, produce effects on Hb oxygen affinity that counteract alterations induced by the respective changes in pH (Bellingham *et al.*, 1971).

4. *Maternal–Fetal Oxygen Transport*

Except for the domestic cat, the oxygen affinity of Hb in fetal blood is higher than that of maternal blood (Bunn and Kitchen, 1973; Novy and Parer, 1969). This difference in oxygen affinity probably enhances the transport of oxygen across the placenta to the fetus (Comline and Silver, 1974; Hebbel *et al.*, 1980). Oxygen is adequately transported to cat fetuses, without the advantage of increased oxygen affinity, due to the nature of the placentation and a countercurrent arrangement of blood flows (Novy and Parer, 1969).

During late gestation, mean umbilical venous pO_2 values of 48, 38, 35, and 30 mm Hg have been reported for horses, cattle, sheep, and pigs, respectively (Comline and Silver, 1974). Fetal systemic arterial pO_2 values may be even lower, especially in species such as the pig and horse which lack a ductus venosus, requiring that all returning umbilical venous blood pass through the liver. These pO_2 values are considerably lower than normal adult arterial pO_2 values of about 100 mm Hg. Because Hb in adult RBCs of these species is only partially saturated at these low arterial pO_2 values (Schmidt-Neilsen and Larimer, 1958), the increased oxygen affinity of fetal blood would result in a greater saturation of Hb and, therefore, a greater oxygen-carrying capacity of blood than would otherwise be present.

Fetal RBCs maintain Hb oxygen affinities higher than those of the mother by one of three mechanisms (Bunn and Kitchen, 1973): (1) Ruminants have structurally distinct fetal Hbs that have higher oxygen affinities than adult Hbs in the absence of organic phosphates (Battaglia *et al.*, 1970; Blunt *et al.*, 1971). Interactions between 2,3DPG and both fetal and adult Hbs in ruminants are weak (Bunn and Kitchen, 1973). (2) A structurally distinct fetal Hb (HbF) also occurs in man, but the oxygen affinity of stripped HbF and adult human Hb is about the same. Differences in whole blood oxygen affinity occur primarily because HbF interacts weakly with 2,3DPG, in contrast to the strong interaction with adult Hbs (Oski and Gottlieb, 1971). (3) Animals without structurally distinct fetal Hbs, such as dog, horse, and pig, have much lower 2,3DPG concen-

trations in fetal RBCs than in adult RBCs, thereby creating higher oxygen affinities in fetal RBCs (Bunn and Kitchen, 1973; Comline and Silver, 1974; Dhindsa *et al.*, 1972; Tweeddale, 1973). The actual *in vivo* difference in oxygen affinity between fetal and maternal RBCs is less than suggested by differences in P_{50} values measured *in vitro* at pH 7.4, because fetal blood pH is lower than that of maternal blood (Comline and Silver, 1974).

5. *Postnatal Changes in 2,3DPG and Oxygen Affinity*

Although the higher oxygen affinity of Hb in fetal RBCs may be beneficial in the uterus, it would seem to be disadvantageous to the newborn animal breathing air. Whole blood P_{50} values and RBC 2,3DPG concentrations (Fig. 7.6) increase after birth in most domestic animals.

RBC 2,3DPG concentrations are higher in fetuses than in adult ruminants (Aufderheide *et al.*, 1980; Zinkl and Kaneko, 1973a), and increase markedly within a few days after birth (Aufderheide *et al.*, 1980; King and Mifsud, 1981; Zinkl and Kaneko, 1973a). Since neither fetal nor adult Hbs from ruminants bind 2,3DPG to any extent, 2,3DPG decreases oxygen affinity primarily by lowering intracellular pH (Aufderheide *et al.*, 1980; Battaglia *et al.*, 1970; Blunt, 1972). Several mechanisms are involved in the 10-fold increase in RBC 2,3DPG during the first 5 days of life in lambs (Noble *et al.*, 1983). (1) Plasma glucose increases from 40 to 100 mg/dl during the first 2 days of life and allows for an increased consumption of glucose by the glucose-permeable neonatal RBC. (2) The blood pH increases during the first day of life and activates the PFK enzyme as evidenced by changes in RBC intermediates. (3) Plasma P_i concentration increases to a level sufficient to increase GAPD activity at 3 days of age. (4) DPGM activity in neonatal RBCs is 12-fold higher than that of adults. (5) RBC PFK activity is still above adult values, but PK activity has decreased to adult values by birth.

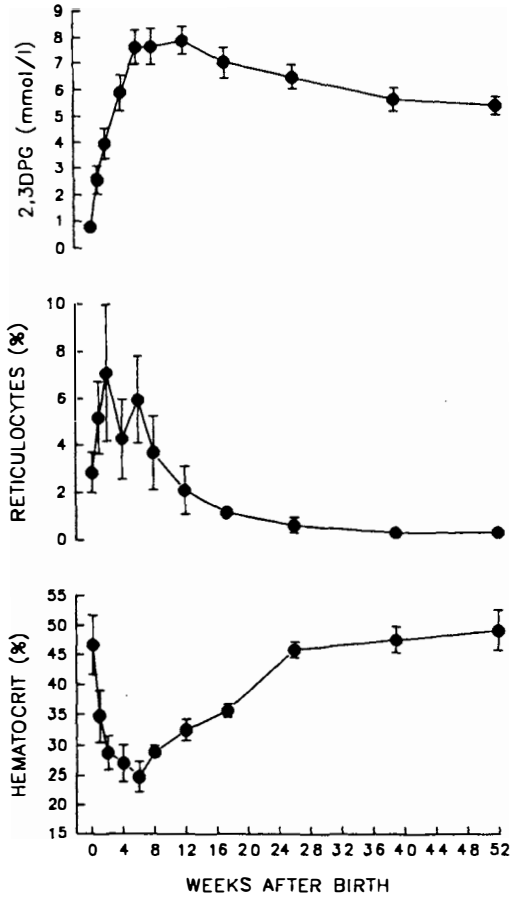

FIGURE 7.6 Changes in hematocrit, uncorrected reticulocyte count, and RBC 2,3DPG content in dogs following birth. Values are mean ± standard deviation (Harvey, 1994).

The decline in 2,3DPG in postnatal ruminant RBCs is more gradual, requiring 1–2 months to reach adult values. The whole blood P_{50} is maintained, however, because of concomitant decreases in HbF and increases in adult Hb types (Aufderheide *et al.*, 1980; Blunt *et al.*, 1971; Lee *et al.*, 1971; Zinkl and Kaneko, 1973a). In goat RBCs HbC replaces most of the HbF initially, but after 2 months other adult Hbs begin to replace HbC (Huisman *et al.*, 1969). Only a small percentage of HbC is present in lambs up to 2 months of age. The percentage of HbF at birth varies from 70 to 100%. The signal to switch production of HbF to HbA in sheep is regulated by a developmental clock inherent to hematopoietic stem cells, rather than a change in the hematopoietic inductive microenvironment (Wood *et al.*, 1985).

Rapid, but modest, increases in 2,3DPG and P_{50} occur after birth in horse RBCs (Bunn and Kitchen, 1973). As in ruminants, blood pH increases significantly within 1 hour after birth (Rose *et al.*, 1982). Plasma P_i concentration also increases during the first 2 weeks of life (Bauer *et al.*, 1984). Gradual, but large, increases in 2,3DPG and P_{50} occur postnatally in blood of dogs (Dhindsa *et al.*, 1972; Mueggler *et al.*, 1980; Harvey and Reddy, 1989) and pigs (Kim and Duhm, 1974; Watts and Kim, 1984). A decreasing activity of PK has been reported to account for the increasing 2,3DPG concentration during the first 60 days of life in dogs (Mueggler and Black, 1982), but activation of PFK may also play a role in this increase (Harvey, 1994).

In man, 2,3DPG increases slightly after birth, but most of the increase in P_{50} that occurs during the first 6 months of life results from the replacement of HbF with adult Hbs (Oski and Gottlieb, 1971). Although P_{50} values changed slightly in kittens after birth, RBC

2,3DPG values remained in the normal adult range (Dhindsa and Metcalfe, 1974). Data concerning changes in these and other species have been compiled by Isaacks and Harkness (1983).

J. Pentose Phosphate Pathway

The pentose phosphate pathway (PPP) generates NADPH, the major source of reducing equivalents in the protection of RBCs against oxidative injury. This pathway also produces ribose 5-phosphate (R5P), which is required for adenine nucleotide synthesis (Eaton and Brewer, 1974). The PPP competes with the EMP for the G6P substrate (Fig. 7.4). Normally only about 5–13% of glucose metabolized by RBCs flows through the PPP (Harvey and Kaneko, 1976a), but this flow can be accelerated markedly by oxidants (Harvey and Kaneko, 1977).

The first step in the metabolism of glucose through the PPP generates NADPH from the oxidation of G6P in the glucose-6-phosphate dehydrogenase (G6PD) reaction. An additional NADPH is generated from the oxidative decarboxylation of 6-phosphogluconate (6PG) to ribulose 5-phosphate in the 6-phosphogluconate dehydrogenase (6PGD) reaction. This is the only known reaction producing CO_2 in mature RBCs. The remainder of the reactions in the PPP are nonoxidative and freely reversible. R5P is produced from ribulose 5-phosphate by the R5P isomerase reaction. The net effect of the metabolism of three molecules of G6P through the PPP is as follows (Eaton and Brewer, 1974):

$$3\ \text{G6P} + 6\ \text{NADP}^+ \rightarrow 3\ \text{CO}_2 + 2\ \text{F6P} + \text{G3P} + 6\ \text{NADPH} + 6\ \text{H}^+.$$

G6PD is the rate-limiting reaction in the PPP under physiologic conditions. Normally, the G6PD reaction in intact human RBCs operates at only 0.1–0.2% of the maximal enzyme activity as determined in hemolysates under optimal conditions. The low rate of this reaction in RBCs occurs because of limited substrate availability (especially $NADP^+$) and because G6PD is strongly inhibited by NADPH and ATP at physiologic concentrations (Yoshida, 1973). The maximal G6PD activities measured in hemolysates from goat and sheep RBCs are much lower than those of humans or of other domestic animals (Tables 7.2 and 7.3). However, this comparatively low enzyme activity does not render sheep RBCs unduly susceptible to the hemolytic effects of oxidant drugs (Maronpot, 1972; Smith, 1968), in part because G6PD is not inhibited by ATP in this species (Smith and Anwer, 1971).

About 91% of total NADP is in the reduced form in horse RBCs (Stockham *et al.*, 1994) and 92-99% of total NADP is NADPH in human RBCs (Kirkman and Gaetani, 1986; Zerez *et al.*, 1987). NADPH is utilized to reduce oxidized glutathione to GSH, the substrate for the glutathione peroxidase reaction, and it is bound to catalase, preventing and reversing the accumulation of an inactive form of catalase that is generated when catalase is exposed to H_2O_2 (Kirkman *et al.*, 1987). In the presence of oxidants, NADPH is oxidized and the PPP is stimulated because the activities of G6PD and 6PGD are directly related to the concentration of NADP and inversely related to that of NADPH (Yoshida, 1973). Glutathione metabolism affects PPP activity via the glutathione reductase (GR) enzyme, which generates NADP as a result of the reduction of GSSG with NADPH (Fig. 7.4).

K. Metabolic Protection Against Oxidants

1. *Nature of Oxidants in Biology*

From a thermodynamic standpoint, oxygen is a strong oxidant, but its reactivity is limited by virtue of its unusual electronic configuration (Green and Hill, 1984). Although relatively unreactive, oxygen can be metabolized *in vivo* to form highly reactive derivatives. A single-electron reduction of O_2 yields the superoxide (O_2^-) free radical. A free radical is defined as any species with one or more unpaired electrons. There are a wide variety of sources of O_2^- production *in vivo;* examples include the ubiquinone-cytochrome b region in mitochondria, uncoupled cytochrome P450 reactions, autoxidation of adrenaline, certain flavins, Hb, and SH groups, enzyme reactions such as xanthine oxidase and tryptophan deoxygenase, and the oxidant burst of activated neutrophils and mononuclear phagocytes (Freeman and Crapo, 1982). Superoxide undergoes spontaneous and enzyme catalyzed dismutation to H_2O_2. In the presence of a metal ion such as iron or copper, O_2^- and H_2O_2 interact to form the highly reactive hydroxyl radical ($OH^\cdot$).

A wide variety of drugs, metabolic intermediates, and environmental agents either exist as free radicals or can be converted to free radicals by cellular metabolic processes (Freeman and Crapo, 1982; Mason, 1982). These free radicals can be more damaging than the partially reduced oxygen species listed earlier. In some situations, the superoxide radical may be beneficial by acting as a free radical scavenger (French *et al.*, 1978).

2. *Superoxide Dismutase*

Superoxide dismutase (SOD) is a copper- and zinc-containing enzyme that was first isolated from cattle blood (McCord and Fridovich, 1969). It dismutates two O_2^- molecules to H_2O_2 and O_2 (Fig. 7.4). The activity of

SOD in RBCs of domestic animals is about the same as or higher than that in man (Harvey and Kaneko, 1977; Suzuki *et al.*, 1984b). RBC SOD activity is reduced in animals fed diets deficient in copper (Andrewartha and Caple, 1980; Williams *et al.*, 1975). Zinc is also needed for optimal activity (Hirose *et al.*, 1992) and, consequently, SOD activity may also be low in zinc-deficient animals (Hirose *et al.*, 1992). The importance of SOD as an oxidant defense in RBCs is unclear. Under conditions where H_2O_2 catabolism is compromised, SOD can increase oxidant injury due to accelerated H_2O_2 generation (Scott *et al.*, 1989).

3. *Glutathione*

Glutathione is a tripeptide of glutamic acid, cysteine, and glycine that occurs in approximately 2 m*M* concentrations in RBCs. It is synthesized *de novo* in RBCs of humans and animals from constituent amino acids via two ATP-requiring reactions, utilizing gamma-glutamylcysteine synthetase and glutathione synthetase (Beutler, 1989). GSH has a highly reactive (easily oxidizable) sulfhydryl (SH) group that, like other thiols, may act nonenzymatically as a free radical acceptor to counteract oxidant damage (Prins and Loos, 1969). GSH also binds free hemin, thereby reducing its potential for membrane injury (Shviro and Shaklai, 1987). Enzyme-mediated reactions involving GSH are discussed later. While GSH is constantly being oxidized to a disulfide (GSSG) to some extent within RBCs, most glutathione is maintained in its reduced form by the GR reaction. GSSG accounts for only about 0.2% of the total glutathione in human RBCs (Beutler, 1984). RBC membranes are not permeable to GSH, but GSSG is transported from RBCs by an active process (Srivastava and Beutler, 1969). The half-life of glutathione in dog and rabbit RBCs (2–5 days) is similar to that in human RBCs (4 days), but longer times (10–12 days) are reported in sheep RBCs. The GSSG transport rate may be the main determinant of glutathione turnover in RBCs (Smith, 1974).

4. *Glutathione Reductase*

Excepting the cat, RBCs of domestic animals have lower GR activity than those of man (Agar *et al.*, 1974; Harvey and Kaneko, 1975b). GR requires flavin adenine dinucleotide (FAD) as a cofactor for activity. Therefore, riboflavin metabolism affects the availability of FAD and the fraction of the protein that exhibits activity (Beutler, 1989; Harvey and Kaneko, 1975b). Horse RBCs are much slower than other species in their ability to regenerate GSH after it has been oxidized *in vitro* (Agar *et al.*, 1974; Mahaffey and Smith, 1975). The nature of the rate-limiting reaction has not been determined. Horse RBCs also appear less able to protect themselves against oxidative injury induced by incubation with high levels of ascorbate, which stimulates the GR reaction by the oxidation of GSH (Harvey and Kaneko, 1977).

5. *Glutathione S-Transferase*

Glutathione S-transferase (GST) catalyzes the formation of glutathione S-conjugates between GSH and certain electrophilic substrates. The same Mg^{+2}–ATPase transport system appears to transport glutathione S-conjugates and GSSG out of RBCs (Beutler, 1989). GST activity is present in RBCs of all mammalian species studied thus far, but natural electrophilic substrates and the potential involvement of these glutathione S-conjugates in glutathione turnover in normal animals are unknown (Board and Agar, 1983). The GST-mediated conjugation of various carcinogens and other electrophilic drugs in the liver is important in the protection of the body against these agents (Chasseaud, 1979), but the importance of this activity in protecting RBCs against xenobiotics is unknown. GST can bind free hemin that is released during Hb oxidation, presumably reducing damage to RBC membranes (Harvey and Beutler, 1982). A direct correlation between GST activity and GSH concentration has been reported in sheep and dog RBCs (Goto *et al.*, 1992). This is probably related to the fact that GST is stabilized by GSH.

6. *Thioltransferase*

Thioltransferase enzymes in human and animal RBCs can catalyze the reduction of not only low-molecular-weight disulfides and intramolecular protein disulfides, but also mixed disulfides (Terada *et al.*, 1992). Using GSH, thioltransferases can restore thiol groups in oxidatively damaged proteins.

7. *Glutathione Peroxidase*

Low levels of H_2O_2 are produced in the course of normal cellular events and higher levels may be generated by exogenously administered redox active compounds (Saltman, 1989). Hydrogen peroxide is catabolized by both glutathione peroxidase (GPx) and catalase. GPx catalyzes the conversion of H_2O_2 to H_2O (Fig. 7.4). In response to the GSSG produced by this reaction, RBCs increase PPP metabolism to provide the NADPH necessary for the regeneration of GSH by the GR reaction (Eaton and Brewer, 1974). The selective oxidation of a renewable thiol helps limit irreversible damage to RBCs that would otherwise occur.

GPx activity in RBCs correlates directly with blood selenium concentration in ruminants, horses, and rats

but not in pigs or higher primates (Anderson *et al.*, 1978; Beilstein and Whanger, 1983; Caple *et al.*, 1978; Thompson *et al.*, 1976). Selenium deficiency results in low GPx activity in RBCs because selenium is an essential cofactor that is incorporated into GPx as the enzyme is formed (Rotruck *et al.*, 1973). Although selenium deficiency can be diagnosed by measuring RBC GPx activity in some species (Anderson *et al.*, 1978; Caple *et al.*, 1978), caution is indicated in using this activity as a direct indicator of selenium status because polymorphism in GPx activity may be present, as occurs in Finn sheep (Sankari and Atroshi, 1983). A wide variety of abnormalities or lesions (most notably in skeletal and cardiac muscle) have been described in association with selenium deficiency in animals (Shamberger, 1986), but hemolytic anemia rarely, if ever, occurs in the absence of external oxidant stress. Heinz body hemolytic anemia has been reported during the summer months in selenium-deficient cattle grazing on St. Augustine grass growing on peaty muck soils in South Florida (Morris *et al.*, 1984). Although Heinz body formation was greatly reduced by selenium supplementation, it is likely that these animals were also exposed to a seasonal oxidant, possibly incorporated in the grass.

Fujii *et al.* (1984) have provided evidence for a GSH-dependent protein in RBCs that provides protection against lipid peroxidation. The nature of this presumed enzyme is unknown, but it does not have GST or GPx activity as normally measured. It may be similar to a selenium-containing membrane-bound enzyme found in other tissues that has been called phospholipid hydroperoxide glutathione peroxidase (Ursini *et al.*, 1985).

8. Catalase

Catalase is a heme-containing enzyme that also destroys H_2O_2 by conversion to H_2O and O_2. Recent *in vitro* studies suggests that catalase is of equal (Gaetani *et al.*, 1994) or greater (Scott *et al.*, 1993) importance than GPx in the defense of human RBCs against H_2O_2-generating reactions. However, the low levels of endogenous H_2O_2 produced *in vivo* are more likely cleared by GPx, which has a much higher affinity for substrate (Eaton, 1991).

Except for dogs, mammalian RBCs generally have high catalase activities (Allison *et al.*, 1957; Paniker and Iyer, 1965; Suzuki *et al.*, 1984a). Catalase is linked metabolically to the PPP because NADPH is tightly bound to catalase (Kirkman *et al.*, 1987). The binding of NADPH prevents and reverses the accumulation of an inactive form of catalase that is generated when catalase is exposed to H_2O_2. In addition to its benefit to RBCs, the presence of catalase in RBCs may help protect somatic cells exposed to high levels of H_2O_2, such as in sites of active inflammation (Agar *et al.*, 1986).

9. Vitamin E

Vitamin E deficiency increases the susceptibility of RBCs to peroxidative hemolysis (Duthie *et al.*, 1989; Pillai *et al.*, 1992; Rotruck *et al.*, 1972). Vitamin E (α-tocopherol) is a lipid-soluble vitamin that acts as a free radical scavenger within the membrane. It donates reducing equivalents to lipid peroxy radicals, thereby limiting chain reaction oxidations of polyunsaturated lipids and thus protecting membranes (Hebbel, 1986). Its location in the membrane provides little protection against cytosolic oxidative injury (Rotruck *et al.*, 1972).

10. Methemoglobin Reduction

MetHb differs from Hb only in that the iron moiety of the heme groups is in the ferric rather than the ferrous state. MetHb forms *in vivo* at low levels normally and at much higher levels in the presence of oxidative compounds (Bodansky, 1951).

MetHb is unable to bind oxygen and must be reduced to Hb to be functional. MetHb reduction is more corrective than protective. It is reduced to Hb primarily by NADH-methemoglobin reductase (NADH-MR) or cytochrome-b_5 reductase (Cb_5R). In the reaction, ferricytochrome b_5 is first reduced enzymatically with NADH, then the resulting ferrocytochrome b_5 reduces MetHb nonenzymatically to Hb (Hultquist *et al.*, 1978).

RBCs contain another enzyme, NADPH diaphorase (NADPH methemoglobin reductase, NADPH dehydrogenase), that is capable of MetHb reduction when appropriate electron carriers are present. In addition to redox dyes, such as methylene blue, various flavins may function as substrates for reduction by NADPH, prompting Yubisui *et al.* (1980) to classify the enzyme as a NADPH flavin reductase. The contribution of this enzyme to MetHb reduction in human RBCs is believed to be insignificant because flavin concentrations are normally low (Hultquist *et al.*, 1993). The recent finding that this protein also binds heme, porphyrins, and fatty acids raises additional questions about its possibly physiologic role in RBCs (Xu *et al.*, 1992).

Following the oxidation of Hb to MetHb with nitrite *in vitro*, horse RBCs reduce MetHb at a slower rate than those of other domestic animals (except pigs) when glucose is added as the substrate for energy (Robin and Harley, 1966). RBCs from adult pigs cannot reduce MetHb with glucose as the substrate because they lack a membrane glucose transporter (Kwong *et al.*, 1986). Interestingly horse RBCs reduce partially oxidized

Hb (25–40% MetHb) at a rapid rate but act on more fully oxidized Hb (80–90% MetHb) at a slower rate (Medeiros *et al.*, 1984). In contrast to NADP, only about half of the total NAD is normally present in the reduced (NADH) form (Zerez *et al.*, 1987). Horse (Robin and Harley, 1967; Medeiros *et al.*, 1984) and pig (Rivkin and Simon, 1965) RBCs utilize lactate better than glucose to generate NADH (by the LDH reaction) for the reduction of MetHb. Because lactate occurs in blood and easily diffuses into RBCs, it may be an important substrate of MetHb reduction *in vivo*.

Methylene blue (MB) is used to treat toxic methemoglobinemia because it causes MetHb to be reduced faster than occurs by the relatively slow Cb_5R reaction. MB is reduced to leukomethylene blue (LMB) by the NADPH-dependent diaphorase discussed earlier (Fig. 7.4), and LMB reacts spontaneously with MetHb, reducing it to Hb and regenerating MB (Sass *et al.*, 1969). MB was suggested to be of limited value in the treatment of methemoglobinemia in horses, since it had a limited ability to stimulate MetHb reduction of horse RBCs *in vitro* with glucose as the substrate (Robin and Harley, 1966). Dixon and McPherson (1977), however, found intravenous MB to be effective in reducing MetHb in a horse with persistent methemoglobinemia.

Being a redox dye, MB can participate in various oxidative reactions on entering RBCs. It is important that it be used judiciously lest it potentiate Heinz body formation and hemolysis that might result from the original oxidative insult (Harvey and Keitt, 1983).

V. DETERMINANTS OF ERYTHROCYTE SURVIVAL

A wide variety of conditions, including immune-mediated hemolytic anemias and infectious diseases, result in shortened RBC survival. Readers are referred to *Schalm's Veterinary Hematology* (Jain, 1986) for information concerning conditions beyond the scope of this chapter.

A. Oxidative Injury

Oxidants produce different patterns of intracellular and membrane damage which may be related to differences in lipid solubility, redox potentials, reactivity with SH groups, binding to heme, and the source or site of oxidant generation. Extracellularly produced oxidants can damage the membrane before reaching the cytosolic protective mechanisms. Oxidants that are generated intracellularly in coupled reactions with OxyHb tend to produce more Hb injury than membrane injury. Hb has been described as a "frustrated" oxidase, because it potentiates the generation of oxidants by a variety of drugs (Carrell *et al.*, 1977).

1. Methemoglobin Formation

Although MetHb formation is reversible and does not enhance RBC destruction per se, it is a component of oxidative injury to RBCs and is generally involved as a step in Heinz body (HzB) formation. Clinical signs associated with methemoglobinemia are the result of hypoxia because MetHb cannot bind O_2. Lethargy, ataxia, and semistupor do not become apparent until MetHb content reaches 50%, with a comalike state and death ensuing when it reaches 80% (Bodansky, 1951). The cyanotic appearance of mucous membranes associated with this condition may not be easily recognized in heavily pigmented animals. MetHb content is quantified spectrophotometrically, but a spot test can be used to determine if clinically significant levels of MetHb are present. One drop of blood from the patient is placed on a piece of absorbent white paper and a drop of normal control blood is placed next to it. If the MetHb content is 10% or greater, the patient's blood should have a noticeably brown coloration.

Approximately 3.0% of Hb is spontaneously oxidized to MetHb each day in normal people (Mansouri and Lurie, 1993) and dogs (Harvey *et al.*, 1991). This formation results from spontaneous autoxidation of OxyHb and possibly secondarily in response to oxidants produced in normal metabolic reactions.

While the iron moiety of DeoxyHb is in the ferrous state, in OxyHb it exists in (or near) the ferric state, with an electron being transferred to the O_2 molecule to give a bound superoxide (O_2^-) ion (Mansouri and Lurie, 1993). During deoxygenation, the electron returns to the iron moiety and O_2 is released. Autoxidation to MetHb with the release of O_2^- occurs when the bound O_2^- is replaced by a nucleophile such as Cl^- (Wallace *et al.*, 1974).

Rather than extracting electrons, oxidant drugs often produce MetHb by donating electrons to OxyHb (Carrell *et al.*, 1977) as is shown here for phenylhydroxylamine (PHA):

$$Hb^{3+}{\cdots}O_2^- + PHA \rightarrow Hb^{3+}{\cdots}O_2^{2-} + PHA^{\cdot},$$
$$Hb^{3+}{\cdots}O_2^{2-} + 2H^+ \rightarrow Hb^{3+} + H_2O_2.$$

Drug free radicals, such as $PHA^{\cdot}$, that are generated can donate the unpaired electron to molecular oxygen to form superoxide or to another OxyHb molecule to form more MetHb and H_2O_2. To achieve greater stability, free radicals may also extract electrons by oxidizing SH groups of Hb, enzymes, membrane proteins, or GSH, by oxidizing membrane unsaturated fatty acids,

by oxidizing NADPH or NADH, and possibly by extracting an electron from DeoxyHb to form MetHb.

Oxidants such as copper appear to oxidize Hb by extracting electrons. Cupric ions oxidize the reactive SH group on the beta chains of human and animal Hbs (Taketa and Antholine, 1982), and then an electron is transferred from heme iron to regenerate the SH group. Cupric ion is regenerated by interaction with oxygen. The series of reactions by which copper catalyzes Hb oxidation to MetHb (Carrell *et al.*, 1978) is as follows:

$$Cu^{2+} + Fe^{2+}S^{-} \rightarrow Cu^{1+} + Fe^{2+}S^{\cdot},$$
$$Fe^{2+}S^{\cdot} \rightarrow Fe^{3+}S^{-},$$
$$Cu^{1+} + O_2 \rightarrow Cu^{2+} + O_2^{-}.$$

These reactions occur rapidly but continue only until about 50% of total hemes are oxidized because α chains are resistant to oxidation (Taketa and Antholine, 1982). Additional oxidative reactions involving copper can denature Hb and damage membranes (Hochstein *et al.*, 1978).

Nitrite produces MetHb without HzB formation or anemia in animals. Methemoglobinemia occurs in ruminants eating nitrate-accumulating plants, especially when the plants have been fertilized with nitrogenous compounds. Nitrate is relatively nontoxic, but it is reduced to nitrite by ruminal microorganisms (Burrows, 1980). The reactions involved in MetHb formation in the presence of nitrite are complex; superoxide appears to be involved (Doyle *et al.*, 1982; Tomoda *et al.*, 1981). Methemoglobinemia can occur in animals following the topical application of benzocaine-containing products to skin (Harvey *et al.*, 1979; Wilkie and Kirby, 1988), or in laryngeal (Krake *et al.*, 1985) or nasopharyngeal sprays (Davis *et al.*, 1993; Lagutchik *et al.*, 1992). Benzocaine appears to have only a limited ability to produce other forms of RBC injury.

Many compounds can produce MetHb (Bodansky, 1951), and most of them also produce variable degrees of Hb denaturation and membrane injury. Following exposure to oxidants, MetHb forms within minutes, but HzB take hours to form. If the oxidant is rapidly metabolized, MetHb content will generally be reduced to values approaching normal within 24 hours (Harvey and Keitt, 1983).

2. *Heinz Body Formation*

Heinz bodies are composed of oxidized denatured Hb. They are often not recognized on routinely stained blood films, because they either are not stained or stain similarly to the remaining intact Hb. If they are of sufficient size (1–2 μm), they may appear as pale inclusions within RBCs or as nipple-like projections from the surface of RBCs. Heinz bodies can be visualized as dark, refractile inclusions in new methylene blue "wet" preparations and as light blue inclusions with reticulocyte stains (Jain, 1986).

The following sequence of biochemical events leading to HzB formation is proposed (Allen and Jandl, 1961; Chiu and Lubin, 1989; Hebbel and Eaton, 1989; Low, 1989): (1) Ferrohemes are oxidized to ferrihemes (MetHb); (2) SH groups of Hb are oxidized, causing conformational changes in globin chains and resultant hemichrome formation (hemichromes have both the ferric iron's fifth and sixth coordinate positions occupied by a ligand provided by the globin chain); (3) hemichromes bind to band 3 and to a lesser degree other membrane components, forming clusters of copolymers; and (4) the precipitation of these denatured Hb molecules results in HzB formation. Precipitation is potentiated by the dissociation of the ferriheme (hemin) moieties from the hemichromes because the resultant free globin chains are unstable.

Hemolytic anemias associated with HzB formation in domestic animals have resulted from a variety of compounds. Dietary causes include consumption of onions by cattle (Lincoln *et al.*, 1992), sheep (Kirk and Bulgin, 1979; Verhoeff *et al.*, 1985), horses (Pierce *et al.*, 1972), cats (Kobayashi, 1981), and dogs (Harvey and Rackear, 1985; Ogawa *et al.*, 1986) and consumption of kale and other *Brassica* species by ruminants (Greenhalgh *et al.*, 1969; Smith, 1980; Suttle *et al.*, 1987). Three novel thiosulfates have been identified as causative factors in onion extracts (Yamato *et al.*, 1994). In the case of *Brassica* species, the hemolytic factor is reported to be dimethyl disulfide, produced by the action of rumen microbes on *S*-methylcysteine sulfoxide contained within the plants (Smith, 1980).

Heinz bodies hemolytic anemia occurs in Florida in cattle grazing on lush rye (*Secale cereale*) pastures in the winter (Simpson and Anderson, 1980) and in selenium-deficient cattle grazing on St. Augustine grass pastures in the summer (Morris *et al.*, 1984). The nature of oxidants involved is unknown. Methemoglobinemia, HzB formation, severe intravascular hemolysis, and death have followed the consumption of red maple leaves by horses (George *et al.*, 1982; Tennant *et al.*, 1981). Dried leaves are toxic, but freshly harvested leaves are not.

Postparturient hemoglobinuria with HzB formation occurs in cattle in New Zealand grazing primarily on perennial ryegrass (*Lolium perenne*) (Martinovich and Woodhouse, 1971). Postparturient cattle may be more susceptible to the development of anemia because increased food consumption associated with lactation could increase exposure to an unidentified dietary oxidant. Both hypocuprosis (Gardner *et al.*, 1976) and hy-

pophosphatemia (Jubb *et al.*, 1990) have been considered to contribute to the severity of the anemia in these cattle. An apparently different syndrome of postparturient hemoglobinuria has also been reported in hypophosphatemic cattle of North America (MacWilliams *et al.*, 1982). Heinz bodies have not been reported in affected animals, and the anemia appears to develop because affected animals have decreased RBC ATP concentrations (Ogawa *et al.*, 1987, 1989).

Methemoglobinemia and HzB hemolytic anemia occur acutely when large amounts of copper are released from the liver of ruminants that have accumulated excessive amounts of liver copper secondary to increased dietary intake (Brewer, 1987; Kerr and McGavin, 1991; Soli and Froslie, 1977). Zinc toxicity has primarily resulted from the consumption and retention of zinc-containing objects within the stomach of dogs. Sources of zinc include U.S. pennies minted after 1982, metallic hardware, and ointment containing zinc oxide (Breitschwerdt *et al.*, 1986). The mechanism(s) by which zinc produces hemolytic anemia is unclear, but HzB have been recognized in some clinical cases (Houston and Myers, 1993; Luttgen *et al.*, 1990).

Clinical cases of HzB hemolytic anemias have occurred following the administration of a variety of drugs including methylene blue in cats (Schechter *et al.*, 1973) and dogs (Fingeroth and Smeak, 1988; Osuna *et al.*, 1990), phenazopyridine in a cat (Harvey and Kornick, 1976), acetaminophen in cats (Finco *et al.*, 1975; Gaunt *et al.*, 1981; Hjelle and Grauer, 1986) and dogs (Harvey *et al.*, 1986; Houston and Myers, 1993), methionine in cats (Maede *et al.*, 1987), menadione (vitamin K_3) in dogs (Fernandez *et al.*, 1984), and phenothiazine in horses (McSherry *et al.*, 1966). Of these drugs, acetaminophen and phenazopyridine also produce clinically significant methemoglobinemia. A variety of additional oxidants produce HzB hemolytic anemias experimentally in animals (Fertman and Fertman, 1955).

Cats are generally recognized as the species most susceptible to HzB formation. Although species differences in metabolism and excretion of various drugs may partially account for this increased susceptibility, cat Hb generally appears more susceptible to oxidative denaturation than do Hbs of other species (Harvey and Kaneko, 1976b). The presence of 8–10 reactive SH groups per Hb tetramer in cat Hb may render it more susceptible to oxidation (Mauk and Taketa, 1972); apparently no other species has more than 4 reactive SH groups per tetramer (Snow, 1962).

Heinz bodies are rarely recognized in RBCs from most species, but are frequently present in cat RBCs because of the susceptibility of cat Hb to form HzB, combined with a poor ability of the cat spleen to remove HzB from RBCs (Jain, 1986) Even normal cats may have low numbers of HzB (<5%), and increased HzB numbers have been seen in kittens fed fish-based diets (Hickman *et al.*, 1990) and in cats fed commercial soft-moist diets containing propylene glycol (Christopher *et al.*, 1989; Hickman *et al.*, 1990). Increased HzB numbers have also been documented in cats with diabetes mellitus, hyperthyroidism and lymphoma (Christopher, 1989). Diabetic cats with ketoacidosis have more HzB and lower PCV than do nonketotic diabetic cats (Christopher *et al.*, 1995). Although RBC survival tends to be shortened, anemia is either absent or mild in the conditions mentioned. The oxidative reactions involved in these conditions are not clearly defined.

3. *Membrane Injury*

Various types of oxidant-induced membrane injury have been recognized. These include oxidation of membrane SH groups, lipid peroxidation, cross-linking of spectrin, inhibition of enzymes and membrane transport systems, and band 3 clustering. Damaged cells exhibit increased membrane rigidity, decreased deformability, and impaired ability to maintain ion gradients (Chiu and Lubin, 1989). The relative importance of HzB formation, hemin release, and the generation of various free radicals remains to be clarified.

The binding of HzB to the inner surface of the RBC membrane and clustering of band 3 and other components alter the normal membrane organization. Potential negative effects include weakening or disruption of the cytoskeleton, altered distribution of membrane phospholipids, altered cell surface charges, and formation of abnormal external cell surface antigens that can be recognized by autologous antibodies (Low, 1989). Heinz bodies cause focal membrane rigidity but do not affect global cellular deformability until they nearly cover the entire internal surface of RBCs (Reinhart *et al.*, 1986).

Hemin released during HzB formation binds to and causes damage to RBC membranes. Evidence has been presented that hemin can mediate the dissociation of RBC cytoskeletal proteins, impair the ability of the RBC membrane to maintain ionic gradients, oxidize membrane sulfhydryl proteins, and potentiate peroxide-induced membrane lipid peroxidation (Chiu and Lubin, 1989; Hebbel and Eaton, 1989; Jarolim *et al.*, 1990). The molecular mechanism(s) has not been clearly defined, but hemin may exert its toxic effects via catalysis of the formation of reactive oxygen species (Vincent, 1989).

Oxidative injury to RBC membranes is sometimes recognized by the appearance of eccentrocytes in stained blood films. These cells have been reported to occur in horses (Reagan *et al.*, 1994) and dogs (Ham *et al.*, 1973; Harvey *et al.*, 1986; Harvey and Rackear, 1985) exposed to exogenous oxidants and in a G6PD-deficient horse with inadequate metabolic protection against endogenous oxidants (Stockham *et al.*, 1994). Denatured spectrin dimers and tetramers are believed to be of primary importance in this cross bonding of membranes (Fischer, 1988; Arese and De Flora, 1990).

4. Erythrocyte Destruction

Following extreme oxidative injury, RBCs may lyse within the circulation. Hemoglobinuria occurs if intravascular hemolysis is of sufficient magnitude to saturate the haptoglobin-binding capacity of plasma and exceed the ability of renal tubules to reabsorb filtered Hb. In most cases, however, enhanced RBC destruction results primarily from increased phagocytosis of injured RBCs by macrophages of the spleen, liver, and bone marrow.

Of the organs of the mononuclear phagocyte system, the spleen is most adept at recognizing and removing damaged RBCs. In most species, RBCs must pass through narrow slits between endothelial cells lining venous sinus walls of the spleen to reenter the general circulation. As a consequence, oxidant-induced decreased RBC deformability tends to result in sequestration of RBC in the splenic reticular meshwork, thereby enhancing the likelihood of phagocytosis by resident macrophages (Baerlocher *et al.*, 1994; Weiss, 1984).

When HzB are larger than openings in walls of splenic venous sinuses, they are retained within the trabecular meshwork of the spleen. The whole cell may be phagocytosed, or the HzB and closely associated membrane may be removed. The remainder of the RBC reseals and passes through the sinus wall. This removal of HzB is the so-called pitting function of the spleen (Weiss, 1984). Cat spleens have poor pitting capabilities (Jain, 1986) owing to the presence of large openings in venous sinus walls (Blue and Weiss, 1981).

Macrophages can recognize damaged RBCs by antibody-dependent and by antibody-independent mechanisms; however, the relative importance of the different mechanisms remains to be defined. Macrophages do not recognize less-deformable cells per se, but phagocytose them at a higher rate because of their slower transit time or entrapment in the spleen as discussed earlier (Baerlocher *et al.*, 1994).

The cross-linking of band 3 molecules by hemichromes during oxidative denaturation of Hb results in clustering of band 3 molecules and greatly enhanced binding of autologous IgG (Low, 1991). Because macrophages contain Fc receptors on their surfaces, the damaged RBCs would presumably become bound to the surface of macrophages once a sufficient number of clusters of band 3 had formed. Sheep with chronic copper toxicity may become direct Coombs' test positive, indicating a possible *in vivo* role of antibody-mediated removal of oxidatively injured RBCs (Wilhelmsen, 1979).

Macrophages contain antibody-independent scavenger receptors that can bind to oxidized lipoproteins, anionic phospholipids, polysaccharides, and polyribonucleotides (Sambrano *et al.*, 1994). Evidence has been presented to indicate that at least two different scavenger receptors may be involved in the recognition and phagocytosis of oxidatively damaged RBCs. Macrophages can bind to altered membrane glycoproteins via a sialosaccharide receptor (Beppu *et al.*, 1994) and to altered lipid-protein conjugates via a receptor with specificity for oxidized low-density lipoproteins (Sambrano *et al.*, 1994).

B. Erythrocyte Aging and Normal Lifespans

Most RBCs circulate in blood for a finite period (survival time or lifespan) that varies from 2 to 5 months in domestic animals, depending on the species (Table 7.1). Methods for measurement of RBC lifespans and results of lifespan determinations from many species have been compiled by Vacha (1983). RBC lifespans are related to body weight (and consequently metabolic rate) with the smallest animals (highest metabolic rate) having the shortest RBC lifespans (Vacha, 1983). The RBC lifespan can be prolonged by reducing the metabolic rate within an individual animal. Examples include thyroidectomy in rats, hibernation in hibernating mammals, and reduced ambient temperatures in poikilotherms (Landaw, 1988). Various changes occur in RBCs as they get older (Kosower, 1993; Low, 1991), but the nature of the factor(s) that initiates age-related changes and the mechanism(s) of removal of senescent RBCs from the circulation require further clarification. Decreased membrane phospholipid asymmetry, modified membrane carbohydrate residues (e.g., desialation of sialoglycoproteins), and/or modified membrane proteins (e.g., partially degraded Band 3) are possible signals for removal (Kosower, 1993).

1. Metabolic Impairment

Because RBCs cannot synthesize new enzymes, one theory is that one or more critical enzymes (e.g., hexokinase), involved in generating ATP or in the protec-

tion against oxidants, may decrease to a point that metabolic impairment results in irreversible RBC membrane changes (Piomelli and Seaman, 1993). Although the inability to maintain normal ATP and NADPH concentrations appears to account for premature destruction of RBCs in patients with hereditary enzyme deficiencies of the EMP and PPP, respectively, the theory that metabolic impairment occurs as a result of age-related decreases in critical enzymes has been questioned (Beutler, 1985; Zimran *et al.*, 1990). Much of the decline in activities of enzymes, considered in the past to be correlated with RBC age, occurs as reticulocytes mature into RBCs. Even if metabolic impairment is not the primary factor responsible for RBC senescence, it may render the aged RBC vulnerable to events in the circulation that require a burst of metabolic activity (Piomelli and Seaman, 1993).

2. *Cumulative Oxidant Damage*

Current evidence indicates that cumulative oxidative injury is probably responsible for normal RBC aging and removal (Low, 1991; Seppi *et al.*, 1991). Even the decrease in RBC enzymes may be the result of oxidative damage (Stadtman, 1992). The presence of HzB in RBCs from splenectomized humans, horses, and dogs and in RBCs from nonsplenectomized cats (Jain, 1986; Low, 1989) provides evidence for ongoing oxidant injury *in vivo*. The inverse correlation discussed earlier between RBC lifespan and metabolic rate may result from differences in endogenous oxidant generation, but other factors such as differing amounts of mechanical stress should also be considered as a possible cause of this relationship (Landaw, 1988).

3. *Senescent Cell Antigen*

Although multiple mechanisms may be involved in the recognition and removal of aged RBCs, current evidence suggests that removal of senescent human RBCs is largely immune mediated, following the appearance of a senescent cell antigen (Kay, 1989). This senescent cell antigen is derived from the band 3 anion transporter. The specific alteration required for band 3 to become antigenic remains to be clarified, but oxidative mechanisms are probably involved. Low (1991) has demonstrated copolymerization between hemichromes and band 3 and has suggested that the senescent antigen represents clusters of band 3. In contrast, studies by Kay *et al.* (1989) suggest that the senescent cell antigen results from band 3 degradation rather than clustering.

A natural antibody against the senescent cell antigen is present in human plasma. This antibody binds to senescent cell antigens on the surface of aged cells and, together with bound complement, promotes the phagocytosis of aged RBCs by macrophages that exhibit Fc and C3b surface receptors (Lutz *et al.*, 1991). Increased autologous immunoglobulin binding also occurs on dog RBCs aged *in vivo*, indicating that a similar process likely occurs in this species (Christian *et al.*, 1993). The possibility that senescent RBCs can also be removed via binding to macrophage scavenger receptors requires further study (Sambrano *et al.*, 1994).

C. Anemia of the Newborn

Animals are generally born with PCVs near values for adults. Following birth, there is a rapid decrease in PCV that is followed by a gradual increase to adult values (Jain, 1986). Factors involved to variable degrees in the development of the anemia of the newborn include the following: (1) absorption of colostral proteins during the first day of life, which increases plasma volume through an osmotic effect (Harvey *et al.*, 1987; Mollerberg *et al.*, 1975); (2) decreased RBC production during the early neonatal period; (3) shortened lifespan of RBCs formed *in utero* (Kim and Luthra, 1977; Lee *et al.*, 1976; Mueggler *et al.*, 1979; Landaw, 1988); and (4) rapid growth with hemodilution resulting from expansion of total plasma volumes more rapidly than total RBC mass (Mueggler *et al.*, 1979).

In some species, production of RBCs is decreased because of low EPO concentrations at birth (Halvorsen and Halvorsen, 1974; Huisman *et al.*, 1969; Meberg, 1980; Meberg *et al.*, 1980; Schwartz and Gill, 1983). The decreased stimulus for EPO production may occur as a result of a placental blood transfusion that increases RBC mass immediately after birth (Rossdale and Ricketts, 1980), a rapid increase in pO_2 associated with breathing air, and an increase in P_{50} as discussed previously.

Much of the postnatal anemia of dogs occurs as a physiological response to increased RBC 2,3DPG and subsequent improved oxygen transport (Mueggler *et al.*, 1981). The "anemia" of childhood in humans is also associated with RBC 2,3DPG above adult values. In children this increase appears to occur secondarily to increased plasma P_i concentrations (Card and Brain, 1973). Serum P_i values are also above adult values in young dogs (Pickrell *et al.*, 1974).

Although not involved in the early, rapid decrease in PCV, iron availability may limit the response to anemia in some rapidly growing animals (Chausow and Czarnecki-Maulden, 1987; Dhindsa *et al.*, 1971; Harvey *et al.*, 1987; Holman and Drew, 1966; Mollerberg *et al.*, 1975; Siimes *et al.*, 1980; Weiser and Kociba, 1983b).

VI. INHERITED DISORDERS OF ERYTHROCYTES

Many hereditary disorders of RBCs have been described in humans (Dacie, 1985). A limited number of inherited RBC disorders have been identified in laboratory and domestic animals (Kaneko, 1987; Smith, 1981). Congenital porphyrias are discussed elsewhere in this volume (Chapter 8).

A. Cytosolic Enzyme Deficiencies

1. Phosphofructokinase Deficiency in Dogs

Autosomal recessive inherited PFK deficiency occurs in English springer spaniel (Giger *et al.*, 1985; Giger and Harvey, 1987) and American cocker spaniel (Giger *et al.*, 1992) dogs. Canine PFK is genetically controlled by three separate loci. They code for muscle- (M), liver- (L), and platelet- (P) type subunits (Vora *et al.*, 1985). Random tetramerization of the subunits produces various isozymes. PFK in normal dog RBCs consists of 86% M-type, 2% L-type, and 12% P-type subunits and normal dog muscle is composed exclusively of M-type subunits (Mhaskar *et al.*, 1992).

A point mutation is reported to occur in the M-type gene of deficient dogs, causing a loss of amino acids from the carboxyl terminus of the polypeptide (Giger *et al.*, 1991c). Studies of brain and RBCs from homozygous deficient dogs indicated that native M-type subunits were not present, but small amounts of a structurally unstable truncated M-type subunit were found (Mhaskar *et al.*, 1991, 1992). As would be expected from the subunit composition of normal tissues, total RBC and muscle PFK activities are markedly reduced in affected dogs (Giger and Harvey, 1987; Vora *et al.*, 1985). Changes in concentrations of glycolytic intermediates in muscle and RBCs reflect the block at the PFK step (Harvey *et al.*, 1992a, 1992b). RBCs from affected dogs also exhibit altered enzyme kinetic properties due to the loss of the M-type subunit (Harvey *et al.*, 1992b).

Homozygously affected dogs have persistent compensated hemolytic anemias and sporadic episodes of intravascular hemolysis with hemoglobinuria (Giger *et al.*, 1985; Giger and Harvey, 1987). RBC mean cell volumes are usually between 80 and 90 fl. Reticulocyte counts are generally between 10 and 30%, with hematocrit values between 30 and 40% (Harvey and Smith, 1994), except during hemolytic crises when the hematocrit may decrease to 15% or less. Lethargy, weakness, pale or icteric mucous membranes, mild hepatosplenomegaly, muscle wasting, and fever as high as 41°C may occur during hemolytic crises (Giger and Harvey, 1987).

Hemolytic crises occur secondarily to hyperventilation-induced alkalemia *in vivo,* and PFK-deficient dog RBCs are extremely alkaline fragile *in vitro* (Giger and Harvey, 1987). For unknown reasons, normal dog RBCs are more alkaline fragile than those of humans and other mammals studied (Iampietro *et al.*, 1967; Waddell, 1956). The even greater alkaline fragility of PFK-deficient dog RBCs results from decreased 2,3DPG, which is formed below the PFK reaction (Harvey *et al.*, 1988). Because 2,3DPG is the major impermeant anion in dog RBCs, a substantial decrease in its concentration results in a higher intracellular pH (Hladky and Rink, 1977) and thereby greater alkaline fragility than normal dog RBCs. As expected, the low 2,3DPG concentration also results in an increased oxygen affinity of Hb in affected dog RBCs (Giger and Harvey, 1987).

Hematologic parameters of affected dogs are similar to normal dogs at birth, because all newborn dogs have RBC PFK activities about three times that of normal adult dogs (Harvey and Reddy, 1989). This high PFK activity results from the presence of the L-type subunit of PFK, which is negligible in normal adult canine RBCs (Harvey and Reddy, 1989; Mhaskar *et al.*, 1992). Both total PFK activities and the amounts of L-type subunit present decrease dramatically during the first 6 to 8 weeks of life. The M-type subunit is low at birth, but increases as the L-type decreases in normal dogs. These changes result from the replacement of RBCs formed in the fetus with those formed after birth.

Deficient dogs generally exhibit less evidence of myopathy than is observed in PFK-deficient people, probably because canine skeletal muscle is less dependent on anaerobic glycolysis than human skeletal muscle, owing to a lack of the classical fast-twitch glycolytic (type IIB) fibers in dogs (Snow *et al.*, 1982). Affected dogs appear to tire more easily than normal, and *in vivo* muscle studies of PFK-deficient dogs indicate altered muscle function in these animals (Brechue *et al.*, 1994; Giger *et al.*, 1988b). A severe progressive myopathy with associated abnormal polysaccharide deposits in skeletal muscle has been recognized in an aged PFK-deficient dog (Harvey *et al.*, 1990a). In contrast to PK deficiency, myelofibrosis and liver failure have not been recognized in dogs with PFK deficiency.

Homozygous affected animals over 3 months of age can easily be identified by measuring RBC PFK activity. Heterozygous carrier dogs have approximately one-half normal enzyme activities in RBCs (Harvey and Reddy, 1989). A DNA test using polymerase chain reaction technology has been developed that can clearly differentiate normal, carrier, and affected dogs regardless of age (Giger *et al.*, 1995b).

2. *Pyruvate Kinase Deficiency in Dogs and Cats*

PK deficiency occurs in basenji (Giger and Noble, 1991; Searcy *et al.*, 1971, 1979), beagle (Giger *et al.*, 1991b; Harvey *et al.*, 1977; Prasse *et al.*, 1975), West Highland white terrier (Chapman and Giger, 1990), cairn terrier (Schaer *et al.*, 1992), and American Eskimo dogs (Harvey, 1994), and Abyssinian cats (Ford *et al.*, 1992). PK deficiency is transmitted as an autosomal recessive trait. Homozygously affected animals have decreased exercise tolerance, pale mucous membranes, tachycardia, and splenomegaly.

Affected animals have mild to severe anemia with marked reticulocytosis. An unexplained feature of the disease in dogs is the progressive development of myelofibrosis and osteosclerosis. Affected dogs generally die by 3 years of age because of bone marrow failure and/or liver disease with hemochromatosis and subsequent cirrhosis (Searcy *et al.*, 1979; Weiden *et al.*, 1981).

RBCs of affected dogs lack the normal adult R isozyme of PK but have a persistence of an M_2 isozyme that normally predominates in fetal RBCs (Black *et al.*, 1978; Whitney *et al.*, 1994). Consequently, many affected dogs have normal or increased PK activity, making it difficult to diagnose this defect based solely on total RBC PK activity. In contrast, total RBC PK activity is markedly reduced in cats, with no evidence of a persistent M_2 isozyme (Ford *et al.*, 1992). Heterozygous animals have approximately 50% of normal RBC PK activity.

The enzyme activity in hemolysates of affected dogs is unstable and decreases rapidly when samples are kept at room temperature (Standerfer *et al.*, 1974). If the M_2-isozyme is unstable *in vivo*, as it is *in vitro*, its rapid loss of activity would explain the dramatically shortened lifespan of RBCs in this disorder (Dhindsa *et al.*, 1976).

Additional assays (an enzyme heat stability test, measurement of RBC glycolytic intermediates, electrophoresis of isozymes, and enzyme immunoprecipitation) may be used to reach a diagnosis of PK deficiency in dogs where the total enzyme activity is not decreased (Giger and Noble, 1991; Harvey *et al.*, 1990b; Schaer *et al.*, 1992). The defect in basenji dogs is the result of a single nucleotide deletion in the R-type PK gene (Whitney *et al.*, 1994). A DNA diagnostic test has recently been developed for basenji dogs (Whitney and Lothrop, 1995). Thus far, this test has not been valid in other dog breeds, indicating that the defect is not identical in all breeds.

Because the defect in glycolysis occurs below the diphosphoglycerate shunt, RBCs from PK-deficient dogs have increased concentrations of 2,3DPG. As a consequence, the whole blood P_{50} is higher than that of normal dogs (Dhindsa *et al.*, 1976).

3. *Glucose-6-Phosphate Dehydrogenase Deficiency in a Dog and Horse*

G6PD deficiency is a very common X-linked inherited defect of human RBCs, affecting millions of people worldwide (Beutler, 1994). Smith *et al.* (1976) screened more than 3000 dogs for G6PD activity and found one male dog to have approximately 44% of normal activity. The enzyme was partially purified and characterized, and it was found to be similar to that of normal dogs. The deficient dog was not anemic and exhibited no clinical signs; studies were not done to determine if his RBCs were more sensitive to oxidant damage than normal.

In contrast, a persistent hemolytic anemia and hyperbilirubinemia has been described in an American saddlebred colt with <1% of normal G6PD activity (Stockham *et al.*, 1994). Morphologic abnormalities of RBCs included eccentrocytosis, pyknocytosis, increased anisocytosis, and increased Howell–Jolly bodies. The presence of eccentrocytes in the absence of exposure to external oxidants indicated that the deficient RBCs did not have adequate metabolic capabilities to defend themselves against endogenous oxidants. Biochemical abnormalities in RBCs included low GSH, markedly reduced NADPH, and increased $NADP^+$. RBC catalase activity was normal even though NADPH concentration was <1% of normal. It was suggested that catalase activity may have been maintained by the action of NADH. Polymerase chain reaction amplification of segments of the G6PD gene of the affected colt revealed a G to A mutation, converting an arginine codon to a histidine codon (Nonneman *et al.*, 1993).

4. *Cytochrome-b_5 Reductase (NADH-Methemoglobin Reductase) Deficiency in Dogs and a Cat*

Persistent methemoglobinemia associated with Cb_5R deficiency has been recognized in a Chihuahua, a borzoi, an English setter, a terrier mix, a cockapoo, a Welsh corgi, miniature poodles, pomeranians, and in toy American Eskimo dogs (Atkins *et al.*, 1981; Harvey *et al.*, 1974, 1991; Letchworth *et al.*, 1977), and in a domestic short-haired cat (Harvey *et al.*, 1994). Several types of enzymatic hereditary methemoglobinemia have been recognized in people (Jaffe, 1986), but the exact nature of the defect(s) and the possibility that cell types in addition to RBCs might be deficient in activity have not been reported in animals. The deficiency is presumed to be a hereditary disorder, but family studies have not been reported.

Affected animals have cyanotic-appearing mucous membranes and may exhibit lethargy or exercise intolerance at times, but they usually have no clinical signs of disease. Blood samples appear dark, suggesting

hypoxemia, but arterial pO_2 values are normal. MetHb content in dogs with Cb_5R deficiency varies from 13 to 41%. The MetHb content in the deficient cat was 50%. An inverse correlation appears to exist between RBC enzyme activity and MetHb content (Harvey *et al.*, 1991). The PCV is sometimes slightly increased secondary to the chronic methemoglobinemia. Animals with Cb_5R deficiency do not require treatment and have normal life expectancy.

5. Gamma-Glutamylcysteine Synthetase Deficiency in Sheep

An autosomal dominant inherited deficiency in RBC GSH in Corriedale and Merino sheep results from low levels of gamma-glutamylcysteine synthetase (GCS), the first enzyme involved in GSH synthesis (Fisher *et al.*, 1986; Smith *et al.*, 1973). Although the specific activity of the enzyme is low, the molecular weight, K_m values for glutamate and cysteine, K_i for GSH, and other characteristics of purified GCS from deficient sheep are remarkably similar to those from normal sheep (Board *et al.*, 1980). Deficient sheep have only about 20–30% of normal RBC GSH but exhibit no clinical signs, are not anemic, and have normal RBC lifespans (Smith *et al.*, 1973). Although RBCs from these low-GSH sheep do not appear to have greater susceptibility to injury by superoxide or hydrogen peroxide than do RBCs from high-GSH sheep (Eaton *et al.*, 1989), they do exhibit greater HzB formation when exposed to acetylphenylhydrazine *in vitro* (Goto *et al.*, 1993) and kale feeding *in vivo* (Tucker *et al.*, 1981).

B. Membrane Abnormalities

1. Amino Acid Transport Deficiency in Sheep and Horses

A second type of GSH deficiency, inherited as an autosomal recessive trait, occurs in Finnish Landrace sheep (Tucker and Kilgour, 1970). Although affected animals are not anemic, the lifespan of deficient RBCs is shortened (Tucker, 1974), possibly from increased oxidant injury as evidenced by the presence of HzB (Tucker *et al.*, 1981). These sheep are more likely to become anemic following the administration of oxidants *in vivo* (Tucker *et al.*, 1981).

The amino acid transporter normally responsible for cysteine transport (system C) into RBCs is defective (Young *et al.*, 1975), thereby limiting cysteine uptake and restricting GSH synthesis. As a consequence, GSH concentrations in RBCs are about 30% of normal (Young *et al.*, 1975). Intracellular Na^+ and K^+ are decreased, because dibasic and other amino acids accumulate in this disorder (Ellory *et al.*, 1972). The transport deficiency appears to develop during reticulocyte maturation, and intracellular amino acids appearing in these cells are believed to come from protein degradation during reticulocyte maturation (Tucker and Young, 1980). When RBCs are separated by age, using density gradients, intracellular GSH decreases and HzB numbers increase in older RBCs from system C-deficient sheep but not from normal or GCS-deficient sheep (Tucker and Young, 1980). This decreasing GSH with RBC age may explain why system C-deficient sheep are more susceptible to oxidants than are GCS-deficient ones, even though they have similar whole blood GSH levels.

About 30% of thoroughbred horses and 3% of ponies are deficient in a similar amino acid transporter. The lesion results in increased amino acid levels and GSH deficiency in some cases (Fincham *et al.*, 1985).

2. High Membrane Na^+, K^+-ATPase Activity in Dogs

Although dog reticulocytes have considerable membrane Na^+, K^+-ATPase (Na^+, K^+-pump) activity, it is rapidly lost during maturation into mature RBCs in most dogs (Maede and Inaba, 1985). Consequently, RBCs from most dogs have low potassium concentrations owing to the absence Na^+, K^+-pump activity (Parker, 1977). However, some Japanese mongrel dogs, some Japanese Akita dogs, and some Japanese Shiba dogs have HK^+ RBCs, because the Na^+, K^+-pump is retained in mature RBCs (Degen, 1987; Maede *et al.*, 1983, 1991). This trait is inherited in an autosomal recessive manner. RBCs from these dogs also have high GSH, glutamate, glutamine, and aspartate concentrations secondary to increased glutamate and aspartate uptake. GSH concentration is increased 5–7 times normal because the feedback inhibition of GCS by GSH is released by the approximately 90 times normal glutamate concentration (Maede *et al.*, 1982).

Dog RBCs have a high affinity Na^+-dependent transport system for glutamate and aspartate (Young, 1983). The increased transport of these amino acids into RBCs of affected dogs apparently occurs as a consequence of the Na^+ and K^+ concentration gradients produced by the presence of a Na^+, K^+-ATPase activity three times higher than that of human RBCs (Inaba and Maede, 1984). The glycolytic rate of HK^+ dog RBCs is about twice that of LK^+ cells, because greater ATP production is required to provide energy for active cation transport by the Na^+, K^+-pump and for increased GSH synthesis (Maede and Inaba, 1987).

HK^+ dog RBCs have increased osmotic fragility, increased MCV, decreased MCHC, and normal MCH values, suggesting an increase in cell water (Maede *et al.*, 1983). Although dogs with HK^+ RBCs are not anemic, their RBCs have shortened lifespans (Maede and Inaba, 1987), and some dogs have slightly increased

reticulocyte counts (Maede *et al.*, 1983). Clinically these dogs appear normal.

The high GSH concentration in the HK^+ dog RBCs provides increased protection against oxidative damage induced by acetylphenylhydrazine (Ogawa *et al.*, 1992), but increased susceptibility to oxidative damage induced by onions (Yamoto and Maede, 1992) and 4-aminophenyl disulfide (Maede *et al.*, 1989). Evidence suggests that the increased GSH concentration potentiates the generation of superoxide through its redox reaction with the aromatic disulfide. It is not known whether a similar redox reaction occurs between GSH and the thiosulfates present in onions (Yamato *et al.*, 1994).

A variant of this HK^+ RBC disorder has been reported that lacks GSH accumulation (Fujise *et al.*, 1993). It was suggested that these dogs had a defect in amino acid metabolism in addition to the persistence of the Na^+, K^+-pump.

3. Hereditary Stomatocytosis in Dogs

Stomatocytes are cup-shaped RBCs that have slitlike areas of central pallor on stained blood films. Stomatocytosis is recognized in association with three different inherited syndromes in dogs. All disorders appear to be transmitted as autosomal recessive traits.

No clinical signs occur in miniature schnauzers with stomatocytosis (Brown *et al.*, 1994b; Giger *et al.*, 1988a). Chondrodysplasia (short-limbed dwarfism) occurs along with stomatocytosis in Alaskan malamutes (Fletch *et al.*, 1975; Pinkerton *et al.*, 1974). This disorder is deforming but not life threatening. The syndrome in Drentse patrijshond dogs has been termed familial stomatocytosis–hypertrophic gastritis (Slappendel *et al.*, 1991). Affected animals have polysystemic disease with growth retardation, diarrhea, polyuria/polydipsia, hind limb weakness, pale and/or icteric mucous membranes, and a somnolent mental state. Pathologic findings include hypertrophic gastritis, progressive liver disease, polyneuropathy, and renal cysts. Affected Drentse patrijshond dogs are usually euthanized by the time they reach young adulthood because of a progressive deterioration in clinical condition.

Hb values and RBC counts are slightly reduced, but PCVs are normal in malamutes (Fletch *et al.*, 1975; Pinkerton *et al.*, 1974) and schnauzers (Brown *et al.*, 1994b; Giger *et al.*, 1988a). The MCV is markedly increased and MCHC moderately decreased even though reticulocyte counts are normal or only slightly increased. Affected Drentse patrijshond dogs have lower PCVs and higher reticulocyte counts than those found in the other breeds (Slappendel *et al.*, 1991, 1994). The MCHC is moderately decreased, but the MCV is normal or only slightly increased. RBCs from all breeds have increased osmotic fragility and shortened RBC survival.

The pathogenesis of stomatocyte formation in malamutes and schnauzers is attributed to an increase in monovalent cation, and consequently water content of RBCs caused by abnormal membrane permeability (Giger *et al.*, 1988a; Pinkerton *et al.*, 1974). The swelling associated with water accumulation accounts for the markedly increased MCV and decreased MCHC values. The GSH content in affected RBCs is about 50–60% of normal (Giger *et al.*, 1988a; Pinkerton *et al.*, 1974). This GSH deficiency appears to occur from increased catabolism, but the mechanism responsible is unknown (Smith *et al.*, 1983b).

In contrast to malamutes and schnauzers with stomatocytosis, RBCs from affected Drentse patrijshond dogs do not have increased total monovalent cations and cell water is only slightly increased; consequently stomatocyte formation appears to be caused by a different mechanism (Slappendel *et al.*, 1994). The composition of phospholipids and cholesterol in plasma and RBC membranes is abnormal in these dogs (Slappendel *et al.*, 1994). The authors suggest that a defect in lipid metabolism results in altered membrane lipid composition and a loss or contracture of membrane components.

Hereditary stomatocytosis appears to be a heterogeneous group of disorders in people as well (Pinkerton *et al.*, 1974). A deficiency of a specific band 7 integral membrane protein has been reported in people with hereditary stomatocytois associated with high RBC cation content. This band 7 protein may function in closing a latent ion channel (Eber *et al.*, 1989; Stewart, 1993).

4. Hereditary Elliptocytosis in Dogs

Persistent elliptocytosis and microcytosis has been described in a crossbred dog that lacked RBC membrane band 4.1 (Smith *et al.*, 1983a). Although the animal was not anemic, the reticulocyte count was about twice normal in compensation for a shortened RBC lifespan. This dog was an offspring of a father–daughter mating. Both parents had decreased band 4.1 and some elliptocytes. This disorder in dogs resembles that in human patients with band 4.1 deficiency (Dacie, 1985).

C. Miscellaneous Abnormalities

1. Familial Nonspherocytic Hemolytic Anemia in Poodles

A nonspherocytic hemolytic anemia occurs in poodles (Randolph *et al.*, 1986). An autosomal dominant with incomplete penetrance mode of transmission was suggested. Affected animals had severe persistent mac-

rocytic hypochromic anemia (PCVs 13–31%) with marked reticulocytosis. As in dogs with PK deficiency, myelofibrosis, osteosclerosis, and excess iron deposition in hepatocytes and mononuclear phagocytes were observed at necropsy. One dog died when 2.5 years old with liver failure. Despite extensive studies, the defect in this disorder could not be determined.

2. *Hereditary Nonspherocytic Hemolytic Anemia in Beagles*

A mild hemolytic anemia with reticulocytosis, slightly increased RBC osmotic fragility, shortened RBC lifespan and normal RBC morphology has been reported in beagle dogs (Maggio-Price *et al.*, 1988). Studies of RBC enzymes, membrane protein electrophoresis and Hb failed to identify a defect. Decreased calcium pump ATPase activity (Hinds *et al.*, 1989) and accelerated RBC swelling under osmotic stress (Pekow *et al.*, 1992) have been reported in RBCs from anemic dogs, but these abnormalities may be the consequence of an unknown membrane defect, rather than representing primary abnormalities. Although the etiology remains elusive, this abnormality appears to be transmitted as an autosomal recessive trait.

3. *Familial Methemoglobinemia and Hemolytic Anemia in Horses*

Methemoglobinemia and mild to moderate hemolytic anemia have been reported in a trotter mare and her dam (Dixon and McPherson, 1977). The animals were examined because of poor performance. GSH values were about 50% of normal and GR activities were 25–50% that of normal RBCs. The GR deficiency was not the result of riboflavin deficiency. It is unclear how these abnormalities in GSH and GR are related to the pathogenesis of this disorder. In the absence of exogenous oxidants, the deficiencies do not seem severe enough to account for the hematologic abnormalities. No abnormal Hb types were present, and G6PD, GPx, and Cb_5R activities were normal.

4. *Familial Erythrocytosis in Cattle*

Marked erythrocytosis (PCVs 60–80%) has been described in calves from a highly inbred Jersey herd (Tennant *et al.*, 1967, 1969). Affected calves had normal Hb types and arterial blood gas values. As with normal calves, PCVs were within the adult range at birth, fell during the first month of life, and then increased during the next 2 months. In contrast to normal calves, however, the PCV continued to increase in affected calves until 6 to 7 months of age. The majority of affected calves died during this time. PCVs of surviving animals returned slowly to normal by maturity. Serum of affected calves lacked measurable EPO but contained a growth factor that appeared to enhance EPO activity *in vitro* (Van Dyke *et al.*, 1968). The pathogenesis of this disorder may involve an abnormally controlled increased RBC production in response to the anemia of the neonate (Tennant *et al.*, 1969). A variety of familial and congenital erythrocytosis syndromes have been described in people (Emanuel *et al.*, 1992). Most are associated with Hb mutations that result in increased oxygen affinity, but some appear to be associated with abnormal responses to EPO.

CHAPTER

8

Porphyrins and the Porphyrias

J. JERRY KANEKO

I. INTRODUCTION

The metal-porphyrin complexes are found widespread in nature as constituents of compounds of fundamental importance in the metabolic processes of life. The photosynthetic pigment of plants, chlorophyll, is a magnesium porphyrin. The iron-porphyrin complexes are found as prosthetic groups of proteins, including the hemoglobins, myoglobins, and the heme enzymes such as the cytochromes, catalase, and peroxidase. The porphyrins also exist in nature in their free or uncombined state or as zinc complexes and it is this group that is associated with the porphyrias and the porphyrinurias.

Present knowledge of the porphyrins has its basis in the classic studies of the German physician and chemist, Hans Fischer, whose work on the porphyrins dates back to 1915. More recently, the development of more elegant methods of detection and identification of porphyrins and sophisticated enzymological techniques have resulted in an extremely clear understanding of the mechanisms of porphyrin biosynthesis and the biochemical and molecular bases for the disorders of porphyrin metabolism.

II. THE PORPHYRINS

A. Structure of the Porphyrins

The parent nucleus of the porphyrins is a cyclic tetrapyrrole, which consists of four pyrrole nuclei with their α (adjacent to the β) carbon atoms linked together by methene (–C=) bridges. This compound is called *porphin* and is shown in Fig. 8.1. The various synthetic and naturally occurring porphyrins are derivatives of porphin, distinguished from each other by the type and position of the radicals substituted for the hydrogen atoms at positions 1 through 8. For convenience in discussing the substitutions, we use the simplified representation of the porphin nucleus as shown in Fig. 8.1.

The classification of the porphyrins is based on the synthetic porphyrin, etioporphyrin (ETIO), in which two different radicals are substituted at positions 1 through 8. The substituted radicals are four methyl (M) and four ethyl (E) groups. The number of structural isomers possible with these eight substituted radicals are the four shown at the top of Fig. 8.2. The naturally occurring porphyrins are only those in which the positioning of their substituted radicals corresponds to iso-

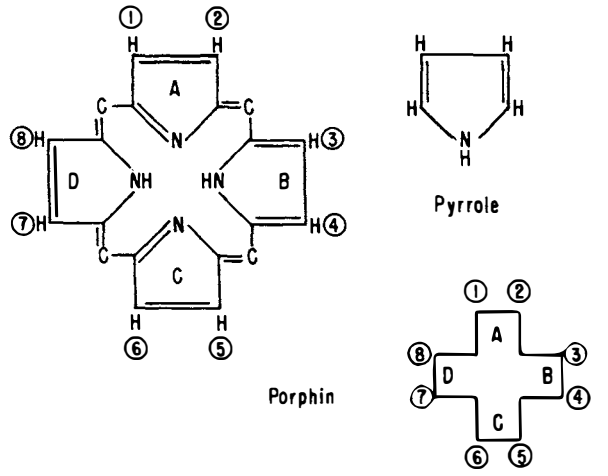

FIGURE 8.1 The precursor pyrrole and the parent porphin nucleus of porphyrins. Sites of isomeric substitutions are given as circled numbers and the pyrrole rings as letters. A schematic representation is also given.

mers I or III of etioporphyrin, ETIO I and ETIO III. This observation led Fischer to speak of a "dualism" of porphyrins in nature, which is in essential agreement with present knowledge of the biosynthesis of the porphyrin isomers as proceeding along parallel and independent paths.

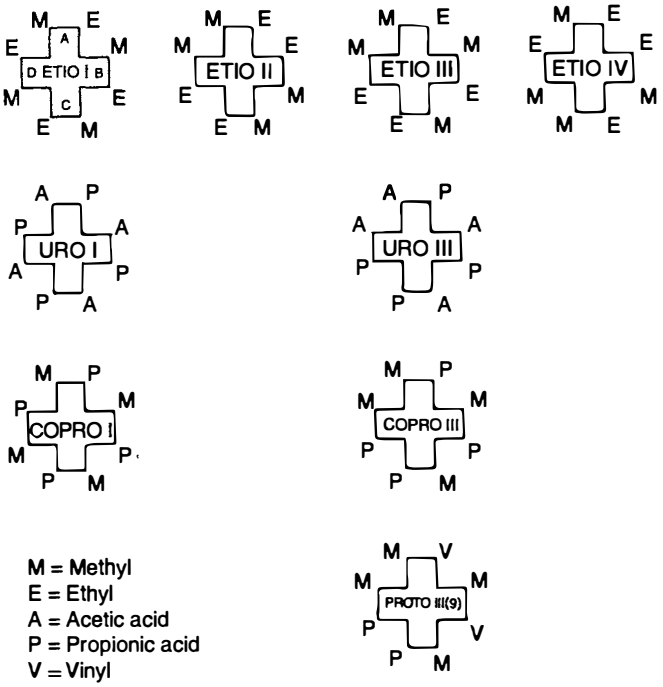

FIGURE 8.2 The isomeric porphyrins. The nomenclature of the porphyrins, URO, COPRO, and PROTO, is based on the isomeric structure of the etioporphyrins. Note that there are only the type I and type III isomers.

The uroporphyrins also contain two different radicals, acetic (A) and propionic (P) acids, and four each of these are arranged to correspond to either isomer ETIO I or ETIO III (Fig. 8.2). In this case, A corresponds to M and P corresponds to E. Therefore, these are designated uroporphyrin I (URO I) or uroporphyrin III (URO III). Similarly, the coproporphyrins contain four M and four P groups and are designated coproporphyrin I (COPRO I) and coproporphyrin III (COPRO III). The protoporphyrin of heme (iron-protoporphyrin, the prosthetic group of hemoglobin) corresponds to the series III isomer. In this case, however, three different radicals instead of two are substituted. These consist of four M, two P, and two vinyl (V) radicals. With three different radicals, a total of 15 isomers is possible, but the protoporphyrin of heme is the only naturally occurring isomer known. This isomer was designated protoporphyrin IX because it was the ninth in the series of protoporphyrin isomers synthesized by Fischer. The arrangement of the methyl groups of this isomer as shown in Fig. 8.2 corresponds to that of a type III etioporphyrin isomer and more properly should be called protoporphyrin III. However, by convention, the name protoporphyrin IX (PROTO IX) is the designation for this porphyrin.

An interesting isomer with only one vinyl group located on the A ring occurs and is known as Harderoporphyrinogen, which is thought to be an intermediate in the synthesis of protoporphyrinogen III. Other naturally occurring or chemically synthesized porphyrins are derivatives of PROTO IX. If the two vinyl groups are hydrogenated to ethyl groups, the product is mesoporphyrin IX. If the two vinyl groups are converted to hydroxy-ethyl groups, the product is hematoporphyrin IX. If the two vinyl groups are replaced by hydrogen atoms, the product is deuteroporphyrin IX. Protoporphyrin and deuteroporphyrin normally occur in feces but these are primarily products of intestestinal bacterial degradation.

B. Synthesis of Porphyrins and Heme

The pathway for heme biosynthesis has its basis in the demonstration by Shemin and Rittenberg (1946a) that the nitrogen atom of glycine is incorporated into the heme of hemoglobin. The concentration of isotopic nitrogen (^{15}N) in heme indicated that the nitrogen atoms of glycine were incorporated as the nitrogen atoms of the porphyrin ring. These findings led to the rapid elucidation of the enzymatic mechanisms of heme synthesis. Porphyrin metabolism and the porphyrias have been periodically reviewed (Meyer and Schmid, 1978; Elder, 1982; Hindmarsh, 1986; Kappas *et al.*, 1995).

In addition to contributing the nitrogen atoms, the methyl carbon atom (C-2) of glycine is also incorporated into the porphyrin ring. These carbons supply 8 of the 34 carbon atoms of protoporphyrin: one for each of the four methene bridges and one for each of the pyrroles (Fig 8.3). The carboxyl carbon atom of glycine is given off as CO_2 and is not incorporated into the protoporhyrin molecule (Fig. 8.3). The direct incorporation of the nitrogen atom and the methyl carbon atom of glycine into the heme of hemoglobin has been the basis for a useful technique to label the erythrocyte and to measure its survival time. In their original studies, Shemin and Rittenberg (1946b) observed that after administering ^{15}N-glycine, the concentration of ^{15}N in heme rose rapidly, remained constant for a time, and then fell. Analysis of the data indicated a survival time of 120 days for the human erythrocyte. On a similar basis, methyl carbon labeled glycine has been used to determine the lifespan of the erythrocytes of a number of domestic animals (Table 8.1).

The remaining carbon atoms of protoporphyrin are supplied by the tricarboxylic acid (TCA) cycle intermediate, succinyl-CoA. An outline of the pathway of heme and porphyrin synthesis is given in Fig. 8.4, which depicts the compartmentalization of their pathways between the mitochondria and cytosol. The nomenclature of the enzymes of porphyrin synthesis varies among authors so a guide to the nomenclature of the enzymes is provided in Table 8.2.

1. δ-Aminolevulinic Acid

The initial step in the pathway of δ-aminolevulinic acid (ALA) synthesis occurs in the mitochondria and involves the enzymatic condensation of glycine with succinyl-CoA to form ALA. This reaction requires vitamin B^6 as pyridoxal phosphate and the pyridoxal–

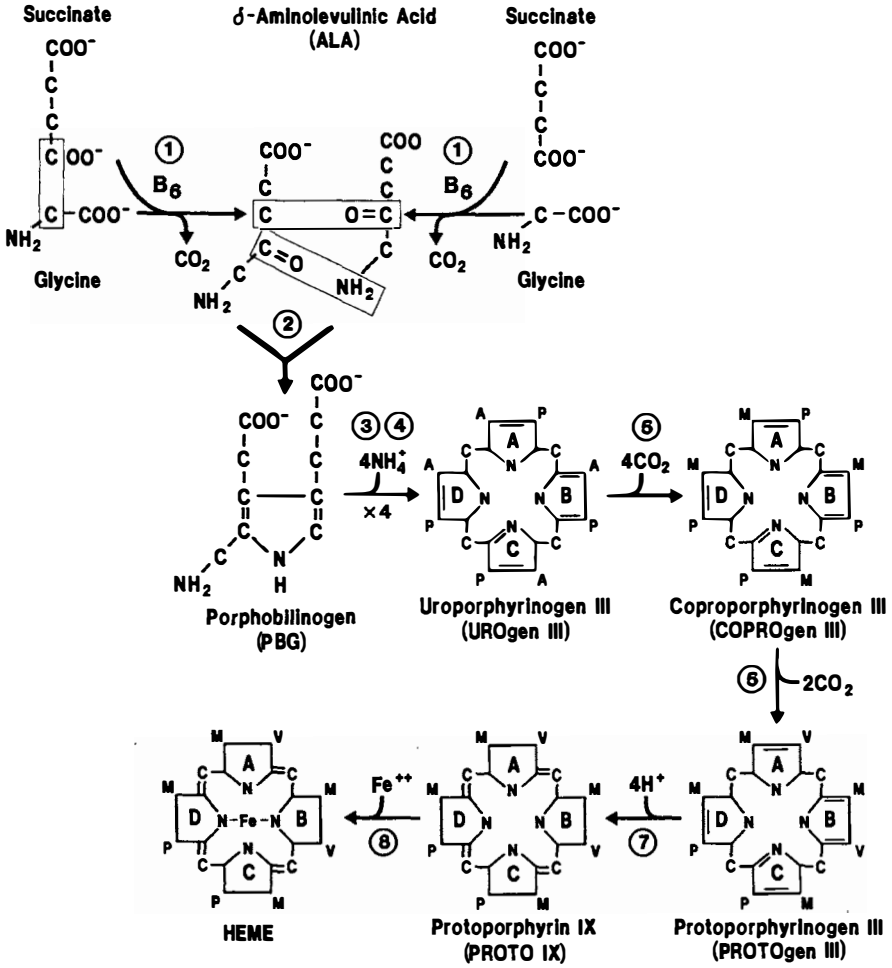

FIGURE 8.3 The synthetic pathway for protoporphyrin and heme. Note that two enzymes are required to catalyze the formation of UROgenIII. The circled numbers correspond to the enzymes listed in Table 8.2.

phosphate–glycine complex condenses with succinyl-CoA (Gibson *et al.*, 1958, Kikuchi *et al.*, 1958). The requirement for pyridoxine explains the pyridoxine responsive anemia of pyridoxine deficiency because in the absence of pyridoxine, the condensation cannot occur. The condensing reaction is catalyzed by the enzyme ALA synthase (ALA-Syn). ALA-Syn is the rate-controlling enzyme for heme synthesis (Granick, 1966). ALA-Syn is induced by heme and is also suppressed by negative feedback inhibition by heme. Thus, the end product, heme, controls its own synthesis (Granick and Levere, 1964). The ALA is next transferred into the cytosol (Sano and Granick, 1961).

2. *Porphobilinogen*

Two molecules of ALA are next condensed to form the precursor pyrrole, porphobilinogen (PBG), in the cytosol (Cookson and Rimington, 1953). This reaction is catalyzed by the enzyme ALA-dehydrase (ALA-D), an enzyme that is strongly inhibited by lead. The activity of this enzyme is commonly assayed in lead poisoning and a reduced activity is generally regarded as presumptive evidence of exposure to lead.

3. *Uroporphrinogen*

Next, two enzymes, uroporphrinogen I synthase (UROgenI-Syn)and uroporphrinogen III cosynthase (UROgenIII-Cosyn) act together to condense 4 moles of PBG into the cyclic tetrapyrrole, uroporphrinogen III (UROgenIII). The mechanism of cyclization continues to escape elucidation. UROgenI-Syn appears to initially catalyze the formation of a symmetrical linear tetrapyrrole. UROgenIII-Cosyn next flips the D ring and closes the pyrroles into an asymmetrical porphyrin ring of the type III configuration. In the absence of the UROgenIII-Cosyn, the symmetrical linear tetrapyrrole spontaneously closes into a symmetrical porphyrin of the type I configuration. Normally, there is a great excess of UROgenIII-Cosyn, and UROgenIII is synthesized. Both enzymes have been isolated from the spleens of anemic

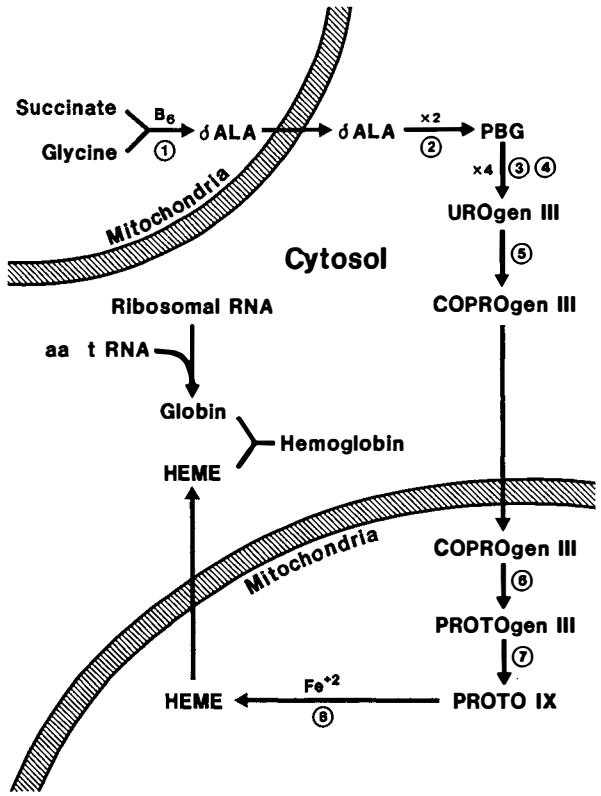

FIGURE 8.4 The synthetic pathway for protoporphyrin and heme. Note the partitioning of the heme synthetic pathway between the mitochondria and the cytosol. The circled numbers correspond to the enzymes listed in Table 8.2.

mice and *in vitro*, in the presence of both enzymes, UROgenIII was produced (Levin and Coleman, 1967).

4. *Coproporphyrinogen*

The eight-carboxyl UROgens I or III are next progressively decarboxylated into the four-carboxyl coproporphyrinogens (COPROgen) I or III with the decarboxylations catalyzed by the enzyme uroporphyrinogen decarboxylase (UROgen-D). UROgen is nonspecific so it catalyzes the decarboxylation of either UROgenI or UROgenIII. The COPROgens now move back into the mitochondria (Fig. 8.4).

TABLE 8.2 Nomenclature for Enzymes of Porphyrin and Heme Synthesis and Their Synonyms

Abbreviations	Nomenclature
1. ALA-Syn	δ-Aminolevulinate synthase (synthetase)
2. ALA-D	δ-Aminolevulinate dehydrase (dehydratase); porphobilinogen synthase
3. UROgenI-Syn	Uroporphyrinogen I synthase (synthetase); porphobilinogen deaminase
4. UROgenIII-Cosyn	Uroporphyrinogen III cosynthase (cosynthetase)
5. UROgen-D	Uroporphyrinogen decarboxylase
6. COPROgenIII-Ox	Coproporphyringen III oxidase
7. PROTOgen-Ox	Protoporphyrinogen oxidase
8. FER-Ch	Ferrochelatase; heme synthase (synthetase)

5. *Protoporphyrinogen*

Within the mitochondria, coproporphyrinogen III oxidase (COPROgenIII-Ox) catalyzes the decarboxylation of the two propionic acid groups on the A and B pyrrole rings of COPROgenIII to vinyl groups and the resulting product is protoporphyrinogen III (PROTOgenIII). COPROgenIII-Ox is highly specific for COPROgenIII and this explains the presence of only type III porphyrin isomers in nature. This also means that COPROgenI is a terminal intermediate that is oxidized to coproporphyrin I, the end product of this path (Fig. 8.5). COPROgenIII, when in excess, is also oxidized to coproporphyrin III. Similarly, the UROgens I and III can be oxidized to their end products, the uroporphyrins. We can see from (Fig. 8.5) that each of the -gen forms can be oxidized to their free forms, which are forms usually found in the circulatory system. These free porphyrins and protoporphyrin are

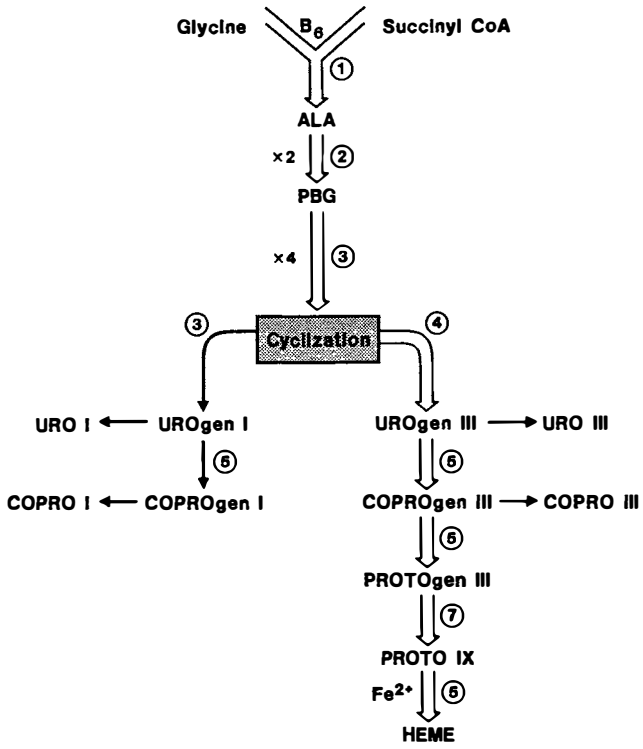

FIGURE 8.5 Alternate pathways for porphyrin synthesis. Normally, enzymes 3 and 4 function together in a coordinated manner to form heme. In the absence of enzyme 4, the alternative and terminal pathway to form the I isomers is taken. The circled numbers correspond to the enzymes listed in Table 8.2.

photoreactive and are the causative agents of the photosensitivity in the porphyrias.

6. Protoporphyrin

PROTOgenIII, the two-carboxyl porphyrinogen, is next oxidized at the carbon bridges to form the methene bridges connecting the pyrroles and is catalyzed by protoporphyrinogen III oxidase (PROTOgenIII-Ox). The resulting product is protoporphyrin IX (PROTO IX).

7. Heme

Within the mitochondria, ferrous iron (Fe^{2+}) is chelated with PROTO IX to form heme and is catalyzed by the enzyme ferrochelatase (FER-Ch). Iron can also be incorporated with relative ease by a nonenzymic method but the enzymic iron incorporation is more than 10 times that of the nonenzymic route (Labbe and Hubbard, 1961). Conditions that help to maintain iron in its ferrous form including the presence of reducing agents (ascorbic acid, cysteine, glutathione) enhance both enzymic and nonenzymic iron incorporation. Because iron is incorporated into heme as an integral part of the molecule, labeled iron can also used as a cohort label to determine the lifespan of the erythrocyte (Table 8.1).

8. Hemoglobin

Heme next moves into the cytosol where it is linked to the heme pocket of globin in a precise and stable position that permits binding of oxygen to the heme. Hemoglobin consists of 4 moles of this heme–globin moiety linked together as a globular tetramer. It is this globular tetrameric form of the hemoglobin molecule that permits the cooperative intearction of oxygen binding, which gives the familiar sigmoid oxygen–hemoglobin saturation curve.

9. Summary

In summary, the synthesis of porphyrins, heme, and globin can only occur in those respiring cells with full complements of mitochondrial and cytosolic enzymes. The TCA cycle is an aerobic cycle and therefore a lack of oxygen would preclude synthesis of succinyl-CoA and hence of heme. PROTO IX formation and the chelation of iron to form heme are also oxygen-requiring systems. Therefore, the reticulocyte with its residual complement of enzymes can synthesize hemoglobin but the mature erythrocyte, which is devoid of mitochondrial enzymes, cannot.

III. METHODOLOGY

The principal method now employed for the detection of porphyrins in biological materials in the clinical laboratory is based on the characteristic red fluorescence observed when acidic solutions of the porphyrins are exposed to ultraviolet light. The color of the fluorescence cannot be used to distinguish between the uroporphyrins and the coproporphyrins and, therefore, these must be separated prior to examination for fluorescence. The separation procedures take advantage of the solubility differences of the porphyrins in various organic solvents. In general, the following solubility properties are principally employed in the separation of the uroporphyrins from the coproprophyrins:

1. The coproporphyrins are soluble in diethyl ether, but the uroporphyrins are not; therefore, uroporphyrins remain in the aqueous phase.
2. Both uroporphyrin and coproporphyrin are soluble in strong acid, 1.5 *N* HCl. Coproporphyrins are therefore extracted from the organic phase with 1.5 *N* HCl. The uroporphyrins in the aqueous phase are absorbed with aluminum trioxide and subsequently eluted with 1.5 *N* HCl.

The acidic solutions of the porphyrins are then observed visually for fluorescence or examined in a sensitive fluorometer. The most suitable condition for the excitation of fluorescence is the use of ultraviolet light in the near visible range using aqueous solutions of the porphyrins at pH 1–2. Further means of identification include spectrophotometric examination, melting points of their methyl esters, and high-performance liquid chromatography. The methods for the quantitative determination of the porphyrins are given by Labbe and Lamon (1986). The following screening procedures are guides for further laboratory examinations.

A. Urinary Porphyrins

The urine for porphyrin examination must be alkalinized because porphyrins readily precipitate in acid urine. Addition of 0.5 g of sodium carbonate to the collecting bottle for each 100 ml of urine will keep the urine alkaline. The alkalinized urine can be stored at 4°C for 2–3 days prior to analysis. All contact of the urine with metal must be avoided and unfiltered urine is used. The following is a simplified screening procedure:

1. Place 5 ml urine in a 250-ml separatory funnel and add 5 ml acetate buffer (4 parts glacial acetic

acid : 1 part saturated sodium acetate) and adjust pH to 4.6–5.0.
2. Add 15 ml cold water.
3. Extract the mixture with two 50-ml aliquots of diethyl ether (or until the ether phases show no fluorescence under UV light) and pool the aliquots. The coproporphyrins will enter the ether phase.
4. Most of the porphyrins in urine are in the form of their nonfluorescent precursors. Storage of the urine for 24 hours in a refrigerator will enhance their conversion to the fluorescent pigments. If fresh urine is used, the ether phase is gently shaken with 5 ml of fresh 0.005% iodine solution (dilute 0.5 ml of a stock 1% iodine in ethanol solution to 100 ml with water) to convert the precursors to the porphyrins.
5. Extract the pooled ether phases with 20 ml 5% HCl (1.5 *N*) and examine for fluorescence under UV light. Fluorescence indicates the presence of coproporphyrins.
6. Uroporphyrins are insoluble in ether. Therefore, fluorescence in the aqueous phase urinary phase indicates the presence of uroporphyrins.

B. Fecal Porphyrins

The screening test as described for urine can also be used with fecal samples after prior extraction with strong acid. Five grams of a fecal sample is emulsified with 10 ml 95% ethanol. Twenty-five milliliters of concentrated HCl and 25 ml water are added to the emulsion and the mixture is kept overnight at room temperature. The mixture is next diluted to 200 ml with water, filtered, and the filtrate examined for porphyrins as described for urine.

C. Blood Porphyrins

Almost all porphyrins in blood are present in the erythrocytes and only trace amounts are in plasma. Therefore, it is important to use whole blood in the test and to understand that the test is a measure of the porphyrin content of the erythrocytes. Mix 2 ml heparinized whole blood and 6 ml ethyl acetate : glacial acetic acid (4 : 1) in a glass centrifuge tube. Stir thoroughly, centrifuge, and pour off the supernate into a second centrifuge tube. Add 1 ml 3 *N* HCl, vortex, and allow the phases to separate. Fluorescence under UV light in the aqueous layer indicates the presence of porphyrins in the erythrocytes. Normally, there will only be a trace of fluorescence so that more than a trace is indicative of an abnormal concentration.

D. Porphobilinogen

The Watson and Schwartz (1941) test is a reliable screening test because false positives are not commonly seen. Mix 3 ml fresh urine and 3 ml Ehrlich's aldehyde reagent (0.7 *g* p-dimethylaminobenzaldehyde, 150 ml concentrated HCl, and 100 ml water), the reagent commonly used for the urine urobilinogen test. Next, 5 ml chloroform is added, shaken vigorously in a separatory flask, and allowed to separate. The porphobilinogen aldehyde formed in the test is insoluble in chloroform and will remain in the lower aqueous phase. If the pink color is due to urobilinogen, it will be extracted into the chloroform phase. Porphobilinogen is found characteristically in the urine of patients with hepatic forms of porphyria, forms that have not been reported in animals.

IV. THE PORPHYRIAS

A. Classification

By convention, the term *porphyria* is used to define those disease states having a hereditary basis and having increased urinary and/or fecal excretion of the uroporphyrins and coproporphyrins. Depending on the fundamental biochemical defect, the porphyrias can be broadly classified on the basis of their tissue of origin, the erythropoietic system, or the liver. The term porphyrinuria is used to define those acquired conditions in which the principal, if not the sole, porphyrins being excreted are the coproporphyrins. Excess coproporphyrin excretion is seen in a wide variety of conditions including infections, hemolytic anemias, liver disease, and lead poisoning. The screening test for coproporphyrinuria has been especially useful for detection of exposure to lead.

Many systems of classification of the porphyrias have been used, most of which are based on the defect in the tissue of origin, erythropoietic, and the liver. There is general agreement on the classification of the erythropoietic forms but there is still some confusion as to the classification of the hepatic forms. These have been classified on the basis of their clinical manifestations, heredity, porphyrins excreted, and on the basis of their enzymatic defects (Eales, 1961; Tschudy, 1965; Elder, 1982; Hindmarsh, 1986; Kappas *et al.*, 1995). A useful system of classification is given in Table 8.3.

Methods are also available for the experimental production of the two major types of porphyria. In lead or phenylhydrazine poisoning, a type of porphyrinuria is seen that has some of the characteristics of erythropoietic porphyria of humans and cattle (Schwartz *et*

TABLE 8.3 Classification of the Porphyrias[a]

Porphyria type	Inheritance	Enzyme deficiency
Erythropoietic porphyrias		
Congenital erythropoietic porphyria	AR	UROgenIII-Cosyn
Erythropoietic protoporphyria	AD	FER-Ch
Hepatic porphyrias		
ALA-D deficiency porphyria	AR	ALA-D
Acute intermittent porphyria	AD	UROgenI-Syn (PBG-D)
Porphyria cutanea tarda	AD	UROgen-D
Hepatoerythropoietic porphyria	AR	UROgen-D
Harderoporphyria	AR	COPROgenIII-Ox
Hereditary coproporphyria	AD	COPROgenIII-Ox
Variegate porphyria	AD	PROTOgen-Ox

[a] Inheritance: A, autosomal; R, recessive; D, dominant. See Table 8.2 for enzyme abbreviations.

al., 1952). A hepatic form can be produced with Sedormid (allylisopropylacetylcarbamide) (Schmid and Schwartz, 1952), dihydrocollidine (Granick and Urata, 1963), or hexachlorobenzene.

B. Erythropoietic Porphyrias

1. *Bovine Congenital Erythropoietic Porphyria*

a. Introduction

One of the characteristic findings in bovine congenital erythropoietic porphyria (CEP) is a reddish brown discoloration of the teeth and bones. Discolorations of this type have been observed in cattle at slaughter since the turn of the century and these cattle are presumed to have had the disease. The first living cases were encountered in South Africa in a herd of grade Shorthorn cattle and were described by Fourie (1936) and Rimington (1936). Since then, CEP has been reported in cattle in Denmark (Jorgensen and With, 1955), the United Kingdom (Amoroso *et al.*, 1957), the United States (Ellis *et al.*, 1958; Rhode and Cornelius, 1958), and Jamaica (Nestel, 1958). The disease has been seen primarily in Holsteins in addition to the cases in the Shorthorns and Jamaican cattle.

The simple Mendelian autosomal recessive heredity of the disease was established by study of the geneology of the affected cattle and by breeding experiments (Fourie, 1939). The affected homozygotes are characterized by discoloration of the teeth and urine, photosensitivity of the light areas of the skin, and generalized lack of condition and weakness. The condition is present at birth and severely affected calves must be protected from sunlight if a state of health is to be maintained.

The predominant symptoms of teeth and urine discoloration and the photosensitization of the severely affected animal are readily apparent and a tentative diagnosis can be confirmed by the orange-red fluorescence of the teeth and urine when examined with near-UV light or a Woods lamp. The symptomatology of affected animals, however, may vary from minimal to severe and with age and time of year (Fourie and Roets, 1939). The discoloration of the teeth may vary in the same animal, being more pronounced in the young and less apparent in the older animals. Porphyrin deposits are heavily concentrated in the dentine so the occlusal surfaces should also be examined. If porphyrins are present, the discoloration and the fluorescence of the dentine will be readily detected.

The degree of photosensitization will vary with the amount of porphyrin deposition in the dermis, coat color, density of the coat and extent of exposure to sunlight. The photosensitization may be so slight as to escape detection. At times, loss of condition may be the only outward symptom for which the veterinarian is called. Marked variations in the urinary excretion of the porphyrins also occur. These may range from minimal to thousands of micrograms in the same animal so that the urine color may vary widely. The variations observed in this disease provide an indication of the dynamic state of flux of porphyrin metabolism in the living animal and the porphyrin deposits constitute a part of this dynamic state.

b. Distribution of Porphyrins

Some normal values for the porphyrins in animals are given in Table 8.4. These values are to be considered best approximations obtained from a relatively few animals. The figures, however, provide an indication

TABLE 8.4 Normal Values of Porphyrin Concentrations[a,b]

of the very low concentrations of the free porphyrins normally found in the body. Thus, the finding of porphyrins in greater than trace amounts is always significant. Porphyrin concentrations in porphyric cows and calves are given in Table 8.5 (Kaneko and Mills, 1969a, 1969b).

i. Urine It is known that porphyrin excretion varies over wide limits. Jorgensen (1961) in 52 cases found values for urinary uroporphyrins between 6.3–3900 μg/dl (0.076–46.96 μmol/liter) and coproporphyrins between 2.1–8300 μg/dl (0.032–126.74 μmol/liter). At concentrations of 100 μg/dl (1.53 μmol/liter) or more, a reddish discoloration is discernible in the urine. At 1000 μg/dl (15.27 μmol/liter) or more, an intense red fluorescence of the urine is readily observed when examined in the dark with a Woods light. The principal porphyrins excreted are URO I and COPRO I and only a small fraction is of the type III isomers. The percentage of each appearing in the urine is also variable. There is usually a greater excretion of URO I than COPRO I but Jorgensen (1961) observed a greater excretion of COPRO I than URO I.

[b] COPRO, coproporphyrins; PROTO, protoporphyrins; URO, uroporphyrins.
[c] *N* denotes number of animals or number of determinations per animal.

Porphobilinogen is not usually found in bovine CEP urine and earlier reports of its presence (Ellis *et al.*, 1958; Jorgensen and With, 1955) have not been confirmed (Jorgensen, 1961b). Normally colored, nonfluorescent urine of a CEP cow has consistently given a definite pink Ehrlich reaction but unlike porphobilinogen aldehyde, the pigment is soluble in chloroform (Kaneko, 1969). The nature of the pigment is unknown. On heating in a steam bath for an hour or standing at room temperature for several days, a red fluorescence is apparent on exposure to UV light. Quantitative porphyrin determinations of this urine yielded values of 135 μg/dl (1.63 μmol/liter) and 87 μg/dl (1.33 μmol/liter) for uroporphyrin and coproporphyrin, respectively. Watson *et al.*, (1959) also described a similar experience with bovine CEP urine.

ii. Bile and Feces Bovine fecal porphyrins may be derived from two sources: the bile and from chlorophyll of the food. The porphyrins derived from chlorophyll are excluded by the usual analytical method. Essentially, the only porphyrin found in the bile and feces of CEP cattle is COPRO I, and its concentration varies over wide limits (Tables 8.4 and 8.5). Fecal coproporphyrin varied between 1.9–11,800 μg/g (0.003–18.0 μmol/g) and biliary coproporphyrin between 320–13,600 μg/dl (4.88–207.67 μmol/liter) (Jorgensen, 1961). Only small amounts of COPRO III have been observed in feces. This preponderance of COPRO I in feces was also observed by Watson *et al.* (1959) who also reported the presence of small amounts of URO I.

iii. Plasma and Erythrocytes Only traces of free porphyrins are normally present in the plasma and in the erythrocytes. In bovine CEP plasma, Watson *et al.* (1959) observed variable amounts of porphyrins that were in general equally URO I (1–27 μg/dl; 0.012–0.33 μmol/liter) and COPRO I (4.2–25 μg/dl; 0.064–0.38 μmol/liter). A striking difference as compared to the human disease was the high level of free protoporphyrin in the erythrocytes of the CEP cow. The significance of this high level of protoporphyrin was unclear but was most likely related to the severe hemolytic anemia in the CEP cow. Excess PROTO IX is commonly found in iron deficiency, hemolytic anemia, and in lead poisoning. In iron deficiency, PROTO IX accumulates because of failure to form hemoglobin, but in CEP, serum iron is normal or elevated (Watson *et al.*, 1959; Kaneko, 1963; Kaneko and Mattheeuws, 1966). Similarly, PROTO IX accumulates in lead poisoning due to inhibition of ferrochelatase and a subsequent inability to insert iron into hemoglobin. An unlikely possibility is that the protoporphyrin in CEP is a type I isomer (Schmid, 1966).

iv. Tissue The range of concentrations of porphyrins in the tissues of CEP cattle is given in Table 8.6. The deposition of porphyrins throughout the bones and soft tissues is readily apparent at postmortem of severe cases by the generalized discoloration. A reddish brown discoloration is most apparent in the teeth, bones, and bone marrow. The greatest amount of discoloration of soft tissues occurs in the lungs and spleen in which characteristic fluorescence may be observed with UV light. The high concentration of porphyrins in the spleen is consistent with the hemolytic type of anemias in CEP. Discoloration of skin, muscle, heart, liver, and kidney is also observed but only a part is due to porphyrins. The discoloration is likely due to other porphyrin derivatives and to hemoglobin staining.

c. Hematology

The hematologic picture of the majority of reported cases is one of a responsive hemolytic anemia. In general, the degree of response is correlated with the severity of the hemolytic anemia. The anemia in mild cases of bovine CEP is normocytic and in the more severe cases is macrocytic. In the severe cases of bovine CEP, there is reticulocytosis, polychromasia, anisocytosis, basophilic stippling, and an increase in nucleated erythrocytes. A consistent monocytosis has been observed (Rhode and Cornelius, 1958; Kaneko, 1963) but remains unexplained. There is a markedly decreased M:E ratio in the presence of the anemia indicating a marked bone marrow hyperplasia. Bone marrow is also a principal site of porphyrin deposition, and Watson *et al.* (1959) found high concentrations of uroporphyrins in the bone marrow of a CEP cow.

The presence of porphyrins in the nucleated erythrocytes is clearly evident by examination of unfixed and unstained bone marrow smears with a fluorescent microscope. These fluorescent cells have been called fluorocytes. This phenomenon was originally observed by Schmid *et al.* (1955) in the bone marrow of a human patient and was an important contribution to the localization of the metabolic lesion in the erythropoietic tissue. They also reported that the fluorescence was seen only in morphologically abnormal nucleated erythrocytes that contained abnormal nuclear inclusions. Similar nuclear abnormalities were observed in bovine CEP bone marrow (Watson *et al.*, 1959). Schmid *et al.* (1955) concluded that there were two populations of erythrocytes, one normal and one containing free porphyrins.

The presence of two populations of erythrocytes was reported in humans but this was attributed to the intermittent hemolytic crises that occurred (Gray *et al.*, 1950). Tschudy (1965) has also pointed out that a single

TABLE 8.6 Tissue Porphyrins in Bovine Congenital Erythropoietic Porphyria[a]

population of erythrocytes is more likely to be present rather than two separate lines of erythrocytes. Runge and Watson (1969) studying fluorescing bovine CEP bone marrow cells after bleeding also concluded that there was only a single population of erythrocytes in bovine CEP.

The hematology of newborn CEP calves also exhibits striking differences when compared to that of older CEP calves and cows (Kaneko and Mills, 1969a). There is an intense erythrogenic response in the neo-natal CEP calf that persists for the first 3 weeks of life. Nucleated erythrocyte counts during the first 24 hours of life ranged from 5000 to 63,500/μl. Reticulocyte counts were lower than expected (6.4%) and increased to a peak of only 12.5% at 4 days of age. The persistent reticulocytosis is thought to be due to a delay in maturation of the reticulocytes (Smith and Kaneko, 1966; Rudolph and Kaneko, 1971). This delay in maturation of the reticulocyte, which is proportional to the degree of anemia, is now a well-established phenomenon during the reticulocyte response to a blood loss or hemolytic anemia. In essence, this delay represents the increase in survival time of the reticulocyte beyond its normal 1-day survival time. This increased survival time is the now commonly used maturation correction factor (MCF) for estimating the reticulocyte production index (RPI) when evaluating the response to an anemia.

d. Mechanism of the Anemia

A responsive hemolytic anemia is a well-established occurrence in CEP. Erythrocyte porphyrins are high in CEP and if these erythrocytes with high porphyrin concentrations were more susceptible to destruction, a shortening of their lifespan would be expected. Erythrocyte lifespan is shortened in bovine (Kaneko, 1963) and in human (Gray *et al.*, 1950) CEP. There is general agreement that this shortening of lifespan is associated with the hemolytic process but the mechanism of the hemolysis remains obscure. It has been shown that erythrocyte survival in bovine CEP is inversely correlated with erythrocyte coproporphyrin concentration (Kaneko *et al.*, 1971). The shortest erythrocyte survival time of 27 days (normal = 150 days) was associated with the highest erythrocyte coproporphyrin concentration, which is a reasonable expectation. The porphyrins through their lipid solubility are presumed to damage the erythrocyte membrane leading to the hemolysis. *In vivo* ^{59}Fe metabolic studies were completely compatible with a hemolytic type of anemia, and ineffective erythropoiesis, that is, bone marrow hemolysis, was also demonstrated (Kaneko, 1963; Kaneko and Mattheeuws, 1966). Plasma iron turnover and transfer rates, erythrocyte iron uptake, and organ uptakes were increased as expected in a hemolytic process.

The mechanism of cell damage has also been studied in reticulocytes and in nucleated erythrocytes. A biochemical defect in the bovine CEP reticulocyte *in vitro* was expressed as an increase in porphyrin synthesis, a marked decrease in heme synthesis and a delay in the maturation time of the reticulocyte (Smith and Kaneko, 1966). The $T_{1/2}$ for the maturation of the reticulocyte was 50 hours compared to a normal of 3–10 hours. This delay in reticulocyte maturation is thought to be

the direct result of the defect in heme synthesis since the rate of heme synthesis controls the rate of maturation of the reticulocyte (Schulman, 1968). This means that the increase in the reticulocyte survival time is inversely proportional to the degree of anemia.

A similar delay in the maturation of the metarubricyte to the reticulocyte was observed in the bone marrow cells of CEP cows (Rudolph and Kaneko, 1971) but there was no effect on the earlier nucleated erythrocytes. Therefore, the more mature erythrocytic cells are the cells most noticeably affected by the high porphyrin content. This is not surprising because heme and hemoglobin synthesis are most active in the later stages of erythrocytic cell development. Ultimately, the accumulation of porphyrins in these cells, whether in bone marrow or in blood, induces hemolysis. On exposure of surface capillaries to sunlight, photohemolysis of the type observed in erythropoietic protoporphyria (Harber *et al.*, 1964) would further aggravate the hemolysis.

This hemolytic mechanism might also explain the striking erythrogenic response seen in the neonatal porphyric calf. Because most of the porphyrins are within the fetal erythrocytes and these would not normally cross the placenta, the porphyrin containing erythrocytes would accumulate in the fetus and a profound hemolysis would occur *in utero*. This hemolysis in turn would induce a marked erythrogenic response in the fetus and this is seen at birth. At birth, porphyrins are high but they fall to their steady-state level in about 3 weeks in CEP calves. This is comparable to the rate of clearance of ^{14}C-porphyrin into urine, which fell to 0.1% of the initial concentration in 3 weeks (Kaneko, 1963). Furthermore, 3 weeks is also the time at which the erythrogenic response is stabilized at a steady-state level in the neonatal calf (Kaneko and Mills, 1969c).

In summary, as a result of the heme synthetic defect in erythropoietic porphyria, there is excess porphyrin accumulation in the mature and developing erythrocytes that induces their hemolysis in the circulation or in the bone marrow. There is a corresponding shortening of erythrocyte lifespan. In addition, the decrease in heme synthesis induces an increase in the survival time of the reticulocyte by inhibiting the maturation of the developing erythrocytes, which further aggravates the anemia. This biochemical defect in heme synthesis is morphologically expressed in the fluorocytes and in the evidence of erythrogenic response in the blood and bone marrow, the degree of which is directly related to the severity of the enzymatic defect of the porphyria.

e. Detection of the Carrier State

Bovine CEP is inherited as an autosomal recessive trait. Previously, carrier animals were detectable only by the occurrence of the disease in their progeny. Levin (1968a) developed an assay for UROgenIII-Cosyn and found that its activity was considerably less in CEP cattle than in normals (Levin, 1968b). Heterozygous cattle, which are the clinically unaffected carriers of the porphyria gene, had UROgenIII-Cosyn activities intermediate between porphyrics and normals (Romeo *et al.*, 1970). Similarly low UROgenIII-Cosyn activity is found in human CEP but carriers are less readily detectable in humans than in cattle (Romeo and Levin, 1969). These findings are also in keeping with the concept that the genetic defect in CEP is a deficiency of UROgenIII-cosyn. Romeo (1977) has reviewed the genetic aspects of all forms of hereditary porphyrias and concludes that the weight of evidence is conclusive for a UROgenIII-Cosyn deficiency in CEP.

f. Metabolic Basis of Bovine Congenital Erythropoietic Porphyria

The mechanisms for heme biosynthesis and the biochemical nature of the porphyrins in the tissues and excreta provide an explanation for the metabolic defect in CEP. Certain features of the biosynthetic mechanism are particularly important in an explanation of the clinical and metabolic manifestations of CEP, which has its ultimate pathogenesis in a hereditary deficiency of UROgenIII-Cosyn. These can be summarized as follows:

1. There is a compartmentation of the enzymes of heme biosynthesis between the mitochondria and the cytosol.
2. Mitochondrial systems are involved in the synthesis of ALA, PROTO IX, and heme.
3. Cytosolic systems catalyze the formation of PBG, UROgenIII or I, and COPROgenIII or I.
4. Mitochondria are present only in the immature nucleated erythropoietic cells and in the reticulocytes. The most active heme and hemoglobin synthesis occurs in the metarubricyte and secondly in the reticulocyte.
5. There is no heme or hemoglobin synthesis in the mature erythrocyte.

The enzymatic deficiency in CEP is localized in the erythropoietic tissue within the developing erythropoietic cells, which are the mitochondria-containing cells. Normally, the combined action of UROgenI-Syn and UROgenIII-Cosyn catalyzes the formation of the normal type III porphyrin isomer, UROgenIII, leading to the formation of heme. In the absence of UROgenIII-Cosyn, the type I isomer, UROgenI, and then COPROgenI is formed. Thus, the relative activities of these enzymes govern the extent as to which of these pathways is traversed. The type I isomers that are formed in the deficiency state cannot be converted into PRO-

TOgenI and into a type I heme. This is because there is no coproporhyrinogen I oxidase and the COPROgenIIIOx is highly specific only for the type III isomer. The type UROgenI and COPROgenI isomers are oxidized to their corresponding uroporphyrins and coproporphyrins. These oxidized free porphyrins accumulate in the erythropoietic tissues, developing erythrocytic cells, and in the mature erythrocytes where they induce the hemolysis characteristic of CEP. In addition, the porphyrins are released into the circulation and are widely distributed throughout the body in all body fluids and are readily excreted in the feces and urine. They are deposited in all tissues, most notably in the teeth, bones, and skin. When exposed to ultraviolet light, the porphyrins in the skin are excited by absorption of the ultraviolet light energy into an unstable higher level energy state. The excitation energy is then be emitted when the excited molecule returns to its ground state. The energy can be emitted as fluorescence or transferred to molecular oxygen to form singlet oxygen. Singlet oxygen is a powerful oxidant for many forms of biologically important compounds including the peroxidation of membrane lipids, membrane and cellular proteins, cell enzymes, and cell organelles. Peroxidation appears to be the primary event in the photosensitivity and photodermatitis seen in the porphyrias (Meyer and Schmid, 1978; Poh-Fitzpatrick, 1982).

Total deficiency of UROgenIII-Cosyn is obviously incompatible with life so that surviving cases of CEP have only a partial deficiency of UROgeIII-Cosyn. Also, there is a wide variation in the severity of the disease commensurate with the degree of enzyme deficiency as well as with the conditions of husbandry. The severity of the disease, however, is quite constant in each bovine if it is kept under standard controlled conditions. The metabolic basis for bovine CEP is summarized in Fig. 8.6 in which the central theme is the genetically controlled UROgenIII-Cosyn deficiency with the resultant type I porphyrin accumulation and a failure in heme synthesis.

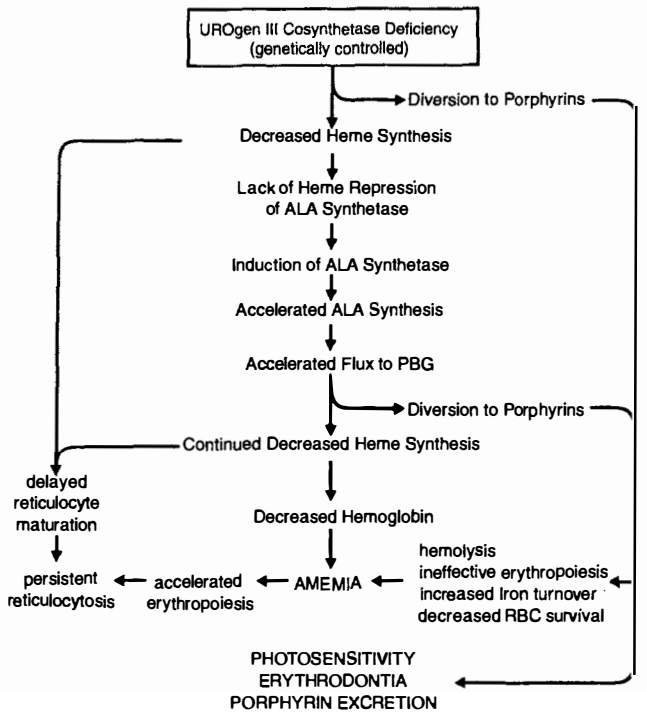

FIGURE 8.6 Metabolic basis of bovine congenital erythropoietic porphyria. The fundamental defect is a deficiency of UROgenIII-Cosyn leading to the accumulation of type I uroporphyrins and coproporphyrins. These type I porphyrins account for the clinical, hematologic, and biochemical features of this disease.

2. *Bovine Erythropoietic Protoporphyria*

This disorder of porphyrin metabolism occurs in humans and in cattle. Erythropoietic protoporphyria (EPP) was first reported in 1961 (Magnus *et al.*, 1961) and is now well recognized in humans (Redeker, 1963; Harber *et al.*, 1964). It is inherited as a dominant autosomal trait (Romeo, 1977). Patients do not have the major signs of CEP such as anemia, porphyrinuria, or discolored teeth. Photosensitivity of the skin is the only significant clinical manifestation of the disease and this is associated with a high plasma protoporphyrin concentration. In the laboratory, the most striking findings are the high concentrations of PROTO IX in the erythrocytes and feces.

In cattle, EPP has a pattern of recessive inheritance in contrast to humans and may be sex linked because to date it has only been seen in females. The photosensitivity also seems to diminish in adult life. Affected cattle also do not have anemia, porphyrinuria, or discoloration of the teeth. Erythrocyte and fecal protoporphyrins are very high in comparison to normal cows (Ruth *et al.*, 1977).

The fundamental enzymatic defect in bovine EPP has been shown to be a deficiency of FER-Ch (Ruth *et al.*, 1977), which results in the accumulation of PROTO IX. Low FER-Ch was found in all tissues of EPP calves so that the defect is a total body defect.

3. *Porphyria of Swine*

Porphyria in swine was first recognized in New Zealand by Clare and Stephens (1944). Later it was recognized in Denmark and a number of studies with these swine have been published (Jorgensen and With, 1955; Jorgensen, 1959). Porphyria in swine is inherited as a dominant characteristic. Except for the very severe cases, there appears to be little or no effect on the

general health of the pig. Photosensitivity is not seen even in the white pigs. The predominant feature in the affected pig is a characteristic reddish discoloration of the teeth, which fluoresces upon exposure to ultraviolet light. Porphyrin deposition in the teeth of the newborn pig is virtually pathognomonic of porhyria in swine. Occasionally, darkly discolored teeth may not fluoresce but porphyrins may be extracted from these teeth with 0.5 *N* HCl (With, 1955). Similar, though less apparent, deposition occurs in the bones. The porphyrins are principally URO I and have been found in concentrations of up to 200 μg/g of teeth or bones. The liver, spleen, lungs, kidneys, bones, and teeth are also discolored by another dark pigment, the nature of which is unknown (Jorgensen, 1959).

The urine of the affected pig is discolored only in the more severely affected pig. The 24-hour urinary excretion of uroporphyrins ranged beween 100–10,000 μg and for coproporphyrin, only 50 μg. These were both the type I isomers. PBG is absent in the urine. Close similarities in this pattern of porphyrin excretion to that found in bovine CEP are apparent but the localization of the defect in the erythropoietic tissue has not been established. This disease has not been seen in pigs since the original occurrences.

4. Porphyria of Cats

Porphyria in cats was first reported in a male kitten (Tobias, 1964). One of its three littermates and kittens from a previous litter were also reported to have had the same unusually discolored teeth. The kitten's teeth were brown and under ultraviolet light, they fluoresced red. Its urine was amber colored and was qualitatively positive for uroporphyrin, coproporphyrin, and porphobilinogen. There was no evidence of anemia or photosensitization. These cats had been kept indoors all their lives. One of these cats was the propositus for a porphyric cat colony (Glenn *et al.*, 1968). Study of the inheritance of the porphyria in these cats indicated it to be of a simple Mendelian autosomal dominant trait analagous to that seen in swine.

A detailed study of porphyria in a family of Siamese cats has been reported (Giddens *et al.*, 1975) in which excessive accumulation of URO I, COPRO I, and PROTO IX were observed in erythrocytes, urine, feces, and tissues. These cats had photosensitivity, severe anemia, and severe renal disease. They concluded that the principal defect in these cats was a deficiency of UROgenIII-Cosyn similar to CEP of humans and cows.

5. Normal Porphyrias

All fox squirrels (*Sciurus niger*) have red bones and this is due to the accumulation of URO I and COPRO I (Flyger and Levin, 1977). The fox squirrel porphyria resembles the disease in humans, cows, and cats by having a deficiency of UROgenIII-Cosyn, type I porphyrins in their urine and feces, and discolored bones, teeth, and tissues that fluoresce on exposure to ultraviolet light. There is increased erythropoiesis but no apparent hemolytic anemia, and no photosensitivity or any other deleterious effects. These relatively benign effects are most likely due to their thick hair coats and nocturnal living habits. It is interesting that an enzyme deficiency with serious health effects in other animals should have evolved as a "normal" characteristic in the fox squirrel. This is understandable when one appreciates that CEP cattle that have always been kept indoors and protected from sunlight thrive and reproduce normally.

The UROgenIII-Cosyn deficiency is found only in the fox squirrel and not in the closely related gray squirrel (*Sciurus carolinensis*). Urine porphyrin excretion in the fox squirrel is 10-fold greater than in the gray squirrel and is markedly increased when erythropoiesis is stimulated by bleeding. The UROgenIII-Cosyn of fox squirrel erythrocytes is very heat sensitive and this may indicate that its CEP is due to an increased lability of the enzyme.

In the feathers of certain brightly colored birds, for example, Touracos and in certain lower animals and microorganisms, porphyrins accumulate but these appear to be normal phenomena.

C. Hepatic Porphyrias

This group of diseases is seen in humans only as naturally occurring diseases. They constitute the most common group of porphyrias seen in humans. The salient features of this group of porphyrias are also summarized in Table 8.2. As the name of this group implies, the predominant site of the metabolic defect is localized in the liver and the group is further subdivided on the bases of their principal clinical manifestations. Specific enzyme deficiencies have been identified for all forms of hereditary porphyria (Table 8.2).

1. δ-Aminolevulinic Acid Dehydratase Porphyria

This rare hepatic form of porphyria has a marked deficiency of the enzyme δ-aminolevulinic acid dehydratase (ALA-D) in the homozygous state (Doss *et al.*, 1979; Brandt and Doss, 1981) and is referred to as ALA-D porphyria (ADP). It is characterized by neurologic symptoms without skin photosensitivity. It is inherited as an autosomal recessive trait. A similar though less marked ALA-D deficiency that was without symptoms was reported (Bird *et al.*, 1979) and this is thought to be the heterozygous state of the deficiency.

2. *Acute Intermittent Porphyria*

Acute intermittent porphyria (AIP) is a common form in humans characterized by acute abdominal attacks and neurologic symptoms. Photosensitivity is not a feature of this form. Most patients are not clinically affected unless some form of aggravating factor is present. The attacks are precipitated by a large number of causative factors, the principal ones being barbiturates, sulfonamides, estrogens, and alcohol. The disease occurs more commonly in the adult female than in the male. The principal urinary finding is the excretion of large amounts of ALA and PBG. This is in keeping with the hereditary deficiency of UROgenI-Syn (PBG-D) in this disease (Strand, 1970). AIP is the major autosomal dominant form of hepatic porphyria.

3. *Porphyria Cutanea Tarda*

Porhyria cutanea tarda (PCT) is caused by a deficiency of UROgen-D and presents as both a sporadic form and a familial form. The sporadic form is the acquired form of PCT and is the most common of all forms of human porphyria. The familial form is inherited as an autosomal dominant. As the name implies, the characteristic clinical signs of PCT are the photosensitive lesions of the skin. The disease occurs in mid to late adult life and common precipitating causes of this disease are alcohol and estrogens. The disease can be successfully treated by avoidance of alcohol and estrogens. There is a decrease in hepatic UROgen-D in both forms but the enzyme deficiency is found in extra-hepatic tissues only in the familial form (Pimstone, 1982). In the sporadic form, erythrocyte UROgen-D activity is normal whereas in the familial form, erythrocyte UROgen-D is less than 50% of normal (McManus *et al.*, 1988). The erythrocyte URO-D assay is difficult and not readily available; therefore, indirect means of distinguishing the sporadic form from the familial are used. One of the most simple indirect methods has been to assay the plasma γ-glutamyltransferase activity (GGT). Sporadic PCT has a significant increase in GGT, whereas the familial form has normal GGT activity (Badcock *et al.*, 1993). Furthermore, the ratio of fecal COPRO III:COPRO I when combined with the plasma GGT was found to give an even more accurate differentiation of the sporadic form from the familial form (Badcock *et al.*, 1995).

4. *Hepatoerythropoietic Porphyria*

Hepatoerythropoietic porphyria (HEP) is a form which clinically resembles CEP but there is a severe deficiency of UROgen-D as in PCT. It is thought to be the homozygous form of familial PCT. HEP is characterized by a very severe photosensitivity but there is no liver involvement.

5. *Harderoporphyria*

This is a rare form of porphyria in which the propionate group on the A ring only is converted to a vinyl group. The normal next step of B-ring conversion is somehow disrupted. There is a deficiency of COPROgenIII-Ox but the mechanism explaining why the groups on both rings are not oxidized is unknown.

6. *Hereditary Coproporphyria*

Hereditary coproporphyria (HCP) is clinically similar to PCT with a mild cutaneous photosensitivity and it may also have neurologic symptoms as in AIP. Like AIP, HCP is commonly precipitated by drugs and alcohol. As in Harderoporphyria, COPROgenIII-Ox is the deficient enzyme.

7. *Variegate Porphyria*

The symptoms of variegate porphyria (VP) are generally more variable than the other forms but in most cases, acute abdominal attacks and photosensitivity are seen. VP is most common among the South African white population. VP is inherited as an autosomal dominant. There is a deficiency of PROTOgenIII-Ox, which can be observed in cultured fibroblasts and in leukocytes of VP patients.

D. Acquired Toxic Porphyrias

1. *Chemical Porphyrias*

The two major forms of the acquired toxic porphyrias are those due to organic chemical intoxication and to heavy metal poisonings, mainly lead. Experimentally, hexachlorobenzene (HCB) (Elder *et al.*, 1976), 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) (Elder and Sheppard, 1982), allylisopropylacetylcarbamide (Sedormid) (Schmid and Schwartz, 1952), or dihydrocollidine (DHC) (Granick and Urata, 1963) has been used to produce the hepatic forms of porphyria.

2. *Lead Poisoning*

Lead poisoning occurs in all domestic animals and is a significant clinical problem, particularly in the dog. In the dog as in other animals, the principal clinical features are related to the gastrointestinal and the nervous systems. Anemia is usually seen only in the long-standing chronic lead toxicities. The anemia has certain features that are suggestive of lead poisoning but are not diagnostic. The anemia is a mild to moderate nor-

mocytic normochromic anemia with basophilic stippling and nucleated erythrocytes (NRBC) out of proportion to the degree of anemia. Zook *et al.* (1970) consider that more than 15 stippled cells per 10,000 erythrocytes is suggestive of and that more than 40 stippled cells per 10,000 erythrocytes is diagnostic of lead poisoning in the dog. Stippling is thought to be accumulated ribosomal RNA aggregates that have not been normally degraded to their nucleotides and subsequently dephosphorylated by pyrimidine-5'-nucleotidase (P5NT). Lead has been shown to decrease the activity of the dephosphorylating enzyme P5NT in humans (Valentine *et al.*, 1976) and in calves (George and Duncan, 1982).

Lead is known to have widespread toxic effects on sulfhydryl-, carboxyl-, and imidazole-containing proteins, which would include enzymes, cell proteins, globins, and membrane proteins (Fell, 1984). However, only a few are altered specifically and significantly to be of diagnostic value. Globin synthesis and therefore hemoglobin synthesis is disrupted and this is the major mechanism of the anemia of lead poisoning. The anemia, however, occurs late in chronic lead poisoning and its nonspecific nature makes it of less diagnostic importance than is usually attributed to it.

A major focus is on the enzyme systems of heme synthesis because several of the enzymes are very sensitive in early exposure to small quantities of lead. The most sensitive are ALA-D and FER-Ch and these enzymes and their accumulated substrates are widely used as screening tests for lead exposure. Erythrocyte ALA-D is strongly inhibited by lead and, as a result, ALA rises in plasma and is excreted in the urine. Measurement of ALA is difficult and the results lack sensitivity for low-level lead exposure; therefore, instead of its substrate ALA, erythrocyte ALA-D is more commonly assayed. Farant and Wigfield (1982) using the ratio of ALA-D activities assayed at two different pH levels demonstrated ALA-D inhibition at blood lead concentrations of 10–15 μg/dl (0.50–0.70 μmol/liter). They found this to be a highly sensitive and reliable index of the blood lead concentration.

Coproporphyrin also rises in plasma and is excreted in urine and, like ALA, it is also difficult to measure and lacks sensitivity. Hence, this method is not used as an index of lead poisoning.

FER-Ch is the second major enzyme that is strongly inhibited by lead and, as a result, PROTO IX accumulates in the erythrocytes. This PROTO IX is zinc PROTO IX instead of the "free" PROTO IX as it is commonly called. Piomelli *et al.* (1982) found that erythgrocyte zinc PROTO IX increased when blood lead concentrations were at 15–18 μg/dl (0.75–0.85 μmol/liter). It is not quite as sensitive an index of blood lead concentration as ALA-D but is well below the diagnostic criteria for lead poisoning. George and Duncan (1981) found marked elevations in erythrocyte PROTO IX in experimental lead poisoning in calves. Modern fluorometers specifically designed to measure porphyrins have greatly simplified the assay. For these reasons, the current test of choice to monitor lead exposure is the blood zinc PROTO IX concentration.

The final diagnosis of lead poisoning ultimately rests on the measurement of blood lead concentration and this is best done using flame atomic absorption spectrophotometry. In children, a blood lead concentration of <30 μg/dl (1.45 μmol/liter) is currently regarded as normal but it has been shown that zinc PROTO IX rises at blood lead levels of one-half that amount (Piomelli *et al.*, 1982). It is clear that the heme synthetic pathway is affected at blood lead concentrations well below that considered normal. Zook *et al.* (1970) reported a normal range for blood lead in the dog of 10–50 μg/dl (0.48–2.41 μmol/liter) and considered a blood lead concentration of >60 μg/dl (2.90 μmol/liter) diagnostic of lead poisoning. In the light of current knowledge, this action level is probably too high. In the domestic rabbit, the blood lead concentration is reported to be 2–27 μg/dl (0.10–1.30 μmol/liter) (Gerken and Swartout, 1986). Therefore, lead concentrations of >30 μg/dl (1.45 μmol/liter) should be considered diagnostic of lead poisoning in the dog as well as in all animals.

CHAPTER

9

Iron Metabolism and Its Disorders

JOSEPH E. SMITH

I. INTRODUCTION

Iron is the second most abundant metal and the fourth most common element. Unfortunately, it is chemically unstable and is easily oxidized to an insoluble ferric form, which is the form found in rocks and soils. Ferric iron is unavailable for most biological systems.

All living organisms, except possibly *Lactobacillus*, require iron. It is important for biological processes because it can exist in two oxidation states: Fe^{2+} and Fe^{3+}, which can be interconverted easily. Because iron is so inaccessible, organisms use a variety of mechanisms to get iron from their environments. Microorganisms have a high-affinity system consisting of three components: (1) a low-molecular-weight, secreted compound with a high affinity for iron, called a *siderophore;* (2) a membrane receptor that attracts the iron-loaded siderophore and transports the ferric chelate across the microbial membrane; and (3) a system to release the iron from the siderophore (Crichton and Charlotteaux-Wauters, 1987).

Because free iron can catalyze free radicals from molecular oxygen and hydrogen ions, it can have disastrous consequences for biological materials. So, intracellular iron is bound to or incorporated into various proteins or other chelates to reduce its toxicity. Those proteins or chelates are responsible for the absorption, storage, and biological activity of iron. Any study of iron metabolism involves a study of the physiological compounds associated with it.

II. IRON COMPARTMENTS

Iron exists in the following compartments (Fig. 9.1) in mammals: hemoglobin, storage, myoglobin, labile iron, tissue iron, and transport (Fairbanks and Beutler, 1983) (Table 9.1).

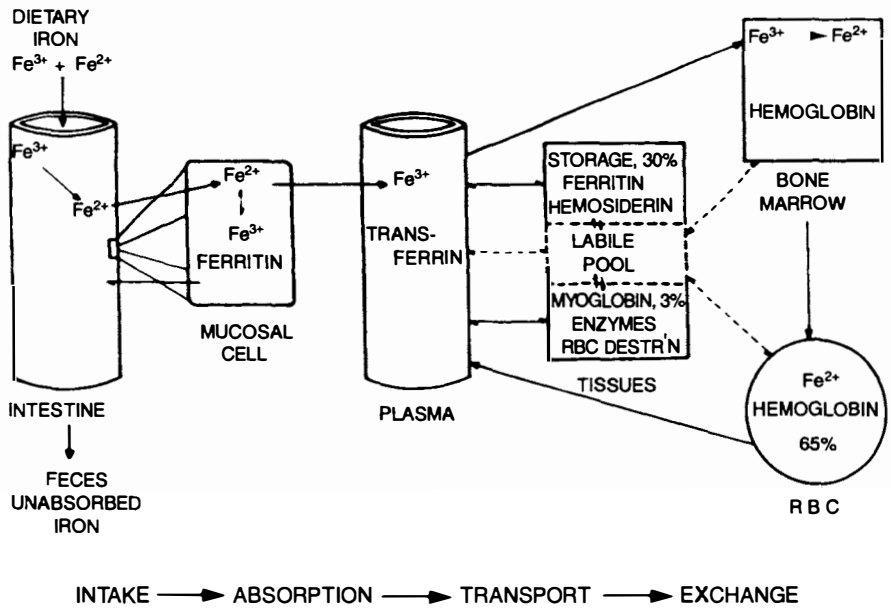

FIGURE 9.1 Pathways of iron metabolism. Single arrows show a unidirectional flow of iron to emphasize the limited excretion of iron and its "closed" cycle in the body. From Kaneko (1964), with permission.

A. Hemoglobin

Most iron in animals is located in erythrocytes as hemoglobin. Each hemoglobin molecule contains four atoms of iron and is 0.34% iron by weight. Each milliliter of erythrocytes contains 1.1 mg of iron, so the exact amount of iron will depend on the animal's packed cell volume and blood volume. Because packed cell volume is constant, but blood volume increases linearly with weight, the total amount of iron in hemoglobin is normally related to body weight (Stahl, 1967).

B. Storage

Iron is stored in various tissues as either a diffuse, soluble, mobile fraction (ferritin) or as insoluble, aggregated deposits (hemosiderin). Storage iron concentration is the major factor affecting the relative distribution of iron between ferritin and hemosiderin in mammals. At low storage levels, more iron is stored as ferritin than as hemosiderin (Torrance and Bothwell, 1980). As the amount of iron increases, the hemosiderin proportion increases. Both hemosiderin and ferritin iron are available to the body. The liver and spleen usually have the highest storage iron concentrations, followed by the kidney, heart, skeletal muscles, and brain (Underwood, 1977).

1. Ferritin

Ferritin consists of protein and iron (Crichton and Charlotteaux-Wauters, 1987). The protein portion, apoferritin, contains 24 monomers of at least two subunit types, designated H and L. The H subunit is predominant in heart ferritin and is larger (21,000 Da) than the L subunit. The L subunit occurs in the liver

TABLE 9.1 Distribution of Iron in Heme and Nonheme[a] Compounds

Species (wt)	Heme iron		Nonheme iron		Reference
	g	%	g	%	
Dog (10 kg)	0.43	55	0.36	45	Lintzel and Radeff (1931)
Horse (400 kg)	11.5	67	5.6	33	Obara and Nakajima (1961a)
Cow (386 kg)	9.2	55	7.7	45	Kaneko (1963)
Man (70 kg)	3.19	76	1.01	24	Drabkin (1951)

[a]Approximate nonheme iron distribution is as follows: 12, hemosiderin; 13%, ferritin; 3%, myoglobin; 1%, transferrin, cytochromes, peroxidase, catalase; 4%, unknown.

and spleen and has a molecular weight of 19,000 Da. Other tissues have ferritins made up of various ratios of H and L subunits. The H/L ratio is species and tissue specific and varies from 1:9 in horse spleen to 8.5:1 in horse heart ferritin. Both subunits are encoded by a family of genes. The active gene has introns, but several pseudogenes without introns exist and are located on different chromosomes.

Each subunit is shaped like a short rod and interacts with other subunits to form a hollow sphere (Fig. 9.2) (Harrison *et al.*, 1986). Pores are formed in the exterior surface between apoferritin monomers. These pores allow iron to enter or leave the interior cavity of the ferritin molecule (Harrison, 1977).

The mineral core of ferritin is hydrated ferric oxide with some phosphate. The apoferritin shell has a molecular weight of 441,000 Da and, if maximally saturated, can hold 4500 iron atoms. The apoferritin and iron together would weigh about 800,000 Da and be 31% iron by weight. Because ferritin more commonly is 620,000 Da and 18% iron, maximal saturation probably is rare.

Acute administration of iron will induce liver ferritin synthesis. The level of chelatable iron within the cell regulates ferritin synthesis by redistributing the messenger RNA between the free mRNA pool and the polyribosomes (Rogers and Munro, 1987). Apparently, iron passes through the pores in the apoferritin coat as the ferrous ion. Once inside the shell, it must be oxidized to the ferric form, hydrolyzed, and polymerized to the ferric oxyhydroxide polymer. Iron can exit ferritin by reversing the process. The physiological compounds involved in reducing the iron back to the ferrous form have not been determined (Crichton and Charlotteaux-Wauters, 1987).

2. *Hemosiderin*

Hemosiderin appears similar in structure to ferritin, but it has a higher iron to protein ratio. It may be formed from soluble cytosol ferritin by lysosomal action. The following sequence of events has been proposed (Richter, 1984):

Cytosol ferritin
↓
Lysosomal-siderosome ferritin
↓
Ferritin protein is denatured
↓
Ferritin protein is decomposed by proteases
↓
FeO·OH core is divested
↓
FE core is disintegrated
↓
Amorphous hemosiderin

Because hemosiderin is insoluble in water, it remains in tissues processed for histological examination. It

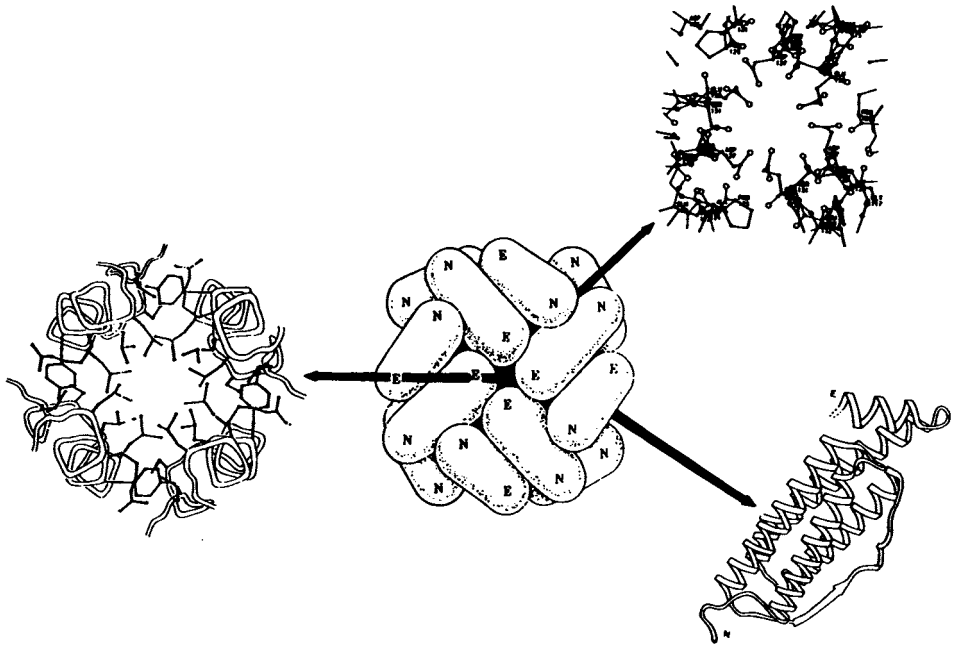

FIGURE 9.2 Structural features of ferritin. The gross structure of the assembled molecule is illustrated in the middle, details of the two types of channels are shown on the left (surrounded by four chains) and upper right (three chains), and the individual subunit in the lower right. From Harrison *et al.* (1986) with permission. N, amino terminal of the polypeptide; E, carboxyterminal of the polypeptide.

appears in unstained sections as clumps or granules of golden refractile pigment and stains readily with the Prussian blue reaction.

C. Myoglobin

Myoglobin is similar to one subunit of hemoglobin and is found mostly in muscle. It serves as a reservoir for oxygen and can temporarily provide oxygen during anaerobic conditions. Each myoglobin molecule contains one atom of iron (0.34% iron by weight). Myoglobin is species related and dependent on muscular activity. For example, the muscle myoglobin content of race horses (7.4 mg/kg) is much higher than that of man (1.2 mg/g) (Kolb, 1963). This iron pool varies between species, because the amount of myoglobin varies among muscles within a species and among species.

D. Labile Iron Pool

When radioiron disappearance curves are analyzed using a multicompartment model, an iron pool is found that is in dynamic equilibrium with the plasma iron pool (Pollycove and Mortimer, 1961). Iron disappears from the plasma into this pool, but can reflux back to the plasma. Although the exact physical nature of the pool is unknown, it may be an intermediate between the plasma, storage, and hemoglobin pools (Fig. 9.1).

E. Tissue Iron Compartment

Although the amount of iron in this compartment is small, it is extremely important. Almost half of the enzymes of the tricarboxylic acid cycle either contain iron or require it as a cofactor. The iron compounds can be classified into four categories (Dallman *et al.*,1978): (1) Heme-containing compounds are structurally similar to hemoglobin and include myoglobin, catalase, peroxidase, and cytochromes. Cytochromes *a*, *b*, and *c* are located in the mitochondria and are important in oxidative phosphorylation. Other cytochromes (such as cytochrome P450) are located in the endoplasmic reticulum and function in the oxidative degradation of endogenous compounds and drugs. (2) Nonheme iron-containing enzymes form another large group that includes iron in nonheme such as iron–sulphur compounds and metalloflavoproteins. This group includes xanthine oxidase, cytochrome c reductase, succinate dehydrogenase, and nicotinamide adenine dinucleotide dehydrogenase, which contain more iron in mitochondria than in cytochromes. (3) Enzymes requiring iron or heme as a cofactor include aconitase and tryptophan pyrrolase. (4) Enzymes containing iron in an unknown form include ribonucleotide reductase and α-glycerophosphate.

F. Transport Compartment

Iron is transported between some compartments by plasma transferrin. Transferrin is a single polypeptide chain of about 700 amino acids (molecular weight: ~80,000 Da). Transferrin is a glycoprotein, as are most plasma proteins. It contains two branched oligosaccharide chains that are attached to asparagine residues (Crichton and Charlotteaux-Wauters, 1987). It has a dilobal structure; the N- and C-terminal halves form separate globular lobes connected by a short α-helix. Each half carries one iron-binding site that requires concomitant binding of one carbonate or bicarbonate ion with each atom of iron. Iron as a ferric ion is bound tightly at neutral pH, but is dissociated when the pH goes below 5.5.

In domestic animals, plasma transferrin type is a polymorphic trait and can be used for parental exclusion. The genetically related, electrophoretic variability resides in both the polypeptide chain and the oligosaccharide side chains (Stratil and Glasnak, 1981; Maeda *et al.*, 1984).

The transfer of iron from transferrin to cells requires internalization of the iron-laden transferrin molecule (Fig. 9.3). Ferrotransferrin binds to a membrane receptor at neutral pH. The receptor-ferrotransferrin complex collects in specialized sites on the plasma membrane called *coated pits.* These pits are coated on the inner surface with a fibrous protein, clathrin. The coated-pit region of the membrane then can invaginate to form a vesicle, with the cell's outer plasma membrane and receptor–ferrotransferrin complex as the inner surface and the clathrin coat as the outer surface. The vesicles are converted into structures with the acronym CURL (compartment of uncoupling of receptor and ligand). An enzyme in the endostomal membrane exploits the energy stored in adenosine triphosphate to pump protons into the CURL lumen and, thus, lower the internal pH. At the lower pH, transferrin's affinity for iron is decreased, and the iron is released. Iron-free apotransferrin remains bound to its receptor and is transported back to the cell surface. When the coated vesicle reaches the surface, iron-free apotransferrin is released from the receptor because the affinity between the two is low at neutral pH. The iron-free apotransferrin can enter the blood plasma to bind more iron, and the receptor can be used to bind more ferrotransferrin. The free iron must escape from the CURL, cross the mitochondrial membrane, and be incorporated into heme. The exact mechanism for free iron movement remains unknown. The entire process requires about

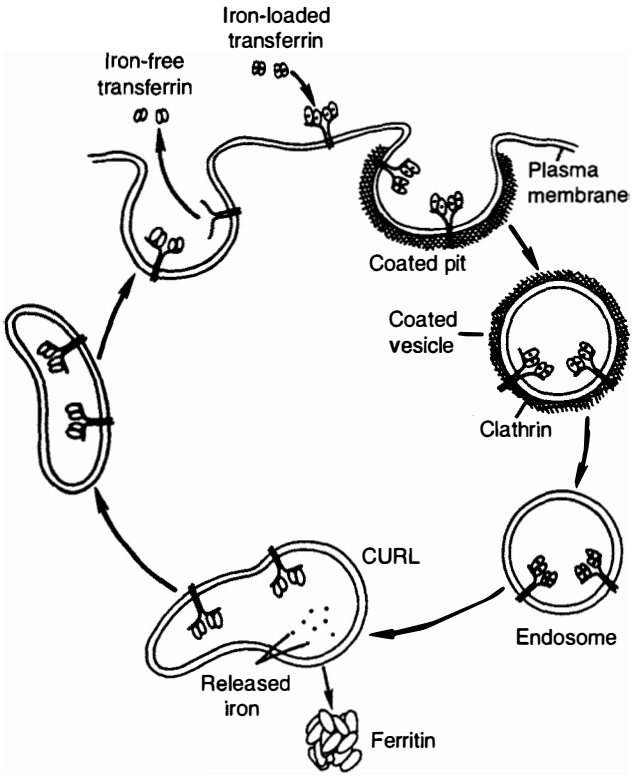

FIGURE 9.3 Transferrin cycle to deliver iron into cells. Iron-loaded transferrin binds to a specific receptor. The receptor–transferrin complex moves to a coated pit and is internalized in a coated vesicle. The coated vesicle is converted to an endosome by losing its clathrin coat and is transformed to the compartment of uncoupling of receptor and ligand (CURL). The iron dissociates from the ferritin–receptor complex at the CURL's low pH and is added to cytoplasmic ferritin. The iron-free transferrin–receptor complex recycles to the surface, where the iron-free transferrin is released, and the receptor is made available to bind more iron-loaded transferrin (Dautry-Varsat and Lodish, 1984).

16 minutes: 4 minutes for a transferrin receptor to bind a ferrotransferrin, 5 minutes for the receptor–ferrotransferrin to be internalized, 7 minutes for iron to dissociate from transferrin and return to the cell surface, and 16 seconds for the apotransferrin to be released (Dautry-Varsat and Lodish, 1984; Dautry-Varsat *et al.*, 1983).

The amount of iron delivered to immature erythrocytes depends on the plasma iron concentration, percent iron saturation, and the number of membrane receptors (Finch and Huebers, 1985). When the percentage of transferrin containing iron is low, most transferrin is monoferric; as the percentage increases, the diferric form increases. That increases the amount of iron delivered in two ways because (1) the payload of the diferric molecules is twice that of monoferric transferrin and (2) diferric transferrin has a higher affinity for the membrane receptor than monoferric transferrin and, thus, is preferentially bound to available receptors (Huebers *et al.*, 1985). The receptor number probably increases when erythropoiesis is increased.

The Belgrade rat is unable to release iron within the CURL. So, these rats have an anemia resembling iron deficiency, despite being hyperferremic (Edwards *et al.*, 1986).

Copper plays an important role in transporting iron across membranes (Rosen *et al.*, 1995). When pigs are copper deficient, they have hypoceruloplasminemia and signs of a functional iron deficiency. Iron accumulates in the liver, macrophage–phagocyte system, and enterocytes. Presumably, this "iron deficiency" results from the inability to mobilize the iron from these sites (Lee *et al.*, 1968). Most of the circulating copper in plasma is attached to the serum glycoprotein, ceruloplasmin. Ceruloplasmin has ferroxidase activity and may be required to deliver iron into the circulation. In man, a genetic defect in the ceruloplasmin gene causes aceruloplasminemia and systemic hemosiderosis (Harris *et al.*, 1995).

Plasma iron in laying hens is high (greater than 500 μg/dl), and about two-thirds of it is bound to a specific phosphoprotein, phosvitin. It is responsible for transporting iron to ovocytes and egg yolks. The average egg contains about 1 mg of iron (Kolb, 1963).

G. Genetic Control of Iron Proteins

Several genes critical to the uptake, storage, and use of iron are regulated posttranslationally. The mRNAs of these proteins contain iron-responsive elements (IREs) in the form of stem-loop structures in untranslated regions (Fig. 9.4). A single IRE in the 5′ untranslated region is involved in controlling translation of the mRNA message. A cluster of IREs in the 3′ untranslated region confers iron-regulated control of mRNA stability (Basilion *et al.*, 1994). IREs are not the definitive iron sensors, but require a cytosolic protein called an *iron regulatory protein* (IRP). The binding of IRP to IREs depends on iron availability. If iron is abundant, the affinity of IRP for IREs is low (Klausner and Harford, 1989; Beinert and Kennedy, 1993).

Two IRPs have been described. When IRP1 occurs in iron-replete cells, it is a cytosolic aconitase. When iron is limiting, IRP1 exists in an alternative form that is devoid of a cubane Fe-S cluster and has a high affinity for IREs (Klausner and Harford, 1989). IRP2 is the product of a second gene, but its mRNA abundance and tissue distribution differ from those of IRP1. IRP2

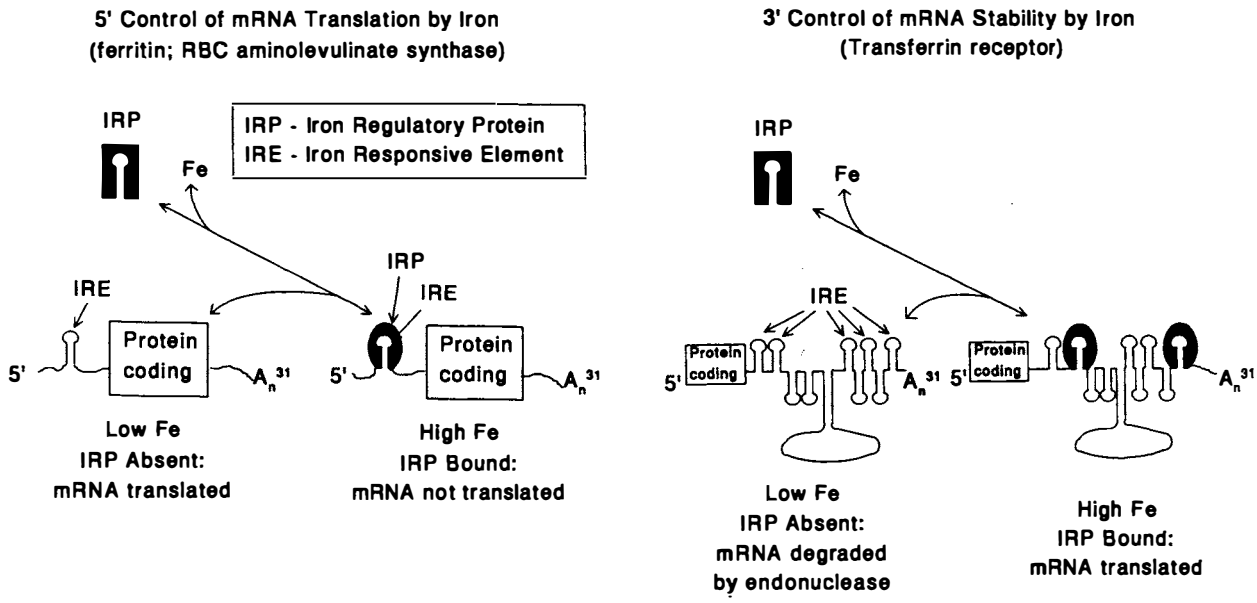

FIGURE 9.4 Posttranslational control of iron proteins. Iron regulatory protein (IRP) binds to the iron responsive element (IRE) of mRNA only when cells are iron replete. If IRP is bound to an IRE on the 5′ end of mRNA, mRNA is not translated (left panel). When it binds to the mRNA's 3′ end, mRNA degradation by endonuclease is inhibited (right panel).

does not have aconitase activity in an iron-adequate environment (Samaniego *et al.*, 1994).

When iron is low, an IRP binds to the 5′ IRE with high affinity and prevents the translation of ferritin mRNA and erythroid 5-aminolevulinate synthase mRNA. Similarly, when IRP binds to 3′IRE, it stabilizes the short-lived transferrin receptor mRNA by blocking its degradation by endonuclease. Thus, IRP exerts an iron-dependent, dual, and reciprocal control of ferritin concentrations and transferrin receptors (Klausner and Harford, 1989).

III. IRON ABSORPTION

A. Iron Requirements

Iron requirements for domestic animals are influenced by age, growth rate, availability of a dietary iron source, and the criteria of adequacy (NRC, 1978b). Definite iron requirements for most domestic species have not been determined. Most recommendations (Table 9.2) are estimates (Harrison, 1977; Rogers and Munro, 1987; NRC, 1975, 1976, 1978a, 1978b, 1979, 1981, 1984, 1985). The intake for mature animals can be adequately met from the usual dietary sources. Because milk is low in iron and growth rates of neonatal animals are high relative to their weights, the young of most species can become iron deficient. Anemia should not be used to determine iron adequacy, because use of dietary iron for hemoglobin synthesis can take precedence over demands for other iron compounds (Nathanson and McLaren, 1984).

B. Dietary Iron

The amount of iron available for absorption by the intestine depends on the amount of iron in the diet and its bioavailability. Iron content of various foods and feeds can be divided into high (greater than 50 ppm), intermediate (10 to 50 mg iron), and low (less than 10 ppm) levels. Those with high iron content include organ meats such as heart and liver, brewer's yeast, wheat germ, egg yolks, oysters, and certain dried beans and fruits. Those with intermediate iron content include most muscle meats, fish and fowl, most green

TABLE 9.2 Estimated Dietary Iron Requirements for Domestic Animals

Species	Iron (ppm)	Reference
Pigs, mature	80	NCR (1979)
neonatal	150	
Cattle, adult	50	NRC (1978b, 1984)
neonatal	100	
Horses, adult	40	NRC (1978)
neonatal	50	
Sheep, adult	30–50	NRC (1975)
Dogs and cats	80	Chausow and Czarnecki-Maulden (1987)

vegetables, and most cereals. Foods low in iron include milk and milk products and most nongreen vegetables (Finch, 1980).

Iron is absorbed as either heme or nonheme compounds. Heme is absorbed readily and independently of the composition of the diet. Nonheme iron is largely unavailable, and its absorption is affected by other ingredients in the diet. Tannates and phosphates inhibit but meat and ascorbate enhance nonheme iron absorption (Finch and Cook, 1984).

C. Mechanisms of Absorption

Despite many investigations over several years, the exact mechanism of intestinal absorption of iron remains unknown. It must be a finely tuned mechanism, to maintain homeostasis without a major excretory mechanism. Because free iron is inherently unstable and can catalyze free-radical-mediated membrane damage, it is unlikely that iron crosses the intestinal cell wall in a free, soluble form. Iron probably is bound to a ligand that is involved in regulating its uptake. Originally, apoferritin was implicated as a transport and regulatory protein. Apoferritin may be important in keeping iron out of the body or in excreting iron. Apoferritin is made as mucosal cells are formed in crypts. The iron trapped in apoferritin is retained in those cells as they migrate to the tips of intestinal villi, and it is lost when the mucosal cells are sloughed. The most recent theory of iron absorption involves mucin and an intestine protein designated mobilferrin. According to this theory, gastric juice stabilizes dietary inorganic iron and prevents iron from being precipitated as insoluble ferric hydroxide. At acid pH, iron combines with mucins. Intestinal mucin delivers inorganic iron to intestinal absorptive cells in a form that is acceptable for absorption. In the small intestine, iron is transferred from mucin to the membrane integrins of the intestinal absorptive cells. Membrane integrins help the transfer of iron through the cell membrane for binding to mobilferrin. Mobilferrin serves as the shuttle protein within the absorptive cell. If an excess of iron occurs in the cell, ferritin synthesis is stimulated, and iron is deposited in ferritin to prevent oxidative damage to the cell from ionic iron. Transferrin receptors located on the basolateral membranes of the absorptive cell act to permit iron to enter the cell from plasma similar to cells in other organs (Conrad and Umbreit, 1993).

Iron uptake is influenced by previous dietary exposure, the amount of storage iron within the body, and erythropoietic activity (Finch and Huebers, 1985). After one dose of iron is given orally, a second dose will be absorbed more slowly (Hahn, 1943). Iron absorption increases 6- to 15-fold in dogs with chronic blood loss anemia and with increased erythropoiesis (Weiden *et al.*, 1981).

The "mucosal blockage" of iron absorption has limited capacity, because higher doses of iron can overcome the blocking mechanism. Several children are poisoned each year because they eat too many sugar-coated iron tablets. In domestic animals, iron toxicity can occur when they are exposed to high iron levels in feed or water.

IV. TESTS FOR EVALUATING IRON METABOLISM

A. Hematology

With certain constraints, hematological examination can be used to evaluate iron adequacy. Blood can be obtained easily and it contains the largest iron pool. Unfortunately, iron is preferentially shunted from other iron pools to hemoglobin (Nathanson and McLaren, 1984). Thus, hemoglobin may be the last pool to show the effects of iron inadequacy.

A high concentration of hemoglobin is a signal to stop cell division and extrude the nucleus (Stohlman, *et al.*, 1963). During severe iron deficiency, hemoglobin synthesis in immature erythrocytes is slowed, and nucleated erythrocytes continue to divide. Erythrocytes released into the circulation are small, contain occasional nuclei, and show increased central pallor because of low hemoglobin content. Hematology has been used to test biological availability of iron in diets or to determine the iron requirements of various species, in spite of the drawbacks. If the erythrocyte number, packed cell volume, and hemoglobin are determined, three erythrocyte indices can be calculated:

$$\text{Mean corpuscular hemoglobin (pg)} = \frac{\text{Hb (g/dl)}}{\text{RBC } (10^6/\mu\text{l})} \times 10,$$

$$\text{Mean corpuscular volume (fl)} = \frac{\text{PCV (\%)}}{\text{RBC } (10^6/\mu\text{l})} \times 10,$$

$$\text{Mean corpuscular hemoglobin concentration (\%)} = \frac{\text{Hb (g/dl)}}{\text{PCV (\%)}} \times 100.$$

Classically, all three indices decrease in iron deficiency anemia. However, similar changes can occur in any deficiency or disease that inhibits hemoglobin synthesis, such as pyridoxine-responsive anemia or copper deficiency.

B. Serum Iron

Serum iron can be measured to assess the transport compartment. Conditions of sample collection are particularly important. Most evacuated containers used for routine serum collection are satisfactory. However, if zinc is to be determined, special trace element tubes are required, because most stoppers are contaminated with zinc (Handy, 1979). Although plasma may be used, the anticoagulant should be tested for iron content. Samples must be handled carefully to avoid post-sampling contamination. Glassware must be cleaned carefully with acid solution. Disposable plastic containers and tubes offer an acceptable alterative and usually do not require acid cleansing.

Iron can be determined by atomic absorption, colorimetry, and coulometry (Henry *et al.*, 1974; Smith *et al.*, 1981). Direct measurement of serum iron by atomic absorption may give unreliable results because the sensitivity is limited, matrix interference occurs, and hemoglobin iron cannot be distinguished from transferrin iron. Colorimetric determination requires that the iron be separated from transferrin by lowering the pH and then reduced to the ferrous ion. The ferrous iron can be determined with reagents such as thiocyanate, *o*-phenanthroline, or 2,2'-dipyridyl. Although most colorimetric methods are not elevated by mild hemolysis, other serum constituents such as bilirubin may interfere. Coulometric methods can determine iron in small samples. They are not affected seriously by mild hemolysis and are free of interference from other compounds such as bilirubin, lipids, and cholesterol in the serum (Smith *et al.*, 1981).

Serum iron declines in severe iron deficiency, acute-phase inflammatory reactions, hypoproteinemia, hypothyroidism, renal disease, and chronic inflammation. It may be elevated in hemolytic anemia, refractory anemia, iron overload, and liver disease (Kaneko, 1980).

C. Serum Total Iron Binding Capacity

Total transferrin can be measured by immunological methods, but the technique is not used commonly. Transferrin usually is measured in terms of iron content after it has been saturated with iron. When transferrin is saturated with iron, the iron content is called the total iron-binding capacity (TIBC). Because transferrin can bind more iron than is normally present, the TIBC is greater than the serum iron and the difference between them is the unsaturated iron-binding capacity (UIBC). Thus, serum iron can be expressed as a percentage of the TIBC and reported as the percent saturation (Henry *et al.*, 1974).

Several strategies are used to measure serum TIBC or UIBC (Henry *et al.*, 1974). (1) Excess iron can be added to the serum, and the increase in "salmon-pink" color can be measured colorimetrically. (2) Iron can be added in excess, and the unbound excess can be measured colorimetrically. (3) Excess iron can be added to saturate transferrin and then removed by adsorption onto a resin. The bound iron remaining in the supernatant can be determined by a typical serum iron assay. (4) A resin that is partially saturated with iron can be incubated with serum. Under proper incubation conditions, transferrin competes successfully for resin-bound iron, but resin-bound iron will not leave without transferrin. If serum iron exceeds the transferrin-binding capacity, the resin can adsorb the excess iron. The supernatant iron can be determined by any serum iron assay (Smith *et al.*, 1981).

D. Serum Ferritin

Although ferritin functions *in vivo* as an iron storage compound and is primarily intracellular, it can be detected in serum (Table 9.3). In man, serum ferritin concentrations correlate with total body iron stores. They are low in iron deficiency and high in iron overload (Addison *et al.*, 1972; Jacobs *et al.*, 1972; Lipschitz *et al.*, 1974; Siimes *et al.*, 1974; Walters *et al.*, 1973).

Serum ferritin is assayed in antibody-driven reactions such as radioimmunoassay and enzyme-linked immunosorbent assay. Unfortunately, the antibodies against ferritin are usually species specific (Richter, 1967); that is, an antibody against human ferritin will not cross-react with horse ferritin. Thus, for each new species, ferritin must be isolated, an antibody must be made, and the assay conditions must be developed. Despite this difficulty, serum ferritin has been measured in horses (Smith *et al.*, 1983), rats (Hunter, 1978; Ward *et al.*, 1977), pigs (Smith *et al.*, 1984), dogs (Weeks *et al.*, 1988b), cats (Andrews *et al.*, 1994), and cows (Miyata *et al.*, 1984). In dogs (Weeks *et al.*, 1989), cats (Andrews *et al.*, 1994), horses (Smith *et al.*, 1983), and pigs (Smith *et al.*, 1984), but not rats (Hunter, 1978; Ward *et al.*, 1977), serum ferritin correlates significantly with nonheme iron in the liver and spleen. In calves, serum ferritin increases after iron therapy (Miyata *et al.*, 1984).

Serum ferritin can be increased in several conditions that are not related to body stores of iron. It is an acute-phase protein and increases during serious inflammatory reactions when interleukin-1 is produced. Clinically, serum ferritin should be monitored relative to other acute-phase proteins such as haptoglobin, fibrinogen, or C-reactive protein, because it is possible for the low serum ferritin associated with iron defi-

TABLE 9.3 Serum Iron Analytes by Domestic Animals

Species	Serum analyte[a]			Reference
	Iron (μg/dl)	TIBC (μg/dl)	Ferritin (ng/ml)	
Horse	50–198	231–455	43–261	Smith *et al.* (1986)
Cattle	39–155	186–270	33–55	Kolb (1963), Furugouri (1984)
Sheep	179–207	298–370		Kolb (1963)

Cat	33–135	169–325	32–123	Andrews *et al.* (1994)

[a] Reference ranges.

ciency to be elevated into the normal range by a concurrent infection (Lorier *et al.*, 1985). Serum ferritin also can be increased during liver disease, hemolytic diseases, and some neoplastic disorders (Newlands *et al.*, 1994). Serum ferritin increases and transferrin decreases with malnutrition in cattle (Furugouri, 1984).

E. Bone Marrow Iron

Cytological examinations of bone marrow are sometimes useful for evaluating disorders of iron metabolism (Fairbanks and Beutler, 1983). A Prussian-blue reaction in which ionic iron reacts with an acid ferrocyanide solution to give a blue color is used commonly. Bone marrow smears are fixed in formalin vapor by placing them in a covered staining jar containing a sponge moistened with formalin for about 3 minutes. Equal volumes of 4% potassium ferrocyanide solution and 4% hydrochloric acid solutions are mixed in a staining jar and heated to 56°C. After slides are immersed in the solution for 30 minutes, they are rinsed with tap water and counterstained for 5 minutes with a dilute basic fuchsin solution, and then rinsed with water, absolute ethanol, and water again.

Except for cats (Harvey, 1981) bone marrow from normal adult domestic animals exhibits stainable iron (hemosiderin) within macrophages. Little or no stainable iron is found in animals with iron deficiency.

Mitochondrial iron of immature erythrocytes occurs as amorphous aggregates called ferruginous micelles. Some nucleated erythrocytes in Prussian-blue stained marrow slides contain one to three, small, blue granules in the cytoplasm. In iron deficiency, macrophages and developing erythrocytes do not contain stainable iron granules. On the other hand, when heme synthesis is impaired, mitochondria accumulate excess amorphous iron aggregates and a ring of large blue siderotic granules may encircle the erythrocyte nucleus (Fairbanks and Beutler, 1983).

F. Erythrocyte Protoporphyrin

In the final step of heme synthesis, iron is inserted into protoporphyrin. When heme synthesis is limited by the availability of iron, protoporphyrin accumulates, and zinc substitutes for iron. The zinc chelate is stable and remains in the erythrocytes throughout their lifespans. Protoporphyrin can be measured by two methods (Trundle, 1984). In one method, protoporphyrin is extracted from erythrocytes with acidified organic solvents. After extraction, the protoporphyrin can be assayed spectrophotometrically or fluorometrically. The method is difficult and time consuming and requires large amounts of blood. The other method uses a front face hematofluorometer to measure zinc protoporphyrin directly on small quantities of unhemolyzed blood samples. Although protoporphyrin and zinc protoporphyrin are the only fluorescent compounds in blood, hemoglobin does absorb some fluorescence. Therefore, it is necessary to correct observed values for hemoglobin concentration.

Erythrocyte protoporphyrin also increases in lead poisoning because ferrocheletase, the enzyme responsible for inserting iron into protoporphyrins, is inhibited by lead. In the anemia of chronic disease, protoporphyrin increases because of internal iron unavailability.

G. Tissue Nonheme Iron

Body iron stores can be determined directly by measuring the iron concentrations in various organs (Torrance and Bothwell, 1980). Although it may be desirable to determine iron in each body tissue, nonheme iron usually is determined in organs containing large quantities of iron that are accessible for biopsy, that is, liver and spleen. Total tissue iron does not reflect stored iron because most tissues contain heme iron compounds such as hemoglobin, myoglobin, or heme enzymes. Only the nonheme iron fraction represents iron stored in ferritin or hemosiderin. Because heme

resists acid hydrolysis, nonheme iron can be separated from heme iron by extraction in acid alone or acid combined with sodium pyrophosphate. Sodium pyrophosphate forms a stable complex with ferrous iron and aids extraction.

The acid extraction method (Torrance and Bothwell, 1980) is simple and effective. Small pieces of tissue are incubated in a mixture of 3 *N* hydrochloric acid and 0.61 *M* trichloroacetic acid. After samples are incubated for 20 hours at 65°C nonheme, iron is determined colorimetrically or coulometrically. It is not necessary to homogenize the tissue if small pieces are used, and no centrifugation is required (Torrance and Bothwell, 1980).

H. Ferrokinetics

The term *ferrokinetics* refers to measurements made following the intravenous injection of radioiron-labeled transferrin. The technique was introduced by Huff and coworkers (Huff *et al.*, 1950), and the complexity of the technique varies (Cook and Finch, 1980). In the simplest method, radioiron is injected intravenously without prior incubation with plasma transferrin, and four or five samples are taken over a 2-hour period. In the most complicated experiment, radioiron-labeled transferrin is used, samples are taken for a period of 2 weeks, and the data are analyzed by sophisticated computer programs. A ferrokinetic approach that falls between the two extremes usually is used to study erythropoiesis. That approach will be described here (Cook and Finch, 1980).

1. Iron Turnover

In this method, serum iron and TIBC are determined to establish that the UIBC is greater than the amount of radioactive iron that will be used. The recipient's plasma is incubated with radioactive iron for 30 minutes at room temperature. An aliquot of the labeled plasma is removed to determine radioactivity. The plasma with radioactive iron-labeled transferrin is injected intravenously. The volume injected can be determined by weighing the syringe containing the radioactive iron before and after the injection. At various intervals, plasma radioactivity is determined and plotted on semilogarithmic coordinates.

The plasma volume can be calculated by isotope dilution. A line representing radioactivity for the first few minutes or hours is extrapolated to time zero. The plasma volume can be determined by the following formula:

$$\text{Plasma volume (ml)} = \frac{\text{total activity injected}}{\text{activity at zero time/ml of plasma}}.$$

The simplest approach to ferrokinetics is to use the initial rapid plasma disappearance to calculate the plasma iron turnover (Fig. 9.5), which is the amount of iron flowing through the plasma per unit time. It depends on the rate of iron clearance and the size of the circulating iron pool (plasma iron concentration × total plasma volume). The halftime ($T1_{1/2}$) of iron (or time required for 50% of plasma radioactivity to disappear) is determined from the initial single exponential clearance. The plasma iron turnover (PIT) can be calculated by the following formula:

$$\text{PIT } (\mu g/\text{dl plasma/day}) = \frac{0.693 \times 24 \times 60 \times \text{plasma iron } (\mu g/\text{dl})}{T_{1/2}} = \frac{\text{plasma iron } (\mu g/\text{dl}) \times 1000}{T_{1/2}}$$

If it is assumed that all iron cleared from the plasma is used for hemoglobin synthesis, the erythrocyte synthetic rate can be calculated. When the circulating erythrocytes are constant, the daily erythrocyte production equals the erythrocyte destruction and is calculated as

$$\text{Erythrocytes (ml/day)} = \frac{\text{packed cell volume} \times 100}{\text{erythrocyte lifespan (days)}}.$$

Because 1 ml of erythrocytes contains 1.1 mg of iron, the plasma iron turnover needed to maintain homeostasis can be determined. The observed plasma iron turnover is usually higher, because some iron flows to nonerythroid tissues and some refluxes early from the extravascular circulation.

Plasma iron turnover rate can be expected to increase in ineffective erythropoiesis and to decrease in erythroid hypoplasia (Erslev, 1983). Erroneous results can be obtained if the blood volume is abnormal, such as in severe dehydration or hydremia. Normal values are shown in Table 9.4.

If plasma radioactivity is followed for the next several days, the disappearance curve is extremely complex (Pollycove and Mortimer, 1961). Normally, the curve can be resolved into a three-component, polynomial expression (Fig. 9.6). Each component presumably represents some iron pool that is in equilibrium with the plasma iron.

2. Erythrocyte Utilization Rate

After radioactive iron-labeled transferrin is injected, some iron is incorporated into hemoglobin. If the reactivity in erythrocytes is determined serially for 10–14 days (Fig. 9.5), the percent of the iron used for erythrocyte production can be determined as follows:

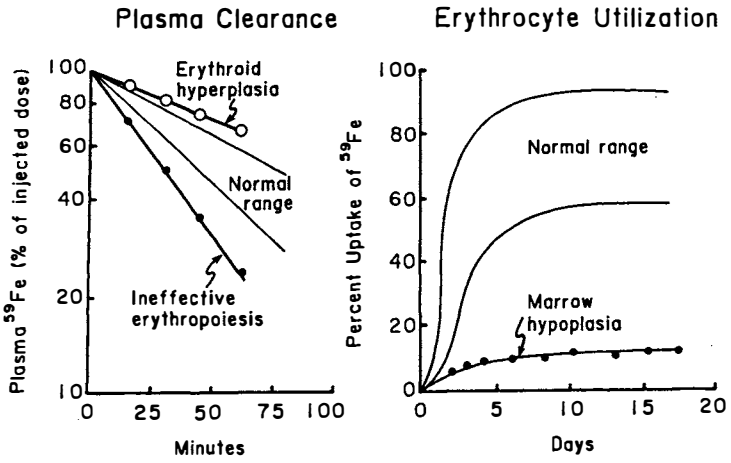

FIGURE 9.5 Iron metabolism in dogs. The left panel shows plasma clearance of injected $_{59}$Fe in normal dogs and those with erythroid hyperplasma and ineffective erythropoiesis. The right panel shows uptake of $_{59}$Fe into erythrocytes as percentage of injected dose and the effect of marrow hypoplasia (Kaneko, 1980; Erslev, 1983).

$$\text{Erythrocyte utilization (\%)} = \frac{\text{radioactivity/ml blood} \times \text{blood volume}}{\text{amount of radioactivity injected}}$$

Normally, erythrocytes incorporate most of the injected radioactive iron (Table 9.4). Decreased utilization can occur in ineffective erythropoiesis and marrow hypoplasia. Those two possibilities can be separated by the plasma iron turnover rate. Ineffective erythropoiesis will shorten the radioactive iron clearance, and marrow hypoplasia will have a prolonged clearance rate. However, increased utilization is difficult to determine, because the normal values are so high (1983).

3. *Marrow Transit Time*

Marrow transit time is the time required for e cytes to mature in the bone marrow. Althou difficult to determine directly, it can be estimate the appearance of radioactively labeled erythr It is defined as the time when 50% of the rad labeled erythrocytes have left the marrow and i by plotting daily erythrocyte iron utilization

TABLE 9.4 Plasma Iron Turnover (Ferrokinetics) in Domestic Animals[a]

Animal	Half-time $T_{1/2}$ (min)	Fractional transfer rate k (day^{-1})	Transfer rate Tr (mg/day)	Tr or plasma iron turnover rate: Tr/kg body wt (mg/kg day)	Tr or plasma iron turnover rate: Tr/100 ml plasma (mg/100 ml day)	Maximum erythrocyte ^{59}Fe uptake (% dose)	Reference
Horse	75–103		111–153	0.45–0.65	0.77–1.48	74–77	Obara and Nakajima (1961b

					(1.80)	(20)	

[a] Values have been recalculated when necessary to maintain consistency. Numbers in parentheses are means.

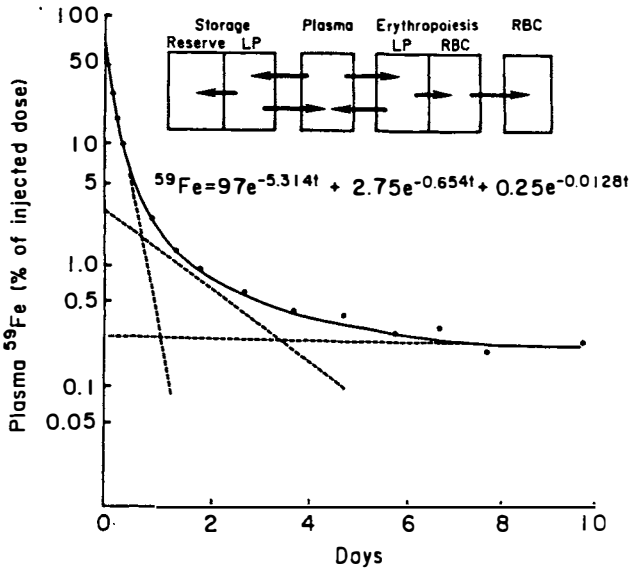

FIGURE 9.6 Plasma ^{59}Fe clearance in a normal steer and the mathematical expression derived from the data, assuming a three-compartment model (Kaneko, 1980). The upper portion shows a possible model of plasma iron disappearance. LP, labile pool (Pollycove and Mortimer, 1961).

time. Thus, it is the time at which 50% of maximum erythrocyte utilization has occurred. A short transit time is found in erythroid hyperactivity and may be caused by early release of reticulocyte. A prolonged marrow transit time indicates erythroid hypoactivity (Erslev, 1983).

V. DISORDERS OF IRON METABOLISM

A. Iron Deficiency

1. General Manifestations of Iron Deficiency

Iron deficiency is probably the most common deficiency in man. Worldwide, it is estimated to occur in hundreds of millions of people. Although iron deficiency is less frequent in domestic animals, it does occur and can adversely affect health and performance.

Three categories of iron deficiency exist in animals: iron deficiency, iron-deficient erythropoiesis, and iron deficiency anemia (Hastka *et al.*, 1994). Various iron analytes can be used to differentiate these categories (Table 9.5). In domestic animals, iron deficiency anemia is the most common form. Transient iron deficiency occurs in the young of most domestic species in association with rapid growth and an all-milk diet. Classical laboratory findings are a microcytic, hypochromic anemia with normal or increased reticulocyte counts. Serum iron is decreased below 50 μg/dl, serum TIBC is increased, serum ferritin is decreased, and erythrocyte

TABLE 9.5 Iron Analytes in Various Stages of Iron Deficiency[a]

Analyte	Iron deficiency	Iron-deficient erythropoiesis	Iron deficiency anemia
Bone marrow iron	↓	↓	↓
Serum ferritin	↓	↓	↓
Serum iron	N	↓	↓
Zinc protoporphyrin	N	↑	↑
Transferrin saturation	N	↓	↓
Hemoglobin	N	N	↓
Erythrocyte size	N	N	↓

[a] Hastka *et al.* (1994).

protoporphyrin is increased. Because the serum iron is decreased while the TIBC is increased, the percent saturation is decreased. That should have an adverse effect on transfer of iron to immature erythrocytes, because transferrin would be mostly monoferric.

Several concepts are important to iron deficiency that occurs in adult animals (Mahaffey, 1986): (1) It results from excessive loss rather than inadequate intake. (2) Iron is usually lost as blood (intestinal malabsorption might be an exception). (3) Blood loss must be prolonged. Normally, storage iron can replace the amount lost in a single bleeding episode, if the animal survives.

The signs of iron deficiency are only partly due to a compromised delivery of oxygen to the tissues from decreased hemoglobin concentration. Iron deficiency depletes important iron-containing compounds in solid tissues. In fact, iron is preferentially shunted from tissue stores and iron-containing enzymes to the erythropoietic tissues. For example, New Hampshire chicks have white feathers instead of a reddish-brown plumage when they are raised on an iron-deficient diet (Davis *et al.*, 1962). Classical signs and symptoms of iron deficiency can occur in human patients phlebotomized for polycythemia vera. The packed cell volumes in those human patients may be greater than 50, yet they may complain of fatigue, weakness, etc.

Biochemical abnormalities have been associated with physiological function in iron deficiency for striated muscle, central nervous system, white blood cells, and the gastrointestinal tract (Dallman *et al.*, 1978).

Iron-deficient rats show decreased work performance that is not reversed by transfusion to correct the associated anemia. Reduced α-glycerophosphate dehydrogenase activity, both during depletion and in response to iron therapy, is temporally related to changes in muscle function. That enzyme is a nonheme iron-containing protein and plays an important role in skeletal muscle metabolism (Finch *et al.*, 1976).

Altered behavior, that is, apathy and irritability, has been associated with iron deficiency. Brain iron decreases rapidly during iron deficiency and the low level persists after iron repletion of other tissues. Aldehyde oxidase, a key enzyme in serotonin degradation, is decreased, and serotonin level is elevated in iron deficiency (Mackler *et al.*, 1978). The accumulation of catecholamines may explain the mental changes associated with the condition.

Iron deficiency often is associated with impaired cell-mediated immunity and ability of polymorphonuclear granulocytes to kill ingested bacteria. Abnormalities result from defective DNA synthesis and decreased activity of ribonucleotide reductase. This enzyme contains iron, but the exact form is uncertain (Hoffbrand *et al.*, 1976).

Neutrophils have many iron-containing compounds. Myeloperoxidase is an iron-containing enzyme that is found in primary granules and contributes to antimicrobial activity. The exact role of the enzyme is unclear, because human patients with a congenital deficiency of myeloperoxidase are asymptomatic. In addition, the neutrophils of some avian species do not normally have myeloperoxidase activity but susceptibility to infections is not increased. Cytochrome is another iron-containing compound that is found in specific granules and is required for the oxidative burst that follows phagocytosis. Cytochrome *c* activity may be preserved preferentially in iron deficiency (Murakawa *et al.*, 1978).

When iron is deficient, acid secretion by the stomach is reduced, and intestinal absorption is impaired. The mucosa of the small intestine can metabolize many foreign compounds. Intestinal transformation plays a major role in the oxidative metabolism of phenacetin and chlorpromazine. When dietary iron is restricted, cytochrome P450 and oxidative enzyme activities fall sharply. Oral iron, but not parenteral iron, will restore cytochrome P450 (Hoensch *et al.*, 1976).

2. *Iron Deficiency in Pigs*

Baby pigs are very susceptible to iron deficiency because they are born with low levels of storage iron (Douglas *et al.*, 1972), they grow rapidly (Braude *et al.*, 1962), and sow's milk is low in iron (Kolb, 1963). The evolution of swine management (to eliminate neonatal pig's access to dirt) has accentuated the problem so that iron compounds are injected parenterally as standard practice. Previously, 100 mg of iron as iron dextran injected within the first 3 days was considered to be adequate, until the pigs were eating enough solid feed to provide needed iron. Although some swine producers continue to inject 100 mg of iron, the recommended level has been increased to 200 mg.

Recently, the growth rate of pigs from birth to weaning at 21 days has increased dramatically. Because weaning weights from 13 to 15 lbs have become increasingly common, an additional 200 mg of iron should be given at 10–14 days (Smith, 1989).

3. *Iron Deficiency in Calves*

Veal calves are purposely fed an iron-deficient diet so meat will be pale. They are anemic, with low erythrocyte numbers, hemoglobin, and packed cell volume. Some neonatal calves may have a congenital iron deficiency, because *in utero* transfer of iron from dam to fetus is impaired (Tennant *et al.*, 1975).

4. *Iron Deficiency in Foals*

Foals have low iron stores during the first 5 months of life as indicated by a decreased serum ferritin concentration, an increased serum TIBC, and a decreased mean erythrocyte volume (Harvey *et al.*, 1987).

5. *Iron Deficiency in Dogs*

Iron deficiency can occur in young animals, but most cases involves chronic blood loss from blood-sucking parasites, gastrointestinal tumors, urinary bladder tumors, or hemorrhagic disorders (Harvey *et al.*, 1982; Dodds and Ward, 1980; Weiser and O'Grady, 1983). Excessive use of dogs as blood donors can deplete iron stores and cause an iron deficiency (Weiser and O'Grady, 1983). Dogs show many of the classical signs and laboratory data of other animals, such as decreased serum iron, lower mean corpuscular volume and mean corpuscular hemoglobin concentration, and variable reticulocytosis, but the serum TIBC does not change significantly. Leptocytosis and erythrocyte fragmentation also occur (Harvey *et al.*, 1982; Weiser and O'Grady, 1983).

6. *Iron Deficiency in Cats*

Transient microcytosis and anemia, which can be attributed to iron deficiency, occur in many 5-week-old kittens. Erythrocyte volume distribution curves are more sensitive than the mean corpuscular volume for detecting microcytosis. Some erythrocyte fragmentation occurs, but hypochromia does not. Serum iron and percent transferrin saturation values decline. The percentage of microcytes (less than 28 fl) can be estimated as follows:

$$\text{Microcytes (\%)} = 1340\ (\%\ \text{transferrin saturation})^{-1.52}.$$

Oral or parenteral iron may be appropriate to decrease neonatal morbidity (Weiser and Kociba, 1983).

B. Iron Overload and Toxicity

Iron overload can be divided into the following categories: (1) genetic, (2) iatrogenic, (3) chronic hemolytic anemia, (4) changes from natural diet, and (5) experimental.

1. Genetic

In man, hemochromatosis is an inherited disease that is characterized by increased iron absorption from the intestine, high or total iron saturation of plasma transferrin, and abnormal iron deposition in parenchymal cells. If patients are untreated, excess hepatic iron can cause cirrhosis, and accumulation in heart muscle can result in cardiac failure. Other signs include arthropathy, endocrine abnormalities, and diabetes mellitus. Generally, it is a disease of middle-aged men with Irish-English ancestry. The incidence in the general population is about 1 in 3000.

Primary iron overload or hemochromatosis occurs in the Salers breed of cattle. Affected animals have increased serum iron and transferrin saturation, decreased UIBC, and increased hepatic iron. The probands were the product of a line breeding program and have several common ancestries (House *et al.*, 1994).

Horses with hepatic cirrhosis, excess hepatic liver iron, and liver failure have been diagnosed as having hemochromatosis (Pearson *et al.*, 1994; Lavoie and Teuscher, 1993; Edens *et al.*, 1993). This syndrome probably is not classical hemochromatosis, because it occurs in different breeds of horses and has a normal transferrin saturation. It is unclear whether the iron accumulation occurs secondarily to liver damage, or the hepatic disorders result from the iron accumulation.

2. Iatrogenic

Many horse owners and trainers as well as a few veterinarians are convinced that iron deficiency occurs commonly in horses. Thus, they provide iron either in feed or parenteral therapy. One race horse had been treated weekly for 2 years. If the horse did not excrete significant quantities of iron, he would have accumulated about 2.5 pounds of iron (Lewis and Moyer, 1975). When the iron status of 100 clinical horses was evaluated, 10% had serum ferritin values that were greater than 6 standard deviations above the mean (Smith *et al.*, 1986).

Foals and calves can be poisoned acutely by oral administration of iron-containing hematinics (Ruhr, 1983; Mullaney and Brown, 1988). Neonatal calves and foals are particularly susceptible to supplements containing large amounts of iron.

Parenterally injected iron dextran also can cause problems. Anaphylactic shock can occur (Landiges and Garlinghouse, 1981), and if selenium-vitamin E are inadequate, animals can die from acute iron toxicity (Lannek *et al.*, 1962).

3. Chronic Hemolytic Anemia

Chronic severe anemias that stimulate erythropoietin production are associated with iron overloading. For example, pyruvate kinase deficiency in Basenji dogs causes a severe hemolytic anemia. Erythroid hyperplasia associated with the anemia results in increased hepatic parenchymal iron deposition and possibly some cirrhosis. When an affected dog's bone marrow is replaced with bone marrow from normal dogs, erythropoiesis becomes normal and hepatic iron overload decreases (Weiden *et al.*, 1981). Similarly, congenital dyserythropoiesis in Polled Hereford cattle is accompanied by a marked increase in stored iron (Steffen *et al.*, 1991).

4. Changes from Natural Diet

When exotic animals are translocated from their natural surroundings to captive environments, their diets usually are altered. Iron overload can occur when iron is more bioavailable in the substitute diet. Hemosiderosis occurs in captive black rhinoceroses (Kock *et al.*, 1992), lemurs (Gonzales *et al.*, 1984), African rock hyrax (Frye, 1982), Svakbard reindeer (Borch-Iohnsen and Nilseen, 1987), Afghan pikas (Madarame *et al.*, 1990), and mynahs and other tropical birds (Iancu, 1993).

5. Experimental

Iron has been given orally or parenterally to various species of animals to reproduce the signs of human hemochromatosis. Unfortunately, many signs of hemochromatosis, including cirrhosis, cannot be induced in most animal species (Iancu, 1993).

C. Acute Phase Reaction

When bacteria invade an animal, their ability to grow and multiply depends on the availability of iron. The animal responds with several inflammatory processes, collectively called the acute-phase reaction. The major mediator of that response is interleukin-1 released by macrophages. Interleukin-1 causes the following changes within hours or days: decreased serum iron and zinc, increased copper and ceruloplasmin, neutrophilia with increased immature forms, fever, and release of acute-phase proteins from the liver. Those acute-phase proteins include ferritin, haptoglobin, ceruloplasmin, amyloid A protein, C-reactive protein, complement components, and fibrinogen (Dinarello, 1984).

The effect on serum iron is dramatic, with levels decreasing to 10–20% of normal within 15 hours. Serum iron then may return to normal within 2–3 days, if the stimulant is removed. Serum ferritin slowly increases to 1.5–2 times normal and then declines over 2–3 weeks (Smith and Cipriano, 1987). If only serum iron is used to determine the iron status of sick animals, misdiagnosis of iron deficiency is possible.

D. Corticosteriods

Corticosteriods can blunt and interfere with the acute-phase response. They also affect serum iron under normal conditions. Serum iron in horses (Smith *et al.*, 1986) and dogs (Harvey *et al.*, 1987) increases dramatically when corticosteroids are given. Other iron analytes such as serum ferritin and TIBC are not affected. In dogs, endogenous cortisone levels seem to be responsible for the diurnal variation of serum iron. In contrast, cattle respond to dexamethasone by decreasing both serum iron and zinc (Weeks *et al.*, 1988a).

E. Anemia of Chronic Disorders

If an inflammatory response becomes chronic, an anemia develops. Serum iron, TIBC, and percent saturation decrease. Ferrokinetically, an inadequate erythropoietic response is partially due to iron unavailability (Feldman *et al.*, 1981a, 1981b). Normally, iron from senescent erythrocytes is distributed into two pools in macrophages. One pool has a rapid turnover with a half-life of 30 minutes; the other, 7 days (Fillet *et al.*, 1974). During chronic inflammation, iron from the rapid pool is severely impaired, and iron remains sequestered in macrophages. Bone marrow iron and storage iron increase. Because iron is sequestered in the reticuloendothelial system, it is unavailable to the erythropoietic tissue (Freireich *et al.*, 1957).

F. Other Disorders

Several other disorders can affect iron metabolism secondarily. Pigs deficient in copper, pyridoxine, and pteroylglutamic acid have an increased iron turnover and anemia (Bush *et al.*, 1956). Increased iron turnover also occurs in polycythemia vera, erythropoietic porphyria, and familial polycythemia (Kaneko, 1980).

CHAPTER

10

Hemostasis

W. JEAN DODDS

I. INTRODUCTION

Hemostasis, the process by which bleeding is arrested, comprises a complex series of physiological and biochemical events that terminate in the formation of a stable plug that seals the blood vessel. The process involves the following sequence of events: interaction between the blood vessel wall, adhesive glycoproteins, and platelets; blood coagulation; and fibrinolysis (Fig. 10.1). The pathophysiological mechanisms involved with each of these components are summarized below. More detailed descriptions can be found elsewhere (Comp, 1990a; Esmon *et al.*, 1991; Preissner and Jenne, 1991; Bauer *et al.*, 1992; Bornstein, 1992; Breider, 1993; Lüscher and Weber, 1993; Marcus and Safier, 1993; Calvete, 1994; Ruf and Edgington, 1994; Andrew, 1995; Broze, Jr., 1995; Caen and Rosa, 1995; Cerletti *et al.*, 1995; Clemetson, 1995; Davie, 1995; Deng *et al.*, 1995; Dowd *et al.*, 1995; Furie and Furie, 1995a; Ginsberg *et al.*, 1995; Grabowski and Lam, 1995; Hawiger, 1995; Hess *et al.*, 1995; Nemerson, 1995; Rapaport and Rao, 1995; Shattil, 1995; Sixma *et al.*, 1995; Ugarova *et al.*, 1995; Verstraete, 1995; Weiss, 1995; Griendling and Alexander, 1996).

II. MECHANISMS OF HEMOSTASIS

A. Blood Vessels and Adhesion Molecules

When a blood vessel is injured or severed, a brief local reflex vasoconstriction occurs that reduces blood flow at the site. Vascular contraction is maintained by the release of vasoactive compounds from adjacent platelets and surrounding tissues. Simultaneously, platelets in the vicinity adhere to exposed subendothelial collagen fibers. This interaction with collagen causes a "release reaction" whereby platelet constituents, such as adenosine diphosphate (ADP), serotonin, epinephrine, and histamine, are released into the surrounding medium. The role of platelets in sustaining hemostasis has been reviewed by Lüscher and Weber (1993), Marcus and Safier (1993), Caen and Rosa (1993), and Hawiger (1995); the process is summarized in Section II.B.

Other constituents of the blood vessel wall and its endothelial cells play important roles in the formation

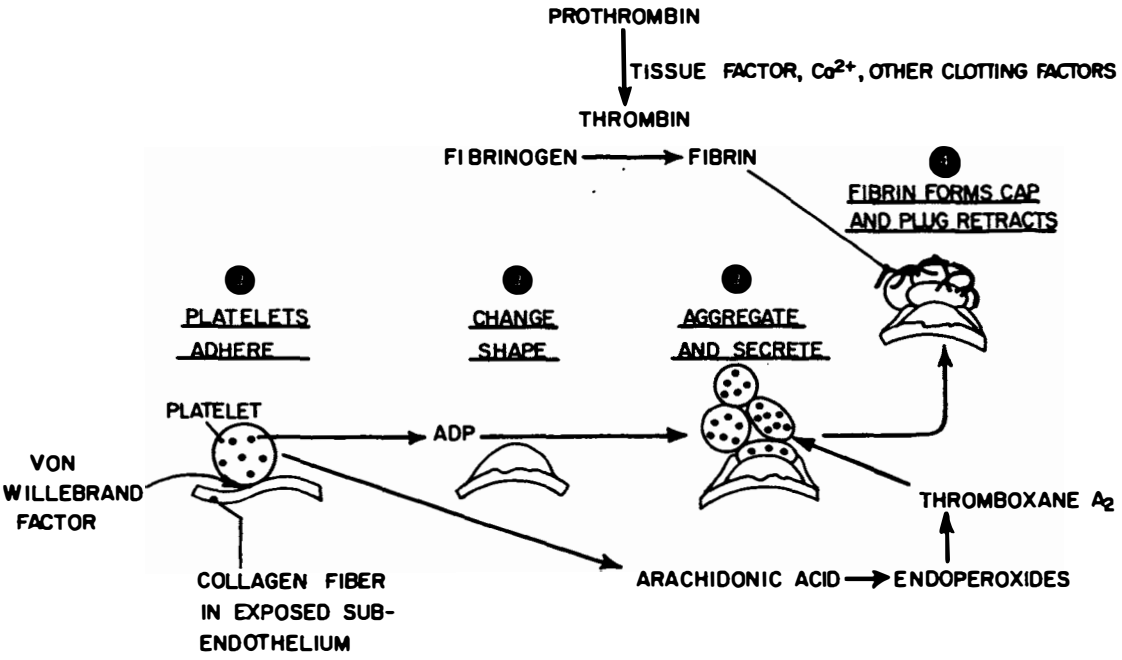

FIGURE 10.1 The hemostatic process (Dodds, 1989a).

and dissolution of hemostatic plugs, thrombi, and atherogenic lesions. The mechanism of interaction among these components has recently been elucidated (Comp, 1990a; Preissner and Jenne, 1991; Breider, 1993; Marcus and Safier, 1993; Caen and Rosa, 1995; Grabowski and Lam, 1995; Hess *et al.*, 1995; Griendling and Alexander, 1996).

One of the basic functions of the intact, normal vascular endothelium is to provide a thromboresistant surface to the flowing blood. Intact endothelium does not promote platelet or leukocyte adherence nor does it activate coagulation. Both active and passive mechanisms apparently play a role in maintaining thromboresistance, and endothelial cells actively contribute to this thromboresistance by regulating a complex balance between the procoagulant and anticoagulant properties of the vasculature (Breider, 1993; Griendling and Alexander, 1996). The procoagulant activities of endothelium include von Willebrand factor, tissue factor, plasminogen activator inhibitor (PAI), and factor V, whereas the anticoagulants of endothelium include its barrier to subendothelium, prostacyclin (prostaglandin I_2 or PGI_2), thrombomodulin, protein S, lipoprotein-associated coagulation inhibitor (LACI), plasminogen activator, and heparan sulfate. Endothelium, particularly in the pulmonary microcirculation, actively removes substances from the circulation that promote platelet aggregation. These include prostaglandin F_1, serotonin, adenine nucleotides, bradykinin, and angiotensin I. In addition, all layers of blood vessels, especially the intima and endothelium, synthesize and release PGI_2, a potent inhibitor of platelet aggregation (Herman *et al.*, 1991; Marcus and Safier, 1993).

The proteoglycan matrix of the blood vessel wall also directly influences thrombogenicity. Three components, heparin, heparan sulfate, and dermatan sulfate, possess anticoagulant activity, whereas other glycosaminoglycans and hyaluronic acid do not. Veins have the highest concentrations of the former compounds and are the most thromboresistant. The antithrombotic proteoglycans differ in potency and mechanism of action. They affect coagulation factors (thrombin, antithrombin III, factor X, and fibrinogen) and platelet functions (inhibit thrombin- and collagen-induced aggregation, and bind to platelet factor 4 and platelet-derived growth factor) (Dodds, 1989a).

Passive mechanisms of thromboresistance also exist but are less contributory. These include protection of the cell surface by its carbohydrate-rich cell coat, the glycocalyx; the negative surface charge of the endothelial lumen, which repels similarly charged cells such as platelets; continuous, nonspecific renewal of cell membranes; and presence at the cell surface of the protease inhibitor α_2-macroglobulin (Breider, 1993; Griendling and Alexander, 1996).

In addition to its role in thromboresistance (Section II.B), the endothelium has important synthetic, metabolic, and pathological functions. Endothelial cells synthesize von Willebrand factor (vWF) (Section II.C.2.g); tissue plasminogen activator (TPA); basement mem-

brane type III and IV collagens and elastin; fibronectin or cold insoluble globulin (CIg), α_2-opsonic protein; numerous metabolic enzymes; and PGI_2. The capacity of endothelium to synthesize large amounts of vWF and fibronectin has permitted these proteins to be used as markers for identifying endothelial cells in tissue specimens and cell cultures.

The endothelium plays an important role in such pathological processes as atherosclerosis, thrombosis, and disseminated intravascular coagulation (DIC), defective hemostasis, inflammation, immune disorders, vascular neoplasia, and metastasis (Comp, 1990a; Esmon *et al.*, 1991; Breider, 1993; Costantini and Zacharski, 1993; Fareed and Callas, 1995; Hemker and Be;aguin, 1995; Griendling and Alexander, 1996). The initiating event in atherogenesis has long been attributed to endothelial injury. After injury, there is increased entrapment of plasma lipoproteins followed by proliferation of arterial smooth muscle cells and/or deposition of free cholesterol and cholesterol esters, *de novo* synthesis of connective tissue, and intracellular and extracellular deposition of lipids in variable amounts. This reaction to injury hypothesis incorporates both the myogenic and lipogenic mechanisms of atherogenesis. Other causes of endothelial injury are infectious agents, especially viruses, gram-negative bacteria, and rickettsia; prolonged hypotension and acidosis or hypoxia; dysproteinemias; primary and secondary immune mechanisms; and acute inflammation. These predispose to either thrombosis and DIC (Joist, 1990), increased vascular permeability (Esmon *et al.*, 1991), or defective hemostasis with purpura or hemorrhage depending on the nature of the incitant (Feldman, 1988; Dodds, 1989a; Mannucci and Giangrande, 1994; Caen and Rosa, 1995).

B. Platelets

Blood platelets are cellular particles produced by megakaryocytes under the influence of a variety of growth regulatory factors (Kaushansky, 1995). The main source is the bone marrow, although the lung and spleen are also sources of platelets. The megakaryocyte is a large (25–50 mm) cell with a polyploid nucleus that is extremely pleomorphic. As the cell matures, pseudopods form and platelets bud off at the extremities (Gewitz, 1995). Megakaryocyte and platelet production are regulated primarily by thrombopoietin, a lineage-specific cytokine that acts as a growth factor for platelet production (Kaushansky, 1995). The normal platelet seen in a Wright's stained blood film is 1–4 mm in diameter and is spherical, oval, or rod shaped. The cytoplasm is pale blue and contains reddish granules. Circulating platelets are disk shaped.

The role of the blood platelet in hemostasis is of equal importance to that of the coagulation mechanism (Lüscher and Weber, 1993; Marcus and Safier, 1993). Platelets are involved with the blood vessel wall and the contact-activated coagulation factors (XII and XI) in the initiation of the hemostatic process. Decrease in the number of circulating platelets (thrombocytopenia) or presence of abnormal, nonfunctional platelets (thrombasthenia, thrombopathia) will impair hemostasis. In some instances of an excess of platelets (thrombocytosis or thrombocythemia), hemostasis may be inadequate, but usually clotting is promoted, which may predispose a patient to thrombosis. The multifaceted role of platelets in biochemical, physiological, and pathological processes has been extensively reviewed (Boudreaux *et al.*, 1989a; Bornstein, 1992; Shukla, 1992; Rao *et al.*, 1993; Calvete, 1994; Gawaz *et al.*, 1994; Caen and Rosa, 1995; Cerletti *et al.*, 1995; Clemetson, 1995; Furie and Furie, 1995a; Ginsberg *et al.*, 1995; Hawiger, 1995; Hess *et al.*, 1995; Nurden, 1995; Shattil, 1995; Sixma *et al.*, 1995; Ugarova *et al.*, 1995; Weiss, 1995).

Platelets promote hemostasis in several ways (Lüscher and Weber, 1993; Marcus and Safier, 1993). When a blood vessel is injured, platelets accumulate at the site of injury. They adhere to the vessel wall, then to each other, and also become involved in the intrinsic coagulation pathway. On exposure of platelets to collagen fibers of the vessel wall, certain active constituents are released from the platelet (serotonin, histamines, ADP) (Sixma *et al.*, 1995). The release of ADP into the ambient fluid induces the adherence and aggregation of platelets to the area. The aggregation process, which requires calcium, fibrinogen, and metabolic energy, forms an initial hemostatic plug of platelets that seals the vessel (Clemetson, 1995). In addition to mediating platelet aggregation, ADP releases a platelet surface phospholipoprotein, platelet factor 3 (PF3), which accelerates coagulation. Platelets also undergo a series of reactions mediated by thrombin and connective tissue that produces marked structural changes (Ugarova *et al.*, 1995). This process has been called viscous metamorphosis. The thrombin associated with *viscous metamorphosis* and evolved from tissue injury rapidly activates the coagulation mechanism, fibrin is formed around the platelet aggregate, and a stable fibrin plug forms.

Platelets are metabolically active in biochemical, physiological, and pathological processes (Table 10.1). In addition to the basic adhesion, aggregation, and release reactions, they agglutinate in the presence of a variety of compounds including bovine factor VIII, ruminant plasma, ristocetin, polylysine, snake venoms, and polybrene (Dodds, 1989a; Smith and Brinkhous, 1991; Brinkhous, 1992; Ermens *et al.*, 1995).

TABLE 10.1 Functions of Blood Platelets[a]

Hemostasis and thrombosis (endothelial cells, coagulation, von Willebrand factor, collagen, adenosine diphosphate, adrenalin, thrombin)
Atherogenesis (platelet-derived growth factor, mitogens, cell-proliferating activity)
Specialized smooth muscle cell (clot retraction)
Inflammation (specialized type of intravascular leukocyte; chemotaxis and phagocytosis)
Prostaglandin metabolism
Immunologic reaction (immune complex disease)
Endotoxin reactivity (Schwartzman reaction)
Monoamines and serotonergic synaptosomes (epinephrine, serotonin)
Interactions with tumor cells (adhesion, aggregation, cell transformation, metastases)
Synthesis of proteins, lipids, carbohydrates, and nucleotides

[a] Modified from Dodds (1989a).

Platelets actively synthesize proteins, lipids, carbohydrates, and nucleotides. Among the proteins synthesized by or contained in platelets are fibrinogen; the components of the contractile system, actomyosin, myosin, actin, tropomyosin, troponin, and sarcoplasmic reticulum relaxing factor; acid hydrolases and other enzymes; and a series of factors including the growth, permeability, bactericidal, and chemotactic activity factors (Dodds, 1989a). The lipids synthesized by platelets include fatty acids, prostaglandins, glycerides, a series of phosphatides, the sphingolipids, sphingomyelin, cerebrosides, and gangliosides; and sterols. The carbohydrates synthesized by or contained within platelets are glycogen, glycosaminoglycans, and glycoproteins, for example, vWF. The adenine nucleotides of platelets include the cyclic AMP and GMP systems, which regulate the production of platelet endoperoxides, thromboxanes, and prostaglandins. Other important components of platelets are serotonin; thrombospondin, the thrombin-sensitive protein contained in platelet alpha granules (Bornstein, 1992); integrins including the platelet glycoprotein IIb/IIIa complex (Calvete, 1994; Ginsberg *et al.*, 1995; Shattil, 1995); vitronectin (Preissner and Jenne, 1991; Hess *et al.*, 1995); P-selectin, a membrane glycoprotein of platelet alpha granules (Furie and Furie, 1995a); calpain, an ubiquitous calcium-activated neutral protease of animal cells (Saido *et al.*, 1994); and metal ions (Ca^{2+}, Mg^{2+}, Zn^{2+}, K^{+}) (Gawaz *et al.*, 1994). Among the group of adhesion proteins that promote hemostasis via platelet–vessel wall interactions are thrombospondin, fibrinogen, and fibronectin (Feldman *et al.*, 1988; Ugarova *et al.*, 1995).

Platelets generate metabolic energy in the form of ATP, via glycolysis, glycogenolysis, and mitochondrial oxidative phosphorylation, which is then utilized to maintain platelet functions (Grauer *et al.*, 1992; Marcus and Safier, 1993). Platelets have many functions, including phagocytosis of viruses, latex, immune complexes and iron; maintenance of vascular integrity by filling gaps that form in the endothelium and by directly supporting endothelial cells; synthesis and release of vWF in humans and some animal species, and fibronectin; participating in surface adhesion and activation processess (Caen and Rosa, 1995; Clemetson, 1995; Nurden, 1995); production and release of potent smooth muscle and endothelial cell proliferating factor(s); and retraction of clots, a process that stabilizes the initial hemostatic plug and activates clot lysis. Clot retraction requires Ca^{2+}, ATP, and thrombasthenin, the platelet contractile protein (Clemetson, 1995).

Additionally, platelets play an important regulatory role via prostaglandin pathways in promoting hemostasis and thrombosis and in maintaining the thromboresistance of intact endothelium (Herman *et al.*, 1991). This involves metabolism of arachidonic acid released from platelet phospholipids. A potent but unstable platelet-aggregating agent and vasoconstrictor, thromboxane A_2 (TxA_2), is produced from cyclic endoperoxides by the action of cyclooxygenase on arachidonic acid (Johnson *et al.*, 1991). The potent aggregating effect of TxA_2 on platelets is inhibited by the production of prostaglandins E_1 and D_2 (PGE_1 and PGD_2) from linolenic and linoleic acids. Thus, platelet phospholipid and lipid metabolism plays a crucial role in the stimulation and inhibition of platelet reactivity. Aspirin is an effective inhibitor of the platelet release reaction because it acetylates cyclooxgenase and inhibits TxA_2 production (Grauer *et al.*, 1992).

A key component of the platelet prostaglandin regulatory mechanism of hemostasis and thrombosis is the production of prostacyclin (PGI_2) by endothelium and other vascular tissues. Prostacyclin is estimated to be about 30 times more potent than PGE_1 and PGD_2 in inhibiting platelet aggregation and also causes relaxation of vascular smooth muscle. Like platelet TxA_2, PGI_2 is formed in blood vessels from cyclic endoperoxides by the action of cyclooxygenase on arachidonic acid. Production of PGI_2 from endogenous or exogenous arachidonic acid is effectively blocked by aspirin and indomethacin, but production from other prostaglandin endoperoxides is not (Herman *et al.*, 1991; Grauer *et al.*, 1992; Goodnight, 1995). The dose of aspirin required to inhibit vascular PGI_2 formation is apparently much greater than that required to prevent platelet synthesis of TxA_2 (Grauer *et al.*, 1992). This observation has considerable significance because the

antithrombogenic properties of aspirin, as mediated by inhibition of platelet TxA_2, can be reversed at high aspirin dosage by inhibition of vessel wall PGI_2.

The final points to emphasize about platelets are the age and species differences encountered in their morphological and functional characteristics. Neonatal platelets are less reactive than adult platelets to physiological agonists (Rajasekhar *et al.*, 1994). The comparative aspects of platelet function in animals and humans have been reviewed (Dodds, 1989a).

C. Coagulation

1. General

The process of blood coagulation has been the subject of intensive investigation for more than 50 years (Brinkhous, 1992). It involves a complex series of reactions among a group of coagulation factors, which are designated by the International Committee for the Nomenclature of Blood Clotting Factors (1962) by Roman numerals. The blood coagulation process participates in hemostasis after the initial interactions of the platelets with the vessel wall and with one another (Caen and Rosa, 1995; Davie, 1995). Blood flowing through an injured vessel contacts exposed foreign surfaces, and the injured cells release tissue thromboplastins (Grabowski and Lam, 1995). These surface contacts and released thromboplastins activate coagulation (Ruf and Edgington, 1994).

Coagulation proceeds by an intrinsic or intravascular pathway (Lozier and High, 1990; Bauer *et al.*, 1992; Davie, 1995; Nemerson, 1995) and by an extrinsic or tissue juice pathway, both of which convert prothrombin to thrombin (Hemker and Béguin, 1995; Nemerson, 1995; Rapaport and Rao, 1995). Thrombin converts fibrinogen to soluble fibrin monomer, which, with factor XIII and calcium, is converted to the fully polymerized, insoluble fibrin clot. This final stage of coagulation is also the end point measured in most coagulation tests.

Once initiated, activation of the intrinsic and extrinsic systems continues sequentially and through an interactive reinforcement loop, forming the end products plasma thromboplastin and prothrombinase, respectively (Lozier and High, 1990; Davie, 1995). These prothrombin-converting principles convert factor X to Xa, which initiates the final common pathway of prothrombin conversion. This pathway involves factor V, prothrombin (factor II), fibrinogen (factor I), and factor XIII. The phospholipid necessary for the interaction of factors IX and VIII and for the activation of factors X and V is supplied *in vivo* primarily by platelet factor 3 (PF-3) with some from red cells and tissue juice. *In vitro*, it can be provided by various phospholipid preparations or their substitutes.

The clotting mechanism can be best described as a series of sequential activating steps that produces a plasma thromboplastic and/or a tissue thromboplastic component, both of which can convert prothrombin to thrombin in the presence of calcium ions (Lozier and High, 1990; Davie, 1995). The enzymatically active factors are protein in nature, and, in general, each of the sequential activations is enzymatic hydrolyses of the inactive precursor forms. Note that factor III (tissue thromboplastin) primarily acts in the extrinsic system and that there is no factor VI designated in the nomenclature. Several clotting factors have more recently been identified that participate in the contact phase of intrinsic clotting (factors XII and XI) and are part of the plasma kallikrein–kinin system responsible for capillary permeability and smooth muscle contraction. These, which have not been given numerical designations, include the Fletcher factor (prekallikrein) and the Williams Fitzgerald–Flaujeac factor (high-molecular-weight kininogen, HMWK).

The fibrin produced by blood coagulation forms at the periphery of the initial hemostatic plug of platelets. The platelet–fibrin mass continues to grow and becomes covered with a cap of fibrin. This stabilized hemostatic plug then contracts to seal the vessel. Thrombin generated during the coagulation process also plays an important part in growth and stabilization of the initial platelet plug (Fenton, 1995). Very low concentrations of thrombin, insufficient to produce visible fibrin formation, cause aggregation of platelets, induce the process of viscous metamorphosis and the release reaction, and make the PF-3 on the platelet surface available for coagulation (Guillin *et al.*, 1995). Thus, the processes of platelet aggregation, release, and contraction are directly enhanced by products evolved after activation of the coagulation mechanism.

The coagulation mechanisms of humans, other animals, and less complex forms are remarkably similar (Dodds, 1989a), but only a few studies have systematically compared platelet function, coagulation, and fibrinolysis among species or have provided a reliable comparison using humans as the reference. Recent studies have compared coagulation activities in fetuses, newborn infants, and adults (Hathaway and Corrigan, 1991; Andrew, 1995) and during fetal development in lambs and lamb neonates (Moalic *et al.*, 1989). Tables 10.2 and 10.3 give comparative species data (Dodds, 1989a).

A major consideration in the understanding of coagulation and hemostasis is the effect of physiological stress on coagulation, fibrinolysis, and platelet function. Alterations from normal hemostasis occur during

fetal and neonatal life, with age, sex, hormonal changes, pregnancy, ethnicity, exercise, mental stress, physical stress, diurnal variation, obesity, smoking, alimentary lipemia, arteriovenous differences, and blood groups (Johnstone *et al.*, 1989; Blombäck *et al.*, 1992; Crossley *et al.*, 1992; Ivankovic *et al.*, 1992; Conlan *et al.*, 1993; Semrad and Dubielzig, 1993; Henkens *et al.*, 1995). Although the significance of many of these changes is unknown, some affect the interpretation of diagnostic test results or place the patient at risk to bleed or thrombose. For example, neonates have low levels of the prothrombin complex vitamin K-dependent clotting factors (Hathaway and Corrigan, 1991; Andrew, 1995) and plasminogen (Andrew *et al.*, 1992; Schmidt *et al.*, 1993), and individuals who are pregnant, markedly stressed, heavy smokers, or grossly overweight may have enhanced hemostasis and be at risk for thrombotic problems (Conlan *et al.*, 1993, 1994), although the bleeding time has been shown to be prolonged in the last trimester of pregnancy (Ivankovic *et al.*, 1992).

The individual clotting factors are discussed in the following sections; detailed reviews are listed among the references.

2. *The Intrinsic System*

a. Hageman Factor (Factor XII)

Hageman factor is involved in the initial stage of clotting through a surface-mediated or "contact activation" process. Factor XII is a single-chain sialoglycoprotein of 80 kDa that is not adsorbed by $Al(OH)_3$, $BaSO_4$, or $Ca_3(PO_4)$, is adsorbed with kaolin or celite, and is stable at 56°C and at various pHs. It is activated by glass, collagen, skin, stearate, vascular basement membranes, ellagic acid, uric acid, and most foreign surfaces. Factor XII activation is inhibited by cytochrome *c*, lysozyme, ribonuclease, spermine, and Cl-esterase inhibitor. Hageman factor migrates electrophoretically as an α-globulin. It is present in plasma as a precursor to a serine protease. It is split by trypsin or plasma kallikrein into two fragments, a 28-kDa active component and an inactive one of 52 kDa. It contains about 17% carbohydrate and no lipid. Hageman factor is synthesized by the liver and its amino acid sequence is known (Davie, 1995). The half-life of factor XII is 52–60 hours and its plasma concentration is about 15–45 μg/ml (Dodds, 1989a).

The functions of activated Hageman factor are numerous and include the conversion of plasma kininogens to kallikrein, the enzyme that elaborates plasma kinins; enhancement of vascular permeability; activation of the fibrinolytic mechanism; initiation of the Schwartzman reaction; activation of the extrinsic coagulation pathway; interaction with the Fletcher (prekallikrein) and Fitzgerald (HMWK) factors in surface-mediated reactions; and mediation of inflammatory and complement (Cl-esterase) reactions (Davie, 1995). The inhibition of the activated first component of complement (Cl-INH) accounts for more than 90% of the plasma inhibitory activity against factor XIIa and its fragments. Most of the properties and functions of Hageman factor apply to plasma thromboplastin antecedent (PTA), which also plays an important role in the initial activation stages of coagulation.

b. Plasma Thromboplastin Antecedent (Factor XI)

Factor XI or PTA is involved in the early stages of coagulation with Hageman factor. It does not require Ca^{2+} for its activity. Factor XI is a fast γ-globulin of about 160 kDa with 5% carbohydrate and a half-life of 30–84 hours. The major plasma protease inhibitor of factor XI is α_1-antitrypsin. Factor XI is present in both serum and plasma and is stable when frozen at −40°C or lower and is stable at room temperature for more than 4 months. Plasma factor XI levels in patients with mild to moderate deficiency tend to increase on storage but not those in the severely deficient patient. The increase in PTA activity of human and canine PTA-deficient plasmas on storage tends to make them unreliable as reagents for factor XI assay. Fortunately, hereditary bovine and several artificial factor XI-deficient plasmas have proved to be excellent substrates (Gentry and Ross, 1993). The adsorbability of factor XI to products such as $Al(OH)_3$, $BaSO_4$, kaolin, and celite can usually be achieved by varying the concentration of adsorbing agent used.

Biochemically, factor XI resembles the Fletcher factor and the precursor of Hageman factor cofactor. It contains two identical polypeptide chains linked by a disulfide bond(s). It is synthesized in the liver and secreted into the plasma as a zymogen that circulates as a complex with HMWK. The cDNA of factor XI has been cloned (Davie, 1995). Normal plasma contains only 2–7 μg/ml of PTA.

c. Plasma Prekallikrein (Fletcher Factor)

Plasma prekallikrein is a 79.5-kDa glycoprotein with about 15% carbohydrate. It is synthesized in the liver and secreted into plasma where nearly 75% circulates with factor XI as a complex with HMWK. The conversion of plasma prekallikrein to kallikrein is catalyzed by factor XIIa in a reaction stimulated by HMWK. Plasma contains 35–50 μg/ml prekallikrein and it migrates electrophoretically as a fast γ-globulin (Geor *et al.*, 1990; Otto *et al.*, 1991). The structure, kinetics, and function of human and rhesus monkey plasma prekallekreins are similar (Veloso *et al.*, 1992).

d. High-Molecular-Weight Kininogen (HMWK or Williams Fitzgerald–Flaujeac Factor)

HMWK has a molecular weight of about 110 kDa and makes up about 15–20% of the total kininogen in plasma. It is an α-globulin with an isoelectric point of pH 4.3 and a plasma concentration of 70–90 μg/ml. HMWK serves as the complexing protein to which both prekallikrein and factor XI are bound (Davie, 1995).

e. Christmas Factor (Factor IX)

Christmas factor is a single-chain glycoprotein with about 17% carbohydrate and a molecular weight of about 55 kDa. It is present in both plasma and serum (Lozier and High, 1990; Davie, 1995). Its activity is higher in serum than in plasma and is increased by contact with glass. It is relatively heat labile, has an aminoterminal tyrosine and is absorbed from plasma or serum by $Al(OH)_3$, $BaSO_4$, and $Ca_3(PO4)_2$. Factor IX is a β-globulin, is stable on storage and is synthesized by the liver (Furie and Furie, 1995b). Its plasma concentration is low, about 4 μg/ml. It is a vitamin K-dependent protein and contains 12 residues of γ-carboxyglutamic acid (Suttie, 1993). Factor IX is activated by the presence of activated factor XI and has an absolute requirement for Ca^{2+}.

Activated factor IX (factor IXa) is a two-chain glycoprotein and acts as a serine protease, which, together with activated factor VIII, phospholipid, and calcium ions, forms a complex that converts factor X to its active form, factor Xa (Bauer *et al.*, 1992). Activated factor VIII acts as the accelerator of this reaction. One of the actions of heparin is to bind to factor IXa and inhibit further activation of the coagulation cascade. The turnover time (18–36 hours) of factor IX in the circulation is longer than that of factor VIII (9–16 hours). The biochemistry of factor IX has been reviewed by Lozier and High (1990) and Furie and Furie (1995b). Factor IX has been cloned and synthesized by recombinant techniques and the genes for human and canine factor IX have been isolated and sequenced (Evans *et al.*, 1989a, 1989b; Lozier and High, 1990; Sommer, 1992; Keith *et al.*, 1994; Davie, 1995; Furie and Furie, 1995b; Sugahara *et al.*, 1996; Walter and High, 1997). This information has led to new developments in gene therapy for hemophilia B in humans and animal models (Palmer *et al.*, 1989; Axelrod *et al.*, 1990). Early experimental data in dogs with hemophilia B have been

promising (Kay *et al.*, 1993, 1994; Marx, 1993; Lozier *et al.*, 1994; Walter and High, 1997).

f. Antihemophilic Factor (Factor VIII)

The following summarizes some of the salient points of this key protein that accelerates intrinsic coagulation. Factor VIII circulates with von Willebrand factor to form a very large glycoprotein complex. The factor VIII:coagulant (FVIII:C) moiety expresses procoagulant activity whereas the vWF protein has several hemostatic properties. Factor VIII has a molecular weight of about 330 kDa and is present in trace amounts in plasma, 15–50 ng/ml. The structure of factor VIII has been characterized for the human, bovine, porcine, and canine proteins (Lozier and High, 1990). Most studies before 1980 included vWF contaminants because vWF makes up about 95% of the complex.

Genomic and cDNA clones of the human factor VIII gene have been characterized (Lozier and High, 1990; Antonarakis, 1995; Fallaux *et al.*, 1995; Thompson, 1995). The protein has 2351 amino acids and a molecular weight of 265 kDa when expressed from cDNA clones. Although it is synthesized as a single polypeptide chain, it circulates in plasma primarily as a two-chain molecule arising from cleavage by an unknown protease during either synthesis, secretion, or in the circulation (Lozier and High, 1990; Davie, 1995). There is significant sequence similarity of factor VIII with portions of factor V and ceruloplasmin. This latter observation suggests that factor VIII may bind to metals such as copper.

Factor VIII is the accelerator protein which, together with factor IXa, phospholipid, and Ca^{2+}, forms a complex that activates factor X (Bauer *et al.*, 1992). Thrombin activates factor VIII *in vivo*, apparently by a proteolytic modification with loss of FVIII:C activity unless both factor IXa and phospholipid vesicles are present to maintain stability (Mansell and Parry, 1989). This thrombin-activated factor VIII then accelerates the activation of factor X. Factor VIII also plays a critical role in the activation of factor X via the extrinsic pathway. Plasma factor VIII concentration varies with exercise, epinephrine, age, gender, pregnancy, central nervous stimulation, and use of oral contraceptives (Blombäuck *et al.*, 1992; Conlan *et al.*, 1993).

Factor VIII migrates electrophoretically in the α_2- and β_2-globulin fractions. It is closely associated with fibrinogen so that only ultrapurified factor VIII is uncontaminated with fibrinogen. It is stable for only short periods at room temperature or at 4°C, but stability is enhanced in heparinized rather than citrated plasma, thus the importance of Ca^{2+} in factor VIII structure and function. For maximum stability, it should be quick frozen and stored at −40°C or lower. It is stable at 56–62°C for relatively long periods, but thermostability is quite variable. Currently, commercial, therapeutic plasma factor VIII concentrates are made by recombinant DNA-derived methods, or by heat and/or chemical treatment to destroy contaminant viruses such as hepatitis and AIDS (Aronson, 1990; Bloom, 1991). Factor VIII is not adsorbed by $Al(OH)_3$ or $BaSO_4$, is activated by thrombin, and is inactivated by plasmin. Factor VIII has a short survival time *in vivo* (9–16 hours) and is synthesized primarily in the liver but in several extrahepatic sites as well. The exact cell(s) site(s) of synthesis remains controversial. The FVIII:C component has its biological activity modified during blood coagulation; is deficient or abnormal in hemophilia A; apparently requires complexing with vWF for expression of full biological activity; and does not influence platelet retention, ristocetin-induced platelet aggregation, or the bleeding time. Production of FVIII:C is controlled by the X chromosome, where the gene is located on the tip of its long arm adjacent to the gene for factor IX (Antonarakis, 1995; Davie, 1995; Fallaux *et al.*, 1995; Thompson, 1995).

Current studies of the factor VIII gene and its product have addressed means of disrupting the gene structure to produce an experimental model of hemophilia A (Bi *et al.*, 1995), as well as approaches for gene therapy including *in vitro* production of factor VIII in mice (Dwarki *et al.*, 1995; Walter and High, 1997).

g. von Willebrand Factor

The increasing prevalence of von Willebrand's disease (vWD) and the importance of vWF in hemostasis and thrombosis have only recently been recognized (Ruggeri and Ware, 1993). In contrast to FVIII:C, the vWF component of the factor VIII complex is biologically inactive during clotting, is deficient or abnormal in vWD, is required for platelet retention in glass bead columns and *in vitro* ristocetin-induced platelet agglutination, and is the major component of the factor VIII complex. It is present in human, bovine, feline, and porcine platelets but is very low in canine platelets. vWF is responsible for the immunoprecipitin line produced in agarose by reactions with heterologous anti-factor VIII, a property now called vWF antigen (vWF:Ag), and is synthesized and released by endothelial cells in all species studied to date and by megakaryocytes of humans and swine but possibly not of dogs (McCarroll *et al.*, 1988; Waters *et al.*, 1989; Catalfamo *et al.*, 1991; Parker *et al.*, 1991; Mannucci, 1995; Meinkoth and Meyers, 1995). vWF is stable during coagulation, has a plasma concentration of about 10 μg/ml, is present in reduced amounts in serum and several other body fluids and tissues, and is required for the stabilization and full activity of FVIII:C

(Blann, 1990; Rand *et al.*, 1993; Ruggeri and Ware, 1993; Hoogstraten-Miller *et al.*, 1995). Production of vWF is controlled by an autosomal locus or loci.

The human vWF gene has been isolated and sequenced (Ruggeri and Ware, 1993). vWF has an unusual macromolecular structure, being composed of a series of very high molecular weight multimers (estimates are between 1 and 15 million with no defined upper limit). The basic subunit has a molecular weight of about 220 kDa and protomeric dimers or tetramers serve as the basic building blocks of the high-molecular-weight, active multimer. The subunit is a single-chain structure of about 2050 amino acids and is very similar in size to the active subunit of factor VIII (Girma *et al.*, 1995). About 5–15% of the vWF glycoprotein is carbohydrate. The higher the multimeric form, the more active its platelet-adhesive (binding) properties. Thus, the great molecular weight heterogeneity of vWF can affect its clinical and laboratory manifestations. For example, lower molecular weight multimers may be active immunologically but may not support platelet agglutination/adhesion efficiently, whereas larger multimers bind efficiently to factor VIII.

Most of the vWF in plasma is produced and secreted by endothelial cells (Blann, 1990; Meyers *et al.*, 1990b; Ruggeri and Ware, 1993; Meinkoth and Meyers, 1995), with some from megakaryocytes (humans and swine), which explains its presence in platelet α-granules (Mannucci, 1995). Curiously, appreciable amounts of vWF are not found in canine megakaryocytes or platelets although the protein is plentiful in vascular endothelium (McCarroll *et al.*, 1988; Catalfamo *et al.*, 1991; Parker *et al.*, 1991). This may explain why canine serum has much less vWF activity than that of human serum because canine platelets release little or no stored vWF during clotting. Cat platelets contain higher amounts of vWF but less than the levels found in human and porcine platelets (Waters *et al.*, 1989). The species differences in vWF are not surprising given the well-recognized species-specific behavior of the platelet- and plasma-agglutinating and enhancing properties of vWF in the presence of ristocetin, certain snake venoms, and desmopressin (DDAVP) (Feldman, 1988; Dodds, 1989a; Giger and Dodds, 1989; Meyers *et al.*, 1990a; Smith and Brinkous, 1991).

3. *The Extrinsic System*

a. Tissue Factor (Factor III)

Tissue factor is a species-specific thromboplastin extracted from tissue juice and is a potent activator of the extrinsic coagulation mechanism. The functions of tissue factor in the extrinsic pathway have been reviewed by Ruf and Edgington (1994), Nemerson (1995), and Rapaport and Rao (1995). Tissue factor also possesses factor VIII bypassing thromboplastic activity. The species specificity of tissue extract disappears if it is first incubated with homologous serum. Purified human brain thromboplastin is more effective for use as a universal activator in coagulation tests than either bovine or rabbit brain thromboplastins, but for practical purposes the latter are satisfactory. Tissue factor has a molecular weight of 37 kDa and accelerates the activation of factor X in the presence of factor VII and Ca^{2+}, thus forming factor Xa according to the scheme shown in Fig. 10.2 (Nemerson, 1995). In combination with factor VII, tissue factor amplifies the procoagulant response via components of the intrinsic pathway (factors VIII, IX, and XI), and so plays an important role in initiating and sustaining coagulation (Broze, 1995; Rapaport and Rao, 1995). The structure of tissue factor includes a protein and a lipid component, neither of which is active alone. The most active lipid in restoring activity to the protein component of tissue factor is phosphatidylethanolamine although lecithin has some activity (Nemerson, 1995). Unsaturated fatty acid side chains are required and mixed lipids are as effective as purified compounds in restoring activity.

A potent inhibitor of tissue factor-mediated coagulation, tissue factor pathway inhibitor (TFPI), has recently been purified and characterized (Broze, 1995). Its structure is unique; TFPI directly inhibits factor Xa and independently produces feedback inhibition of the factor VIIa–tissue factor catalytic complex. In plasma, TFPI forms are predominantly 34–41 kDa, but higher molecular weight forms are also present. The plasma concentration is low (about 2 nmol/liter) and much of it is bound to lipoproteins, especially low-density lipoprotein (LDL). TFPI levels fluctuate with LDL levels.

b. Proconvertin (Factor VII)

Factor VII is a single-chain, stable, glycoprotein that functions primarily in the extrinsic pathway of coagulation. It is present in both plasma and serum in trace amounts (5–10 ng/ml) (Howard *et al.*, 1994). Factor VII has the most rapid turnover rate of any coagulation factor, with a half-life of 2–7 hours (Dodds, 1989a). It is interesting that a factor not essential for primary hemostasis is synthesized and metabolized so rapidly (Brinkhous, 1992). Its molecular weight has been estimated to be about 50 kDa (Davie, 1995). Factor VII is synthesized by the liver and secreted into the blood as a zymogen (Suttie, 1993; Davie, 1995). It is the second component, along with tissue factor, that rapidly accelerates coagulation via the extrinsic pathway. Calcium ions are required, and the reaction proceeds by activating factor IX to factor IXa and factor X to factor Xa.

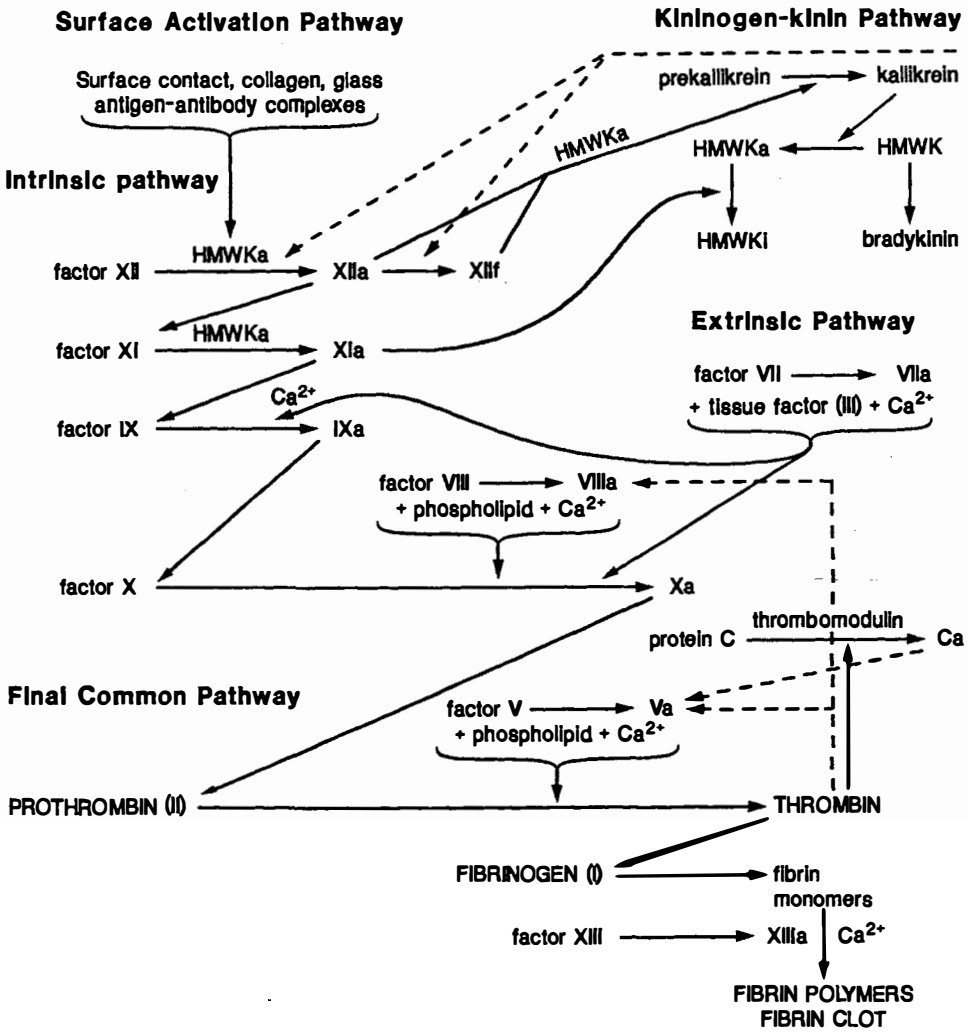

FIGURE 10.2 Instrinsic and extrinsic systems of blood coagulation. HMWK, high molecular weight kininogen.

Thus, many of the early stages of coagulation in the intrinsic pathway can be bypassed, although it is still unclear which of these two activation reactions is more important physiologically (Chabbat *et al.*, 1989). The extrinsic system needs only factors VII, X, V, prothrombin, and fibrinogen to form fibrin (Kitchen and Preston, 1994).

Bovine factor VII consists of 85% protein and 15% carbohydrate and has 406 amino acids. There is marked sequence similarity in the aminotermini of factor VII, prothrombin, factors IX, X, and protein C (Suttie, 1993). Despite structural similarities to the other vitamin K-dependent proteins, factor VII differs significantly in its metabolic behavior. The single chain form of factor VII as found in plasma, after enzymatic cleavage, becomes a two-chain form with a 60- to 80-fold increase in coagulant activity. Factor VII activity can be increased in a variety of ways, including storage at 0–4°C, contact activation with glass, kaolin, or celite, and either intrinsic or extrinsic coagulation. Enhancement of factor VII by contact activation requires factors XII, X, IX, and plasmin (Nemerson, 1995; Rapaport and Rao, 1995). Formation of factor Xa by either pathway causes a 900-fold increase in the rate of factor VII activation in the presence of phospholipid and Ca^{2+}. Thus, factor Xa is a positive feedback regulator enzyme for factor VII activity during coagulation.

4. *The Common System*

a. Stuart Factor (Factor X)

Factor X is activated by the action of factor IXa, phospholipid, and Ca^{2+}. Activation is accelerated by factor VIII of the intrinsic system in combination with phospholipid and Ca^{2+} and is accelerated by tissue factor of the extrinsic system (Lozier and High, 1990).

Factor Xa activates factor V. Thus, the intrinsic and extrinsic pathways converge at the step involving the activation of factor X to proceed via a common pathway to fibrin formation (Davie, 1995). Factor X is an α-globulin of about 59 kDa in plasma and 36 kDa in serum, is synthesized by the liver in the presence of vitamin K and is secreted into the plasma as a precursor to a serine protease. It is present in both plasma and serum at about 10 μg/ml. A number of compounds, such as Russell's viper venom (Stypven), promote the activation of factor X. Its half-life is 20–40 hours. Factor X is destroyed by heating to 56°C and is stable when frozen at −40°C or lower for several months. Its activity disappears from blood that is clotted with an excess of brain extract and can be adsorbed out of plasma by $Al(OH)_3$, $BaSO_2$, and $Ca_3(PO4)_2$.

Because of the pivotal role of factor X in both coagulation pathways, there has been considerable emphasis on the biochemistry and function of factor X in coagulation. The inactive zymogen is converted to its active form during clotting. Factor X has two aminoterminal amino acids and activation involves cleavage of a specific peptide bond to yield factor Xa. The activated form has very potent coagulant and esterolytic activities that are inhibited by plasma antithrombin III (heparin cofactor) and a variety of other serine proteases. The major substrate for factor Xa is prothrombin. In the presence of factor V, a cofactor that accelerates the reaction, phospholipid, and Ca^{2+}, factor Xa readily converts prothrombin to thrombin.

Most (85–90%) of the factor X in plasma is present in its monomeric form and the rest as a dimer. Human and bovine factor X are glycoprotein dimers with 15% carbohydrate and are linked by disulfide bonds. The heavy chain is 38–42 kDa, and the light chain is 16.2–17 kDa. The heavy chain contains the catalytic domain and all the carbohydrate. The light chain is highly acidic and remains intact on activation of the parent molecule. It also contains two potential growth factor domains having sequence similarity with human epidermal growth factor (Davie, 1995). The dimeric structure of factor X is unique since the zymogens of the other serine proteases and the prothrombin complex clotting factors all exist as a single chain. Activation of factor X is stimulated by intrinsic or extrinsic clotting, Stypven, insolubilized trypsin, and 25% sodium citrate. During prolonged activation, the coagulant activity of factor Xa is reduced but the esterase activity remains unchanged. Factor Xa is under positive feedback control via its activation of factor VII. Additional feedback control of factor X activation includes the activation of factor IX by factor Xa and thus the intrinsic pathway primes the extrinsic pathway but does not initiate it (Davie, 1995).

b. Proaccelerin or Accelerator Globulin (Factor V)

Factor V is also required for both the intrinsic and extrinsic coagulation pathways. When activated by thrombin, factor V accelerates the factor Xa-mediated conversion of prothrombin to thrombin up to 278,000-fold (Lozier and High, 1990). Factor V is extremely labile and disappears from plasma as it ages. The factor V of bovine plasma is more stable and found in much higher concentrations than in human plasma. Bovine and human factor V have been isolated and characterized (Davie, 1995). In human plasma, factor V concentrations are 4–14 μg/ml.

Originally, both factors V and VIII were thought to be enzymes converted to their active forms during coagulation. It is now known that factor V is a high-molecular-weight glycoprotein, which, like factor VIII, is nonenzymatic and acts as an accelerator or cofactor of specific coagulation reactions thereby producing enormous biological amplification. In the presence of factor Xa, phospholipid, and Ca^{2+}, factor V converts prothrombin to thrombin. It also serves as a cofactor for the thrombin-catalyzed activation of protein C, and activated protein C rapidly destroys factor Va. Factor V is the receptor on platelets for factor Xa binding to accelerate factor Xa hydrolysis and to inhibit platelet thromboxane A_2 formation. Finally, factor V serves as a receptor on endothelial cells to promote prothrombin conversion and inhibition of prostaglandin synthesis by factor Xa. Thus, with its numerous activities, the factor V–factor Xa interaction affords precise control of the final stages of both intrinsic and extrinsic coagulation (Davie, 1995).

The molecular weight of human and bovine factor V is 330 kDa (Davie, 1995). Calcium is thought to play a significant role in maintaining structural integrity and as a chelating agent to rapidly and irreversibly inactivate factor V. Factor V has very high affinity for hydrophobic surfaces such as phospholipid, and its reactivity is increased about 10-fold with partial proteolysis by thrombin. Factor V also reacts with other proteolytic enzymes, especially Stypven. Factor V is an α-globulin with 10–20% carbohydrate and high sialic acid content. Although the sialic acid is not essential for activity, the penultimate galactose residues are essential. The isoelectric point of factor V is 4.65. It requires lipid for its coagulant properties and avidly binds lipids. In the presence of phospholipid and Ca^{2+} but not prothrombin, factor V increases the esterase activity of factor Xa more than threefold. Thus, factor V directly or indirectly, via binding to phospholipid, regulates factor Xa activity. Procoagulant phospholipids, such as phosphatidylethanolamine, are much more active in complexing with factor V than are other phos-

pholipids (phosphatidylcholine, phosphatidylserine, or cardiolipin). A surprising feature of factor V, in contrast to prothrombin and factor Xa, is its ability to bind to phospholipid micelles in the absence of calcium. Each factor V molecule, however, has a single, tightly bound calcium ion that is important for its interaction with phospholipid.

Factor V is synthesized by endothelial cells, megakaryocytes, and hepatocytes and is tightly bound to platelet membranes, an association regulated by its carbohydrate moiety. Platelet factor V originates from megakaryocytic synthesis as well as binding from plasma. Other coagulation factors, such as fibrinogen, vWF, and factor XIII are present in both platelets and plasma. The half-life of factor V varies between 12–36 hours (Davie, 1995).

c. Protein C

Protein C is a vitamin K-dependent glycoprotein of 67 kDa that acts as a regulator of blood coagulation (Comp, 1990a; Walker and Fay, 1992; Davie, 1995). It is another of the precursors to serine proteases that regulate blood coagulation and inflammation (Welles *et al.*, 1990b; Esmon *et al.*, 1991). It is converted to activated protein C by thrombin in the presence of thrombomodulin, an endothelial cell protein (Fig. 10.2). Activated protein C then inactivates factors Va and VIIIa by a proteolytic process (Davie, 1995). Human protein C is composed of heavy (41-kDa) and light (21-kDa) chains held together by a disulfide bond. The light chain contains γ-carboxyglutamic and β-hydroxyaspartic acids as well as two potential epidermal growth factor domains similar to factor X (Davie, 1995). The heavy chain contains the catalytic domain. The amino acid sequences of human and bovine protein C have been established by sequence analysis and cDNA cloning (Walker and Fay, 1992; Aiach *et al.*, 1995). They express significant structural similarity with factors IX and X. The human protein contains 419 amino acids and has a plasma concentration of about 4 μg/ml.

d. Prothrombin (Factor II) and Thrombin

Prothrombin is a glycoprotein of 71.6 kDa and 8.2% carbohydrate (Davie, 1995). It contains three N-linked carbohydrate chains and is an α-globulin present in plasma at a concentration of 300 Iowa units/ml or 100 μg/ml. Prothrombin is converted to the active enzyme, thrombin, by the action of several factors known as plasma or tissue thromboplastins (Fig. 10.2). These prothrombin activators are a complex mixture. Prothrombin is synthesized by the liver, and its half-life is as short as 10–12 hours and as long as 60 hours, averaging about 36 hours. Both the synthesis and release of prothrombin require vitamin K (Pechlaner *et al.*, 1992). Warfarin (a coumarin derivative), the ingredient of first-generation rat poisons, blocks prothrombin synthesis at an intermediate step, and this can be reversed by the administration of vitamin K_1 (Vermeer and Hamulyák, 1991; Woody *et al.*, 1992). Vitamin K is also a known requirement for four other clotting factors, factors VII, IX, X, and protein C (Mount and Kass, 1989; Miletich, 1990; Soute *et al.*, 1992; Suttie, 1993). The amino acid sequences of human and bovine prothrombin is known (Davie, 1995). The mature polypeptide chain contains 579 amino acids.

Interest has been renewed interest in prothrombin synthesis. The vitamin K-dependent coagulation factors are synthesized from inactive precursor proteins by the action of vitamin K, which converts their glutamic acid groups to active γ-carboxyglutamic acid residues (Suttie, 1993; Dowd *et al.*, 1995). The clotting proteins are then anchored by the dicarboxyl groups on these residues, via Ca^{2+}, to a phospholipid surface during coagulation.

Prothrombin is a metal-binding protein containing two high affinity and several lower affinity metal-binding sites. The presence of 10 γ-carboxyglutamic acid residues near the aminoterminus of the molecule is an integral part of its metal-binding properties. These amino acids have unique properties and participate as metal ligands in prothrombin. Metal ions play a key role in the activation of prothrombin to thrombin, and the interaction of all the vitamin K-dependent clotting proteins is metal dependent.

Thrombin, the active enzyme form of prothrombin, has two chains of unequal size (α and β) held together by a disulfide bond (Fenton, 1995). The active site of thrombin, located on the α chain, includes a serine residue that, like similar serine proteases, can readily be inhibited by diisopropyl fluorophosphate (Guillin *et al.*, 1995). The molecular mass of thrombin is 36 kDa. Heparin acts as an effective anticoagulant primarily by inhibiting the action of thrombin on fibrinogen and, to a lesser extent, by preventing activation of factor IX by factor XIa.

Thrombin has many critical functions in hemostasis, including the formation of fibrin from fibrinogen, regulation of factor XIIIa (fibrinoligase) production, activation of factors V, VII, and VIII, and participation in platelet reactions (Hemker and Béguin, 1995). Thrombin is inhibited by antithrombin (heparin cofactor), fibrin degradation products, α_1-antitrypsin, and α_2-macroglobulin (Section II.E) (Fareed and Callas, 1995). In addition to its role in hemostasis, thrombin is a key regulatory enzyme in many tissue events including inflammation, complement activation, wound healing, macrophage function, and fibroblast function (Fenton,

1995). It functions as a potent mitogen for various cells, a mitogenic conditioner, and an angiogenic substance.

e. Fibrinogen (Factor I) and Fibrin

Fibrinogen is a complex glycoprotein, the substrate for thrombin, and the precursor of fibrin. It occurs in plasma at levels of 2–4 mg/ml. The molecular mass of the human and bovine protein is 340 kDa. They have a dimeric structure composed of three pairs of peptide chains (α, β, γ) joined by disulfide bonds (Davie, 1995). Most vertebrate fibrinogens share a similar structure. Each unit of the dimer is held together by disulfide bridges between the two α chains and between the two γ chains near the aminoterminus of the molecule. The β and γ chains contain carbohydrate but the α chain does not. Following the action of thrombin on fibrinogen, two major fibrinopeptides (A and B) are released from the aminotermini of the α and β chains, respectively. The remaining fibrin monomers are then polymerized to form insoluble, cross-linked fibrin by the interaction of fibrin-stabilizing factor (factor XIII) and Ca^{2+} (Coyne *et al.*, 1992).

Fibrinogen is believed to be synthesized as a heterogeneous group of molecules. This degree of heterogeneity may explain the large number of abnormal or dysfibrinogens known to occur as inherited disorders, in fetal life, or in the presence of underlying disease, especially liver disease (Moalic *et al.*, 1989; Hathaway and Corrigan, 1991; Andrew, 1995). The α chain is especially heterogeneous and has been shown to vary in size during evolutionary development. Except in the orangutan, there is a continuous decrease in the size of the α chains with a slight increase in the size of the β chains during development up the evolutionary scale from closely related higher primates to humans. The mature polypeptide chains contain 610, 461, and 411 amino acid residues for the α, β, and γ chains, respectively (Davie, 1995).

Fibrinogen is an important cofactor in mediating platelet aggregation responses *in vivo* and *in vitro* and platelets contain relatively large amounts of fibrinogen. Fibrinogen is synthesized by hepatic parenchymal cells and has a half-life of about 36 hours. Its synthesis and turnover rate can be markedly accelerated during the acute phase response induced by tissue damage, inflammation, stress, and ACTH (Davie, 1995). Other properties of fibrinogen and fibrin include their interactions with plasmin and with other enzymes such as trypsin, chymotrypsin, brinase, pronase, elastase, and collagenase. They also have high sequence similarity, as demonstrated by the high degree of immunological cross-reactivity among individual vertebrate classes, especially mammals and birds.

f. Fibrin Stabilizing Factor (Factor XIII)

Discovered in 1948, fibrin stabilizing factor (FSF) is the latest one to be given a Roman numeral according to the International Committee classification. It is synthesized by monocytes and hepatic parenchymal cells (Coyne *et al.*, 1992). A very small amount (2–10%) of factor XIII is sufficient for adequate hemostasis. The half-life of FSF is 3–7 days. FSF is a thrombin-labile protein, requires Ca^{2+} for its activity, and is in the α_2-globulin fraction in plasma. It is present in platelets, but occurs in only trace amounts in serum. It is inhibited by silver, lead and zinc and by snake venoms. Its molecular weight is about 320 kDa and it contains two subunits structurally similar to fibrinogen. Its function is to convert unstable, soluble fibrin monomers into insoluble, stable fibrin polymers by forming cross-links between adjacent fibrin strands. Fibrin bonding is strengthened by the FSF-dependent formation of intermolecular γ-glutamyl-ε-lysine bridges.

Factor XIII in plasma is the inactive zymogen for factor XIIIa or fibrinoligase, a transamidase formed by the action of thrombin and Ca^{2+}. Thrombin, therefore, has a dual regulatory role since it controls the rate of fibrin network formation and the generation of fibrinoligase. Factor XIIIa activity can be assayed by clot solubility in 1% monochloroacetic acid or 5 M urea, direct or indirect quantitation of the number of γ-glutamyl-ε-lysine peptides formed, electrophoresis of reduced and nonreduced fibrin in sodium dodecyl sulfate gels or by incorporation of monodansylcadaverine into purified casein substate (Coyne *et al.*, 1992).

The FSF zymogen of human and bovine plasma has a heterologous structure with two subunits differing in amino acid composition and size (*a*, 75 kDa; *b*, 80 kDa). It exists in an equilibrium; $2ab = a_2b_2$. The platelet zymogen, in contrast, is composed of two identical subunits but has no b subunit. The FSF activity of platelets is about 20% of that of whole blood.

D. Fibrinolysis

1. General

The counterpart of the coagulation mechanism is a group of zymogens and enzymes that forms the fibrinolytic system. Fibrinolysis involves a series of events critical to the removal of the hemostatic plug in the course of vessel healing and repair (Fareed *et al.*, 1995; Lijnen and Collen, 1995; Verstraete, 1995). An outline is shown in Fig. 10.3, and a detailed description is given by Verstraete (1995). After direct or indirect activation of the fibrinolytic system, plasminogen is converted to plasmin. Plasmin actively digests fibrin, fibrinogen, and factors V and VIII. This mechanism is

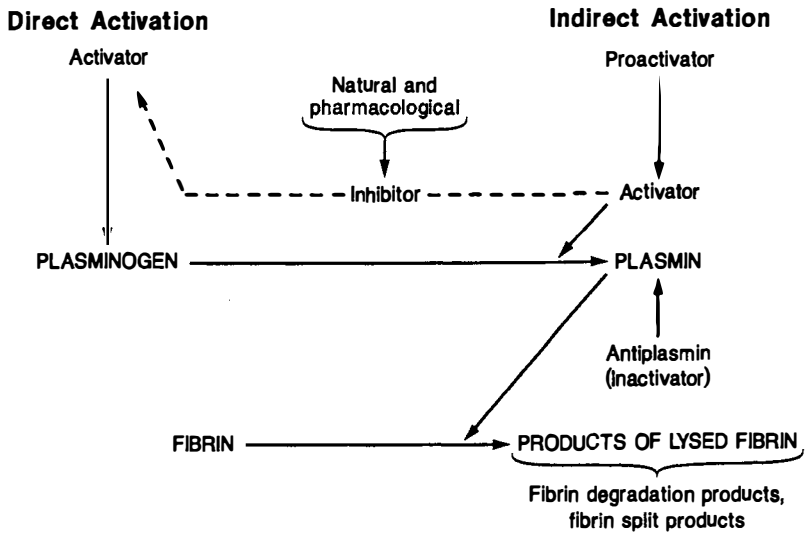

FIGURE 10.3 Scheme of the fibrinolytic mechanism. Solid lines indicate direct activation of precursor zymogen to enzyme; dashed lines show paths of positive and negative feedback.

analogous to that of coagulation in that an active enzyme, plasmin, is formed by activation of its precursor, plasminogen (McKeever *et al.*, 1990). The fibrinolytic system is controlled physiologically by natural fibrinolytic inhibitors. *In vivo*, fibrinolysis is usually limited to the area in and around the fibrin deposits. Plasmin within the hemostatic plug is provided by the action of fibrin in adsorbing plasminogen, which in turn is activated by substances released by the vessel wall and the cells of the blood. Plasmin and activators escaping from the plug are immediately diluted by the blood and neutralized by antiplasmins (Comp, 1990a).

2. *Plasminogen and Plasmin*

Mammalian plasminogens, from plasma or serum, are single-chain monomers with multiple isoelectric forms. The plasminogens of humans, cat, dog, pig, cow, rabbit,and horse have been characterized (Welles *et al.*, 1990a). Plasminogen is a β-globulin of about 85 kDa in either the glutamate or lysine form and is synthesized by the kidney and liver. The human protein contains 790 amino acids. Plasminogen levels are low in newborns, the cause of their impaired fibrin clot lysis (Andrew *et al.*, 1992; Schmidt *et al.*, 1993).

Many naturally occurring substances are plasminogen activators. These include the tissue activators known as cytokinases–urokinases in urine, tears, saliva, milk, bile, and prostatic, cerebrospinal, synovial, and amniotic fluids; streptokinase from β-hemolytic streptococci, niacin, and vitamin B_1; vascular endothelial and circulating activators; erythrocyte erythrokinase; neutrophilic granulocyte activator; and the factor XII-dependent activator which requires factor XII, prekallikrein, and Hageman factor cofactor for its activity. Thus, activators of plasminogen are present in blood, the vessel wall, body fluids, and most tissues.

Plasmin, the active enzyme form of plasminogen, is a serine protease with trypsin-like specificity which has two chains: a heavy (A) chain and a light (B) chain. These chains also have multiple isoelectric forms and molecular weights of about 49 and 26 kDa, respectively. The lysine form of plasmin has a molecular weight of about 77 kDa. Plasmin readily hydrolyzes a variety of proteins, such as factor V, gelatin, casein, arginine esters, and lysine, in addition to fibrinogen and fibrin (Hajjar, 1995).

In contrast to plasminogen, plasmin is normally absent from blood and body fluids because a group of circulating antiplasmins readily inactivates free plasmin. These include α_2-macroglobulin, α_1-antitrypsin, Cl inactivator, and antithrombin III.

3. *Tissue Plasminogen Activator (TPA)*

Tissue plasminogen activator (TPA), a serine protease of 68 kDa, has been isolated from many mammalian tissues (Gerding *et al.*, 1994; Lijnen and Collen, 1995). Its principal site of synthesis is the endothelial cell. The enzyme is present in very small amounts in tissues and is tightly bound to particulate cell constituents, making its isolation very difficult. The cDNA sequence and primary amino acid sequence of TPA are known. TPA is released into the circulation by stimuli such as exercise, venous occlusion, and intravenous injection of vasoactive drugs. Vascular PA isolated from plasma

of rigorously exercised subjects appears to be identical in size and properties to TPA. Both TPA and vascular PA are specifically inhibited by a rapid-acting PA inhibitor.

A zymogen form of TPA has not yet been identified. The single-chain human TPA molecule is not a zymogen and is readily converted by plasmin to a double-chain form. In the presence of fibrin, both forms are equally active (Fareed and Callas, 1995; Verstraete, 1995). TPA has four domains: the fibronectin finger, epidermal growth factor, kringle, and serine protease domains. TPA has received great attention in recent years because of its potent thrombolytic ability in lysing clots of patients experiencing thrombotic states (Lijnen and Collen, 1995; Verstraete, 1995; Verstraete and Zoldhelyi, 1995).

E. Inhibitors of Coagulation and Fibrinolysis

1. *Coagulation Inhibitors*

Much less is known about the naturally occurring inhibitors of coagulation than about the procoagulants of blood. Without an inhibitor mechanism to neutralize the effects of thromboplastins and thrombin, however, widespread intravascular coagulation and thrombosis could result from a simple vascular injury (Fareed *et al.*, 1995). The known types of natural anticoagulants include the circulating antithrombins (designated I through VI), heparin, protein S (a vitamin K-dependent anticoagulant), and anticoagulants to factors IXa, Xa, and XIa (Comp, 1990a, 1990b; Fareed and Callas, 1995; Henkens *et al.*, 1995). The most widely studied antithrombins are I (a reversible inhibitor) and III (a heparin cofactor, progressive irreversible inhibitor and an α_2-globulin). Of the six major protease inhibitors of blood, four have inhibitory action against one or more clotting factors and bind thrombin *in vitro* and *in vivo*. These are antithrombin III, Cl inactivator, α_2-macroglobulin, and α_1-antitrypsin (Exner, 1995).

a. Antithrombin III

Antithrombin III (ATIII) is a relatively heat-stable α_2-globulin of about 54 kDa with a carbohydrate content of about 15%. It is a single-chain glycoprotein synthesized in the liver and secreted into the plasma. This plasma protease inhibitor plays an important role in the regulation of blood coagulation. It is the principal physiological thrombin inhibitor in human plasma and constitutes about 50% of the total progressive antithrombin activity while the remaining activity is shared by α_2-macroglobulin and α_1-antitrypsin. The total progressive antithrombin activity of human plasma is decreased in inherited disorders of ATIII and in certain disease states such as DIC (Menache *et al.*, 1992; Conlan *et al.*, 1994). Similar decreases have been reported in animals with DIC (Boudreaux *et al.*, 1989b; Johnstone *et al.*, 1989). Other functions of ATIII are neutralization of factor Xa, which is accelerated 50- to 100-fold in the presence of heparin, and heparin-potentiated inhibition of factors VII, IXa, XIa, and XIIa and plasma kallikrein. The amino acid sequence of human ATIII is known (Davie, 1995) and the glycoprotein has 432 amino acid residues.

b. Cl Inactivator

Cl inactivator is a neuraminoglycoprotein capable of inhibiting its natural substrate, Cl-esterase, as well as plasma kallikrein, and factors XIa and XIIa, but not factor Xa or plasmin. It has a molecular weight of about 105 kDa and a 35% carbohydrate content.

c. α_1-Antitrypsin

α_1-Antitrypsin, the major trypsin inhibitor of plasma, is a glycoprotein with a molecular weight of about 50 kDa. In addition to inhibiting trypsin, it inhibits other proteases such as chymotrypsin, plasmin, and elastase in an irreversible reaction and is the major inhibitor of XIa (Verstraete, 1995).

d. α_2-Macroglobulin

α_2-Macroglobulin, a large (650-kDa) glycoprotein with subunits of 185 kd, complexes with a number of proteases, including thrombin, kallikrein, and plasmin. The binding of α_2-macroglobulin to thrombin is slow whereas its binding to plasmin is rapid.

e. Factor XIa Inhibitor

Factor XIa inhibitor, one of several known inhibitors of factor XIa, has a molecular weight of 65 kDa and is an α-globulin.

f. Lipoprotein Factor Xa Inhibitor

The lipoprotein factor Xa inhibitor is contained in the LDL fraction of plasma. Its action is facilitated by Ca^{2+}.

g. Protein S

Protein S, a vitamin K-dependent protein, has a molecular weight of 80 kDa, is present in plasma at a concentration of 25 μg/ml, and functions as an anticoagulant by facilitating the action of activated protein C on factors VIIIa and Va (Comp, 1990b; Aiach *et al.*, 1995; Henkens *et al.*, 1995). It is a membrane-binding protein and has a unique carboxyterminal structure that bears no sequence similarity to regions of other proteins. Protein S is synthesized as a single chain and

exists in blood in two forms, a free form and one bound to C4b-binding protein.

2. *Fibrinolytic Inhibitors*

The naturally occurring inhibitors of the fibrinolytic system have been summarized by Verstraete (1995). These can be categorized as inhibitors of plasmin, plasminogen activator inhibitors, inhibitors of the factor XII-dependent fibrinolytic pathway, and tissue inhibitors of fibrinolysis.

a. Plasmin Inhibitors

Plasma inhibitors include α_2-macroglobulin, α_1-antitrypsin, Cl inactivator, ATIII, and other uncharacterized antiplasmins of plasma and platelets.

b. Plasminogen Activator Inhibitors

Plasminogen activator inhibitors of various molecular masses have been identified, including those of 70 and 20 kDa. There is a coagulation-dependent inhibitor and another released from platelets. α_2-Macroglobulin also possesses PAI activity, but α_1-antitrypsin and ATIII apparently do not.

c. Factor XII-Dependent Inhibitors

Factor XII-dependent inhibitors are discussed in Section II.C.2.a.

d. Tissue Inhibitors

Inhibitors of fibrinolysis have been isolated from placenta and have molecular weights of 105 and 43 kDa (Broze, 1995).

III. LABORATORY DIAGNOSIS OF BLEEDING DISORDERS

A. General

The following briefly outlines the major points to consider for the diagnosis of bleeding disorders. Further details can be found elsewhere (Dodds, 1989a; Forsythe and Willis, 1989; Mansell and Parry, 1989; Comp, 1990b; Miletich, 1990; Tollefson, 1990; Welles *et al.*, 1990a, 1990b; Benson *et al.*, 1991, 1992; Poggio *et al.*, 1991; Šrámek *et al.*, 1992; Andreasen and Lovelady, 1993; Bath, 1993; Brooks and Catalfamo, 1993; Johnstone, 1993; Howard *et al.*, 1994; Giger, 1994; Kitchen and Preston, 1994; Brandt *et al.*, 1995; Exner, 1995; Brooks *et al.*, 1996b).

1. *Sample Collection and Preparation*

The importance of proper collection and preparation of blood samples for laboratory diagnosis of coagulation disorders cannot be overemphasized (Dodds, 1989a; Johnstone, 1993). Scrupulous cleanliness and avoidance of rough handling or rough surfaces must be observed in order to obtain satisfactory results. Smooth surfaces are a must to prevent activation of factor XII and to inhibit spontaneous platelet clumping. Therefore, plastic or siliconized glassware, syringes, and test tubes should be used in all sample preparations and storage. Blood must be taken by clean venipuncture to avoid contamination with tissue juices that will activate the coagulation system within a few seconds. Collection of samples from intravenous catheters is generally not advisable except in certain clinical or experimental situations where alternative sites are not readily available. A small clot in a blood sample will activate and consume enough clotting activity to invalidate the interpretation of results. Because most animal blood coagulates more rapidly than human blood, unless very rapid blood flow is achieved during collection, it is best to add the anticoagulant to the syringe beforehand and then draw the sample.

After collection, blood is centrifuged immediately for platelet-poor plasma (PPP) or platelet-rich plasma (PRP). Platelet-poor plasma is obtained for routine studies by centrifugation at 800–1000 *g* for 15 minutes and contains about 30,000–80,000 platelets/μl. If relatively platelet-free (<10,000/μl) or hard-spun plasma is desired for specialized or research tests, centrifugation at 3500–5000 *g* for 30 minutes or, preferably, 10,000–29,000 *g* for 15 minutes is required. After centrifugation the PPP is drawn off with plastic or siliconized pipets or with plastic syringes and tubing into plastic or siliconized glass tubes. It is then mixed, dispensed in small aliquots, and tested immediately or frozen at −20°C or preferably at −70°C for assay in the near future. Frozen plasma should be thawed only once and tested immediately; clotting factors are labile, and repeated freezing and thawing denatures proteins and destroys their biological activity.

PRP for platelet function tests (250,000–450,000 platelets/μl) can be prepared at room temperature by centrifugation at either 300 *g* for 2–3 minutes or 150 *g* for 5–10 minutes. Platelets undergo shape changes in the cold and improper freezing disrupts their membranes. After preparation, PRP is drawn off, put into plastic tubes (preferably polycarbonate), allowed to sit undisturbed for 30 minutes for equilibration of intra- and extracellular constituents, and then used within 2 hours.

2. *Anticoagulants*

Trisodium citrate is the anticoagulant of choice for coagulation studies. The preferred technique is to use 1 part 3.8% trisodium citrate to 9 parts blood. Maintain-

ing this fixed citrate-to-blood ratio is important to ensure reliable results (Johnstone, 1993). Sodium oxalate is also used but less frequently. Heparin, which inhibits thrombin and factor IX activation and activates platelets, interferes with the assay of coagulation factors, whereas EDTA inhibits platelet interactions, so that neither of these anticoagulants is appropriate for assessing coagulation with biological activity methods (Lewis and Meyers, 1994; Greinacher, 1995). Of course, if the animal is receiving anticoagulant therapy (e.g., heparin or coumarin), assay results and methods will need to be adjusted accordingly (Dodds, 1989a).

3. Standard Reference Plasmas and Controls

Because of the many physiological factors and species specificities affecting hemostatic parameters (Tables 10.2 and 10.3; Dodds, 1989a), it is extremely important that the appropriate reference and control plasmas be used for diagnostic evaluation. Reference and control reagents include fresh-frozen, pooled, citrated plasmas deficient in specific clotting factor activities (either congenitally deficient or artificially depleted), which are used as substrates in specific coagulation assays and as reference blanks; and fresh-frozen, pooled plasma from healthy animals of the species being studied. This homologous, pooled plasma should be obtained from at least eight animals (four of each sex) and should be age-matched whenever possible with the patient sample. In some cases, both age- and sex-matched reference plasma is desirable (Johnstone *et al.*, 1989; Moalic *et al.*, 1989; Hathaway and Corrigan, 1991; Blombäck *et al.*, 1992; Conlan *et al.*, 1993, 1994; Henkens *et al.*, 1995).

The deficient substrate plasmas need not be obtained from the same species as the reference standard or test samples. In fact, heterologous deficient substrates have been used successfully for years in the quantitation of specific coagulation factor activities (Dodds, 1989a). Examples are the use of canine factor VII-, VIII-, and IX-deficient plasmas for the assay of their respective clotting factor activities in all mammalian plasmas including human; bovine factor XI-deficient plasma,an excellent reagent for the assay of factor XI in all species (Gentry and Ross, 1993); and coagulation factor-deficient plasmas from human patients used to assay clotting factor levels in other animal species (MacGregor *et al.*, 1991; Ni and Giles, 1992). Therefore, deficient substrate plasmas are interchangeable, provided that the reference control plasma used to quantitate or to compare with the patient sample is a pool from the same species.

For practical purposes, general screening tests of coagulation and assays of specific coagulation factors are best performed on fresh-frozen patient and reference plasmas. Frozen reference plasmas should be stored in small aliquots in plastic tubes at −40°C or lower. The comparison of fresh patient samples with an individual, fresh control plasma is not advisable, as mild or moderately abnormal results can easily be masked. There is a relatively wide normal range for most coagulation assays and the range for the specific method and laboratory should be established by testing of at least 20 normal, healthy individuals. Results obtained with fresh plasma differ from those obtained with frozen samples so comparison of fresh patient plasma with a frozen standard plasma is misleading. Most laboratories find it impractical to prepare a fresh, homologous plasma pool each time assays are run. It is often advisable, when test samples are shipped frozen to a diagnostic laboratory, to request an individual control sample as well, which will serve as a monitor of sample collection and processing.

B. Evaluation of Platelet Function

1. Quantitative Disorders

Thrombocytopenic states and thrombocytoses are diagnosed by direct or indirect platelet counting (see Table 10.8 in Section IV.B, and also Section IV.C).

a. Platelet Count

The first step in assessment of platelet function is a direct or indirect platelet count. The direct method uses diluents, such as 3.8% trisodium citrate, 2% disodium EDTA, 1% ammonium oxalate, or commercial counting fluids (Bath, 1993). The sample is counted by a hemacytometer, preferably using phase-contrast microscopy or by an electronic cell counter. The normal range for most animal species except rodents is 200,000–500,000/μl, and less than 100,000/μl can be considered significant. Rodents usually have platelet counts of at least 900,000/μl. The indirect method of platelet counting is more practical for routine screening purposes and gives a satisfactory estimate. The platelets per oil immersion field (/oil) on a stained blood smear are counted and compared with the number of red or white cells. For example, the number of platelets per 100 white blood cells multiplied by the total white count is an estimate of the platelet count. Another method is to simply count the number of platelets per oil immersion field where one/oil is equivalent to 15,000/μl.

b. Clot Retraction

The phenomenon whereby a whole blood or PRP clot retracts from the sides of a glass container depends on normal platelet quantity and function. Clot retrac-

tion time may be reduced in anemia and accelerated in polycythemia because the hematocrit tends to influence the retraction of whole blood clots. A variation of this test, which is more sensitive to differences in the platelet count, uses blood diluted 1 : 10 with cold, buffered saline and clotted with a standardized concentration of thrombin (Boudreaux *et al.*, 1989b; Dodds, 1989a). Specifically, 0.5 ml of fresh whole blood is taken by plastic syringe and added to 4.5 ml of the saline. Two milliliters of this diluted mixture is added in duplicate to two small glass test tubes, each containing 1 unit of bovine thrombin (0.1 ml of a 10 U/ml solution), and mixed by inversion. The tubes are kept in an ice bath or refrigerator for 30 minutes and transferred to a 37°C water bath. They are examined for retraction every 30 minutes for up to 2 hours. For most animal species, normal samples are maximally retracted by 1–2 hours, after which time the clot commences to lyse (Boudreaux *et al.*, 1989). Clot lysis time can also be recorded here by monitoring the sample until lysis is complete.

c. Russell's Viper Venom Time (RVVT)

The Russell's viper venom or Stypven assay measures extrinsic clotting and is described in more detail in Section III.C. It also, however, assesses platelet function since the venom needs a source of phospholipid for its activation. In PPP or PRP, the phospholipid is supplied by an adequate number of functional platelets. Normal animals have a 9–14 second RVVT. The assays of thrombocytopenic or thrombopathic patients are usually prolonged by 3–10 seconds.

d. Bleeding Time

The bleeding time measures hemostasis from a standardized skin or mucosal incision or by transection of a nail or the tail (Feldman, 1988; Forsythe and Willis, 1989; Kraus *et al.*, 1989; Brassard and Meyers, 1991; Cowles *et al.*, 1992; Šrámek *et al.*, 1992; Brooks and Catalfamo, 1993; Bright *et al.*, 1994; Schermerhorn *et al.*, 1994; Panciera and Johnson, 1996). Meaningful results can be obtained only if the test is performed under controlled conditions that regulate the size and depth of the incision or transection. The skin, gingival biopsy, and tail transection bleeding times are performed under anesthesia, whereas the toenail or mucosal methods can be performed on awake, sedated, or anesthetized animals (Forsythe and Willis, 1989; Brooks and Catalfamo, 1993). Choice of skin sites is complicated in animals by their relatively thick, hairy skin, but the tip of the ear, lip, and inner thigh can be used. Normal skin bleeding times vary from 1 to 5 minutes in dogs, and 1 to 3.5 minutes in cats and times are prolonged in platelet defects, vascular lesions, and vWD.

The toenail (transection) method involves severing the apex of the nail bed with a sharp guillotine-type nail cutter. Repeated bleeding times are readily obtained on the same animal by cutting one or more nails. The animal should be in lateral recumbency for the procedure. Normal transection bleeding times are between 2 and 5 minutes in dogs and 1.5 and 3 minutes in cats (Brooks and Catalfamo, 1993). Using the buccal mucosal technique, the mean bleeding time for 34 healthy dogs was 2.62 ± 0.49 m (Forsythe and Willis, 1989; Brooks and Catalfamo, 1993). In healthy horses and cattle, the lip bleeding time is 8–10 minutes.

The transection bleeding time measures all components of hemostasis (vessel wall, platelets, coagulation). As such it is a practical way to assess the bleeding risk of a patient prior to surgery as well as the efficacy of therapeutic response after treatment has been initiated to control or correct a bleeding diathesis (Dodds, 1992; Brooks and Catalfamo, 1993).

e. Whole Blood Clotting Time (WBCT)

The WBCT in plastic or silicone-coated tubes may be prolonged in thrombocytopenic states. The glass tube clotting time is usually normal.

2. *Qualitative Disorders*

a. Platelet Aggregation and Release

The effect of various aggregating agents such as ADP, collagen, adrenalin, and thrombin on PRP or platelet suspensions is used to evaluate platelet function. The assay measures the change in optical density of standardized platelet preparations kept at 37°C and stirred at 1000 rpm after the addition of an aggregating agent. The optimal concentration of these agents varies with the species from which the platelets were prepared. In general, low doses of ADP cause reversible aggregation, whereas higher doses trigger the release reaction and a secondary wave of irreversible aggregation. Platelet aggregation with collagen or connective tissue suspensions results from adherence of platelets to collagen fibers followed by the release of platelet ADP, which in turn causes secondary aggregation and is irreversible. Epinephrine- and thrombin-induced aggregation are also mediated by platelet ADP release. Marked species differences are noted in the responses to aggregating agents (Table II; Dodds, 1989a). The platelet release reaction can be assessed by the degree of secondary ADP-mediated aggregation. It can be quantitated by measuring the amount of PF-3, platelet factor 4, nucleotide, [^{14}C] serotonin, or other materials released by optimal concentrations of agents that induce release (Callan *et al.*, 1995).

Newer techniques have been developed for assessing platelet function in whole blood (Catalfamo *et al.*, 1989; Forsythe *et al.*, 1989; Willis *et al.*, 1989; Grauer *et al.*, 1992; Rajasekhar *et al.*, 1994; Schermerhorn *et al.*, 1994). The latter referenced method is based on adding 1 ml of fresh, citrate anticoagulated whole blood from fasted normal and patient animals to each of paired tubes containing 0.1 ml 0.15 *M* NaCl (control) and 0.1 ml 50 *M* ADP (agonist), respectively. The paired tubes are immediately capped and mixed *simultaneously* at room temperature for 8–12 gentle inversions. This mixing process should last for at least 15 but not longer than 30 seconds. The reaction is then stopped immediately by adding 1 ml of 2% formalin stabilizer, first to the ADP-containing tube, and then to the saline control tube for each of the normal and patient animals. The tubes are recapped and mixed by gentle inversion three or four times. These completed sets of normal and patient tubes are left upright undisturbed overnight (16–18 hours) in a test tube rack at room temperature. The following day, the reaction is complete and the heaviest blood cells have settled to the bottom of the tubes. The supernatant from each tube is carefully aspirated down to about $\frac{1}{16}$ inch above the settled cells (not less or more), and transferred to another set of prelabeled tubes. The extent of platelet reactivity to ADP is measured by comparing the number of free, unaggregated platelets in the ADP-containing sample to that of the nonreactive saline control tube. If aggregability of the patient sample is impaired, a relatively high number of platelets should be left in the supernatant of the ADP tube versus the patient's saline control tube. This same methodology can also be used to assess platelet responses to other agonists including ristocetin.

Methods for platelet function testing have been reviewed (Catalfamo and Dodds, 1988; Boudreaux *et al.*, 1989a,b; Brassard and Meyers, 1991; Johnson *et al.*, 1991; Barr *et al.*, 1992; Bath, 1993; Brooks and Catalfamo, 1993; Boudreaux *et al.*, 1994; Behrend *et al.*, 1996).

b. Platelet Retention (Adhesiveness)

Retention of platelets in a glass bead column or filter of standard size measures their ability to adhere to foreign surfaces (Brassard and Meyers, 1991). When normal animal blood is passed through these columns, more than 75% of the platelets are retained so that the platelet count in the filtrate is low. In animals with platelet function defects or vWD, platelet retention is abnormally low, varying from 0 to 50%. A similar finding occurs with human blood except that platelet retention in normal subjects varies with the assay method and is generally lower (25–80%) than in animals. The most widely used platelet retention assays are the Salzman method, in which blood is collected directly from the patient's vein and passed though a glass bead column by vacuum, and the Bowie technique, in which blood is taken by syringe into heparin and then pumped or drawn by vacuum through a bead column. A two-stage method has been described that depends on fibrinogen for adhesion in the first stage and vWF in the second stage, thus permitting a distinction between these two adhesive proteins (Dodds, 1989a).

In animal species, a modification of the Salzman technique has given the best results for clinical use. Six milliliters of whole blood are drawn as quickly as possible into a plastic syringe. A 1-ml aliquot is immediately added to and mixed in a plastic tube containing 0.1 ml of 3.8% trisodium citrate. The remainder is passed by syringe pump at an even flow rate of 6–8 ml/minute over a standardized l-g glass bead column and collected in four successive l-ml aliquots in a series of plastic tubes containing 0.1-ml citrate anticoagulant. The percentage of platelet retention is calculated as follows:

$$\% \text{ Retention} = \frac{\text{init. plt. ct.} - \text{av. plt. ct. of last 3 ml}}{\text{initial platelet count}} \times 100.$$

C. Evaluation of Coagulation

1. General Screening Tests

A great variety of screening tests is available for the diagnosis of hemostatic and thrombotic disorders (Table 10.4). These screening tests are not very sensitive to minor abnormalities. This should be kept in mind, especially when a diagnostic workup is performed on patients with only mild bleeding tendencies. If a defect is not found on screening but the history strongly sug-

TABLE 10.4 Practical Screening Tests for Bleeding Disorders

Assay for fibrin–fibrinogen degradation products (FDP)[a]

[a] Performed for definitive diagnosis of suspected intravascular coagulation.

gests a hemorrhagic problem, more specialized coagulation tests should be performed. Obviously, the screening assays may not demonstrate an abnormality in a mildly affected patient but are often diagnostic in severe deficiencies. The methods for platelet counting, and whole blood clot retraction and lysis are discussed in Sections III.B.1.a and b.

a. One-Stage Prothrombin Time (PT or OSPT)

The PT measures the activity of clotting factors I, II, V, VII, and X in plasma after activation with tissue thromboplastin and recalcification. The most commonly used commercial thromboplastins are made from crude extracts of rabbit brain although research coagulation laboratories may prepare their own homologous brain extracts for optimal activation (Poggio *et al.*, 1991; Kitchen and Preston, 1994). Regardless of the brain extract used, it is essential that homologous, normal plasmas serve as the assay control because erroneous interpretation often occurs when the control and patient plasmas are from different species. Animal plasmas frequently clot very rapidly (<10 seconds) when activated by commercial rabbit brain extract. Therefore, it is difficult to detect minor deficiencies that prolong the assay by only 1 or 2 seconds. This problem can be overcome by diluting the commercial reagent until the clotting time of the control ranges between 10 and 15 seconds. With this adjusted assay system, mild deficiencies usually produce a 2–5 second longer clotting time. A commercial PT assay kit was recently evaluated for use in dogs and cats (Monce *et al.*, 1995).

b. Activated Partial Thromboplastin Time (APTT)

The APTT performed on kaolin- or ellagic acid-activated plasma is a reliable indicator of intrinsic clotting. The test using activated plasma gives shorter clotting times and is more widely used and reliable than tests in which plasma is not exposed to surface activators. The APTT varies with different species, with the source of partial thromboplastin, and with the method and with the type of instrument used to determine the end point. Furthermore, dilution of animal plasmas in order to slow the coagulation process in the APTT has given variable results. Pooled, homologous plasma is therefore essential as a control. With commercial partial thromboplastins of rabbit origin, the APTT of dog and human plasmas are usually 14–18 and 25–45 seconds respectively.

If the APTT is abnormal, differential mixing tests can be used qualitatively to determine which clotting factor(s) is reduced. An equal mixture of test plasma and plasma from a human or animal known to have a specific coagulation abnormality is assayed by the APTT. Failure to correct the APTT to normal or nearly normal identifies the defect.

A simplified variation of the APTT, which measures the intrinsic clotting activity of whole blood, is the activated coagulation time (ACT). The advantage of using this test is that it requires only whole blood, activator, and calcium and depends for activation on the platelets supplied by the sample. Thus, the ACT is sensitive to significant changes in the platelet count. It has been used successfully in small and large animals as a screening test, although the APTT is still preferred by most coagulation laboratories (Dodds, 1989a).

c. Thrombin Time (TT)

The time required for a standardized thrombin solution to clot plasma is a measure of the rate of conversion of fibrinogen to fibrin. This test provides important information on fibrinogen clottability and gives abnormal results in hypofibrinogenemic states, with heparin or heparin-like anticoagulants, in fibrinolytic disease, and in dysfibrinogenemia. The TT is thus an indicator of quantitative and/or qualitative fibrinogen disorders. In DIC with secondary fibrinolysis, the presence of fibrinogen and/or fibrin breakdown products prolongs the TT. Dysfibrinogenemias caused by an abnormal fibrinogen molecule are often detectable only by this test, because fibrinogen concentration is normal.

d. Fibrinogen Assays

Fibrinogen concentrations can be quantitated by several methods, including biological, physical, and immunological assays. Physical methods include an estimation of fibrinogen levels by determining the amount of precipitate formed when plasma is heated to 56°C or treated with 25% ammonium sulfate. A practical method for clinical use in human and veterinary medicine is based on heat precipitability. Plasma samples are placed in microhematocrit tubes and the amount of precipitate formed after heating the tubes for 3–9 minutes at 56°C is quantitated by ocular micrometry. More accurate, biological methods are the quantitative Ratnoff–Menzie assay and its modifications and the measurement of clot weight. The first assay is based on thrombin clottability; the latter method determines the weight of dried recalcified plasma clots. Another common technique is the immunological assay of fibrinogen, which quantitates the immunoprecipitate formed with specific antifibrinogen antisera.

e. Assay for Fibrin–Fibrinogen Degradation Products (FDP)

A commercially available latex agglutination method for measuring FDP in human blood can also be used for several animal species, including dogs. The

test, although expensive, is helpful and reliable for confirming selected cases of DIC. Other tests include the ethanol gel test, which depends on the separation of FDP from fibrinogen by ethanol, and the protamine paracoagulation test, which detects fibrin monomers and early FDP by their ability to cause gelation or to form fibrin strands when mixed with a 1% solution of protamine sulfate at pH 6.5. More specialized, quantitative tests are the staphylococcal clumping test, in which FDP induce clumping of most strains of *Staphylococcus aureus* by activating their cell wall coagulase and the very sensitive hemagglutination inhibition assay, which measures FDP in the presence of antifibrinogen serum and tanned, formalinized, fibrinogen-coated homologous erythrocytes.

f. Other Assays

The *RVVT* or *Stypven time* is a measure of extrinsic elotting like the PT, except that it is insensitive to factor VII and requires phospholipid (supplied by PF-3) for its activation. A long PT and normal RVVT are diagnostic of factor VII deficiency. The Stypven assay gives essentially the same clotting time in all species and so eliminates the problems encountered with species specificities of brain thromboplastin. Stypven is quite expensive and is not practical for routine use.

The *WBCT* is measured on a small blood sample (1.5–2 ml) collected by venipuncture into a plastic syringe. The syringe is tilted back and forth until a solid clot forms or the blood is rapidly dispensed into small glass, plastic, or siliconized tubes and the clotting time recorded. The results are more referable to the *in vivo* situation if the tubes are held at 37°C. The clotting time in plastic syringes and tubes or in siliconized tubes is usually about twice that in glass tubes because glass contact activates factor XII and enhances clotting. Canine blood clots in about 2–10 minutes in glass and 9–20 minutes in plastic or silicone. Because of its variability, this test is not recommended for diagnostic use.

The *recalcification* or *plasma clot time* is a more sensitive measure of intrinsic thromboplastin formation than is the WBCT. It times the fibrin end point at 37°C when calcium chloride is added to plasma. Since the recalcification time varies inversely with the platelet count, the speed and time of centrifugation for plasma collection must be standardized for control and test samples. Normal plasma clots in 65–100 seconds; abnormal times occur in thrombocytopenias, deficiencies of the intrinsic system, or in the presence of circulating anticoagulants. Inhibitors can be ruled out by showing correction of the defect in the test plasma after it has been mixed with an equal volume of normal plasma and incubated for 30–60 minutes at 37°C; a double aliquot of normal plasma incubated in parallel serves as the control.

The *prothrombin consumption* (PCT) or *serum clot time* measures the amount of prothrombin remaining after a clot has formed and is actually the prothrombin time of serum. To be reliable, the assay must be performed immediately on the serum of fresh control and test blood incubated at 37°C for 1–2 hours. A source of factor V and fibrinogen is required for the test and is supplied by aluminum hydroxide-adsorbed normal rabbit or bovine plasma. The test serum and adsorbed plasma are activated by rabbit brain tissue extract and recalcified. In normal individuals, coagulation is complete and there is very little prothrombin left in the serum. The PCT is thus long (>40 seconds). Patients with defective intrinsic clotting, thrombocytopenia, or thrombopathia cannot consume prothrombin properly and there is an excess of prothrombin in their serum. The PCT is therefore short in severe defects such as hemophilia, where it may be less than 10 seconds. Thrombocytopenia or thrombopathia can be ruled out by allowing the whole blood for this test to clot in the presence of a source of PF-3 activity such as inosithin.

2. *Specific Assays*

a. Functional Activity Assays

Specific quantitative assays of intrinsic clotting activity are relatively difficult to perform, time consuming, and costly. These assays measure factors VIII:C, IX, XI, and XII and are based on either manual or automated one-stage (PTT) or two-stage (thromboplastin generation) techniques. The clotting factor in question is measured in dilutions of test plasma mixed with standard aliquots of substrate plasma specifically deficient in this factor. The clotting activities of the diluted test plasma are compared by double logarithmic plots (calculated manually or by automated instrumentation) to those obtained for a standard pool of normal plasma from the same species and are reported as a percentage of the normal plasma or reported as units per milliliter. (One unit is defined as the clotting activity present in 1 ml of normal plasma.) As long as the control and test plasmas are homologous, the deficient substrate plasma can be heterologous (animal or human source).

Specific quantitative assays of extrinsic clotting activity are based on the PT and/or RVVT tests. Measurements of factors II, V, VII, and X are usually based on these techniques. Animal or human plasma known to be deficient in one of these factors serves as the substrate and is mixed with dilutions of test plasma (Poggio *et al.*, 1991). Equivalent dilutions of a normal,

pooled homologous plasma serve as the control. The results are compared by double logarithmic plot and the activity of the patient's sample is reported as the percentage of normal or as units per milliliter.

Factor X assays usually use either brain tissue extract or Stypven for activation but may use both of these activators. Factor V and VII assays use the PT technique although factor V can also be measured by RVVT and by a more complex, two-stage technique.

Quantitative assays of prothrombin (factor II) are either one-stage methods, based on specific activation of factor II by snake venoms (Smith and Brinkhous, 1991), or two-stage clottability assays. Although the one-stage assay is more easily performed, availability of the Taipan or tiger snake venom used in the reaction is limited by its expense.

Fibrinogen assays are discussed in Section III.C.I.d. The clot solubility time depends on the concentration of factor XIII and is thus a measure of its activity. Recalcified PRP or PPP clots are put into a solution of 5 *M* urea or 1% monochloroacetic acid and held at room temperature for 48 hours. Normal clots do not dissolve, whereas factor XIII-deficient clots usually dissolve within 24 hours.

b. Immunological Assays

The most widely used immunological assay for diagnosis of bleeding disorders measures vWF:Ag [formerly called factor VIII-related antigen (FVIIIR:Ag)]. The functions of this component of the factor VIII complex are discussed in Section II.C.2.g. vWF:Ag is usually quantitated by the very reliable and sensitive ELISA technique, including the commercially available patented test developed by this author and colleagues (Zymtec vWF, Iatric Corp., Tempe, Arizona) (Benson *et al.*, 1991, 1992), and other ELISA-based methods (Meyers *et al.*, 1990a, 1990b; Johnstone and Crane, 1991; Hoogstraten-Miller *et al.*, 1995; Meinkoth and Meyers, 1995). Alternative methods are the quantitative radioimmunoassay of Kraus *et al.*, 1989 (described in Feldman, 1988), and the original Laurell electroimmunoassay used until the ELISA technology was perfected (Dodds, 1989a). Humans and animals affected with the common forms of vWD (types 1 and 3) will typically have low levels of plasma vWF:Ag (Brooks *et al.*, 1991b, 1992, 1996b; Dodds *et al.*, 1993; Johnstone *et al.*, 1993; Ruggeri and Ware, 1993; Ermens *et al.*, 1995; Konkle, 1995), and patients with severe vWD may also have low FVIII:C (Stokol *et al.*, 1995). When used in conjunction with the FVIII:C assay, the ratio of FVIII:C to vWF:Ag is then calculated to confirm a suspected diagnosis of hemophilia A and can also be used to assist in identifying hemophilic carrier females because of their lowered FVIII:C but normal vWF:Ag levels (Murtaugh and Dodds, 1988; Dodds, 1991b, 1992; Joseph *et al.*, 1996). Immunological assays have also been developed for the antigens related to most of the other coagulation proteins (Dodds, 1989a), and include a new ELISA method for thrombin-ATIII complexes (Topper *et al.*, 1996). These assays include neutralizing, precipitating, and radioimmunoassays and have been used to examine whether the plasma of patients with specific functional deficiencies of clotting factors contains normal, reduced, or undetectable amounts of the related antigens (Howard *et al.*, 1994).

c. Other Assays

Quantitative assays of vWF activity include various measurements of ristocetin- and venom-induced platelet agglutination and macroscopic platelet aggregation tests (Ermens *et al.*, 1995; Konkle, 1995). There are many demonstrable species differences in the interaction of mammalian plasmas with ristocetin (Feldman, 1988; Dodds, 1989a). These differences have necessitated modification of existing assays designed for measuring ristocetin cofactor in human plasma to permit its quantitation in animal plasmas. One such modification for canines involves diluting normal and patient plasmas to a final concentration of not more than 2.5% in the reaction mixture (50 μl diluted test plasma; 350 μl washed, formalin-fixed human platelets at 200,000/μl; and 100 μl of ristocetin at 10 mg/ml). The optical density settings of a platelet aggregometer are set at zero baseline for each plasma dilution using a blank tube containing 350 μl Tris buffered saline, 50 μl diluted test plasma and 100 μl ristocetin at 10 mg/ml. It is important to recognize that specific assays for the platelet-related property of human vWF may not be applicable to other species. The snake venom (botrocetin) cofactor assay appears to work well with many species and thus avoids the problems encountered with ristocetin (Smith and Brinkhous, 1991).

Chromogenic substrates are also used to assay several coagulation and kinin components. For example, chromogenic assays are available for prothrombin, thrombin, ATIII, factors VII and X, plasminogen, kininogen, and prekallikrein (Tollefsen, 1990; Welles *et al.*, 1990a; Andreasen and Lovelady, 1993).

D. Evaluation of Fibrinolysis

1. General Screening Tests

Tests of the fibrinolytic system are used with the appropriate coagulation and platelet function assays to distinguish between primary fibrinolysis, a rare entity, and the fibrinolysis commonly seen secondary to DIC and consumption coagulopathy (Feldman, 1988;

Comp, 1990a; McKeever *et al.*, 1990; Hargis and Feldman, 1991; Welch *et al.*, 1992; Joist *et al.*, 1994; Fareed *et al.*, 1995; Lijnen and Collen, 1995; Verstraete, 1995).

a. Clot Lysis Time

The time required for whole blood clots to lyse at 37°C is proportional to the plasmin activity of the blood. It is also dependent on the degree of clot retraction and fibrinogen content of the sample. Poor clot retraction retards clot lysis whereas hypofibrinogenemic clots are friable. A simple, sensitive method for measuring clot retraction and lysis in dilute whole blood is described in Section III.B.l.b. Normal human blood clots take about 16–36 hours to lyse. Most animals have more active fibrinolytic mechanisms and their blood is usually lysed by 8–20 hours. Clot lysis tends to be more active in females than males and to increase with age and stress.

b. Euglobulin Lysis Time

The euglobulins of plasma, such as fibrinogen, plasminogen, plasmin, and plasminogen activator, precipitate on dilution with water. Fibrinolytic inhibitors, such as antiplasmin and antiactivator, do not. The plasma euglobulin lysis test measures the time for redissolved, thrombin-clotted euglobulin precipitates to be lysed by endogenous plasmin. The assay should be performed on fresh PPP prepared at 4°C since platelets contain fibrinolytic inhibitor activity and chilling retards the inactivation of plasminogen activator. The use of a tourniquet or other trauma at the site of venipuncture should be minimal because it enhances fibrinolysis.

c. Fibrin Plate Test

The ability of plasma to lyse standardized fibrin plates is a measure of its lytic capacity and depends on the plasminogen and plasminogen activator concentration. A standard fibrinogen solution (250 mg/ml) is clotted uniformly with bovine thrombin (50 NIH units/ml) in a petri dish. The fresh test plasma or its euglobulin precipitate and a standard urokinase solution are applied to duplicate fibrin plates and incubated for 18 hours at 37°C. The same precautions apply to plasma collection and preparation as described for the euglobulin lysis test. The area of lysis on each fibrin plate is expressed in square millimeters as the product of its two perpendicular diameters.

2. Specific Assays

a. Functional Activity Assays

An accurate functional measure of plasma plasminogen content is obtained with a caseinolytic assay based on the ability of plasmin to digest a standard solution of α-casein. The plasma is first acidified to decrease its antiplasmin content and then converted by streptokinase (for human plasma) or urokinase (for animal plasmas) to plasmin. The caseinolytic activity of the resultant plasmin is quantified and compared to that of a known plasmin standard.

b. Other Assays

A variety of other assays are used to measure plasminogen levels by quantifying the plasmin generated. These include use of chromogenic substrates, rate assays of plasmin activity using basic amino acid ester substrates, specific active-site titration, fluorometric immunoassays, radioimmunoassays, protein inhibitor, and affinity chromatographic methods (Fareed *et al.*, 1995; Verstraete, 1995). Assays for TPA are also available (Gerding *et al.*, 1994; Fareed *et al.*, 1995; Lijnen and Collen, 1995).

E. Interpretation of Practical Screening Tests

Table 10.5 outlines the diagnosis of bleeding disorders based on results of screening tests. These can be expanded on the basis of results for the APTT, PT, TT, and platelet count. Similar approaches are used in humans to interpret the significance of hemostatic tests (Hathaway and Corrigan, 1991; Blombäck *et al.*, 1992; Schmidt *et al.*, 1993; Andrew, 1995; Exner, 1995).

1. Elevated TT, APTT, and PT, Variable Platelet Count

These cases usually have a variable reduction in platelet count and may have abnormally shaped red blood cells on the blood smear. The prolonged TT indicates a reduced amount of functional fibrinogen most likely caused by the presence of *in vivo* coagulation with production of FDP. The APTT and PT are prolonged whenever fibrinogen-thrombin clottability is impaired. The probable diagnosis is DIC with its requisite underlying cause.

2. Elevated APTT (Slight), Normal PT and TT, Decreased Platelet Count

Thrombocytopenia results in less available PF-3 to promote intrinsic coagulation and the APTT is thus slightly prolonged. vWD may present this picture especially if there is concomitant hypothyroidism. A vWD test is needed to confirm the diagnosis.

3. Elevated APTT (Moderate), Normal PT and TT, Normal or Increased Platelet Count

A moderate intrinsic system clotting defect is present. If the patient is a young male with an active bleeding history, hemophilia is a primary consideration.

TABLE 10.5 Diagnosis of Bleeding Disorders

Test Results						
Bleeding time	**APTT**	**PT**	**TT**	**Platelet count**	**vWF**	**Probable diagnoses**
Elevated	Elevated	Elevated	Elevated	±Decreased[a]	±Decreased	Disseminated intravascular coagulation (DIC), acute
±Elevated	±Elevated	±Elevated	±Elevated	±Decreased	±Decreased	DIC, chronic
Elevated	Slightly elevated	Normal	Normal	Decreased	Normal	Thrombocytopenia
Elevated	Slightly elevated	Normal	Normal	±Decreased	Decreased	vWD (especially with concomitant hypothyroidism)
±Elevated[b]	Moderately elevated	Normal	Normal	±Elevated	Normal	Hemophilias A or B; Factors X or XI deficiencies
±Elevated[b]	Markedly elevated	Normal	Normal	±Elevated	Normal	Hemophilias A or B; Factors X or XI deficiencies
Normal	Markedly elevated	Normal	Normal	Normal	Normal	Factor XII deficiency (Hageman trait), especially in cats; prekallikrein deficiency (Fletcher trait)
±Elevated	Markedly elevated	Normal	Normal	Decreased	Normal	Factor XII deficiency with concomitant thrombocytopenia (cats)
±Elevated	Slightly to moderately elevated	Moderately to markedly elevated	Normal	±Decreased	Normal	Rodenticide toxicosis, severe liver disease
Normal	Slightly to moderately elevated	Slightly to moderately elevated	Normal	Normal	Normal	Factors II or X deficiencies
Normal	Normal	Moderately to markedly elevated	Normal	Normal	Normal	Factor VII deficiency or early liver disease

[a] ±, variably.
[b] Primary (platelet-dependent) bleeding time is usually normal but secondary (fibrin-dependent) bleeding time is prolonged; rebleeding is also commonly seen.

During the stress caused by bleeding, fibrinogen levels will increase rapidly with resultant shortening of the APTT despite the presence of underlying hemophilia. Alternatively, this profile may indicate another moderate defect of intrinsic coagulation (e.g., factor X or XI deficiency), but these are relatively rare. Hemophilia should be ruled out first. Specific assays of factors VIII:C (hemophilia A) and IX (hemophilia B)are needed for confirmation. The vWF levels should be normal unless both hemophilia and vWD are present (e.g., in Doberman pinschers where vWD is so prevalent).

4. Elevated APTT (Marked), Normal PT and TT, Normal or Increased Platelet Count

A severe, intrinsic system clotting defect is present. In a young male with an active bleeding history, hemophilia is most likely. Both hemophilia and vWD could be present in an affected Doberman pinscher. In other cases of a significant bleeding history, some other intrinsic clotting defect may be present (e.g., factor X or XI deficiency). In the absence of a bleeding history, especially in cats with very long (>60 seconds) APTTs, congenital factor XII deficiency (Hageman trait) should be the first choice. This defect by itself is not of clinical consequence. In animals with a mild to moderate bleeding history and another disease process (e.g., kidney or liver disease), a very long APTT may reflect Fletcher trait (prekallikrein deficiency).

A prolonged PT with normal APTT and TT is most likely caused by factor VII deficiency or early liver disease. If the defect is vitamin K responsive, liver disease is the likely cause.

5. Elevated APTT (Marked), Normal PT and TT, Decreased Platelet Count

When a mild bleeding diathesis is present, especially in cats, the very long APTT is usually caused by an incidental familial factor XII deficiency (Hageman trait), and the bleeding results from concomitant thrombocytopenia.

6. Elevated APTT and PT (Moderate to Marked), Normal TT and Platelet Count

A significantly prolonged PT with a concomitant prolonged APTT and normal TT is most likely caused by rodenticide toxicosis or severe liver disease. The platelet count may also be reduced. The source of the rodenticide should be investigated and treatment with vitamin K_1 instituted for 1–6 weeks depending on the type of rodenticide involved (Mount and Kass, 1989).

7. Elevated APTT, PT (Slight to Moderate), Normal TT and Platelet Count

Mild to moderate prothrombin or factor X deficiencies can prolong both the APTT and PT somewhat but the TT is normal.

8. Normal APTT, TT, and Platelet Count, Elevated PT

A prolonged PT with normal APTT and TT is most likely caused by factor VII deficiency or early liver disease. If the defect is vitamin K responsive, liver disease is the likely cause.

9. Diagnosis of von Willebrand's Disease

Table 10.6 gives a breakdown of the various categories for diagnosing vWD based on the bleeding time and vWF antigen level.

10. Distinguishing Between Rodenticide Toxicosis and Thrombosis

Animals admitted on an emergency basis for acute nontraumatic bleeding pose a difficult diagnostic challenge. While the most likely diagnosis is rodenticide toxicosis, the clinician can be misled if the client insists that there has been no opportunity for exposure. With the newer toxicants available today, a nontarget companion animal can become poisoned secondarily, without the owner's knowledge upon ingesting a poisoned rodent that enters the premises. The presumptive diagnosis of rodenticide poisoning must be distinguished from bleeding associated with DIC because the clinical signs and presentation can be similar. In the case of thrombosis, an underlying cause must be present but may not be immediately obvious.

A complete coagulation profile can readily distinguish between rodenticide poisoning and DIC if it detects the presence of FDP either by direct measurement or with the TT. This test is dependent not only on the quantity of fibrinogen present, but also on its ability to be coagulated by thrombin. In the presence of significant amounts of FDP, the TT is elevated because the fibrinogen molecule has been cleaved by the *in vivo* enzymatic action of thrombin and thereby has been rendered less coagulable.

The typical results of coagulation screening tests for either rodenticide toxicosis or DIC are mild to moderate thrombocytopenia; variable prolongation of the PT and APTT—often exceeding 60 seconds each; and quantitative fibrinogen levels varying from low to elevated. At this point, the critical assay that distinguishes between these two potentially life-threatening problems is the TT. If the TT is normal, the diagnosis is rodenticide toxicosis; if it is elevated, DIC is present.

In mild cases of rodenticide exposure or thrombosis, prolongation of the PT and APTT may be subtle. For example, patients undergoing the stress of a bleeding episode may have elevated fibrinogen and platelet numbers as an acute phase response so that the PT and APTT are shortened below the normal ranges. This also occurs in the early hypercoagulative phase of a thrombotic event. In the case of rodenticide poisoning or acute, generalized liver disease, the PT may appear relatively prolonged in comparison to the APTT, TT, and fibrinogen levels, which are all shortened from increased activity. Thus, the PT may be at the upper limit of normal range or slightly prolonged when the APTT and TT are at the lower range or below the normal range.

This discordance (elevated PT with shortened APTT and TT) is sufficient to diagnose impairment of the vitamin K-dependent prothrombin complex by either rodenticide exposure, liver disease, or even vitamin K-deficiency in neonates or from sterilization of the bowel by prolonged antibiotic usage. This pattern of coagulation test results is explained by two opposing actions: the increased generation of thromboplastic activity following a stress event, which shortens the intrinsic coagulation pathway and elevates fibrinogen, as measured by the APTT and TT, respectively, versus the inhibition of prothrombin complex/vitamin K metabolism by rodenticide, which blocks shortening of the PT in parallel. The difference between the PT and APTT results can be as little as a 1–2 seconds lengthening of the PT and a 1–2 seconds shortening of the APTT, with a resulting gap of 4–5 seconds between the end points of both tests.

IV. BLEEDING DISORDERS

A. General

During the past 40 years, a variety of hemorrhagic diseases have been recognized and studied in animals and humans. Historically, these disorders in animals

TABLE 10.6 Diagnosis of von Willebrand's Disease

Bleeding time[a]	von Willebrand factor antigen (%)[b]	Interpretation
Normal	≥70	Normal range is 70–180%.
Normal[c]	70–79	Lower end of normal range; caution advised for breeding stock. Mates should have higher levels and pups should be checked.
Normal	50–69	Borderline normal (equivocal result) or heterozygous carrier of vWD gene. Recommend retesting and/or breeding only to higher testing mates. Pups should be checked.
Normal or elevated[c]	<50	Type I vWD. This is the most common form of vWD. Heterozygous carrier of vWD.[c] Recommend breeding only to higher testing mates. Pups should be checked.
Elevated[c]	<50	Type I vWD. Has exhibited some bleeding problems (e.g., hematuria, epistaxis, melena, postsurgical bleeding).[c] Clinically affected animals should not be used for breeding. Normal or <50 Type II vWD. Clinically elevated[c] affected animals exhibit severe bleeding symptoms. Multimeric analysis of vWF reveals absence of high-molecular-weight multimers. These animals should not be used for breeding. Has been reported in German shorthair and wirehaired pointers.
Elevated	<0.01	Type III vWD. Exhibits bleeding symptoms and is homozygous for vWD. This animal is the product of two asymptomatic, heterozygous carrier parents and should not be used for breeding.
Normal	>180	Probably reflects stress, an improper sample, or activation from disease. Recommend retesting. Test invalid for prediction of genetic status for vWD trait.

[a] Abnormal bleeding time is not specific for vWD; hemostatic disorders including thrombocytopenia and platelet dysfunction will also cause variable prolongation of bleeding time tests.

[b] Formerly called factor VIII-related antigen; measured by ELISA methodology. When measured by Laurell or RIA methods, normal ranges may vary slightly.

[c] Development of concomitant thyroid dysfunction may aggravate existing vWD or increase the risk of bleeding in some previously asymptomatic carriers.

have been among the most successfully exploited areas of biomedical research in comparative medicine (Dodds, 1988; Brinkous, 1992). Today, reliable and useful animal models exist for nearly all of the inherited and acquired hemostatic and thrombotic disorders (Dodds, 1988, 1989a, 1992). Some deficiencies (e.g., factors V and XIII) have yet to be discovered in domestic or other animals. Numerous reviews describe the clinical, pathophysiological, genetic, management, and treatment aspects of these diseases in animals (Catalfamo and Dodds, 1988; Feldman, 1988; Dodds, 1989a, 1992; McKeever *et al.*, 1990; Prasse *et al.*, 1993; Stefanon *et al.*, 1993; Carr and Johnson, 1994; Mannucci and Giangrande, 1994; Nichols and Hohenhaus, 1994; Sullivan, 1994; Peterson *et al.*, 1995).

1. Medical History

A list of the common causes of hemorrhage in animals is given in Table 10.7. A complete medical history should point to one or more of these causes of bleeding. This should include information about the current bleeding problem, previous bleeding problems, family history, environmental influences, and drugs. Knowledge of the patient's present and past bleeding episodes often provides the key to diagnosis since bleeding problems, especially when internal, can mimic a variety of other disease states. It is therefore important to reevaluate previous illnesses in light of possible clinical signs of bleeding.

2. Physical Examination

A thorough physical examination is essential to determine the location, severity, and nature of the bleeding and to identify the underlying disease that may be present. The type and site of bleeding should be considered carefully. Is the hemorrhage superficial or deep? Is there epistaxis, hematuria, melena, petechiation or ecchymosis on mucosal surfaces or hematoma formation in soft tissues or body cavities? Chronic mucosal surface bleeding suggests a platelet disorder or von Willebrand's disease, whereas large hematomas are more common in clotting factor disorders. Other findings, which suggest acquired rather than inherited causes are splenomegaly, hepatomegaly, and lymphadenopathy.

3. Management and Treatment

Appropriate physiological and physical environments for hemostasis, tissue repair, and prevention of recurrence are important adjuncts to management and treatment of bleeding disorders. Drugs known to interfere with hemostasis are contraindicated for patients

TABLE 10.7 Some Causes of Hemorrhage in Animals

Hereditary defects
- Coagulation disorders
  - X-chromosome-linked recessive traits: hemophilia A, hemophilia B (Christmas disease)
  - Autosomal traits: factor VII deficiency, factor X deficiency, factor XI deficiency, factor XII deficiency, von Willebrand's disease, fibrinogen deficiency (afibrinogenemia, dysfibrinogenemia, and hypofibrinogenemia), prothrombin deficiency (dysprothrombinemia and hypoprothrombinemia)
- Platelet disorders
  - Autosomal traits: thrombasthenia (Glanzmann's disease), thrombopathia (storage-pool disease, thrombocytopathy)

Acquired defects
- Trauma: accidental or from surgical intervention
- Poisoning: warfarin, moldy sweet clover, cottonseed meal, aspirin overdose
- Vitamin deficiency: scurvy, absorptive failure, vitamin K deficiency
- Liver disease: obstructive jaundice, infectious canine hepatitis, tumors, liver failure
- Thrombocytopenia: idiopathic, virus-induced, autoimmune disease, septicemia, splenomegaly, aplastic anemia
- Intravascular coagulation and fibrinolysis syndrome: obstetric complications, sepsis, malignancy, shock, liver disease, heat stroke, incompatible transfusions, heartworm disease
- Platelet function defects: uremia, hyperestrogenism, allergies, drugs, chronic disease, malignancy
- Drug-induced defects: aspirin, steroids, phenylbutazone, live virus vaccines, furacins, sulfonamides, antihistamines, local anesthetics, tranquilizers

with moderate to severe hemostatic defects since they impair platelet function and further compromise the stability of the hemostatic plug (Dodds, 1989a, 1991b, 1992; Dodds *et al.*, 1993). These include aspirin, promazine tranquilizers, phenylbutazone, nitrofurans, potentiated sulfonamides, glycosaminoglycans, penicillins, phenothiazines, antihistamines, local anesthetics, estrogens, antiinflammatory drugs, plasma expanders such as dextran and hydroxyethyl starch, and live virus vaccines (Dodds, 1992; Gentry *et al.*, 1992; Dodds, *et al.*, 1993) (Section IV.C). The latter, like virus infections, affect platelet and/or endothelial function during the viremic phase (3–10 days after vaccination or exposure). Elective surgical procedures, such as ear cropping, spaying, castration, or dentistry, should be performed within 48 hours after vaccination or postponed for 10–14 days (Dodds, 1989a, 1992; Brooks, 1992; Dodds *et al.*, 1993).

Adequate replacement therapy of the correct type is essential for the control of moderate or severe hemostatic defects (Cotter, 1991; Dodds, 1991a; Hohenhaus, 1992; Wagner and Dunlop, 1993; Dodds *et al.*, 1993; Giger, 1994). In general, guidelines for treating human patients with hemostatic disorders are followed for parallel problems in animals. Because platelets and coagulation factors are relatively labile, whole blood, plasma or platelet-enriched products should be processed and stored for use later or transfused as soon as possible after collection and preparation. Although plasma is typically frozen soon after preparation (i.e., fresh-frozen plasma) and then stored at −20°C or lower for long periods, newer techniques for freezing and storing human and animal red blood cells and platelets have not yet been applied to the clinical care of animal patients (Cotter, 1991; Hohenhaus, 1992; Rao *et al.*, 1993; Wagner and Dunlop, 1993; Machin *et al.*, 1995). An efficient method of obtaining maximal utilization of blood products involves removing and freezing the plasma from anticoagulated fresh whole blood and storing the packed red blood cells in nutrient solution (e.g., Adsol, Optisol) at 4°C for 5–6 weeks. The collection, storage, and utilization of whole blood, packed red blood cells, fresh-frozen plasma or other blood components obtained from animal species are best accomplished under conditions used for human blood. Plastic bags are preferable to vacuum bottles for collection and red cells retain viability longer in citrate-phosphate-dextrose (CPD) anticoagulant than in acid-citrate-dextrose (ACD) (Cotter, 1991; Dodds, 1991a; Hohenhaus, 1992).

Until recently, most veterinarians have had to resort to using random (unmatched) blood donors, because typing sera for detemining animal blood groups are generally not commercially available (Dodds, 1993). Blood typing is typically obtained, therefore, by sending samples to one of the few specialized laboratories offering this service for domestic animals. With respect to the dog and cat, a commercial card-typing system for the canine DEA 1.1 antigen has been introduced and a parallel card system for the feline A and B antigens has been developed (Iatric Corp., Tempe, Arizona).

The ideal canine blood donor (a universal donor) is negative at the DEA 1.1, 1.2 and 7 loci; is a healthy, young adult (1–6 years) of good temperament; weighs at least 50 lb; and has never been transfused. A donor dog can safely donate 10 ml of blood/lb of body weight every 3–4 weeks or 5 ml of blood/lb every 2 weeks. Donor dogs should be given an iron-vitamin dietary supplement to enhance hematopoiesis if they are to be bled repeatedly. Today, veterinarins can purchase blood from the handful of private commercial blood banks recently established for dogs and horses. Alternatively, practitioners may keep DEA 1-negative dog donors in their hospital to provide fresh blood for emergency use to treat patients in need of repeated transfusions (Dodds, 1993). These include dogs with

such conditions as inherited or acquired bleeding disease, autoimmune hemolytic anemia, other chronic anemias of primary or secondary origin, and animals known to have received prior transfusions of unknown type (e.g., for puppies with severe hookworm anemia, accident cases given blood transfusions for shock or blood loss).

Cross-matching blood from donor and recipient dogs before transfusion is not a substitute for blood typing because, unless the recipient dog has been previously sensitized by an incompatible transfusion, the serum will not contain red cell antibodies that react in the cross-match test. However, if commercial blood products or local compatible donors are unavailable, the best alternative is to cross-match donor and recipient (Dodds, 1993). The recipient's blood must be compatible in the major cross-match (donor red cells and recipient serum) at 37°C, room temperature, and at 4°C and should be compatible in the minor cross-match (recipient red cells and donor serum) at least at 37°C. Incompatibilities by cross-matching indicate prior sensitization of the recipient. Animals in need of repeated transfusions or those with autoimmune hemolytic anemia should always be given blood from typed and compatible (universal) donors.

The major blood types in cats are types A and B with type AB being very rare. In some cat breeds, 30–50% of the animals are blood type B (Hohenhaus, 1992). The ideal feline blood donor has blood type A, which is the most common type found in more than 90% of random-source cats and 50% or more or purebred cats; is a healthy, young adult of good temperament; weighs at least 8 lb; and has never been transfused. Unlike the dog, cats have naturally occurring isoantibodies against the other blood types. Blood type A cats have weak anti-B antibodies, whereas type B cats have more potent anti-A antibodies. This has important clinical significance because transfusion of type A blood to a type B cat, even the first time, can produce a serious adverse transfusion reaction and mating of a type B queen with a type A tom can result in hemolytic disease of newborn kittens of type A (Cotter, 1991; Hohenhaus, 1992). Donor cats can safely donate 5 ml of blood/lb body weight for a maximum of 60 ml every 3–4 weeks and should be supplemented with hematinics. Cat blood is not presently offered by any of the commercial animal blood banks so practitioners must maintain their own feline donors or donor colonies (Hohenhaus, 1992).

Whole blood is not the treatment of choice nor is it desirable for the primary therapy of most veterinary transfusions (Cotter, 1991; Hohenhaus, 1992; Dodds, 1993). Processing freshly collected blood into several clinically useful components is a more cost-effective, efficient, and safer use of blood. The most commonly used blood components in veterinary medicine parallel those in human medicine, namely, packed red blood cells and fresh-frozen plasma. The red blood cells are primarily used to treat acute blood loss anemia from trauma, surgery, or acute hemolytic disease and for chronic anemia caused by internal and external parasites, bone marrow failure, and chronic hemolytic disease. Fresh-frozen plasma is used to treat or control bleeding disorders and to provide passive immunity to alleviate or protect against acute or chronic infectious diseases, especially those of viral origin such as parvovirus or herpes virus disease. Specialty canine blood products such as PRP (for clinically severe platelet defects) and cryoprecipitate (for hemophiliacs and severe cases of vWD) are also available for clinical use at some veterinary schools and from this author's private blood bank (Dodds, 1993; Ching *et al.*, 1994). The high purity and recombinant factor VIII and IX clotting factor concentrates used for treating human hemophiliacs or vWD patients (Aronson, 1990; Bloom, 1991; Hanna *et al.*, 1994) are unlikely to even become available in parallel homologous form for treating animal patients, because of the need for large volumes of starting plasma (low yields) and the unrealistically high preparatory costs (Cotter, 1991; Hohenhaus, 1992). Blood substitutes are also used in veterinary medicine in a manner similar to that of human medicine (Dodds, 1991a).

B. Hereditary Disorders

Table 10.7 lists the inherited coagulation and platelet function defects currently recognized in animals. These disorders have been reviewed in detail elsewhere (Catalfamo and Dodds, 1988; Feldman, 1988; Raymond *et al.*, 1990; Dodds, 1991b, 1992; Brooks *et al.*, 1992; Dodds *et al.*, 1993; Stefanon *et al.*, 1993; Carr and Johnson, 1994; Peterson *et al.*, 1995).

1. Fibrinogen (Factor I) Deficiencies

Hereditary fibrinogen deficiencies have been recognized in goats and dogs. These can be caused by a complete lack of fibrinogen (afibrinogenemia), reduced fibrinogen (hypofibrinogenemia), or an abnormal fibrinogen (dysfibrinogenemia). These defects produce a mild to severe bleeding diathesis and have an autosomal inheritance pattern (Dodds, 1989a, 1992).

Fibrinogen defects, quantitative or qualitative, result in a complete failure of plasma or whole blood to clot in any coagulation test or when thrombin is added and plasma does not form a precipitate when heated to 56°C or treated with 25% ammonium sulfate. Some

abnormalities of platelet function, a prolonged bleeding time and abnormal clot retraction also may occur. Although biological assays of fibrinogen are abnormal, the presence of fibrinogen is usually detected immunologically.

Caprine afibrinogenemia was recognized in the Netherlands in a large family of Saanen dairy goats (Dodds, 1989a). It was characterized by a severe hemorrhagic diathesis in newborn and young kids, incompletely dominant inheritance, umbilical bleeding, recurrent hemarthroses, and bleeding into subcutaneous tissues and from mucous membranes. Fibrinogen was undetectable by bio- and immunoassays. Heterozygotes had hypofibrinogenemia.

Canine hypofibrinogenemia was recognized in a family of Saint Bernards from West Germany. Both biological and immunological assays of fibrinogen were decreased. The propositus succumbed to a severe hemorrhagic crisis. Related dogs appeared to be heterozygous for the trait. Inherited dysfibrinogenemia has been observed in families of borzoi and vizslas and in a collie.

2. Prothrombin (Factor II) Deficiency

Prothrombin defects prolong the extrinsic system tests (PT and RVVT) while intrinsic coagulation tests are normal. Both hypo- and dysprothrombinemia are recognized as clinical entities in humans. These are autosomal characteristics that produce mild to moderately severe bleeding problems.

Canine hypoprothrombinemia is the only inherited prothrombin abnormality seen in animals (Dodds, 1989a). Two generations of an affected family of boxers from Texas were studied. The defect was characterized by epistaxis and umbilical bleeding in newborn puppies and mild mucosal surface bleeding in young adults. Although the disease appeared initially to resemble dysprothrombinemia with reduced prothrombin activity and normal antigen, additional studies indicated a metabolic or kinetic problem in turnover of all the vitamin K-dependent clotting factors. These dogs were also warfarin sensitive and had a considerably delayed warfarin turnover time. Prothrombin deficiency has also been reported in an English cocker spaniel.

3. Vitamin K-Dependent Coagulation Factor Deficiency

Combined deficiency of all vitamin K-dependent coagulation factor (II, VII, IX and X) has occasionally been reported in humans (Pechlaner *et al.*, 1992) and was thoroughly investigated in a family of Devon Rex cats (Maddison *et al.*, 1990; Soute *et al.*, 1992). The feline disorder was vitamin K responsive and was inherited as an autosomal trait (Maddison *et al.*, 1990). A defective vitamin K-dependent carboxylase was identified that had decreased affinity for both vitamin K hydroquinone and propeptide (Soute *et al.*, 1992).

4. Factor VII Deficiency

Human factor VII deficiency, although relatively rare, has been thorougly characterized from both genetic and molecular perspectives (Tuddenham *et al.*, 1995). By contrast, this disorder is commonly reported worldwide in beagle dogs from large commercial breeding colonies. The apparent high incidence of the defect in this breed probably reflects the widespread use of beagles in biomedical research (Dodds, 1989a). It has also been described in an Alaskan malamute, bulldogs, and mixed breeds. The disorder is usually discovered fortuitously during routine hematological screening for drug testing, research, or clinical workup.

Canine factor VII deficiency is a mild disease with no overt bleeding tendency except for easy bruisability and a predisposition to systemic demodecosis, presumably because the animals' defective extrinsic clotting provides an ideal, moist environment for mange mites (Dodds, 1989a). Homozygotes are detected by the presence of a long PT, normal RVVT, and reduced factor VII activity. Heterozygotes are more difficult to identify with screening tests only because the PT may fall within the upper end of normal range or be only slightly elevated. Affected dogs have less than 15% and usually below 5% factor VII, whereas heterozygotes have about 15–65% of normal levels. The prothrombin consumption time of factor VII-deficient dogs is usually prolonged because factor VII is absent from their serum.

Factor VII-deficient dogs have served as important models for biomedical research (Dodds, 1989a). Plasma from affected dogs is an excellent standard source of deficient substrate for quantitating factor VII in humans and other species and for quality control of various tissue thromboplastins. The model has been used to investigate the role of factor VII in mediating endotoxin-induced intravascular coagulation and shock. Cross-circulation studies between normal and factor VII-deficient dogs confirmed the rapid turnover and short half-life of this clotting factor as predicted from studies in humans (Dodds, 1989a). A human plasma concentrate containing mostly activated factor VII (FVIIa) and proteins C and S has been given to dogs with hemophilia A to demonstrate its hemostatic benefit in bypassing the intrinsic system requirement for factor VIII (Chabbat *et al.*, 1989). This approach may be useful in treating hemophilic patients with coagulation inhibitors.

5. Hemophilia A (Factor VIII:C Deficiency, Classic Hemophilia)

The most common of the severe inherited coagulopathies, hemophilia A occurs in humans, dogs, horses, sheep, cattle, and cats (Feldman, 1988; Dodds, 1992, 1995b; Stefanon *et al.*, 1993). Clinical signs and laboratory studies have shown the disease to be similar if not identical in these species (Feldman, 1988; Carr and Johnson, 1994; Peterson *et al.*, 1995). Mild, moderate, and severe forms of hemophilia have been recognized in humans and dogs, whereas the equine defect is usually severe and the feline defect tends to be mild. The canine disease has been reported in nearly every pure breed of dogs and in mongrels (Dodds, 1992; Carr and Johnson, 1994; Joseph *et al.*, 1996), but is most common in German shepherds worldwide having descended from the obligatory carrier progeny of an influential hemophilic stud (Feldman, 1988; Stefanon *et al.*, 1993; Stokol *et al.*, 1994). Smaller breeds tend to be less severely affected than larger breeds, which appears to be related to weight bearing and is consistent with the severe expression in horses and the mild problem in cats. Thoroughbred, standardbred, and quarter horses have all developed this disease as have several breeds and mixed breeds of cats (Henninger, 1988; Dodds, 1991b; Peterson *et al.*, 1995). The bovine defect arose in Australian Hereford cattle and the ovine in Dutch sheep (Dodds, 1989a).

Hemophilia is an X chromosome-linked recessive trait in humans and other animals. Affected males are hemizygous for the trait, whereas carrier females are heterozygous and affected females (the product of a hemizygous and heterozygous mating) are homozygotes. Affected individuals have markedly prolonged screening tests of intrinsic clotting and very low levels of FVIII:C activity but normal or elevated levels of vWF:Ag. In accord with the Lyon hypothesis whereby heterozygous females have one active and one inactivated X chromosome, hemophilic carriers have about half of the normal amount of FVIII:C. They synthesize a full complement of vWF:Ag, however, so carrier females may be identified by their moderately reduced FVIII:C (40–60% of normal) and normal or elevated vWF:Ag. This finding (Section II.C.2.f) has been used effectively for carrier detection in both humans and animals (Feldman, 1988; Dodds, 1989a, 1991a, 1992, 1995b). More recently, prenatal diagnosis by amniocentesis has been used in humans to predict accurately the genotype of a developing fetus in known or suspected carrier females (Lozier and High,1990; Antonarakis, 1995).

Studies of animals with hemophilia A have contributed significantly to current knowledge of the analogous human disease and to knowledge of the biochemical and physiological roles of factor VIII (Do 1989a; Feldman, 1988; Patterson *et al.*, 1988; 1989; Chabbat *et al.*, 1989; Ni and Giles, 1992 *al.*, 1993). Hemophilic dogs have been used hemostatic plug formation, development of ous canine–anticanine factor VIII inhibitor half-life, and sites of synthesis of factor VIII (B 1992; Ni and Giles, 1992; Tinlin *et al.*, 1993). T provided an extremely valuable standard deficient substrate for quantitating FVIII:C i cies and helped in the development of the A method. Affected animals have also been use tigate the biochemical nature and molecular of factor VIII and to test the *in vivo* efficac homologous and heterologous factor VIII an centrates and the factor VIII-bypassing activ sue factor, factor VIIa, factor Xa, and pho vesicles (Chabbat *et al.*, 1989; Ni and Giles, 1 safety and efficacy of heat-treated factors V concentrates were established in hemophilia dogs, respectively.

Infusions of highly purified rDNA-derive FVIII:C concentrates in dogs with hemop proved the efficacy and safety of this type o leading to its present clinical use in humans (1990). This recombinant form of factor VI available for routine treatment of hemophilia, ther reducing the risk of transfusion-transm eases, such as hepatitis B and C, and acquire deficiency syndrome (Bloom, 1991; Dodds, 1

Genetic studies with hemophilic dogs hav terized the hemophilic phenotype and genot vided the proof of X chromosome-linked rec heritance and examined linkage of other c distantly located X chromosomal markers production of canine double hemophilia, he AB, Section IV.B.12.b). The specific gene de substitution in many human and several cani philic families has been identified by cDN techniques (Lozier and High, 1990; Antonaral

The most challenging and potentially imp search with animal models of hemophilia A is at molecular genetics and gene therapy (Bi *et* Dwarki *et al.*, 1995; Fallaux *et al.*, 1995; T 1995). The canine hemophilia models have tinue to play a key role in this effort (Sectio (Walter and High, 1997).

6. Hemophilia B (Factor IX Deficiency, Christmas Disease)

Hemophilia B, also an X chromosome-link sive trait, is less common than hemophilia A a in humans, about 20 breeds of dogs, and seve of cats as well as mixed breeds (Feldman, 198

and Dodds, 1989; Dodds, 1989a; Maggio-Price and Dodds, 1993; Feldman *et al.*, 1995). Christmas disease occurs as a mild to moderate disorder of small dog breeds (e.g., Cairn terrier, American cocker spaniel, Shetland sheepdog, Scottish terrier, and French bulldog) and cats and as a severe diathesis in larger breeds (e.g., black and tan coonhounds, Saint Bernards, Alaskan malamutes, Old English sheepdogs, and German shepherds) (Dodds, 1992; Stefanon *et al.*, 1993; Carr and Johnson, 1994; Peterson *et al.*, 1995).

As in classic hemophilia, carrier females can be identified by reduced (40–60%) levels of factor IX (Maggio-Price and Dodds, 1993; Feldman *et al.*, 1995). However, in contrast to hemophilia A, in which mild, moderate, and severe factor VIII:C deficiencies exist, most reported cases of hemophilia B in animals have had less than 5% factor IX. Gene cloning studies with the human and canine disease have identified two types of patients, those with undetectable or very low levels of factor IX antigen and a few with normal amounts of a mutant antigen (Evans *et al.*, 1989a, 1989b; Sommer, 1992). An intriguing hemophilia B mutant was recently described in which affected family members gradually recover under the influence of androgens (Crossley *et al.*, 1992).

It is important to perform accurate diagnostic tests to differentiate between the hemophilias as both disorders have markedly prolonged intrinsic system clotting tests. The propositi in several of these dog and cat families were referred for confirmation of suspected hemophilia A or severe vWD and were found to have hemophilia B (Maggio-Price and Dodds, 1993; Feldman *et al.*, 1995). The plasma defect of hemophilia B is corrected by addition of fresh normal serum, whereas that of hemophilia A is not because serum contains factor IX but not FVIII:C activity. Like hemophilia A dogs, hemophilia B dogs are important models for biomedical science (Dodds, 1988; Evans *et al.*, 1989a, 1989b) and have played a pivotal role in recent gene therapy experiments (Axelrod *et al.*, 1990; Kay *et al.*, 1993, 1994; Marx, 1993; Lozier *et al.*, 1994; Sugahara *et al.*, 1996; Walter and High, 1997). Their plasma is an excellent deficient substrate of standard source for quantitating factor IX activity and they were used in organ transplantation studies that established the liver to be the sole site of factor IX synthesis (Kay *et al.*, 1993, 1994; Furie and Furie, 1995b). Genetic cross-breeding studies with hemophilia A dogs produced double hemophiliacs (hemophilia AB; see Section IV.B.12.b) and infusion studies determined the half-life of factor IX and efficacy of human factor IX concentrates. The occasional thrombogenicity of human prothrombin complex clotting factor concentrates prompted comparison studies with highly purified factor IX in a canine thrombogenic model (MacGregor *et al.*, 1991). As some human patients with mild hemophilia respond to danazol treatment given as a nontransfusional form of therapy, cats with hemophilia B were also treated with danazol but no therapeutic benefit was observed (Boudreaux and Dillon, 1988).

Development of highly purified rDNA-derived factor IX has permitted *in vivo* pharmacokinetic studies in rats and dogs (Keith *et al.*, 1994). Definitive studies of factor IX biosynthesis have elucidated practical approaches for factor IX gene therapy (Palmer *et al.*, 1989; Sommer, 1992; Furie and Furie, 1995b). Initial experiments with skin fibroblasts in factor IX-deficient dogs (Axelrod *et al.*, 1990) began a series of factor IX gene therapy studies including development of a partially hepatectomized hemophilic puppy model (Kay *et al.*, 1993, 1994; Marx, 1993) and other less invasive approaches (Lozier *et al.*, 1994; Fallaux *et al.*, 1995; Thompson, 1995; Sugahara *et al.*, 1996; Walter and High, 1997). Although a cure for hemophilia is still distant, results to date are encouraging. The main stumbling block is the need to ellicit long-term vector expression of functional factor IX (Walter and High, 1996).

7. *Von Willebrand's Disease*

von Willebrand first described the complex, multifaceted syndrome known as vWD in 1926 (Ginsburg and Sadler, 1993; Ruggeri and Ware, 1993). The bleeding diathesis, usually more mild than the hemophilias, primarily involves mucous membranes and skin, with gastrointestinal and urogenital bleeding and epistaxis as common symptoms (Raymond *et al.*, 1990; Brooks, 1992; Mazurier, 1992; Dodds *et al.*, 1993; Lock, 1994; Sullivan *et al.*, 1994). The prolonged bleeding time also results in excessive surgically induced hemorrhage (Dodds *et al.*, 1993; Lock, 1994). vWD is the most common inherited bleeding disorder of humans and has been recognized in swine, more than 60 dog breeds, several breeds of cats, a quarterhorse family, and inbred strains of laboratory rabbits and mice (Dodds, 1988, 1991b, 1992; Feldman, 1988; Sweeney *et al.*, 1990; Brooks *et al.*, 1991b, 1992, 1996a; Huss and Ettinger, 1992; Dodds *et al.*, 1993; Carr and Johnson, 1994). The affected breeds with a high prevalence of the gene are Doberman pinscher (70% prevalence), German shepherd, miniature schnauzer, golden retriever, Shetland sheepdog, basset hound, standard poodle, keeshond, rottweiler, dachshund, Scottish terrier, Manchester terrier, and Pembroke Welsh corgi. In other breeds, the disorder is either less prevalent or the true prevalence is unknown because too few animals have been studied.

By far the most common form of canine vWD is type 1, a situation analogous to human vWD (Feldman, 1988; Dodds *et al.*, 1993; Sadler, 1994; Sadler *et al.*, 1995). Type 1 vWD is inherited as an autosomal, incompletely dominant trait with variable clinical and laboratory expression based on the degree of penetrance of the mutant gene. Homozygosity is lethal in type 1 vWD; affected pups are resorbed *in utero*, born dead, or live only a few days (Dodds, 1988). Heterozygotes are either asymptomatic carriers or express a mild to moderately severe bleeding diathesis, especially involving mucosal surfaces or associated with surgery.

In four dog breeds, Scottish terriers, Chesapeake Bay retrievers, Shetland sheepdogs, and German wirehaired pointers (Dodds, 1988, 1989a, 1991b, 1992; Raymond *et al.*, 1990; Dodds *et al.*, 1993; Johnstone *et al.*, 1993; Brooks *et al.*, 1996a), in Himalayan cats and in Poland-China swine, vWD is analogous to the autosomal recessive type 3 vWD of humans. The homozygote manifests a moderate to severe bleeding tendency and heterozygotes are detected by laboratory tests but are otherwise asymptomatic. The clinical and laboratory spectrum of canine vWD closely parallels that of human vWD (McCarroll *et al.*, 1987, 1988; Dodds, 1988, 1992; Feldman, 1988; Kraus *et al.*, 1989; Waters *et al.*, 1989; Meyers *et al.*, 1990a, 1990b; Ruggeri and Ware, 1993; Konkle, 1995; Meinkoth and Meyers, 1995; Sadler *et al.*, 1995; Brooks, 1996a, 1996b).

Only severely affected individuals will exhibit prolonged screening tests of intrinsic clotting, whereas the bleeding time is consistently prolonged. Individuals with type 1 disease have a variable reduction in FVIII:C but a definite reduction in vWF:Ag and platelet vWF activity (Dodds *et al.*, 1993; Stokol *et al.*, 1995; Zang, 1995). In contrast, the homozygous type 3 vWD patient has low FVIII:C and undetectable vWF:Ag and platelet vWF activity (Raymond *et al.*, 1990; Brooks *et al.*, 1992, 1996a; Johnstone *et al.*, 1993). Platelet retention in glass bead columns is impaired as is ristocetin- or botrocetin-induced platelet agglutination (Feldman, 1988; Smith and Brinkhous, 1991). The other phenomenon observed in classic vWD is a paradoxical increase in FVIII:C, which does not parallel the behavior of vWF:Ag or bleeding time, following transfusion of normal or hemophilic plasma. Correction of the other components of the factor VIII complex is usually more immediate and transient, whereas the increase in FVIII:C is delayed. The vWF:Ag present in the infused material provides the missing vWF component which somehow causes the patient to release or synthesize FVIII:C at some remote site not yet identified (Sections II.C.2.f).

In addition to the more commonly recognized types 1 and 3 vWD, many variants exist in humans (Ginsburg and Sadler, 1993; Sadler, 1994; Sadler *et al.*, 1995), and variants have been described in a families of German shorthair pointer dogs (Feldman, 1988), quarterhorses (Brooks *et al.*, 1991b) and other dog breeds (Brooks *et al.*, 1991a).

The genetics of vWD are complex and have been studied in humans by several groups (Ginsburg and Sadler, 1993; Ruggeri and Ware, 1993; Girma *et al.*, 1995; Sadler *et al.*, 1995; Zang, 1995). In the nationwide genetic screening program for canine vWD begun by our group in 1980 (Dodds, 1995b), about 30,000 Doberman pinschers, 12,000 Shetland sheepdogs, 9000 golden retrievers, 8000 Scottish terriers, 5000 Pembroke Welsh corgis, 5000 standard and miniature poodles, and several thousand miniature schnauzers, basset hounds, Akitas, and rottweilers have been tested for vWD (Raymond *et al.*, 1990; Brooks *et al.*, 1992). For other breeds, smaller numbers have been examined.

Studies of canine vWD have sustained interest in the physiological and disease states that alter factor VIII metabolism. In dogs, vWD is exacerbated by concurrent hypothyroidism (Dodds, 1988, 1992, 1995a; Avgeris *et al.*, 1990; Dodds *et al.*, 1993) so that asymptomatic carriers of vWD may exhibit a bleeding tendency if they develop autoimmune thyroiditis and become hypothyroid, a common situation found in many breeds but especially prevalent in Doberman pinschers (Dodds *et al.*,1993; Dodds 1995b). The concomitant prevalence of vWD and hypothyroidism in these breeds of dogs suggests a link between the synthesis and/or metabolic regulation of thyroid hormones and vWF (Dodds, 1995a). Furthermore, hypothyroid dogs may exhibit thrombocytopenia and associated mucosal surface bleeding. While this connection has come into question from results of experimental and other studies (Panciera and Johnson, 1994, 1995, 1996), the clinical evidence for a regulatory relationship between vWD and hypothyroidism is solid (Avgeris *et al.*, 1990; Dodds, 1991a, 1995a).

In humans, hemostatic abnormalities may be an early manifestation of hypothyroidism (Dodds, 1991a). These include easy bruising and thrombocytopenia, low platelet retention in glass bead columns, which is normalized after treatment with L-thyroxine, low thrombin-induced platelet serotonin release, decreased levels of FVIII:C, and an acquired form of vWD (Avgeris *et al.*, 1990; Dodds *et al.*, 1993; van Genderen, 1994; Dodds, 1995a). Clinical experience with use of thyroid supplement, which nonspecifically shortens the bleeding time in animals with inherited or acquired vWD and other platelet dysfunctions, has supported the efficacy, safety, and low cost of this approach (Dodds, 1991a, 1995a; Dodds *et al.*, 1993).

Thyroid supplementation alone may suffice to control bleeding in mild to moderate vWD, a situation analogous to the use of desmopressin (DDAVP) or danazol to control bleeding in humans and animals (Dodds, 1989b, 1991a; Giger and Dodds, 1989; Kraus *et al.*, 1989; Meyers *et al.*, 1990a; Mansell and Parry, 1991; Lattuada *et al.*, 1992; Pietraszek *et al.*, 1992; Nichols and Hohenhaus, 1994). DDAVP treatment has recently been shown to improve vWF levels in dogs with vWD, although relatively high doses are required and the response is short lived (Giger and Dodds, 1989; Meyers *et al.*, 1990a; Dodds, 1991a). Because of the important role of vWF in sustaining platelet adhesion, animals that are asymptomatic heterozygotes for vWD (as determined by reduced levels of vWF:Ag, Brooks *et al.*, 1996b) are at risk to express a bleeding tendency if some other hemostatic disorder develops (e.g., rodenticide toxicosis, thrombocytopenia, liver disease, hypothyroidism) (Dodds, 1992; Dodds *et al.*, 1993).

Another area of interest is the relationship of vWF to atherogenesis (Hawiger, 1995; Griendling and Alexander, 1996). Studies of normal and vWD swine showed that affected pigs had significantly fewer vascular lesions and less atherosclerosis than did control swine fed the same diet and raised in the same environment. These observations led to the theory that platelet components of the factor VIII complex are involved in the endothelial and vessel wall proliferation of atherogenesis (Meyers *et al.*, 1990b; Rand *et al.*, 1993; Caen and Rosa, 1995; Hawiger, 1995).

8. Factor X Deficiency

A rare coagulation disorder, factor X deficiency was first described in humans in the mid-1950s in the United Kingdom and the United States. In the early 1970s it was recognized in a family of American cocker spaniels (Dodds, 1989a, 1992). Since then, factor X deficiency has been diagnosed occasionally in mongrel dogs and more recently in the Jack Russell terrier (Cook *et al.*, 1993). Homozygotes and strongly penetrant heterozygotes have very low levels of factor X (<6–35%) and a clinically expressed bleeding disease, whereas weakly penetrant heterozygotes (40–70% factor X) are usually asymptomatic. Severely affected humans have <1–10% factor X, and affected dogs with less than 20% factor X usually do not survive neonatal life. The exception was an affected mongrel puppy with 6% factor X that lived for nearly a year before experiencing a fatal bleeding episode. Complete absence of factor X is thought to be a lethal mutation because of its central role in coagulation.

In addition to reduced factor X levels, clinically affected individuals have mild to moderately prolonged APTT, PT, and RVVT. In heterozygotes, these screening tests may be slightly prolonged. Two types of disease have been recognized in humans, one with undetectable antigen related to factor X (classic form) and another with normal or reduced amounts of mutant protein detectable by immunoassay. In affected newborn pups, as in infants, serious bleeding occurs. This disease mimics the "fading puppy syndrome," in which severely affected pups are stillborn or fade and die in the first week or two of life. Necropsies show massive internal bleeding. Signs in adults are mild and referable to mucosal surfaces (Cook *et al.*, 1993).

9. Factor XI (PTA) Deficiency

Factor XI deficiency is a rare disorder of humans in which more than 90% of cases occurs in person of Jewish background. Clinical signs are mild (hematuria, bruising, epistaxis, menorrhagia) unless the patient is subjected to surgical procedures. Bleeding usually starts 12–24 hours after surgery and can be severe and protracted. Lethal bleeding has also been reported after minor procedures such as biopsies and tonsillectomy. The disorder has also been recognized in Holstein cattle, English springer spaniels, great Pyrenees, and Kerry blue terrier dogs (Dodds, 1989a; Gentry and Ross, 1993; Knowler *et al.*, 1994).

In cattle and dogs, PTA deficiency is similar to that of humans—there is protracted bleeding after surgery. Clinically affected animals are homozygotes and have very low factor XI levels, prolonged APTT, recalcification time, and abnormal PCT. Heterozygotes are asymptomatic and have 25–50% factor XI, which is somewhat lower than levels seen in human heterozygotes (Gentry and Ross, 1993). The defect has not been erradicated from the Kerry blue terrier or great Pyrenees breeds. The affected springer spaniel family is now deceased. Affected cattle are still being maintained and they are a valuable source of large quantities of deficient substrate plasma for measuring factor XI levels in humans and other species (Gentry and Ross, 1993). Factor XI activity is also deficient in several early diverging mammalian and nonmammalian species such as cetaceans and fowl. This is a normal phenomenon, however and the significance of the apparent absence of PTA-like activity is unknown. Many of these species also lack Hageman and Fletcher factor activities (Sections IV,B,10 and IV,B,12,c). A cat with an inhibitor of PTA has been described (Feldman, 1988).

10. Factor XII Deficiency (Hageman Trait)

Hageman trait is an asymptomatic coagulation deficiency recognized in humans, dogs, and cats (Otto *et al.*, 1991; Peterson *et al.*, 1995). The first feline case

involved one animal discovered fortuitously by prolonged screening tests of intrinsic clotting. It had less than 5% factor XII and died without progeny. The second case, also discovered by screening tests, had less than 1% factor XII and has provided several generations of progeny. Affected individuals have significantly prolonged APTT, recalcification times, and WBCT in glass tubes and usually do not bleed unless hemostasis is otherwise compromised (Peterson *et al.*, 1995). Hageman trait appears to be quite common in cats.

In addition to these defects, the absence of detectable biological or immunological factor XII is a normal phenomenon of a variety of other vertebrates and invertebrates (Dodds, 1989a) such as whales, birds (including the common domestic fowl and waterfowl), reptiles, and possibly fish. Other uncommon mammalian and nonmammaliam species that contain Hageman activity are seals, echidnas, marsupials, and amphibians (Dodds, 1989a). However, the difficulties of interpreting results of clotting factor tests in nonmammalian plasmas measured with human factor XII-deficient substrate should be considered.

11. Platelet Function Defects

a. Thrombasthenia (Glanzmann's Disease)

The term *thrombasthenia* literally means "weak thrombocytes" and was coined by Glanzmann to describe an autosomal recessive bleeding disorder in which there was no clot retraction. There may be low normal platelet counts or mild thrombocytopenia but platelet morphology is essentially normal. Affected patients have long bleeding times, defective platelet aggregation with standard aggregating agents, especially ADP, and abnormal platelet retention. In most cases platelet vWF is normal. Platelet fibrinogen levels, PF-3 availability, and platelet membrane glycoproteins IIb and IIIa are usually significantly reduced. The latter abnormalities are thought to be responsible for the defective aggregation and clot retraction (Catalfamo and Dodds, 1988). The bleeding diathesis is severe and of the purpuric type and epistaxis is common and profuse. In severely affected humans, low-level estrogen treatment has reduced and controlled bleeding.

In 1967, a family of otterhounds was described with an inherited platelet function defect similar to human Glanzmann's disease except for the presence of some bizarre giant platelets (Catalfamo and Dodds, 1988). The morphological abnormality in these giant platelets resembled that of human Bernard Soulier syndrome but the functional disorder was indistinguishable from thrombasthenia, including the typical platelet membrane glycoprotein abnormalities (Nurden, 1995). The disease was therefore termed thrombasthenic–thrombopathia and was inherited as an autosomal dominant trait with variable expression. Both homozygotes and heterozygotes could be identified by specific platelet function tests.

A variant form of this original otterhound platelet defect has surfaced again in several animals related distantly to the original affected family. The present defect may be either a mutated or self-selected variant of the initial problem. Eight affected dogs have been studied, and six were found to have platelet abnormalities detectable by traditional platelet function tests but the other two did not. The new expression of the platelet disorder is characterized by bleeding episodes that are triggered by stress events.

b. Thrombopathia

A group of inherited thrombopathias has been described in humans, many of which have unique characteristics. These include primary or function thrombopathy, Bernard–Soulier syndrome, storage-pool disease or deficit thrombopathy and other platelet release defects. The specific features of each of these disorders are described elsewhere (Catalfamo and Dodds, 1998; Patterson *et al.*, 1989; Boudreaux *et al.*, 1994; Bray, 1994; Callan *et al.*, 1995).

Animal thrombopathias have been recognized in fawn-hooded rats, basset hounds, spitz dogs, American cocker spaniels, Simmental cattle, and cats (Catalfamo and Dodds, 1988; Patterson *et al.*, 1989). The defect in fawn-hooded rats and American cocker spaniels is similar to that of human platelet storage-pool disease (Catalfamo and Dodds, 1988; Callan *et al.*, 1995). Affected rats have reduced platelet serotonin and release. Interesting concomitant findings are a focal glomerulonephritis and proteinuria associated with aging and docile behavior, thought to be related to reduced content of brain serotonin. Hypertension is also a feature of their defect. These rats are thus useful models for hemostatic, immunological, pathological, and behavioral studies. The disorder in American cocker spaniels has been attributed to a deficient platelet δ-granule storage pool of ADP (Callan *et al.*, 1995) and is similar to the platelet defect seen in Chediak–Higashi disease of mice and cats (Pratt *et al.*, 1991; Cowles *et al.*, 1992).

Canine thrombopathia (CTP) is an autosomally inherited bleeding disorder of the basset hound (Catalfamo and Dodds, 1988). The recently described platelet defect of spitz dogs is similar (Boudreaux *et al.*, 1994). These conditions produce a bleeding tendency primarily of mucosal surfaces and intrinsic to the platelet. Thrombopathic platelets fail to respond normally to very high concentrations of most physiologic agents

that activate platelets. Of these, only thrombin causes CTP platelets to aggregate at a measurable though reduced rate. The preservation of this key platelet activation pathway probably explains why affected dogs can survive.

Despite the fact that CTP platelets have normal amounts of fibrinogen and surface receptor proteins, they fail to interact normally with fibrinogen (Catalfamo and Dodds, 1988). The platelet dysfunction observed in CTP is associated with abnormally high levels of cyclic adenosine monophosphate (cAMP), which couples the signal generated by a stimulatory agent to platelet activation and ultimately hemostatic plug formation. Metabolism of cAMP and utilization of mobilized ionized calcium are abnormal in CTP platelets (Boudreaux *et al.*, 1994).

In 1990, Searcy and Petrie described a bleeding disorder of eight Simmental cattle attributed to a platelet dysfunction. Subsequent studies by this group (Searcy *et al.*, 1990, 1994) characterized the defect as having abnormal platelet cytoskeletal assembly and reduced platelet aggregation in response to ADP. A similar clinical disorder was described in a newborn Simmental calf (Navarre *et al.*, 1995) and a different explanation for the bleeding diathesis of this cattle breed was reported by Sullivan *et al.* (1994). In this latter case, the bleeding diathesis was attributed to a variant vWF molecule of truncated structure, which apparently contributed to the reduced platelet adhesion and aggregation in response to ADP observed in earlier studies.

12. Other Defects

a. Complement Deficiencies

A variety of inherited complement deficiencies are recognized in humans. In contrast, there are only three known complement deficiencies of other species. These are C4 deficiency in guinea pigs and rats, C5 deficiency in mice, and C6 deficiency in hamsters and rabbits (Dodds, 1989a). Of these, the hemostatic mechanism has been evaluated only in the C4-deficient guinea pig and C6-deficient rabbit. Intrinsic coagulation was found to be reduced in both models relative to species-specific controls. These animals have proved to be useful models for pathophysiological studies of hemostasis and thrombosis and the interrelationships between the complement and hemostatic mechanisms (Esmon *et al.*, 1991).

b. Double Hemophilia (Hemophilia AB)

A planned cross-breeding study between dogs with hemophilia A and hemophilia B was undertaken to study possible linkage between these two X chromosome genes. Dogs with double hemophilia were readily produced, thus demonstrating that the loci for hemophilia A and B are not linked and are located far apart on the X chromosome (Dodds, 1989a).

c. Prekallikrein Deficiency (Fletcher Trait)

Prekallikrein activity has been recognized in apes, swine, guinea pigs, mice, goats, sheep, and horses but is absent or minimal in dogs, cats, cattle, rabbits, whales, ducks, and chickens (Veloso *et al.*, 1992). These results must be interpreted with caution, because human Fletcher factor deficient plasma was used to make these measurements. For example, rabbit plasma without prekallikrein activity actually contains a prekallikrein-like protein. Fletcher trait has recently been described in dogs and in miniature and Belgian horses (Geor *et al.*, 1990; Otto *et al.*, 1991).

d. Coagulopathies Not Recognized in Animals

Other coagulopathies of humans include factor V and XIII (FSF) deficiencies, both rare autosomal traits. The factor V deficiencies have a moderate to severe bleeding diathesis, prolonged APTT, PT, WBCT, short serum PCT, and very low factor V activity. Factor XIII-deficient patients have poor wound healing, bleed at delivery, bruise easily, and bleed after minor surgery, especially dental extractions. FSF-deficient clots dissolve within 24 hours when placed in 5 *M* urea or 1% monochloroacetic acid. A factor XIIIa-like enzyme from equine plasma has recently been evaluated for therapeutic potential (Coyne *et al.*, 1992).

Another defect not recognized in animals is HMWK (Williams Fitzgerald–Flaujeac trait) deficiency. Several nonmammalian species, however, normally lack this activity. HMWK activity is detectable in primate, dog, and whale plasmas, is very low in rabbit and cattle plasmas, and is apparently absent in fowl, reptilian, and amphibian plasmas using conventional assays.

C. Acquired Disorders

Acquired bleeding disorders are numerous and more common than the inherited deficiencies of clotting factors and platelets (Table 10.7). The major causes are briefly discussed in the following subsections, and additional information can be found elsewhere (Johnstone *et al.*, 1991; Dodds, 1992; McClay *et al.*, 1992; Welch *et al.*, 1992; Prasse *et al.*, 1993; Welles *et al.*, 1993a, 1993b, 1994; Carr and Johnson, 1994; Joist *et al.*, 1994; Mannucci and Giangrande, 1994; Goodnight, 1995; Verstraete and Zoldhelyi, 1995).

1. Platelet Function Defects

a. Quantitative (Thrombocytopenias and Thrombocytosis)

Quantitative platelet defects are listed in Table 10.8. Of these, immune-mediated thrombocytopenia accounts for the majority of chronic cases (Grindem *et al.*,

TABLE 10.8 Quantitative Platelet Function Defects[a]

Thrombocytopenia
- Increased platelet destruction, utilization, or sequestration
  - Immunological: primary (ITP), secondary to incompatible blood transfusions, autoimmune diseases (SLE, AIHA, RA), lymphoproliferative disorders, allergies, drugs, toxic agents, live virus vaccines
  - Nonimmunological: hemolytic disease of newborn, severe infections, malignancy, drugs (heparin), DIC, hemolytic uremic syndrome, splenomegaly, hypothermia
- Decrease platelet production
  - Congenital or hereditary: neonatal virus disease, X-chromosome-linked trait (Wiskott–Aldrich syndrome), autosomal traits (various diseases such as Bernard–Soulier syndrome)
  - Acquired: marrow depression (drugs, anemias), marrow infiltration, infections especially viral, drugs (diuretics, estrogens), cyclic thrombocytopenia, paroxysmal nocturnal hemoglobinuria

Thrombocytosis
- Increased platelet production
  - Myeloproliferative disorders: polycythemia vera, chronic leukemia, thrombocythemia
  - Chronic inflammatory disorders: autoimmune diseases (RA), cirrhosis, granulomatosis, tuberculosis, sarcoidosis, chronic pneumonitis, osteomyelitis
  - Malignancy: lymphomas, carcinomas
  - Miscellaneous: acute hemorrhage, iron deficiency, postoperative rebound, osteoporosis
- Release from tissue stores (spleen, lung)
  - Response to exercise
  - Drugs, adrenalin, vincristine

[a] AIHA, autoimmune hemolytic anemia; DIC, disseminated intravascular coagulation; ITP, idiopathic thrombocytopenia purpura; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

1991; Northern and Tvedten, 1992). The immunological basis has been examined in humans and in the dog, cat, and horse (Grindem *et al.*, 1991; Jordan *et al.*, 1993). Primary immunological thrombocytopenia, of unknown etiology, has been termed idiopathic thrombocytopenic purpura (Kristensen *et al.*, 1994a; Sullivan, 1994; Kelton, 1995; Lewis *et al.*, 1995b). The majority of cases, however, appear secondary to a variety of underlying conditions such as use of heparin or estrogens, thrombosis, neoplasia, viral diseases, vaccine-associated reactions, or other drugs and chemicals (Grindem *et al.*, 1994; Hart and Nolte, 1994; Kristensen *et al.*, 1994b; Greinacher, 1995; McCann *et al.*, 1995; Moake, 1995; Sullivan *et al.*, 1995).

Nonimmunological thrombocytopenias are less common and have a better prognosis than the immunological cases, if the causative agent for disease can be eliminated. Several diagnostic tests are available for detecting circulating humoral or cell-mediated antibodies directed against autologous or homologous platelets. Methods include a variety of platelet release tests ([^{14}C] serotonin, PF-3 release), platelet migration inhibition, radioimmunoassays, complement fixation, platelet-bound immunoglobulin, latex particle assay, hemagglutination inhibition assays, and flow cytometry (Ramos *et al.*, 1992; Kristensen *et al.*, 1994b; Lewis and Meyers, 1994; Kelton, 1995; Lewis *et al.*, 1995a, 1995b; Sullivan *et al.*, 1995).

b. Qualitative

The major causes of qualitative platelet function defects are listed in Table 10.9. In addition to hereditary defects, a group of diseases and a large number of drugs are now known to produce thrombopathias (Herman *et al.*, 1991; Bright *et al.*, 1994; Coller *et al.*, 1995). Most drugs act by inhibiting the adhesion of platelets to subendothelium (aspirin, which blocks platelet cyclic endoperoxides) and/or the platelet release reaction (phenylbutazone, sulfonamides, antiinflammatory drugs, ticlopidine, promazine tranquilizers) (Boudreaux *et al.*, 1991a, 1991b; Barr *et al.*, 1992; Gentry *et al.*, 1992; Grauer *et al.*, 1992; Semprad and Dubielzig, 1993; Grindem *et al.*, 1994; Caen and Rosa, 1995; Goodnight, 1995; Behrend *et al.*, 1996). Drugs that interfere with platelet function are contraindicated or must be used with caution in moderate or severely affected individuals (Section IV.A.3). Similarly, elective surgery should be avoided during the viremic phase (3–10 days) after live virus vaccination or viral exposure.

The most common diseases manifesting a bleeding tendency attributable to platelet dysfunction are renal failure with uremia (Forsythe *et al.*, 1989; Wardrop *et al.*, 1989; Pietraszek *et al.*, 1992; Escolar *et al.*, 1993; Joist *et al.*, 1994) and liver disease (Willis *et al.*, 1989). Less common causes are the dysproteinemias such as myelomas and macroglobulinemias and estrogen toxicity. The classic clinical case of uremic bleeding is that of

TABLE 10.9 Qualitative Platelet Function Defects

Hereditary
- Thrombasthenia (Glanzmann's disease)
- Thrombopathia: Bernard–Soulier syndrome, storage-pool disease, albinism, Ehlers–Danlos syndrome, Wiskott–Aldrich syndrome, osteogenesis imperfecta, others

Acquired
- Uremia, myeloproliferative disorders, macroglobulinemia, liver disease, fibrinolysis, thrombocytopenia, systemic lupus erythematosus, congenital heart disease, anemias, leukemias
- Drugs: aspirin, phenylbutazone, promazine tranquilizers, estrogens, plasma expanders, nitrofurans, sulfonamides, antiinflammatory drugs, local anesthetics, phenothiazines, live virus vaccines

the old dog with compensated chronic interstitial nephritis, inflamed gums, and chronic periodontal disease. Dentistry on such a patient frequently results in excessive and prolonged gingival bleeding.

2. *Disseminated Intravascular Coagulation with Fibrinolysis*

The combined syndrome of DIC and secondary fibrinolysis is an important acute, subacute, or chronic disease process of humans and other animals. Several reviews discuss the pathophysiology of this syndrome (Comp, 1990a; Joist, 1990; Vermeer and Hamulyák, 1991; Andrew, 1995; Hirsh *et al.*, 1995; Verstraete, 1995; Verstraete and Zoldhelyi, 1995). The major causes of DIC and thrombosis in humans and animals include viral, bacterial, protozoal, and parasitic infections; neoplasia; obstetric complications; and miscellaneous conditions such as trauma, shock, laminitis, heat stroke, colic, burns, drowning, liver disease, and canine heartworm disease (Gerhards and Eberhardt, 1988; Boudreaux *et al.*, 1989a, 1989b, 1991a, 1991b,; Prasse *et al.*, 1990, 1993; Boudreaux and Dillon, 1991; Al-Mondhiry *et al.*, 1992; Welch *et al.*, 1992; Edens *et al.*, 1993; Kitoh *et al.*, 1994; Baty and Harpster, 1995; Laste and Harpster, 1995).

a. Infections

A number of spontaneous and induced viral infections cause DIC in animals and serve as models for research. Among these are hog cholera, African swine fever, infectious canine hepatitis, feline infectious peritonitis, fowl plague, epizootic hemorrhagic disease of deer and equine viral arteritis (Boudreaux *et al.*, 1989b). Bacterial infections include leptospirosis in cattle and guinea pigs, gram-negative sepsis and the endotoxin-mediated Schwartzman reaction of rabbits, horses, rats, guinea pigs, and dogs. Malaria in monkeys and trypanosomiasis and babesiosis of dogs and cattle also produce DIC. Some dogs with the pulmonary or vena caval lesions of complicated or treated heartworm disease and occult heartworm disease succumb to DIC (Boudreaux *et al.*, 1989a; Kitoh *et al.*, 1994).

b. Neoplasia

Neoplasia is a common cause of DIC in animals, perhaps because many neoplasms are not diagnosed early or the owner elects not to treat the animal (Feldman *et al.*, 1988; Costantini and Zacharski, 1993). Naturally occurring adenocarcinomas of the mammary gland, testicles, and thyroid gland, and carcinomas of the lymphatic and hematopoietic systems, liver, and spleen have been the common tumors involved (Hammer *et al.*, 1991; Hargis and Feldman, 1991).

c. Obstetric Complications

A life-threatening complication of pregnancy in women, DIC is also associated with obstetric problems in animals. These include dystocias, eclampsia, and retained fetus(es). Other causes are amniotic fluid embolism and abruptio placentae.

d. Heat Stroke

Spontaneous heat stroke in dogs and pigs has been associated with DIC and is often fatal.

e. Atrial Thrombosis

A high incidence of atrial thrombosis and concomitant DIC has been reported to occur with aging in Syrian hamsters (Dodds, 1989a). The diagnosis of DIC is complicated by the various stages of the syndrome, which include initial activation of hemostatic elements (hypercoagulability) followed by thrombosis and consumption, which depletes hemostatic elements. This results in the "consumption coagulopathy" phase of the syndrome with secondary enhancement of fibrinolysis and bleeding.

The pathophysiological process of DIC is dynamic and proceeds, without treatment, to death of the host or becomes reversible once healing and repair have restored homeostatic balance. The selection of the most appropriate management and treatment is often a crucial decision. Procoagulants given at the wrong stage may promote further thrombosis, whereas antiplatelet and fibrinolytic drugs or anticoagulants may facilitate bleeding (Gerhards and Eberhardt, 1988; Boudreaux *et al.*, 1991a, 1991b; Semrad and Dubielzig, 1993; Collet *et al.*, 1995; Fareed and Callas, 1995; Goodnight, 1995 Hirsh *et al.*, 1995; Laste and Harpster, 1995; Lijnen and Collen, 1995; McCann *et al.*, 1995; Monreal *et al.*, 1995 Verstraete and Zoldhelyi, 1995). In many cases, removal of the primary cause is the only way to manage the patient effectively.

Diagnostic tests for ongoing DIC have been described (Section III.C.1.e). Classically, the consumption phase of DIC shows thrombocytopenia, prolonged APTT, PT, and TT, reduced factor V and VIII:C activities, and enhanced fibrinolysis with elevated FDP. There may also be reduced antithrombin activity or protein C deficiency (Boudreaux *et al.*, 1989b Boudreaux and Dillon, 1991; Edens *et al.*, 1993).

3. *Liver Disease*

Because the liver is the primary site of clotting factor synthesis, acute or chronic generalized hepatic disease often results in a bleeding tendency (Willis *et al.*, 1989) Hepatitis may also produce DIC and platelet dysfunction. Usually, the most significant findings in liver dis

ease are a prolonged PT with low factor VII early in the disease, followed by reduction of other prothrombin complex clotting factors as the disease progresses and a variable prolongation of APTT and TT.

4. Vitamin K Deficiency and Rodenticide Toxicity

The vitamin K-dependent clotting factors (II, VII, IX, X) are reduced in rodenticide toxicity, malabsorption syndromes, and in sterilization of the gut by prolonged use of antibiotics (Mount and Kass, 1989; Maddison *et al.*, 1990; Vermeer and Hamulyák, 1991; Woody *et al.*, 1992; Neer and Savant, 1992; Soute *et al.*, 1992; Brooks, 1996). Diagnosis is confirmed by identifying the cause and finding a moderate to markedly prolonged PT, variable APTT, normal TT, and low normal platelet count or mild to moderate thrombocytopenia. A therapeutic response to whole blood or plasma transfusion and/or vitamin K_1 is diagnostic of vitamin K antagonism or depletion. The newer second-generation rodenticides are 20–50 times more potent and longer lasting (several weeks) than first-generation warfarin compounds. Poisoning with these new toxicants is thus more serious and expensive to treat (Mount and Kass, 1989; Dodds, 1992; Brooks, 1996).

5. Other Causes

Monoclonal gammopathies produce a nonspecific bleeding tendency characterized by such problems as epistaxis, oozing from surface abrasions, and mucosal surface bleeding (Ruiz-Gopegui *et al.*, 1994). *Amyloidosis* is also associated with an acquired coagulopathy but this has been restricted in most cases to isolated factor X deficiency although some patients also have factor IX deficiency or platelet defects. *Lupus anticoagulants* are antiphospholipid-protein-based antibodies that appear spontaneously in some patients with systemic lupus erythematosus (Triplett, 1995). The methodology used for detecting these antibodies has been standardized (Brandt *et al.*, 1995; de Groot and Derksen, 1995).

Acknowledgments

The author thanks Ms. Lynette Palma for her excellent secretarial assistance in preparing this chapter.

CHAPTER

11

Neutrophil Function

JOSEPH G. ZINKL AND MAHENDRA B. KABBUR

I. INTRODUCTION

The main function of neutrophils is degrading and killing microbes, especially bacteria. Neutrophils are distributed to the tissues by the circulatory system. They adhere to endothelial cells, migrate through vessel walls into tissues, phagocytize microorganisms and foreign subtances, and degrade and kill microorganisms. This chapter provides an overview of the mechanisms of neutrophil adherence, migration (chemotaxis), phagocytosis, and bacteria killing. Defects of neutrophils that prevent them from performing these functions are reviewed. Methods for evaluating the various functions of the phagocytes are briefly described.

II. NEUTROPHIL FUNCTIONS

A. Adherence

In order for neutrophils in the blood to migrate into tissues they must adhere to the endothelial cells. The blood neutrophil population is made up of marginated (adhered) cells and circulating (nonadhered) cells. These populations are in continual flux as neutrophils marginate, demarginate, and remarginate. Eventually, marginated neutrophils strongly adhere to the endothelium before they migrate into tissues under the influence of chemotactic agents. Adherence of neutrophils to endothelial cells involves the interaction of blood dynamics and cellular adhesion molecules and their receptors or ligands. The adhesive actions are initial contact of the neutrophil with the endothelial cell, rolling of the neutrophil along the endothelium, firm adhesion to the endothelial cells, and migration through the endothelium (Jones *et al.*, 1995). This process is complex and is driven by inflammatory mediators derived from pathogens, endothelial cells, leukocytes, platelets, cells of the tissues, and substances in the plasma.

Although there are many factors that influence the interaction of neutrophils and endothelial cells, the

action of adhesion molecules with their ligands that results in the attachment of the neutrophil to the endothelial cell is the most important. There are two classes of adhesion molecules that promote the attachment of neutrophils to endothelial cells, the selectins and the integrins (Meuer, 1994).

There are three members of the selectin family of adhesion molecules, L-selectin, P-selectin, and E-selectin. The three selectins are structurally related, differing primarily in the lengths of their complement binding domain (L-selectin is the shortest, P-selectin is the longest, and E-selectin is slightly shorter than P-selectin). They all have a terminal lectin domain. L-selectin is expressed by leukocytes, whereas E-selectin and P-selectin are expressed by endothelial cells. P-selectin is also expressed by platelets (Forrest and Paulson, 1995). In endothelial cells, P-selectin and E-selectin synthesis is induced by several substance, including thrombin and histamine (P-selectin) and interleukin-1 (IL-1) and tumor necrosis factor-α (TNFα) (E-selectin). L-selectin is constitutively expressed on the surface of mature neutrophils (Oppenheimer-Marks and Lipssky, 1994). Selectins are involved early in neutrophil to endothelial cell binding when the cells roll along the endothelium (Jones *et al.*, 1995) . They apparently interact with ligands that are oligosaccharides, particularly those containing sialic acid and fucose moieties of glycoproteins and glycolipids (Forrest and Paulson, 1995). They may also bind to certain carbohydrate moieties containing esterified sulfate groups, the sulfatides (Mulligan *et al.*, 1995). The sialylated and fucosylated glycoproteins and glycolipids to which selectins bind are on the surface of many cells, including endothelial cells and leukocytes (Forrest and Paulson, 1995). The adhesive interactions between the selectins and their ligands are of low affinity, resulting in temporary attachment followed by detachment so that the leukocyte slowly rolls along the endothelium. This event, along with the initial step in inflammation, vascular dilation, slows the neutrophil and places it near the endothelial cell, where integrin activity results in stronger binding to the endothelial cell and flattening of the leukocyte along the endothelium (Shappell and Smith, 1994).

The integrin family consists of interrelated heterodimers, consisting of α- and β-subunits. There are three distinct subfamilies based on the nature of the β-subunit used to form the heterodimer. Neutrophils primarily express the β2 subunit CD18 associated with one of three different α-subunits, CD11a, CD11b, and CD11c (Meuer, 1994) . The combination of these subunits results in the development of a group of unique integrins, each of which has primary affinity for certain ligands although there apparently is some overlap in their ligand affinity. The combination of CD18 and CD11a is named leukocyte function-associated antigen-1 (LAF-1) and has particular affinity for intercellular adhesion molecule-1 (ICAM-1). CD18 combined with CD11b is named macrophage antigen-1 (Mac-1) and has particular affinity for inactivated third component of complement (iC3b). CD18 combined with CD11c is named p150,95, but its most specific ligand has not been determined (Meuer, 1994; Anderson, 1995) . Integrins are preformed in cells and are, in part, stored in granules. Activation of the cells by a variety of substances causes the cells to externalize or express the preformed integrins. The binding affinities of integrins for their receptors are stronger than those of selectins. This results in greater affinity of the leukocyte to the endothelial cells, essentially anchoring and flattening the leukocyte prior to its movement through the endothelium into tissues.

Endothelial cells express ICAM-1 and ICAM-2 on their surface as well as VCAM-1. ICAM-2 is constitutively expressed on endothelial cells, whereas ICAM-1 and vascular cell adhesion molecule-1 (VCAM-1) are increased by a variety of factors, including IL-1 and TNF-α (Oppenheimer-Marks and Lipsky, 1994).

Neutrophils undergo four interrelated activities in order to move from the bloodstream into the tissues: initial contact, rolling, firm adhesion, and migration (Jones *et al.*, 1995). The interaction of selectins and integrins with their binding molecules is necessary for these activities to occur. Initial contact and rolling are functions of blood-flow dynamics and binding of selectin to glycoproteins and glycolipids. Firm adhesion, flattening, and migration rely on the actions of the integrins and their receptors. Selectin binding is transient, and it is weaker than that of integrins. Selectin-mediated binding of neutrophils to endothelial cells can occur at the wall shear stress found in postcapillary venules (Jones *et al.*, 1995; Doré *et al.*, 1995). This binding decreases the velocity of the leukocyte enough that integrin interaction with their binding molecules can occur. At wall shear stresses of 1-4 dyn/cm^2, neutrophils adhere to endothelial cells through the action of selectins, whereas integrins acting alone do not adhere until the wall shear stress is less than 1 dyn/cm^2 (Jones *et al.*, 1995; Doré *et al.*, 1995). Not only is selectin binding weaker than intregin binding, it is probably more flexible. In addition, neutrophils contain approximately one-tenth as many selectin molecules as integrin moieties ($2–4 \times 10^4$ sites per cell, vs 30×10^4 Mac-1 sites per cell) (Jones *et al.*, 1995). The rolling action mediated through selectin activity causes the velocity of the cells to slow sufficiently that newly exposed and upregulated integrins can interact with their exposed and upregulated ligands, causing the leukocyte to attach

firmly to the endothelial cell (Jones *et al.*, 1995; Doré *et al.*, 1995). At this time the neutrophil changes from a spherical shape, to a flat disk shape, which increases the contact area between it and the endothelial cell and causes the neutrophil to flatten onto endothelial cells. In order for neutrophils to move away from this pavemented zone, it is necessary for the integrin-mediated attachment to weaken slightly. The precise mechanism for this weakening is unknown.

Numerous substances, some of which are also chemoattractants, upregulate integrins, selectins, or their ligands. Among the upregulating factors are complement factor 5a (C5a), formyl methionylleacyl phenyalinine (fMLP), leukotriene B_4 (LTB_4), platelet-activating factor (PAF), granulocyte monocyte-colony stimulating factor (GM-CSF), tumor necrosis factor-α (TNF-α), lipopolysaccharide (LPS), interleukin-1 (IL-1), interleukin-6 (IL-6), interferon-γ (INFγ), histamine, thrombin, and hydrogen peroxide (Shappel and Smith, 1994). Some of these factors can also act as downregulating agents. For example, C5a downregulates L-selectin but upregulates Mac-1 (CD18/CD11a) (Anderson, 1995). Endothelial-derived relaxing factor (EDRF), which is nitric oxide radical ($NO\cdot$) produced by endothelial cells, is a powerful antiadhesive agent that may inhibit the function of $\beta 2$ integrins (Thom *et al.*, 1994).

The activities that allow the neutrophil to detach from the endothelial cell and move between or through the endothelial cells have not been defined. It is possible that the endothelial cells actively guide or move attached neutrophils to cell junctions, or that the neutrophil migrates along the membrane of the endothelial cell by responding to chemoattractants bound to the endothelial cell surface (a process called heptotaxis) in order to move to and find the locations through which it can migrate. Adhesion molecules, such as CD31 (also known as platelet endothelial cell adhesion molecule—PECAM-1), present at intercellular junctions may also be involved (Argenbright, 1995).

B. Chemotaxis

After neutrophils adhere to the endothelium they migrate through the endothelium into the interstitial spaces. Leukocytes move in the direction of higher concentration of the attractant. The ability of cells to respond to chemotaxins implies that they have sensory mechanisms that are able to detect differences in concentration of chemotaxins in the local environment. Furthermore, the sensory mechanism must be sensitive to concentrations over a very short distance, the diameter of the cell. Cell-surface receptors provide the sensory apparatus. Detection of the chemical gradient is caused by variations in the degree of saturation of the receptors across the diameter of the cell. The cell is stimulated to move in the direction of increasing saturation of the receptors. However, at very high concentrations of a chemotaxin, cell movement stops even though a chemical gradient exists, because the receptors are completely saturated and the cell is unable to detect the gradient (Ramsey, 1974).

Leukocytes move by adhering to and moving along solid surfaces. Locomotion is dependent on the nature of the adhesion of the cell with the surface on which it moves, the substratum (Wilkinson, 1982). Neutrophils change from round, smooth cells to elongated, ruffled cells with pseudopodia. The pseudopodia are broad, thin lamellipodia that extend in the direction of increasing chemoattractant concentration. A uropod is formed behind the cell. Neutrophils extend their lamellipodia in the direction of the gradient and retract their uropodia toward the cell body (Senda *et al.*, 1975; Wilkinson, 1982; McPhail and Harvath, 1993). The protrusion is thin and ruffled, and it rapidly changes shape. It does not contain cytoplasmic organelles, but it is rich in actin and actin-associated proteins (Oliver *et al.*, 1978). A distinct posterior tail or uropod may remain. The process recurs, resulting in a slow, undulatory shape change as the cell moves forward.

Because inflammatory cells crawl during chemotaxis, it is essential for the cells to adhere to surfaces. Adhesion must be strong enough for the cell to pull itself along, but not so strong that the cell becomes immobilized. Integrins bind to extracellular matrix components such as fibronectin, fibrinogen, collagen, and other extracellular matrix components, as well as membrane components of other cells (Edwards, 1994). Reversible adherence to these subtances facilitates movement of phagocytes.

At least three activities are required for cells to move. A pseudopodium forms in the direction of movement, the cell body and the pseudopodium anchor to the substratum, and contraction of the actin–myosin occurs to pull the cell toward the pseudopodium. Actin–myosin contraction revolves around a sol–gel transition that interacts with the cytoskeletal network and is regulated by localized calcium changes (Edwards, 1994).

Energy is required to drive the contractile machinery of the neutrophil. This energy is supplied mainly through ATP generated by anaerobic glycolysis (Klebanoff and Clark, 1978). Glucose may be supplied from the cell's environment or from endogenous glycogen. When neutrophils contact an active chemotactic factor, glucose metabolism is stimulated (Goetzl and Austen, 1974). Some substances that inhibit chemotaxis appear to increase cAMP levels, whereas chemoattractants appear to increase the intracellular levels of cGMP (Smith

and Lumsden, 1983). Prostaglandins may be involved in the regulation of the relative concentrations of cAMP and cGMP and thus regulate chemotaxtic ability of neutrophils (DeChatelet, 1979).

There are many substances that are chemoattractants for neutrophils, including *N*-formyl peptides, C5a, LTB_4, interleukin-8 (IL-8), and platelet-activating factor (PAF). Neutrophils have receptors for each of these substances, and they are members of the GTPase-coupled receptor superfamily. These substances have seven transmembrane domains (McPhail and Harvath, 1993). Chemoattractant receptors couple with G proteins (also known as GTPase proteins). These proteins carry out the cycle of guanine nucleotide exchange and GTP hydrolysis that is involved in generating second messengers, which initiate the activity of the contractile proteins of the cell. There are two general classes of G proteins: heterotrimeric, consisting of α-, β-, and γ-subunits, and monomeric or small G proteins.

The α-subunit of the heterotrimeric G proteins activates phospholipases to produce a variety of substances, including inositol phosphate (IP_3). Calcium concentrations within the cells increase markedly through binding of IP_3 to intracellular calciosomes and influx of calcium from the external medium (Edwards, 1994). The increased intracellular calcium activates protein kinase C. Phosphoproteins interact with actin and myosin, resulting in cell motility (Edwards, 1994; Shepro, 1995).

Actin exists in two forms in neutrophils, monomeric (G) actin and polymeric (F) actin. Actin comprises about 5–8% of the total protein in the neutrophil, and in resting cells about 50–70% of the actin is in the monomeric form. In resting cells the large, unpolymerized pool is spread throughout the cytoplasm. This provides the cell with the advantage of rapid polymerization of actin at whatever location it may be required in the cell without the need for depolymerization and redistribution of the monomers first. Polymerized actin is primarily concentrated in the submembrane layer in resting cells. The initial step in actin polymerization is the activation of actin monomers by binding to divalent cations. Monomeric actin binds 1 mol ATP, which is hydrolyzed to ADP during the assembly into F-actin (Edwards, 1994).

There are several proteins that bind to actin and are important for affecting filament growth, cross-linking, anchoring, and function. Profilin, gelsolin, and acumentin affect filament growth by binding to G-actin (profilin) and capping the barbed ends (gelsolin) or pointed ends (acumentin) of growing F-actin filaments. Actin filaments form thick filaments by cross linking through the activities of filamin, caldesmon, and α-actinin. Two filamin subunits bind actin filaments at 40-nm intervals to form perpendicularly cross-linked, branched filaments. Caldesmon also cross-links F-actin chains. Its effects are inhibited by calcium and calmodulin. α-Actinin is a short, rodlike proteins that joins actin filaments side by side as bundles. Vinculin is one of a number of proteins that bind the actin network to the plasma membrane. Vinculin function is calcium dependent, and it is found in close association with α-actinin. Myosin is composed of a pair of heavy chains (200 kDa) and two pairs of light chains (15–20 kDa) that are located near the heads of the heavy chains. Myosin molecules form short, bipolar filaments in which the rodlike tails form the filament and globular heads project from both ends of the shaft of the filament. The heads of these filaments interact with F-actin. Myosin headpieces bind both ADP and ATP and possess magnesium-dependent ATPase activity. In the resting state, myosin binds ADP and inorganic phosphate. Upon stimulation the headpiece binds to actin in a perpendicular manner, the ADP and inorganic phosphate are released, and the head tilts 45° to the actin molecule, causing filament movement. The head then binds ATP and detaches from actin, and the ATP is hydrolyzed to ADP and inorganic phosphate. The kinase is activated by calcium and calmodulin. Increase in calcium concentration stimulate the binding of actin to the myosin–ADP–inorganic phosphate complex (Edwards, 1994).

The cytoskeleton of neutrophils is made up of microtubules and intermediate filaments. The microtubules are composed of equal molar amounts of α- and β-subunits of tubulin, which form a helical complex of interrelated heterodimers in the shape of a tube 25 nm in diameter with a wall width of 5 nm. A large amount of the tubulin is not assembled in the resting neutrophil, but rapid assembly into microtubules occurs upon stimulation. Intermediate filaments of neutrophils are made up of vimentin. Vimentin readily polymerizes to produce filaments 10–12 nm in diameter (Edwards, 1994).

C. Phagocytosis

When a neutrophil reaches the site of bacterial infection, the cell phagocytizes the organism. Before particles can be phagocytized, they must first be opsonized (DeChatelet, 1979). Opsonization causes bacteria to adhere to neutrophil receptors before they are internalized. The most important opsonins are those derived from complement and the immunoglobulins (Klebanoff and Clark, 1978). The most important opsonins of the complement pathway are bound fragments of C3 and C4 generated during complement activation on the particle surface (Morgan, 1990). Activation of the

classical or alternative pathway on a target particle causes deposition of C3b. C3b generated by the classical pathway is degraded to C3bi, but C3b generated by the alternative pathway is degraded slowly. C3b has greater affinity for neutrophil receptors, but C3bi is generally in higher density on target particles. Activation of the classical pathway results in deposition of fragments of C4, including the opsinin C4b. Complement receptors on neutrophils include CR1, CR3, and CR4. The primary ligand for CR1 (CD35) is C3b, but it also finds C3bi and C4b with considerably lower affinities. CR1 increases up to 10-fold on the surface of neutrophils and monocytes upon stimulation of the cell. CR3 and CR4 are derived from the CD18/CD11 heterodimer integrins. CR3 (CD18/CD11b or Mac-1) recognizes C3bi. The binding requires high concentrations of calcium and magnesium. CR4 (CD18/CD11c or p150,95) apparently also binds C3bi (Morgan, 1990).

The immunoglobulins serve both to identify organisms and to initiate complement activity. The Fab portion of the antibody binds to the bacteria, whereas the Fc portion binds to the phagocyte (Quie, 1972). The receptor sites for IgG on phagocytes are distinct from the sites for attachment of the opsonically active fragment of C3 (Stossel, 1974). There are three families of receptors for IgG: FcγRI, FcγRII, and FcγRIII. Neutrophils and monocytes also have receptors that specifically bind IgA. The immunoglobulin receptors generally have extracellular, transmembrane, and intracytoplasmic domains, although FcγRIII may only contain an extracellar domain (Edwards, 1994). Interferon γ upregulates the expression of FcγRI on neutrophils (Rosales and Brown, 1993). The functions of the immunoglobulin receptors are mediated through binding of IgG. In general, they bind IgG_3 and IgG_1 better than IgG_2 and IgG_4. These immunoglobulin receptors have numerous functions, including initiation of phagocytosis, activation of the respiratory burst, removal of immune complexes, release of inflammatory mediators, and antibody-dependent cell-mediated cytotoxicity (ADCC) (Rosales and Brown, 1993). Apparently, these receptors act in a cooperative manner, such that one receptor may bind the immunoglobulin ligand while the other actually transduces a signal into the cell (Rosales and Brown, 1993).

Fibronectin, serum amyloid P, and laminin promote phagocytosis. They bind to a large variety of substrates, including fibrin, collagen, heparin, and some bacteria. Plasma fibronectin binds weakly to macrophages, but its binding is enhanced by heparin (Hormann, 1982). Fibronectin increases the attachment of bacteria to neutrophils (Proctor *et al.*, 1982). Fibrinectin receptors on phagocytes recognize the Arg–Gly–Asp sequence of several of the extracellar matrix proteins. Occupancy of the fibrinectin receptors some how activates CR1 and CR3 (Edwards, 1994) or a distinct integrin of the β_3 subfamily (Rosales and Brown, 1993).

Phagocytosis by neutrophils, monocytes, and macrophages is enhanced by a small peptide called tuftsin (Thr–Lys–Pro–Arg) (Najjar, 1983; Nishioka *et al.*, 1994). Tuftsin acts directly on the phagocyte. The spleen acts on the IgG_1 molecule leukokinin in the blood to release leukokinin-S. Then, a protease of the neutrophil membrane cleaves leukokinin-S to tuftsin (Najjar, 1983). Tuftsin markedly increases the rate of phagocytosis (Najjar, 1983), increases the number of organisms phagocytized per cell (Nishioka *et al.*, 1994; Kubo *et al.*, 1994), stimulates respiratory burst (Singh *et al.*, 1992), and increases $NO^{\cdot}$ production (Cillari *et al.*, 1994).

In order to avoid destruction, organisms may evade opsonization, prevent attachment or phagocytosis, or inhibit phagosome and granule fusion. The degree of hydrophobicity of a bacteria relative to that of the neutrophil influences the ability of neutrophils to ingest bacteria (van Oss and Gillman, 1972). Bacteria more hydrophobic than neutrophils are easily phagocytized, whereas those less hydrophobic (or more hydrophilic) are more difficult to phagocytize. Besides their opsonization activity, another action of complement fragments and immunoglobulins may be to increase the hydrophobicity of bacteria, thus making them more susceptible to phagocytosis (van Oss and Gillman, 1973; van Oss *et al.*, 1974). Lipopolysaccharide capsules of gram-negative bacteria may partially increase their virulence by preventing phagocytosis, possibly because of the hydrophilic nature of the capsule (van Oss and Gillman, 1972; Horwitz and Silverstein, 1980; Verhoef and Visser, 1993). Other bacteria cell-wall components such as peptidoglycan, teichoic acids, protein A, M protein, and pili may affect the susceptibility of organisms to phagocytosis (Hendricks *et al.*, 1986). Microorganisms may escape opsonization by varying their antigenic structure (Verhoef and Visser, 1993). Protein A binds to the Fc terminal of IgG, resulting in complement consumption or preventing antibody activity (Verhoef and Visser, 1993). M protein and perhaps protein A of *Streptococcus* organisms interfere with opsonization, probably because they are highly negatively charged. The negative charge may inhibit contact between bacteria and phagocytes. Some organisms such as *Mycobacterium* inhibit the fusion of phagosomes and granules (Verhoef and Vissser, 1993).

After attachment of the bacterium to the neutrophil, the cell extends pseudopodia over and around the particle. Eventually the cytoplasmic processes meet and fuse and enclose the particle to form a phagosome. Glycolysis provides the energy for phagocytosis, and

the divalent cations calcium and magnesium are necessary for phagocytosis by neutrophils (Klebanoff and Clark, 1978; DeChatelet, 1979). C3b apparently enhances the action of the cations (DeChatelet, 1979). Actin filaments are preferentially associated with the sites of particle ingestion. Myosin and filamin are also located at these sites. Apparently, assembly of actin filaments occurs at the pointed ends during phagocytosis, but at the barbed ends during locomotion (Edwards, 1994).

D. Bactericidal Mechanisms

The antibacterial mechanisms of phagocytes are classified as either oxygen dependent or oxygen independent (Klebanoff, 1975). The oxygen dependent mechanisms involve a series of reactions that produce highly reactive oxygen containing reactants that interact with other reactants or directly with bacteria. The oxygen independent mechanisms are varied.

1. Oxygen-Dependent Mechanisms

The oxygen-dependent mechanism is initiated by phagocytosis or disturbances of the cell membrane (Rossi *et al.*, 1985). Membrane-bound nicotinamide–adenine dinucleotide phosphate (NADPH) oxidase is activated (Babior, 1978a; Rossi *et al.*, 1985). This reaction depends upon the interaction of membrane associated cytochrome b and other proteins within the cell (Borregaard, 1985; Edwards, 1994). The NADPH oxidase system has at least four components consisting of two closely associated membrane proteins and two cytosolic components. The membrane component, cytochrome b_{558}, is a heterodimer consisting of a 91-kDa glycoprotein (β-subunit) and a 22-kDa protein (α-subunit). The cytosolic compontents are a 47-kDa protein (p47-*phox*) and a 67-kDa component (p67-*phox*) (McPhail and Harvath, 1993). Upon stimulation the cytosolic proteins are translocated to the membrane and the complete NADPH oxidase system is assembled. In addition, a G protein, *rap1A*, is strongly associated with the membrane cytochrome heterodimer, perhaps by guiding the assembly and/or activating NADPH oxidase (McPhail and Harvath, 1993). G proteins may act as receptors for second messengers generated through membrane disturbance (McPhail and Harvath, 1993). Other cytosolic compontents including flavoproteins are also involved with the electron transport system of NADPH oxidase (Cross, 1992; Edwards, 1994).

The NADPH oxidase system catalyzes the reduction of molecular oxygen to superoxide anion ($O_2^{\cdot}$). The rapid increase in oxidase activity causes a burst of oxygen consumption (the "respiratory burst"). The respiratory burst reactions are followed by a rapid production of toxic oxygen derivatives in the phagocytic vacuole (Babior, 1978a; Badwey and Karnovsky, 1980). The reaction is dependent upon a continuous reduction of NADP to supply the electron acceptor NADPH for the reduction of O_2 to $O_2^{\cdot}$ (Babior, 1978a; Rossi *et al.*, 1985). NADPH is supplied by a marked increase in glucose metabolism through the hexose monophosphate shunt pathway (Fig. 11.1) (Babior, 1978a).

After $O_2^{\cdot}$ is produced, it is rapidly dismutated to H_2O_2. $O_2^{\cdot}$ and H_2O_2 give rise to $^{\cdot}OH$ and $^1O_2$. Myeloperoxidase catalyzes the formation of hypohalous acids from H_2O_2 and halide ions. Because the concentration of Cl^- is greater than that of Br^- or I^-, hypochlorous acid (HOCl) is formed (Edwards, 1994). The reactive oxygen substances produce secondary oxidative decarboxylation, oxidative deamination, peroxidation, and halogenation reactions that destroy bacteria and other cells (Babior, 1978a; Borregaard, 1985). The formation of hypochlorous acid through the myeloperoxidase reaction is not essential for antimicrobial activity because humans with a deficiency of myeloperoxidase do not have severe bacterial infections. Furthermore, chicken heterophils lack myeloperoxidase, yet they are quite capable of destroying bacteria (Brune and Spitznagel, 1973).

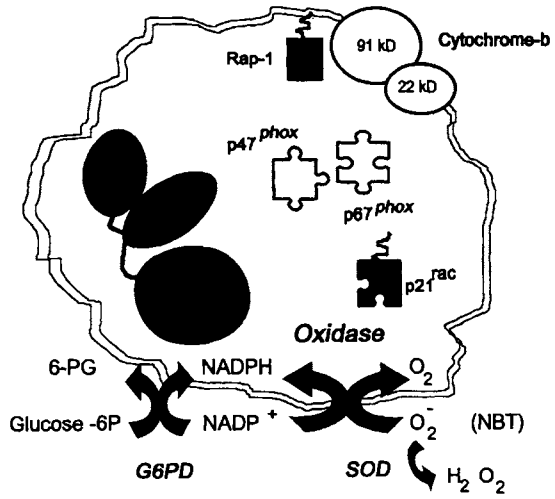

FIGURE 11.1 The neutrophil–NADPH oxidase complex consists of two cytochrome b membrane subunits, α (22 kDa) and β (91 kDa), and two cytosolic cofactors (67 kDa) and 47 (kDa) required of the respiratory burst. RAC p21 and RAP-1, members of the RAS superfamily of GTP-binding proteins, also participate in the stimulation of NADPH oxidase. NADPH serves as a substrate for the reduction of O_2 to superoxide $O_2^{\cdot}$, which in turn is rapidly dismutased either spontaneously or by superoxide dismutase (SOD) to H_2O_2, which then gives rise to hydroxyl radical ($^{\cdot}OH$) and singlet oxygen ($^1O_2$) (not shown). NADPH is generated from glucose-6-phosphate through the hexose monophosphate shunt by glucose-6-phosphate dehydrogenase. (From Baehner, 1995, with permission.)

Macrophages generate nitric oxide radicals ($NO^{\cdot}$), which may be bacteriacidal. In addition, $NO^{\cdot}$ reacts with $O_2^{\cdot}$ to form peroxynitrite anion ($ONOO^-$), which can denature nucleic acids, proteins, carbohydrates, and lipids (Ward and Mulligan, 1992). The importance of $NO^{\cdot}$ as an antibacterial material has not yet been determined. Along with other neutrophil-derived oxidants, it can cause tissue damage (Ward and Mulligan, 1992).

The products of the respiratory burst are toxic to the cells (Badwey and Karnovsky, 1980; Gabig and Babior, 1981; Rossi *et al.*, 1985; Ward and Mulligan, 1992). Cytoplasmic superoxide dismutase and glutathione peroxidase, glutathione reductase, and perhaps catalase convert these products to water (Klebanoff and Clark, 1978). The glutathione needed for the reaction is maintained in the reduced state by reduced NADPH supplied by the HMP (Babior, 1978a).

2. *Oxygen-Independent Mechanisms*

The oxygen-independent mechanisms of the granulocyte are heterogenous. Primary granules contain, in addition to the oxygen-dependent systems, cationic proteins including defensins, cathepsin G, azurocidin, and bactericidal/permeability-increasing (BPI) protein (Klebanoff and Clark, 1978; Lehrer and Ganz, 1990). These proteins are rich in arginine or cysteine or both (Ganz *et al.*, 1986). In addition, the primary granules contain hydrolases such as elastase, collagenase, and β-glucuronidase (Lehrer and Ganz, 1990). The secondary granules contain much of the lysozyme, lactoferrin, vitamin B_{12}-binding protein, adhesin receptors, chemoattractant receptors, and gelatinase (Leffell and Spitznagel, 1972; Kane and Peters, 1975; Klebanoff and Clark, 1978; Lehrer and Ganz, 1990). Both primary and secondary granules contain lysozyme. A third granule has been found in neutrophils of several species, including humans, rabbits, cows, sheep, goats, dogs, and horses (Bertram, 1985). In some species gelatinase and some acid hydrolases have been identified in these granules (Klebanoff and Clark, 1978; Baggiolini and DeWald, 1984). The large tertiary granules of bovine neutrophils are probably different from the tertiary granules of rabbits and humans (Bertram, 1985). The tertiary granules of bovine neutrophils have a potent antimicrobial system that is distinct from those of other species (Gennaro *et al.*, 1983).

The pH in phagolysosomes becomes slightly alkaline after activation of NADPH oxidase because the enzyme is a proton pump. Thereafter, the phagolysosome become acidic (Edwards, 1994). An antibacterial action of neutrophils is acidification, probably as the result of increased lactic acid production. A lactate dehydrogenase with affinity for NADPH rather than NADH has been identified in neutrophils (Evans and Karnovsky, 1962). This enzyme has low activity at pH 7.4, but its activity is high at pH 6.0. This lactate dehydrogenase enzyme is probably linked with the hexose monophosphate pathway that provides the NADPH needed for activity and acidification.

Defensins are a family of cysteine- and arginine-rich, low-molecular-weight, antimicrobial peptides. Defensins have been isolated from heterophils or neutrophils of rabbits, rats, guinea pigs, and humans (Ganz *et al.*, 1985; Lehrer and Ganz, 1990; Evans and Harmon, 1995). They contain six invariant cysteines and are arginine rich (Lehrer and Ganz, 1990). The six cysteine residues form disulfide bonds, and the pairing of the first and sixth residues creates a cyclic structure. A similar group of peptides called β-defensins have been isolated from bovine neutrophils (Selsted *et al.*, 1993). They are larger than defensins, having 38–42 amino acid residues, and their cysteine residues vary slightly from those of defensins. Similar peptides have been isolated from heterophils of chickens (Evans and Harmon, 1995). Cysteine-rich antimicrobial proteins have been found in equine neutrophils (Couto *et al.*, 1992a,b). These are also larger than defensins and contain 10 cysteine residues. Small peptides containing 16–18 residues and 4 cysteines have been isolated from pig neutrophils (Evans and Harmon, 1995). The defensin-like peptides have a broad spectrum of antimicrobial activity at micromolar concentrations. They are active against gram-positive, gram-negative, and anaerobic bacteria, several fungi, some enveloped viruses, protozoa, and cells (Ganz *et al.*, 1986; Lehrer *et al.*, 1991; Evans and Harmon, 1995).

Cathepsin G is found in neutrophils and monocytes (Ohlsson *et al.*, 1977; Edwards, 1994). It is rich in arginine but not in cysteine (Ganz *et al.*, 1986). It has microbicidal activity against both gram-positive and gram-negative bacteria, as well as against some fungi (Lehrer *et al.*, 1975; Odeberg and Olsson, 1975). Cathepsin G inhibits bacterial respiration and energy dependent transport systems, as well as protein, DNA, and RNA biosynthesis. (Edwards, 1994). The microbicidal activity decreases with increased ionic strength. Cathepsin G loses its proteolytic activity when heated, but it retains its microbicidal activity (Odeberg and Olsson, 1975; Edwards, 1994).

BPI protein is a large (55–60 kDa), lysine-rich protein. The large amounts of lysine in BPI account for most of its positive charge (Weiss *et al.*, 1978). BPI protein is highly active against *E. coli* and *Salmonella typhimurium*, but it lacks activity against gram-positive bacteria and fungi (Ganz *et al.*, 1986; Lehrer and Ganz, 1990). Strains of bacteria with short-chain polysaccha-

ride envelopes ("rough" strains) are more sensitive than bacteria whose envelopes contain long-chain polysaccharides ("smooth" strains) (Weiss *et al.*, 1978; Lehrer and Ganz, 1990). Apparently, BPI rapidly binds to the outer membrane of susceptible gram-negative bacteria and increases outer membrane permeability to hydrophobic molecules and activation of enzymes that degrade envelope phospholipids and peptidoglycans. BPI also affects inner bacterial membrane functions. In addition, BPI inhibits the respiration of intact susceptible *E. coli* (Lehrer and Ganz, 1990).

Azurocidin, a 29-kDa protein, kills *E. coli, S. fecalis,* and *C. albicans in vitro,* showing maximum activity in low-ionic-strength, acid conditions. A related polypeptide, p29b, also has antimicrobial activity *in vitro.* Another protein, 37-kDa CAP (cationic antimicrobial protein), which may be identical to azurocidin, has considerable activity against several gram-negative bacteria (Lehrer and Ganz, 1990).

Granulocytes also contain a variety of neutral proteases with optimal activities at about neutral pH (Spitznagel, 1984). Most neutral proteases are in the primary granules. The major neutral proteases are cathepsin G, elastase, and collagenase. The antimicrobial activity of cathepsin G is related to its action as a cationic protein and has little to do with its enzymic (chymotrypsin-like) activity (Odeberg and Olsson, 1975). Elastase, a highly cationic glycoprotein, degrades bacterial cell-wall protein and potentiates the lytic activity of lysozyme and the microbicidal activity of cathepsin G (Janoff and Scherer, 1968; Blondin and Janoff, 1976; Lehrer and Ganz, 1990). Elastase enhances the activity of cathepsin G and cathepsin B (another protease), probably by exposing proteins that are susceptible to the action of these enzymes (Spitznagel, 1984). By predigesting bacterial cell-wall structures, elastase and other proteases may facilitate penetration of other antimicrobial substances with subsequent disposal of dead microorganisms by proteolysis (Ganz *et al.*, 1986). The microbicidal action of collagenase has not been determined. Perhaps collagenase has a function in maintaining the inflammatory reaction and breaking down extracellular connective-tissue components (Klebanoff and Clark, 1978; Bertram, 1985).

Lysozyme is a very cationic protein of approximately 14,400 Da found in both the primary and the secondary granules of neutrophils, the granules of monocytes, and macrophages and in plasma, tears, saliva, and airway secretions (Ganz *et al.*, 1986). Lysozyme hydrolyzes bacterial cell walls by attacking the β1–4 glycosidic linkage that joins *N*-acetyl muramic acid and *N*-acetyl glucosamine of peptidoglycan (Spitznagel, 1984; Ganz *et al.*, 1986). Lysozyme is absent or has very low activity in a number of species (Padgett and Hirsch, 1967; Rausch and Moore, 1975). A wide variety of bacteria are sensitive to the action of lysozyme, but resistance is frequently encountered. Group A streptococci, staphylococci, and nearly all Gram-negative organisms resist the action of lysozyme. However, many resistant bacteria may become susceptible to the action of lysozyme when exposed to synergistic bactericidal activity of antibody and complement or H_2O_2–ascorbic acid (Wilson and Spitznagel, 1968; Miller, 1969). Lysozyme may also be capable of bactericidal activity by nonenzymatic mechanisms (Ganz *et al.*, 1986).

Lactoferrin is a 78-kDa, slightly basic, iron-binding protein related to transferrin. Lactoferrin is found in many secretions, including tears, semen, and milk, as well as in the secondary granules of neutrophils. It has two binding sites for ferric iron. The bacteriostatic activity of lactoferrin is associated with iron-unsaturated lactoferrin. Presumably the inhibitory action of lactoferrin is due to its ability to sequester iron from bacteria that require it for synthesis of multiple components (Bullen *et al.*, 1978). Lactoferrin also exerts bactericidal effects that are independent of its bacteriostatic effects (Lehrer and Ganz, 1990).

Acid hydrolases are present in the primary granules and probably act after the microbe has been killed (Bertram, 1985). These enzymes have broad specificities to a variety of substrates. The acid hydrolases include acid phosphatases, cathepsins, aryl sulfatases, neuraminidase, and nucleases (Klebanoff and Clark, 1978). The acid hydrolases are inhibited by sulfated glycosaminoglycans, heparin, and chondroitin sulfate at acid pH (Avila and Convit, 1976).

III. LEUKOTRIENES AND PROSTAGLANDINS

Prostaglandins and leukotrienes are synthesized by many cells, including neutrophils, macrophages, mast cells, basophils, and eosinophils. Arachidonic acid and other C_{20} polyunsaturated fatty acids containing three, four, and five carbon–carbon double bonds are the immediate precursors to the prostaglandins and leukotrienes. Since arachidonic acid and most of its metabolites contain 20 carbon atoms, they are referred to as eicosanoids. The precursor eicosanoids are released from phospholipids by the action of phospholipase A_2 or phospholipase C and diacylglycerol lipase (Van den Bosch, 1980; Bell *et al.*, 1979; Bates, 1995). Dihomo-γ-linoleic acid (C_{20}-Δ8,11,14) is the precursor for PGE_1 and $PGE_{1\alpha}$; arachidonic acid (C_{20}-Δ5,8,11,14) is the precursor for PGE_2, $PGE_{2\alpha}$, PGG_2, PGH_2, prostacyclin (PGI_2), the thromboxanes (TXA_2 and TXB_2), and the leukotrienes

and eicosopentaenoic acid (C_{20}-Δ5,8,11,14,17) is the precursor for PGE_3 and $PGF_{3\alpha}$ (Glew, 1992). Among the leukocytes, macrophages appear to be the major producer of prostaglandins (Kurland and Bockman, 1978). Prostaglandin and thromboxane synthesis begins with the action of cyclooxygenase on arachidonic acid to produce endoperoxides PGG_2 and PGH_2. PGH_2 is the common substrate for PGE_2, PGD_2, $PGF_{2\alpha}$, PGI_2 (prostacyclin), and TXA_2 (Roubin and Benveniste, 1985).

In contrast to the broad array of cells that synthesize prostaglandins, the synthesis of leukotrienes is restricted. Neutrophils, monocytes, macrophages, eosinophils, and mast cells are the major producers of leukotrienes (Lewis and Austen, 1984). Leukotriene synthesis begins when 5-lipoxygenase catalyzes the production of 5-monohydroperoxy-eicosatetraenoic acid (5-HPETE) from arachidonic acid. 5-HPETE is spontaneously or catalytically converted to 5-hydroxy-eicosatetraenoic acid (5-HETE). In addition, 5-lipoxygenase converts 5-HPETE to LTA_4 (Roubin and Benveniste, 1985). Separate pathways synthesize LTB_4, and the sulfidopeptide leukotrienes (LTC_4, LTD_4, LTE_4 and LTF_4). LTB_4 may be oxidized to less active compounds through oxidation, and the sulfidopeptide leukotrienes may be oxidized to sulfoxides followed by cleavage of the peptide portion to produce 5,12-diHETEs. Further metabolism of the leukotrienes probably involves extensive β-oxidation (Davies *et al.*, 1984).

Prostaglandins and leukotrienes are synthesized and immediately released rather than being stored. The synthesis of these substances is triggered by lymphokines and phagocytosis (Roubin and Benveniste, 1985). Large amounts of prostaglandins and leukotrienes are released by stimulated macrophages. In addition, macrophages are able to synthesize prostaglandins and leukotrienes from exogenous sources of arachidonic acid such as the lipids of necrotic cells. Among the cells of inflammation, there is a remarkable specificity in the generation of the leukotrienes. Neutrophils synthesize mostly LTB_4, eosinophils and mast cells synthesize most LTC_4 (and presumably the other sulfidopeptide leukotrienes), and macrophages and monocytes synthesize large amounts of both leukotriene series (Lewis and Austen, 1984).

The activities of the prostaglandins and leukotrienes are broad. Their activities include enhanced vascular permeability and affecting blood pressure, platelet aggregation, slow-reacting substance activity, and chemotaxis. The actions produced by some of these products may be counteracted by an opposite effect of another product. For example, thromboxane A_2 is a very potent platelet-aggregating agent, whereas prostacyclin antagonizes this effect (Roubin and Benveniste, 1985).

LTB_4 has both a priming and a direct agonist effect on neutrophils. LTB_4 is a potent chemotactic and chemokinetic agent for neutrophils, monocytes, and eosinophils. It stimulates aggregation of neutrophils and enhances lysosomal enzyme releases, superoxide production, expression of CD11a/CD18 and CD11b/CD18, endothelial cell adherence, and complement-dependent killing reactions (Ford-Hutchinson, 1983; Koenig *et al.*, 1983; Czarnetzki and Grabbe, 1983; Lewis and Austen, 1984; Bates, 1995).

LTC_4 and LTD_4 cause contraction of smooth muscle such as that of the small airways and intestinal tract. They also increase neutrophil adherence and microvascular permeability. These slow-reacting substances of anaphylaxis (SRS-As) also affect arteriolar constriction and augment vascular permeability. Apparently, the constrictive effects are immediate and direct effects, and the increased permeability is a subsequent response that may last for several hours (Lewis and Austen, 1984).

Macrophages are the main PGE_2-producing cell of the phagocytic/immune system. PGE_2 production is caused by a variety of stimuli. PGE_2 causes downregulation of the immune activity or immunosuppression by causing T cells to produce lymphokines that are able to inhibit the activity of lymphocytes (Cueppens and Goodwin, 1982). Prostaglandins may inhibit chemotaxis by causing the intracellular production of cAMP; they may inhibit phagocytosis and the release of lysosomal enzymes (DeChatelet, 1979).

IV. CYTOKINES AND HOST RESISTANCE TO DISEASE

Cytokines are a diverse collection of molecules that are involved in activation or priming of macrophages (Mannel *et al.*, 1980). Neutrophils can also be primed by cytokines to have enhanced functional activity (Bajaj *et al.*, 1992; Sample and Czuprynski, 1991). Cytokines have been defined as a group of protein cell regulators produced by a wide variety of cells in the body. They play an important role in many physiological responses, and they are involved in the pathophysiology of many diseases. They also have therapeutic potential (Balkwill and Burke, 1989). The immune system produces cytokines and other humoral factors of biological importance to protect the host when threatened by inflammatory agents or microbial infections.

In general, cytokines are involved in regulating immune and inflammatory responses. They are not found in cells as preformed molecules, and their production is transient. Many individual cytokines are produced by diverse cell types. For example, interferons, tumor

necrosis factors, interleukin-1, and colony-stimulating factors (G-CSF, GM-CSF) are individually or collectively produced and released by leukocytes (Bienhoff *et al.*, 1992; Simon and Willoughby, 1981; Scales, 1992; Tiku *et al.*, 1986), epidermal cells (Luger *et al.*, 1985), and other cells in response to biological and physical injury. Research during the last few years has shown that (1) a single cytokine is not only produced from one or multiple cell types, but it also interacts with more than one cell type, (2) a single cytokine has multiple biological activities, (3) a single cell can interact with more than one cytokine, and (4) many cytokines have overlapping biological activities (Mayer *et al.*, 1989; Tsuji and Tori, 1992; Scales, 1992).

Cells that respond to various cytokines must bear receptors for these ligands. The lack of sequence homology among various cytokines suggested that each cytokine would bind a unique receptor type (Rapoport *et al.*, 1992; Steinbeck and Roth, 1989; Tkatch and Tweardy, 1993). For example, two types of receptors have been described for interleukin-1: The type I receptor is found on T-lymphocytes, fibroblasts, endothelial cells, and hepatocytes (Dinarello, 1988; Urdal *et al.* 1988), whereas the type II receptor is found on B-lymphocytes, neutrophils, and bone marrow cells (Dinarello, 1988). Similarly, two distinct receptor types, A and B, specifically bind TNF-α and TNF-β and are found on a wide variety of cells (Dembic *et al.*, 1990; Schall *et al.*, 1990; Loetscher *et al.*, 1990). The receptor for IFN-γ has been identified and its gene localized to chromosome 6 in humans (Pfizenmaier *et al.*, 1988). A single class of high-affinity binding sites for G-CSF (Fukunaga *et al.*, 1990; Larsen *et al.*, 1990) and both high-affinity and low-affinity binding sites for GM-CSF have been detected on various hematopoietic cells, including granulocytes (Goodall *et al.*, 1993; Park *et al.*, 1992; Lopez *et al.*, 1992). Recently, it has been possible to define the structure of some of these cytokine receptors at the molecular level (Schreiber *et al.*, 1992; Lederer and Czuprynski, 1992). The cell surface receptor density may vary from as little as a few hundred to several thousand binding sites per cell (Rapoport *et al.*, 1992; Steinbeck and Roth, 1989; Cairo, 1991; Tkatch and Tweardy, 1993).

By binding to specific receptors on the neutrophil surface, cytokines augment different cell functions. *In vitro* and *in vivo* studies on neutrophils from humans and animals indicate that cytokines can augment their functional activities, including the ability to localize at the site of inflammation, phagocytic activity, production of oxygen metabolites, and release of lysosomal enzymes (Steinbeck and Roth, 1989; Rapoport *et al.*, 1992; Cairo, 1991; Gasson, 1991; Tkatch and Tweardy, 1993). For example, *in vivo* enhancement of neutrophil functions in humans by rhIFN-γ and rhG-CSF has been associated with increased resistance to microbial infections (Morrison *et al.*, 1989; Daifuku *et al.*, 1993; Hengge *et al.*, 1992). Administration of recombinant bovine IFN-γ and rhG-CSF in dairy cows was found to reduce development of experimental *E. coli* (Sordillo *et al.*, 1991) and *S. aureus* mastitis, respectively (Nickerson *et al.*, 1989). The profound influence of these cytokines on phagocytic cells suggests a possible clinical application for prevention of bacterial infections.

V. NEUTROPHIL-MEDIATED TISSUE INJURY

Products of neutrophils cause tissue damage. In numerous experimental models of inflammation, depletion of neutrophils attenuates the intensity of tissue damage. Proteases and reactive oxygen products, including $O_2^{\cdot}$, H_2O_2, $^{\cdot}OH$, and HOCl, as well as $NO^{\cdot}$ and its metabolites, contribute to the tissue damage. In addition, neutrophil elastase may convert endothelial cell xanthine dehydrogenase to xanthine oxidase, which generates $O_2^{\cdot}$ from xanthine or hypoxanthine. The active oxygen products injure the cell. In addition, $O_2^{\cdot}$ may react with $NO^{\cdot}$ to produce peroxynitrite anion ($ONOO^-$), which also damages tissue (Ward and Mulligan, 1992). Tissue damage during inflammation can be reduced by *N*-monomethyl-L-arginine (NMA). NMA competitively inhibits nitric oxide synthetase (Marletta, 1989).

VI. DEFECTS IN NEUTROPHIL FUNCTION

Numerous defects in neutrophil function have been described in humans. Despite this, only a few defects have been recognized in animals. Leukocyte adhesion defects have been described in Holstein–Friesian calves and Irish setter dogs. Chediak–Higashi syndome has been found in several species of animals. A poorly characterized syndrome probably caused by defective neutrophils has been found in Doberman pinscher dogs.

A. Granule Abnormalities

Specific granule deficiency is a very rare condition (Gallin, 1985). Humans with this disorder have depressed inflammatory response and recurrent severe bacterial infections of the skin and deep tissues (Malech and Gallin, 1987). Neutrophils have small, elongated granules that appear late in maturation. The granules

associated with defensins are smaller (Parmley *et al.*, 1989). In addition, nuclear morphological abnormalities such as bilobulation and nuclear blebs and clefts are present (Mills and Noya, 1993). Neutrophils of patients with specific granule deficiency lack lactoferrin, vitamin B_{12}-binding protein, and defensins. Tertiary granule gelatinase activity is decreased. Myeloperoxidase activity is normal, and nonstimulated adherence, aggregation, and respiratory-burst activity are normal or enhanced. However, upregulation of receptors does not occur, because these are normally present on the mobilizable pools on the specific granule membranes. (Edwards, 1994). Chemotaxis of these neutrophils is impaired, probably because of the failure to upregulate receptors stored within granules (Mills and Noya, 1993).

Chediak–Higashi (CH) syndrome has been described in children and in beige mice, mink, Hereford cattle, and a killer whale (Jain, 1986). Humans and animals have partial oculocutaneous albinism, frequent infections, and mild bleeding diatheses. Melanocytes, neutrophils, and monocytes contain giant granules (Edwards, 1994). Increased incidence of infections occurs because granule membrane fusion and activation are defective, and the discharge of granule contents into phagocytic vacuoles is delayed (Mills and Noya, 1993). Defective chemotaxis has been described in children, mink, and the beige mouse with CH (Clark, 1978; Smith and Lumsden, 1983). However, this appears to be, at least in part, an artifact caused by performing the test in filters with small pore size. When chemotaxis is evaluated with large-pore-size filters the chemotaxis approachs that of normal cells (Wilkinson, 1982).

B. Adhesion Defects

A genetic disorder termed leukocyte adhesion deficiency (LAD) has been recognized and extensively described in humans (Anderson and Springer, 1987; Kishimoto *et al.*, 1987; Todd and Freyer, 1988). Similar disorders have been described in Irish setter dogs and Hostein–Friesian cattle (Renshaw and Davis, 1979; Giger *et al.*, 1987; Hagemoser *et al.*, 1983; Trowald-Wigh *et al.*, 1992).

This autosomal recessive trait is characterized by recurrent soft-tissue infections, severely impaired pus formation, constant leukocytosis, and profound *in vitro* abnormalities of a wide spectrum of adhesion-dependent functions of granulocytes, monocytes, and lymphocytes. Leukocytes of human patients with LAD have a deficiency or total lack of the family of structurally and functionally related CD11/CD18 glycoproteins, including Mac-1, LFA-1, and p150,95 (Sanchez-Madrid *et al.*, 1983). Each of these molecule contains an α- and a β-subunit, noncovalently associated in an $\alpha_1\beta_1$ structure. They share an identical β-subunit (CD18) and are distinguished immunologically by their α-subunits, designated CD11a, CD11b, and CD11c (LFA-1α, Mac-1α, and p150,95α, respectively). Heterogeneous mutations of the gene encoding the common β subunits (CD18) have been identified as the primary basis for disease in all human cases (Kishimoto *et al.*, 1987; Dana *et al.*, 1987; Kishimoto *et al.*, 1989).

Although the pathogenesis of disease in Irish setters has not been completely studied, the reported findings of deficient expression of Mac-1, LFA-1, and p150,95 on leukocyte surfaces suggests a similar underlying defect of the gene encoding canine CD18 (Giger *et al.*, 1987; Trowald-Wigh *et al.*, 1992).

Bovine leukocyte adhesion deficiency (BLAD), formerly called bovine granulocytopathy syndrome, is a neutrophil function defect of Holstein–Friesian cattle (Hagemoser *et al.*, 1983; Takahashi *et al.*, 1987; Kehrli *et al.*, 1990). Clinical features of this syndrome include recurrent infection of soft tissues and delayed wound healing. Prominent features include persistent and progressive neutrophilia, decreased neutrophil infiltration into infected tissues, and impaired neutrophil chemotaxis, phagocytosis, and oxidative burst (Kehrli *et al.*, 1990; Nagahata *et al.*, 1994). The molecular basis is similar to that of human LAD, the genetic deficiency of CD11/CD18 adhesion molecules. Specifically, a calf with the granulocytopathy syndrome was severely deficiency in Mac-1 (CD11b/CD18) (Kehrli *et al.*, 1990). The genetic lesion in calves was determined to be a homozygous point mutation of adenine to guanine at nucleotide 383 in the gene encoding CD18. This point mutation causes replacement of asparate with glycine at amino acid 128 and resides in the highly conserved extracellular domain, amino acids 96–389 (Shuster *et al.*, 1992a, b). A defect in this region either prevents association with the α-subunit to form LFA-1, MAC-1, and P150,95, or alters adhesion to ICAM-1 (CD54) and ICAM-2 (CD102) (Springer, 1990; Shuster *et al.*, 1992a, b).

A second syndrome of defective neutrophil adhesion has been described in humans. This syndrome involves the selectin system of adherence rather than the β_2 integrins. The molecular mechanism underlying this syndrome is probably a fucose metabolism defect that results in an inability of leukocytes to produce sialylated glycoprotein ligands for the vascular selectins (Jones *et al.*, 1995). As a consequence, the defect involving β_2 integrins has been renamed leukocyte adhesion deficiency type 1 (LAD-1) and the defect involving selectins has been named type 2 (LAD-2) (Jones *et al.*, 1995).

C. Defects in Chemotaxis

Abnormalities of chemotaxis can be divided into cellular defects and chemotactic factor defects. In the former, the patient's leukocytes respond poorly to chemoattractants or there are cell-directed inhibitors of chemotaxis. In the latter, there is a failure of synthesis of chemoattractants, or the serum contains inhibitors of chemoattractants (Clark, 1978; Wilkinson, 1982; Quie, 1983).

Several defects in the chemotactic ability (or locomotor ability) of neutrophils have been described in humans. The "lazy leukocyte syndrome," originally described in two children, is characterized by neutrophils that have decreased random and directional locomotion (Miller *et al.*, 1971). Neutropenia accompanies some of the cases and is ascribed to an inability to mobilize neutrophils from the marrow (Wilkinson, 1982).

Neutrophil actin dysfunction was found in a male infant who had repeated infections from birth and failed to produce pus (Boxer *et al.*, 1974). The neutrophils of the patient were morphologically normal. Serum was active in generating chemotactic factors and opsonins. However, the neutrophils failed to migrate toward chemotactic substances, and they phagocytized at a markedly depressed rate. Actin from the neutrophils failed to polymerize.

Neutrophils of patients with Pelger–Huet anomaly have impaired locomotion through narrow-pore-size filters and less impairment through filters of wider pore size (Park *et al.*, 1977). Neutrophils of dogs with Pelger–Huet anomaly have given variable results in chemotaxis tests (Smith and Lumsden, 1983). If chemotaxis is impaired in the Pelger–Huet anomaly, the impairment is not severe enough to result in severe infections. Furthermore, the impairment of chemotaxis that has been found in patients with left shifts may be related to the small pore size used in the assay system causing the nuclei of band neutrophils, metamyelocytes, and so forth, to detain the cells in the filter pores (Frei *et al.*, 1978).

Neutrophils of humans with hyperimmunoglobulin E-recurrent infection syndrome have defective chemotaxis. These people have depressed inflammatory response. Despite marked local infection, neutrophils are present only in low numbers. Chemotaxis is variable and probably does not account fully for impaired host protection. The basis for the association between excess IgE and impaired chemotaxis may be the IgE-mediated release of histamine causing the activation of H_2 receptors on the neutrophil with subsequent elevation of the cAMP levels in the cell (Hill, 1984). Although the mechanism is unknown, the ratio of cAMP to cGMP is important for normal chemotactic function of neutrophils. The effect of cyclic nucleotides appears to be on the microtubular system (Hill, 1978).

Other conditions in which a cellular defect in chemotaxis has been observed include hyperimmunoglobulin A (IgA), chronic mucocutaneous candidiasis, diabetes mellitus, thermal injury, hypophosphatemia, and juvenile periodontitis. Inhibitors of cellular mechanism of chemotaxis has been suggested in a few people with IgA myeloma (Clark, 1978).

Defective production of the chemoattractant C5a is associated with the total absence of C3 and C5 and results in defective inflammatory responses and severe and recurrent infections. Deficiencies in C1, C2, and C4 are not as important, because C3, the activator of C5, can be activated by either the alternative or the classical pathway. However, the more rapid generation of complement derived chemoattractant occurs through the classical pathway (Clark, 1978). Abnormalities in the formation of the Hageman factor-dependent chemotactic agents, kallikrein and plasminogen activator, have been demonstrated (Clark, 1978). Inhibitors of chemotactic factors have been demonstrated in various conditions, including uremia and cirrhosis (Clark, 1978).

D. Defective Phagocytosis

Defects of phagocytosis often accompany cellular defects of chemotaxis (Hill, 1984). In addition, failure to opsonize bacteria can also result in inability to phagocytize the bacteria. Impaired opsonization of particles by serum occurs with deficiencies of complement components, immunoglobulin, or tuftsin (Klebanoff and Clark, 1978). The ability of some microorganisms to resist phagocytosis probably accounts for their virulence. Perhaps the surface components decrease the hydrophobicity of the organisms and make them less susceptible to phagocytosis (Van Oss *et al.*, 1974). Phagocytosis by neutrophils is better in colostrum-fed calves and lambs than in colostrum-deprived calves and lambs (Lamotte and Eberhart, 1976; Piercy, 1973). Presumably, the decreased ability of the neutrophils of the colostrum-deprived animals is caused by decreased opsonization of organisms rather than by a defect in the neutrophils that could be corrected by a factor in colostrum.

E. Defective Bacteria Killing

In humans, there are several conditions that can lead to chronic infections due to defects in the respiratory burst mechanisms. The most severe of these conditions is chronic granulomatous disease (CGD). In addition,

glutathione peroxidase deficiency, severe glucose-6-phosphate deficiency, and myeloperoxidase deficiency may produce defects in bacteria killing by neutrophils (Babior, 1978b; van der Valk and Herman, 1987).

CGD is characterized by recurrent and severe bacterial infections with abscess formation from early childhood. The infections are usually not fatal. The functional defect in CGD is the inability to mount a respiratory burst. The defect is due to an inability to activate the NADPH oxidase system (Segal *et al.*, 1983; Borregaard, 1985). Four different types of CGD have been characterized. These correspond to defects in the proteins integral to assembly of complete NADPH oxidase. A defective β-subunit is the most common form of CGD. It is inherited in an X-linked fashion.The lesion in the gene encoding gp91-*phox* can lead to absence of the protein product, presence of a nonfunctional protein, partial deficiency of gp91-*phox*, or assembly of an abnormal oxidase (Mills and Noya, 1993). A small percentage of people with CGD have abnormal p22-*phox*. Absence of the cytosolic components of NADPH oxidase has also been described, with absence of p46-*phox* being much more common than absence of p67-*phox* (Mills and Noya, 1993). The diagnosis of CGD is based on the demonstration of absent or extemely low respiratory burst in stimulated neutrophils (Mills and Noya, 1993).

Glutathione peroxidase (GPx) deficiency causes a condition similar to CGD (Klebanoff and Clark, 1978; Babior, 1978b). Apparently this is due to an inability to maintain the electron-transport chain necessary for the generation of NADPH. Impaired neutrophil bactericidal ability has been found in selenium-deficient cattle and in selenium- and copper-deficient cattle (Boyne and Arthur, 1979, 1981). The requirement for selenium in glutathione metabolism and the relationship of glutathione to the HMP and respiratory burst suggests that selenium deficiency may result in a defect in the oxygen dependent pathway of bacteria killing (Serfass and Ganther, 1975).

Severe glucose-6-phosphate deficiency (G6P-D) also causes impairment of the respiratory burst in neutrophils. The failure of the neutrophils to mount a respiratory burst is also due to insufficient generation of NADPH (Babior, 1978).

Myeloperoxidase (MPO) deficiency produces few clinical signs (van der Valk and Herman, 1987). Destruction of bacteria by MPO cells is delayed but is usually complete. Oxidizing radicals apparently fulfill the antibacterial role of the peroxide–halide–MPO system in the deficient cells (Babior, 1978b). Myeloperoxidase deficiency is the most common of the inherited neutrophil defects. Flow cytometric methods for determining neutrophil differential counts by peroxidase staining of neutrophil has revealed that the defect is quite common in humans. Yet the number of individuals that develop severe infections is very small. This observation indicates that alternative pathways for killing organisms, which may be slower than the hypochlorous acid mechanism, act to prevent severe, chonic infections in people with MPO deficiency (Mills and Noya, 1993; Edwards, 1994).

In glutathione reductase (GR) deficiency, there is no defect in the killing ability of the cells, but rather there is an inability to detoxify excess H_2O_2. H_2O_2 is toxic to cells and tissues. The oxidant stress precipitates acute hemolysis. People with GR deficiency also develope cataracts early in life. No increase in susceptibility to infections has been noted (Babior, 1978b).

Defective bacteria killing by neutrophils in several closely related Doberman pinschers has been reported. Neutrophils phagocytized bacteria normally, but had impaired bactericidal ability. Stimulated neutrophils had reduced ability to reduce nitroblue tetrazolium (NBT) and generate oxygen radicals. Neutrophils phagocytized opsonized Oil Red O and *Staphylococcus epidermidis* normally. However, killing of *S. .epidermidis* was depressed in neutrophils of the affected dogs. The authors concluded that the disease was similar to CGD or complement receptor deficiency in man (Breitschwerdt *et al.*, 1987) . Because several of the dogs continued to live with no or mild infections, it is unlikely that they had a complement receptor deficiency such as CD18/CD11b deficiency of man. Although decreased NBT reduction was found, it was not as pronounced as found in human CGD neutrophils. It is possible that the dogs had a variation of some other oxygen-dependent bactericidal mechanism such as myeloperoxidase deficiency.

Bovine, ovine, and porcine neutrophils produced less superoxide and consumed less oxygen than human neutrophils when they were challenged with serum-treated zymosan (Young and Beswick, 1986). The iodination reaction, which evaluates the activity of the myeloperoxidase-H_2O_2-halide antibacterial system and the NBT reduction, is decreased in young calves when compared to that in older calves (Hauser *et al.*, 1986).

Neutrophils of humans and dogs with primary ciliary dyskinesia may have defective chemotaxis. Neutrophils of dogs with primary ciliary dyskinesia show increased distance of random migration, but fewer of the neutrophils migrate. Phagocytosis is enhanced and cytochrome c reduction, iodination, and antibody-dependent, cell-mediated cytotoxicity are unaffected in dogs with primary ciliary dyskinesia. The contribution of neutrophil chemotaxis dysfunction to the increased susceptibility of dogs with primary ciliary dys-

kinesia to respiratory diseases is not known. It is likely that this susceptibility is due to respiratory ciliary dysfunction rather than to neutrophil dysfunction (Morrison *et al.*, 1987).

VII. METHODS FOR TESTING NEUTROPHIL FUNCTION

A. Cell Isolation

Many functions of neutrophils can be tested *in vitro*. Although some functions can be evaluated using whole blood, a preparation of nearly pure neutrophils is usually required. Neutrophils can be isolated from blood through sedimentation, differential centrifugation, or erythrocyte lysis.

A mixed population of leukocytes may be obtained from horse blood by allowing an anticoagulated (EDTA or heparin) sample to stand vertically for 15 to 30 minutes (Zinkl and Brown, 1982). The leukocytes of some other species can be isolated by causing erythrocyte rouleaux with a 3–6% suspension of high-molecular-weight dextran (200,000–500,000) (Metcalf *et al.*, 1986).

Differential centrifugation of whole blood or isolated leukocytes in a density gradient formed by sodium diatrizoate (Hypaque) and ficoll can be used to separate erythrocytes from leukocytes or separate the mononuclear leukocytes from the segmented leukocytes (English and Andersen, 1974). The cells separate based on their densities, with the lighter platelets, the mononuclears (lymphocytes and monocytes), and basophils found in the upper layer. The neutrophils and the eosinophils are intermediate in specific gravity and are above the heavy erythrocytes (Metcalf *et al.*, 1986).

Centrifugation of blood over a discontinuous gradient of Percoll [silica particles coated with poly(vinyl pyrrolidone)] can isolate leukocytes from blood (Riding and Willadsen, 1981; Sedgwick *et al.*, 1986). A discontinuous gradient of Percoll is made by layering a 60–68% Percoll solution over a 70–75% solution. (The concentrations of the Percoll that will successfully isolate the various leukocytes will vary with the species. Initially, several concentrations should be used until a pair of concentrations is found that allows separation of the cells into mononuclear, neutrophil, and erythrocyte layers.) After centrifugation at 200 to 500 *g* for 10 to 15 minutes, the blood will be separated into an upper plasma layer, a mononuclear zone just under the plasma, a polymorphonuclear zone at the interface of the two Percoll concentrations, and an erythrocyte layer at the bottom of the tube.

Techniques that lyse erythrocytes while leaving leukocytes intact can be used to isolate leukocytes from blood or to remove erythrocytes that contaminate leukocytes isolated by another technique. Short (20 to 60 seconds, depending upon the species) hypotonic shock lyses the erythrocytes, and isotonicity is restored with a hypertonic solution before the leukocytes are adversely affected (Carlson and Kaneko, 1973).

B. Adherence

Adherence can be studied by several methods. Most techniques involve sticking the cell to a glass surface, nylon fibers, or plastic. Whole blood or purified neutrophil fractions can be used (Metcalf *et al.*, 1986).

C. Chemotaxis

There are several methods to evaluate neutrophil chemotaxis. The most commonly used techniques are the micropore filter methods (Boyden, 1962; Nelson *et al.*, 1975). Many modifications of Boyden's original method have been used, but the basic technique remains unchanged. A chamber consisting of two compartments separated by a membrane filter with pores of about 2–8 μm is used to separate cells from the chemoattractant. The chemoattractant is placed in the lower compartment, and the suspension of leukocytes is placed in the upper compartment. The chamber is incubated at body temperature for 1 to 4 hours. The leukocytes respond to the chemoattractant by migrating into or through the filter. The number of cells migrating through the filter is determined and compared to the numbers migrating spontaneously. This method has been criticized because it does not distinguish between chemotactic and chemokinetic response. The checkerboard assay modification of the filter technique allows the differentiation of chemotactic and chemokinetic responses. With this modification, chemoattractant at various combinations of concentrations is placed in the cell compartment and the attractant compartment. The distances migrated are compared in order to determine the degree of response due to chemotaxis and that due to chemokinesis (Wilkinson, 1982; Metcalf *et al.*, 1986).

Migration under agarose and direct visulalization with specially designed chambers have also been useful for evaluating chemotaxis (Nelson *et al.*, 1975; Zigmond, 1978). A simple microdroplet assay for chemokinesis has been developed in which the migration of leukocytes out of agarose is measured (Smith and Walker, 1980). This technique has been used to determine that LTB_4 and PGE_2 are chemotactic to equine neutrophils (Lees *et al.*, 1986).

The ability of cells to respond to chemotactic stimuli can be determined by observation of shape change.

This technique is a rapid assay for the study of prechemotactic events in neutrophils. Isolated neutrophils are incubated with potential chemoattractants, the cells are fixed in 2% glutaraldehyde, and wet mounts of the fixed cells are examined by phase-contrast microscopy. If the substance to which the neutrophils are exposed has chemotactic activity, the neutrophils have a bipolar shape. They may or may not have a uropod. Unstimulated neutrophils remain round (Smith *et al.*, 1979).

In vivo techniques for evaluation of chemotaxis include the Rebuck skin window and similar methods in which cells are collected in chambers that have been adhered to abraded skin or implanted in various locations in the body. A chemoattractant is placed in the chamber and migrating cells are collected and counted (Klebanoff and Clark, 1978). A modification that eliminates the chamber is to inject chemoattractant intradermally and collect cells from the intradermal site (Hayashi *et al.*, 1974).

D. Phagocytosis

Phagocytosis can be measured by several methods. A common technique is to allow bacteria, yeast, or other particles and neutrophils to incubate together, and then to determine by light microscopy the number of neutrophils that contain particles, as well as the number of particles phagocytized per neutrophil (Metcalf *et al.*, 1986; Silva *et al.*, 1988; Kabbur *et al.*, 1991).

Ingestion of paraffin oil particles containing Oil Red O and bacterial lipopolysaccharide by neutrophils has been used to evaluate phagocytosis. After incubation is complete, extracellular paraffin is removed by washing and centrifugation, the cells are lysed, and the concentration of Oil Red O is determined by spectrophotometry (Stossel, 1973).

Other methods for determining phagocytosis include using *Candida albicans*, zymosan (cell-wall ghosts of *Saccharomyces cerevisiae*), and ^{51}Cr-labeled sheep erythrocytes (Metcalf *et al.*, 1986).

More recently, flow cytometric technology has been applied to evaluate phagocytosis by neutrophils. Latex particles, zymosan, and bacteria labeled with fluorescent material are incubated with neutrophils. The number of particles in numerous neutrophils can be determined rapidly with flow cytometric analysis (Dunn and Tyrer, 1981; Saad and Hageltorn, 1985; Kabbur *et al.*, 1995).

E. The Respiratory Burst

There are many methods for determining the activity of the oxygen-dependent mechanisms of bacteria killing. These include methods that depend upon the intact pathway for the generation of active oxygen species, as well as methods that determine the activity of the individual enzymes of the system. Among those methods that indicate the complete function of the oxygen-dependent pathways are reduction of nitrobluetetrazolium, chemiluminescence of stimulated cells, reduction of cytochrome c, oxygen consumption, production of H_2O_2, and detection of intracellular oxidized 2′,7-dichlorofluorescein diacetate dye (Babior, 1978a; Bertram, 1985; Rossi *et al.*, 1985; van der Valk and Herman, 1987; Bass *et al.*, 1983).

Oxygen consumption can be measured using an oxygen electrode. The rate of oxygen consumption is determined in resting neutrophils and in cells that have been stimulated (Metcalf *et al.*, 1986).

Production of H_2O_2 can be determined in several ways, including oxidation of leucodiacetyl-2,7-dichlorofluorescein, oxidation of scopletin, and the release of oxygen by catalase (Klebanoff and Clark, 1978; Metcalf *et al.*, 1986).

Ferricytochrome c reduction is useful to determine the amount of $O_2^{\cdot}$ produced. The assay is run with and without the addition of superoxide dismutase. Reduced ferricytochrome c absorbs light at 550 nm. The rate of superoxide dismutase-inhibitable ferricytochrome c reduction is proportional to the production of O_2-(Klebanoff and Clark, 1978).

Nitrobluetetrazolium is reduced to formazan by $O_2^{\cdot}$. NBT is a blue-black insoluble material that precipitates intracellularly. Microscopic visualization of the formazan provides a qualitative means of identifying cells producing $O_2^{\cdot}$. Formazan can also be quantified spectrophotometrically after extraction with *N,N*-dimethylformamide or hot pyridine (Metcalf *et al.*, 1986). The NBT reduction test has been combined with the phagocytosis test to provide information on phagocytic ability and active oxygen production simultaneously (Stossel, 1973; Jabs *et al.*, 1980; Valinoti *et al.*, 1988).

The respiratory burst of neutrophils causes generation of low-intensity light energy known as chemiluminescence (CL). CL is dependent upon the production of singlet oxygen (O^12). Singlet oxygen is produced when one of the unpaired electrons of oxygen is raised to a higher orbit with an inversion of spin. Light is emitted when the electron reverts to the ground state. The light is enhanced by luminol (5-amino-2,3-dihydro-1,4-phthalazinedione) and is measured with equipment designed to detect short luminescent events. The number of luminescent events over a specific time is recorded in stimulated and nonstimulated cells and provides an index of the respiratory burst (Anderson *et al.*, 1980).

Flow cytometric technology has also applied to measure respiratory burst activities of neutrophils. 2',7-Dichlorofluorescein diacetate dye has been used in flow cytometric studies to measure respiratory burst activity. 2',7-Dichlorofluorescein diacetate (DCFH-DA) is a stable, nonfluorescent, nonpolar compound that can diffuse through granulocyte cell membranes. Once inside the cell, the acetyl groups are cleaved by cytosolic enzymes. The intracellular 2',7'-dichlorofluorescein (DCFH) produced is polar and is thus trapped within the cell. DCFH is nonfluorescent, but it is rapidly oxidized to highly fluorescent 2',7'-dichlorofluorescein (DCF) in the presence of hydrogen peroxide generated during the oxidative burst of neutrophils. With flow cytometry used to measure cellular fluorescence, the DCF assay provides quantitative assessment of the oxidative metabolic burst in individual granulocytes (Bass *et al.*, 1983).

To measure the activity of myeloperoxidase, a homogenate of cells is added to an H_2O_2 and 4-aminoantipyrine mixture. The rate of oxidation of 4-aminoantipyrine is measured by the increase in absorption at 510 nm (Metcalf *et al.*, 1986).

Iodination ability is determined by incubating neutrophils with zymosan and ^{125}I. After a prescribed incubation time, the protein is precipitated with trichloroacetic acid and the ^{125}I activity in the protein is determined (Klebanoff and Clark, 1978).

F. Other Enzymes of the Phagocytes

The activities of other enzymes such as *N*-acetyl-β-Glucosaminidase, β-glucuronidase, elastase, lysozyme, lactoferrin, vitamin B_{12}-binding protein, catalase, and other enzymes can be determined using isolated granules or cell homogenates (Metcalf *et al.*, 1986).

CHAPTER

12

Clinical Enzymology

JOHN W. KRAMER AND WALTER E. HOFFMANN

I. INTRODUCTION

Clinical enzymology has made great advances since the introduction of serum alkaline phosphatase as a diagnostic aid in 1927 by King and Armstrong. Advancement in bioengineering and computer technology linked enzymology, immunology, and molecular genetics to produce new clinical diagnostic procedures. Qualitative and quantitative nonradioisotopic immunodiagnostics with enzyme-linked monoclonal antibodies enhances the specificity and sensitivity of assays for metabolites, hormones, and infectious agents. Immunocytochemistry has advanced the specificity and sensitivity of light and electron microscopic histology and cytology. Endonucleases combined with DNA probes enable the diagnostician to detect the fingerprints of prepatent genetic defects and infectious agents before or without the aid of endogenous antibody development. Although enzymes appear to have only a passive part in these forms of biotechnology, understanding their fundamental action is essential to clinical diagnostics and basic research.

This chapter is intended to be an introduction to enzymes as primary clinical diagnostic aids and their secondary role in other diagnostic techniques. Additional information on clinical enzymology can be lo-

cated in the following serial publications: *Veterinary Clinical Pathology* and *Clinical Chemistry*, the respective publications of the American Society of Veterinary Clinical Pathology and the American Association of Clinical Chemistry, a division of Animal Clinical Chemistry. *Advances in Clinical Chemistry* and *Methods in Enzymology* are annual serials containing information on clinical enzymology. Organizations that help standardize enzymology are the International Union of Biochemistry's (IUB) Nomenclature Committee (EC) and the Expert Panel of the International Federation of Clinical Chemistry (IFCC).

I. BASIC ENZYMOLOGY

A. Enzyme Nomenclature

Enzyme nomenclature is based on the reaction an enzyme catalyzes. The suffix "-ase" identifies an enzyme. The IUB established a commission on enzyme nomenclature to systematize, categorize, and catalog enzymes (Webb, 1984). The system is numerical and based on the type of reaction catalyzed: a formal name, a common name, initials, and a number for each enzyme. Lactate dehydrogenase (LDH) illustrates this system. Lactate dehydrogenase is an "oxidoreductase" that can catalyze an oxidation or reduction reaction. When the enzyme incorporates a redox cofactor, such as NAD+, it is a dehydrogenase. Therefore, the formal name for LDH is L-lactate: NAD oxidoreductase, its common name is lactate dehydrogenase, and its Enzyme Commission number is EC 1.1.1.27. The abbreviation, common name, and EC number of some enzymes are listed in Table 12.1 and others are obtainable from the IUB listings (Webb, 1984).

Glutamic pyruvate transaminase (GPT) and glutamic oxaloacetate transaminase (GOT) are the former common names and abbreviations of enzymes frequently used in clinical medicine. The IUB commission recommends that these enzymes be classified as alanine aminotransferase (ALT) and aspartate aminotransferase (AST), respectively. The formal names and abbreviations recommended by the IUB for some clinically diagnostic enzymes are listed in Table 12.1.

B. Units of Enzyme Activity

The concentration of an enzyme can be expressed directly as mass or indirectly as activity. Currently the most accepted expression of enzyme concentration is the rate of the reaction catalyzed, activity, per unit mass or volume. It would be more precise to express the concentration as mole of enzyme per unit volume.

TABLE 12.1 Enzymes Used in Veterinary Medicine

Abbreviation	Recommended name	EC number
ALT (GPT)	Alanine aminotransferase	2.6.1.2
AP	Alkaline phosphatase	3.1.3.1
Amyl	α-Amylase	3.2.1.1
ARG	Arginase	3.5.3.1
AST (GOT)	Aspartate aminotransferase	2.6.1.1
ChE	Cholinesterase	3.1.1.8
CK (CPK)	Creatine kinase	2.7.3.2
GGT	γ-Glutamyltransferase	2.3.2.2
GPx	Glutathione peroxidase	1.11.1.9
LDH	L-Lactate dehydrogenase	1.1.1.27
LIP	Lipase (triacylglycerol lipase)	3.1.1.3
OCT	Ornithine carbamoyltransferase	2.1.3.3
SDH	Sorbitol dehydrogenase (L-iditol dehydrogenase)	1.1.1.14
PK	Pyruvate kinase	2.7.1.40
TK	Transketolase	2.2.1.1
—	Trypsin	3.4.21.4

The concentrations, however, of most enzymes in serum and tissues are usually very low and immeasurable as mass by current state-of-the-art enzymology. As an example, ALT occurs in plasma at less than 1 mg/liter. With a total plasma protein concentration of 70 g/ per liter, the proportion of enzyme protein to total protein would be less than 1 in 7000. Purification, isolation, and determination of enzyme concentration against this background would be an impractical clinical chemistry procedure.

The IUB defines an international unit (U) of enzyme activity as the amount of enzyme that catalyzes the conversion of 1 mol of a substrate or product per minute. The U is expressed per liter. Unit only specifies amount of substrate consumed or product formed per unit time by defined volume of sample. Variables between laboratories are time, temperature, pH, and substrate concentrations. These variables play an essential role in the evaluation of results among laboratories, and for these reasons laboratories must establish their own normal values. To avoid discrepancies, the discussion of enzyme activity changes should include a relative magnitude of change from normal rather than in actual units of enzyme activity.

The IUB and the IUPAC recommended a new unit to express enzyme activity, the katal (1 kat = 1 mol/s), which is consistent with the Système Internationale d'Unites. One U per liter is equal to 16.67 nkat per liter The U remains the preferred unit of enzyme activity in the United States.

C. Kinetics

Enzymes catalyze reactions by complexing with the substrates to lower the energy of activation of the reaction without changing the equilibrium constant. In the absences of enzyme the reaction will occur, but at a much slower velocity. Enzymes can catalyze reactions in four ways: general acid–base catalysis, covalent catalysis, approximation of reactant catalysis, and induction of strain in the substrate or enzyme. As the product forms, the enzyme–product complex disassociates, freeing the enzyme to associate with another mole of substrate.

Enzymes are characterized on the basis of their affinity with their specific substrate and cofactors and on the effects of inhibitors, activators, pH, and temperature on the reaction.

An enzyme's optimum substrate affinity is expressed as the Michaelis constant (K_m), the substrate concentration at one-half the maximum velocity (V_{max}) of the reaction. Advanced recording systems permit a direct measurement of the enzyme's affinity with its substrate (K_s).

Calculation of the K_m for two substrate reactions, such as for the dehydrogenases, requires a complex approach. The concentration of the primary substrate is varied while the enzyme and secondary substrate, the cofactor, such as NADH, are supplied in sufficient concentration that they do not limit the velocity of the reaction. Once the K_m for the primary substrate is determined, it is held constant at its V_{max} and the concentration of the cofactor is varied.

The affinity of the inhibitor or activator and its mechanism of binding is characterized by plotting (Lineweaver–Burke plot) the effect of the inhibitor on the substrates V_{max} and K_m. The lower the numerical value of the inhibitor constant (K_i) or activator constant (K_a) the greater the affinity with the enzyme.

D. Enzyme Structure

An active enzyme, the holoenzyme, consists of a complex of proteins with posttranslational, nonprotein modifications. The protein portion consists of individual protomers. One or more such protomers may make up the protein, apoenzyme, portion of the holoenzyme. The apoenzyme may undergo posttranslational glycosylation, acylation, phosphorylation, deamidation, sulfhydryl oxidation, or aggregation within the confines of the sinus of the rough endoplastic reticulum. Posttranslation modification of a single protomer results in the formation of a monomer. Monomers can combine to form dimers, tetramers, and oligomers to make up the conformation of the holoenzyme. The three-dimensional configuration of the protein gives it its specific catalytic activity. Modification of the enzyme's environment, or matrix, such as temperature, pH, protein, or urea concentration, alters its configuration. Therefore, the assay matrix determines an enzyme's conformation and, in turn, its catalytic specificity and kinetic characteristics.

No specific amino acid sequence characterizes a protein as an enzyme. Among some enzymes there are similarities in the amino acid sequences of their catalytic site. The serine proteases are a group of enzymes that have serine residue common to their catalytic site. This similarity more closely reflects phylogeny than the essential nature of the enzyme's catalytic site. An enzyme's antigenic site may not be the same as its active site, and if dissimilar, antibody binding may or may not interfere with the enzyme's activity. Enzymes can be bound to the walls of plastic tubes or fibers of filters with little or no loss of their activity.

Enzymes secreted by cells for extracellular function can be synthesized and secreted as inactive proenzymes or zymogens. They are given the suffix "-ogen" or the prefix "pro-" to connote their inactive form. Proteases cleave the proenzyme into its holoenzyme and a remnant peptide. An example is the trypsinogen of trypsin. Coagulation, fibrinolysis, and complement systems contain proenzyme proteases that have a cascading proteolytic effect.

E. Isoenzymes

Isoenzymes are multiple structural forms of enzymes with the same catalytic activity, in the same species, but with apoenzymes derived from different genes. Previously, the IUB definition of the isoenzyme did not require derivation from separate genes, only that they be located in different tissues and have different physical features. The study of posttranslational changes, development of monoclonal antibodies, amino acid sequencing and DNA hybridization has increased the specificity of the isoenzyme definition. Posttranslational modifications of the apoenzyme to form the holoenzyme consist of glycosylation, acylation, phosphorylation, deamidation, sulfhydryl oxidation, or aggregation. An example is the alkaline phosphatase (AP) isoenzymes. When human hepatic, osseus, and renal AP are stripped of their sialic acid residues they have similar catalytic characteristics and electrophoretic mobility, but differ from the AP of intestine and placental. It appears, therefore, that human placental, intestinal and the three multiple forms of tissue-nonspecific APs are derived from three separate genes (Stigbrand *et al.*, 1982). By IUB definition there are only three, not the formerly defined five, AP isoen-

zymes. The IUB definition for an isoenzyme is not widely accepted in clinical chemistry in the United States. The definition of the isoenzyme as having multiple forms, pretranslational or posttranslational, continues in use.

Allelozymes are isoenzymes derived from the same loci, but with a differing or an allelic genome. When there is a high frequency of different allelozymes for a locus, it is described as being *polymorphic.* Human placental AP has a large amount of allelozyme polymorphism, but other species' placental AP contains very little. Allelozymes are well characterized in only a few nonhuman species. The X-linked phosphoglycerate kinase of mice and the glucose-6-phosphate dehydrogenases (G-6-PD) in the hare are allelozymes, and the artificially produced mosaicism of crossbred domestic cats with the Geoffrey cat X-linked G-6-PD results from alleloenzyme polymorphism. These X-linked allelozymes in the mouse and cat were used to demonstrate the monoclonal origin of neoplasia (Abkowitz *et al.*, 1985).

Hybrid isoenzymes result from the aggregation of two or more protomers. In the LDH isoenzyme, two different protomers aggregate to form the tetramers of the five isoenzymes. Of these five LDH isoenzymes, only LDH-1 and LDH-5 are made up of all of the same protomer. The remaining three isoenzymes, LDH-2, LDH-3, and LDH-4, are hybrids of the various combinations of the two protomers.

Macroenzymes are complexes of an enzyme or enzymes bound to immunoglobulins of the IgG, IgA, and sometimes IgM classes (Remaley and Wilding, 1989). Most diagnostically significant serum enzymes may exist in part as macroenzymes: macroamylase, macro-LDH, macro-AST, macrolipase, and macro-AP. They occur in varying amounts in most species where they have been sought. Although macroenzyme formation may be an autoimmune phenomenon, no association with autoimmune disease process has been established (Corazza *et al.*, 1994; Galasso *et al.*, 1993). Unfortunately they present a diagnostic problem. Macroenzymes may have longer half-lives than the native unbound enzyme and their serum values may change without an accompanying change in the enzyme's tissue of origin (Corazza *et al.*, 1994). The irregular formation of macroenzymes decreases diagnostic specificity and broadens the reference ranges, which in turn decreases their clinical sensitivity.

Characterization of isoenzymes is by zone and column electrophoresis, kinetically with different substrates, inhibitors, and activators, and immunologically with antibodies against the isoenzyme (Weiser and Pardue, 1987). Zone electrophoresis as a function of total enzyme activity has been the most common clinical procedure used to quantify isoenzymes.

Isoenzymes are valuable for phenotyping the genetic pool of both plants and animals (Rattazzi *et al.*, 1982). Quantification of isoenzymes has added to the specificity and sensitivity of clinical enzymology in human medicine, but less so in veterinary medicine. In human medicine LDH and CK isoenzymes are highly efficacious diagnostic and prognostic aids in cardiac infarction.

F. Substrate

Although enzymes are specific for the reaction they catalyze, they may not be specific for the substrate on which the reaction is catalyzed. An enzyme's affinity for one substrate may not be the same for a second. This absence of substrate specificity *in vitro* leads to confusion when comparing data between two or more laboratories using different substrates and reporting their values as U. This confusion is illustrated with AP. Synthetic substrates have been used to assay AP since its inception as a diagnostic aid in the 1920s. Activity has been expressed as an eponym unit, for example, Bodansky and King-Armstrong units. With the advent of the U, investigators calculated a numerical conversion factor to convert the eponym unit to U/liter. They did not standardize the assay and the user of the conversion factor failed to recognize the difference among assays. The most appropriate method of comparing values among reports of various laboratories is on the basis of the magnitude of change, rather than numerical units of activity.

Some enzymes have specificity for groups of substrates, such as hexokinase (HK), which has the same specificity for D-glucose, D-fructose, and D-mannose. For enzymes, such as L(+)-LDH (EC 1.1.1.27), used to measure blood lactate, there is a strict requirement for L(+)-lactate and only poorly oxidizes its mirror image, D(−)-lactate. This specificity of L(+)-LDH is especially important when measuring the plasma lactate in herbivores with grain overload leading to lactate acidosis. The patient absorbs large amounts of D(−)-lactate produced by rumen bacteria from grains. Use of an L(+)-LDH to assay for D(-)-lactate underestimates total plasma lactate concentration (Buttery and Pannall, 1986).

When measuring enzyme activity for diagnostic purposes, the activity of the enzyme must be maximized. This requires knowledge of the equilibrium of the reaction and concentration of substrate. An equilibrium constant (K_{eq}) of 100 indicates that when the reaction has gone to completion there will be 100 times more product than substrate. However, if $K_{eq} = 1$, as

in the ALT reaction, only 50% of substrate is converted to product at equilibrium and the reaction appears to stop. If the reaction is reversible, the product may be reconverted to substrate as quickly as product is formed. This reconversion is stopped by converting the product into a second irreversible product. This process is called *trapping*. In the reverse LDH reaction, lactate is converted to pyruvate by LDH. To drive the reaction in the direction of pyruvate, hydrazine is used to "trap" pyruvate as an irreversible pyruvate–hydrazine product. This technique permits a large amount of LDH activity to be determined with a smaller amount of substrate than would have been possible without trapping the pyruvate.

"Substrate exhaustion" is a technical reason for erroneously reporting low activity in samples with a large amount of activity. This is the result of an unusually large amount of enzyme activity consuming the substrate before the first reading is taken for either an end point or kinetic assay. Substrate exhaustion errors can be avoided by the setting of minimum or maximum starting absorption limits. When the limits are exceeded, the sample is diluted with an appropriate diluent and the assay repeated.

When a substrate or product is immeasurable, measurement of a cofactor may suffice. Two convenient and accurately measured cofactors as stoichiometric markers of enzyme activity are NADH and NADPH. Their absorption peaks are at 340 nm and they have absorption coefficients (formerly the extinction coefficient) of 6.22×10^3 M/liter. The rate of appearance or disappearance of NADH is stoichiometrically related to substrate consumption and it is commonly used to express the oxidation–reduction of enzyme activity.

No cofactor is required in some reactions and the substrate or the product may be immeasurable. In these enzymes the primary reaction is "coupled" or "linked" to a second reaction utilizing a measurable product in the coupled reaction. An example of a coupled reaction in which three reactions are linked is that of creatine kinase (CK) assay [Equations (12.1)–(12.3)].

$$\text{Creatine phosphate} + \text{ADP} \xrightarrow{\text{CK}} \text{creatine} + \text{ATP}, \quad (12.1)$$

$$\text{ATP} + \text{glucose} \xrightarrow{\text{hexokinase}} \text{glucose-6-phosphate} + \text{ADP}, \quad (12.2)$$

$$\text{Glucose-6-phosphate} + \text{NADP} \xrightarrow{\text{G-6-PD-D}} \text{6-phosphogluconate NADPH} + \text{H}^+. \quad (12.3)$$

In the example the coupled CK assay, the substrate of the first reaction, cofactors, and secondary enzymes are supplied in unlimited quantities. In a coupled reaction, only the primary enzyme's activity can be a variable, in this case CK. The rate of generation of NADPH [Eq. (12.3)] is then stoichiometrically proportional to the ADP consumed.

Synthetic substrates are available for many enzymes having products or substrates not easily quantified. Those of hemostasis, trypsin, plasmin, cathepsin, and kinases, are a few with diagnostic value. Some poorly or undetectable natural substrates can be conjugated to chromogens to form synthetic substrates. When the reaction occurs, chromogen is freed or modified to a form that can be spectrophotometrically measured and its absorption coefficient used to calculate the rate of the reaction.

The development of synthetic substrates for proteolytic enzymes of the coagulation pathway has been revolutionized in the study of hemostasis (Triplett, 1986). Assay of a single coagulation enzyme formerly required complete linkage of a large portion of the pathway to form a fibrin clot. Now a specific enzyme of the coagulation pathway can be assayed independent of the remainder of the pathway's enzyme.

G. Cofactors

Cofactors are small molecules, loosely or closely associated with enzymes as cyclic secondary bisubstrates. As cyclic substrates they are common to a number of enzymes, where they are specific for the type of reaction catalyzed. They are secondary to the enzyme's primary specific substrate. All water-soluble vitamins, except C, are precursors of cofactors that have no stable storage forms. The animal's inability to synthesize and store water-soluble vitamins and its cofactors' "loose" binding with enzymes make them pivotal points in homeostasis. An example of a water-soluble vitamin's importance is niacin, vitamin B^3. Niacin is the substrate for the cofactors NAD and NADP, the essential electron transporters of respiration. Twenty-five percent of the body's enzymes have metal cofactors and are called *metalloenzymes*. Some metalloenzymes are complexed with vitamin-derived cofactors, such as the metalloflavoproteins of the oxidation–reduction enzymes.

For optimum enzyme assay reaction rates, loosely bound cofactors must be supplied in optimum amounts. However, when tightly bound, the addition of cofactor makes no difference to the assay unless the patient is deficient in the factor. When a deficiency of a tightly bound cofactor is suspected, such as a mineral, an assay of the appropriate metalloenzyme before and after supplementation can serve to confirm the diagnosis and a prognosis. Selenium and copper deficiencies are detected by measuring their respective metalloen-

zymes, red blood cell (RBC) glutathione peroxidase, and superoxide dismutase.

Cofactor-activation enzyme assays are used to detect deficiencies of the loosely bound vitamin cofactors (Bayoumi and Rosalki, 1976). They are performed by deleting and adding the suspected deficient cofactor to the appropriate enzyme assay. A difference in the reaction rate between the deleted and added cofactor in a sample from affected versus the reference animals serves as the indicator of a deficiency. An activation assay is used in the study of polioencephalomalacia, an idiopathic disease of cattle and sheep with cerebrocortical necrosis and low RBC transketolase activity. Low transketolase activity is related to the deficiency of thiamin cofactor, thiamin pyrophosphate (TPP) (Loew *et al.*, 1975; Edwin *et al.*, 1979; Jackman, 1985). Transketolase activity is measured before and after adding TPP to the assay. The change in activity that results from the addition of TPP to a patient's sample is compared to that observed in the control sample. The greater the amount of transketolase activation, the greater the thiamin deficiency.

H. Inhibitors and Activators

Inhibitors and activators modify the rate of a reaction in which they are not substrates. They are generally small molecules and ions, and can even be other enzymes. Their action may be reversible or irreversible. If covalently bound, they are irreversible. Reversible inhibition and activation are initiated by electrostatic, hydrogen, and van der Waals' bonds. The action may be competitive with the substrate at the enzyme's catalytic site, or noncompetitive at an allosteric site elsewhere on the enzyme, or, less commonly, uncompetitive.

Feedback inhibition of enzymes by the pathway's end products are well-recognized physiological controls and occur in *in vitro* enzyme assays. Some inhibitors, essential to the homeostasis of the body, occur naturally in plasma. The acute phase reactants of plasma, α_2-antichymotrypsin, α_2-antitrypsin, anti-α-trypsin inhibitor, antithrombin III, and antiplasmin inhibit the proteolytic enzymes of digestion and coagulation.

Inhibitors and activators are therapeutic agents as well as controls of enzymatic assays in the laboratory. Heparin, a commonly used enzyme inhibitor, activates plasma antithrombin, the inhibitor of thrombin and other serine proteases of the coagulation pathway. Without heparin, antithrombin has low inhibitory activity, and without antithrombin, heparin has no anticoagulation activity. Other inhibitors are lead, an inhibitor of the enzymes of the porphyrin synthetic pathway, and the organic phosphate insecticides, inhibitors of esterases, including cholinesterase of nerve endings.

Activators accelerate enzyme reaction rates by promoting the active state of the substrate or the enzyme. Unlike cofactors, activators do not enter into the reaction as bisubstrates. Some activators are proteases, such as those that activate the plasma and pancreatic zymogens. Metal ions that activate enzymes do so by stabilizing the conformation of the active site.

Some divalent metal ions are essential to an enzyme's action. They play an integral role in the structure of the enzyme and cannot be readily exchanged, whereas others can be freely exchanged with the surrounding matrix. The anticoagulant EDTA chelates Ca^{2+} and Mg^{2+} thereby inactivating Ca^{2+}-dependent alkaline phosphatase. Creatine kinases and all other kinases require Mg^{2+} for phosphate transfer.

The substrates of allosteric enzymes serve as self-activators. Allosteric enzymes are polymers with two or more reactive sites. Binding of the first mole of substrate results in a conformational change that enhances the binding of additional substrate. Allosteric activation produces a sigmoidal curve, similar to that of the O_2 saturation curve of hemoglobin, and is inconsistent with the Michaelis–Menten model.

I. Temperature Effects

Change in the temperature of incubation alters the rate of the reaction and rate of denaturation of the enzyme. The higher the temperature, the more rapid the reaction rate, and the faster the denaturation of the enzyme. However, with computerized recording systems it is possible to perform enzyme assays in short periods of time, at higher temperatures with little or no denaturation during the assay period. Enzyme assays are performed at 37°, 30°, 25°, and 22°C. The recommended temperature for reference assays, is 30°C, but most clinical laboratories in the United States prefer to use a 37°C incubation temperature

The rate at which temperature changes the velocity of a reaction is fairly constant for the enzyme. A 0.1° temperature difference is readily detectable as a change in enzyme activity. A reaction conducted at 37°C is about twice as fast as one performed at 25°C (Appendix III). Temperature conversion factors are available for approximate conversion in comparative studies (Hafkenschied and Kholer, 1986; Junge and Grutzman, 1987). When the activity is converted it should be reported as converted, along with the method of conversion.

J. pH Effects

Modification of pH alters the enzyme's configuration and its reaction characteristics. An enzyme assay's optimal pH has a narrow range, and its buffer type

and concentration are critical. When the assay's pH is in the range of the substrate's pK, a change in pH changes the concentration of the disassociated and the undissociated substrate forms.

The type of buffer used in an assay should be one that has a pK_a within 1 pH unit of the optimum pH of the assay. Some buffers chelate metal ions and would be inappropriate for an assay of a metal requiring enzyme. Some products are ionized and require buffering. It is essential that the buffer be capable of maintaining the optimum pH for the reaction throughout the assay period for as high a concentration of product as is anticipated.

III. CLINICAL LABORATORY ENZYMOLOGY

A. Natural History of a Clinically Diagnostic Serum Enzyme

A number of variables affect the appearance of an enzyme in plasma. In the steady state, the amount of any single enzyme in serum is a function of its concentration in the cell, the total tissue mass, magnitude of injury to the cell, normal death of the cell, apoptosis, and the degradation rate of the enzyme in plasma or its half-life.

An enzyme's plasma concentration is proportional to its intracellular concentration or specific activity. When the an enzyme's cellular specific activity increases or deceases so will the amount of activity entering plasma. As an example, normal dog liver contains little or no intestinal alkaline phosphatase (IAP) and little is normally found in plasma. When a dog is treated with glucocorticoid, the hepatocellular IAP gene is expressed and a hyperglycosylated form of IAP appears in serum. Without cell death, the newly synthesized hepatic IAP-like enzyme enters plasma to increase the total serum AP activity (Solter and Hoffmann, 1995; Sanecki *et al.*, 1993). The same is true for a decrease in specific activity. In cyclosporin-treated dogs and rats, the hepatocyte ALT's specific activity decrease is accompanied by a decrease in plasma ALT activity (Rhodes *et al.*, 1986).

A change in the total amount of tissue mass results in a change in a serum enzyme's activity without induction or loss of integrity of the cell. The amount of serum CK increases in proportion to muscle mass. A decrease in liver size is accompanied by a decrease in hepatic enzymes in plasma.

Cells need not die to release their enzymes. A short period of hypoxia is sufficient to disrupt the integrity of a cell membrane and potentially allow soluble cytosolic enzymes to escape or "leak" into their surrounding matrix to be drained away in lymph (Mattenheimer and Friedel, 1977; Diederichs *et al.*, 1979; Lindena *et al.*, 1979). Alternatively, hypoxic or toxic injury results in exocytosis or formation of membrane blebs where their cytosolic enzymes are released into the surrounding plasma (Gores *et al.*, 1990). The shedding of blebs and release of cytosolic LDH in the absences of cell necrosis have been demonstrated in the isolated perfused rat liver (Lemasters *et al.*, 1983).

Another consideration is the detectability of an enzyme once it leaves the cell and is diluted by plasma or other body fluids. A small tissue, such as the adrenal glands, has specific enzymes. But, even if the adrenals were to undergo complete acute lysis, the enzymes would be so diluted by plasma they would be clinically undetectable.

Degradation of plasma enzymes' is poorly understood. An enzymes mass is not easily measured, but rather it is the rate of disappearance of its activity, half-life ($T_{1/2}$), that is accepted as the $T_{1/2}$ of the enzyme. An enzyme's $T_{1/2}$ is determined by grinding the tissue of origin, centrifugating and then extracting the enzyme from the supernatant. The extract is then injected into a homologous species and the disappearance rate plotted. It is assumed that the enzyme in the injected preparation is homogenous and the rate of degradation constant. Some enzymes, like GGT and AP, may be soluble but unless extracted with detergents, a variable amount of the activity occurs as a suspended, particulate high-molecular-weight form. These two forms of AP can be cleared at different rates. An example of how an enzyme complex's size makes a difference when calculating $T_{1/2}$ is apparent in the study of macroenzymes, naturally occurring endogenous enzyme–autoantibody complexes. Macroenzymes have greater $T_{1/2}$'s than their native holoenzyme. Their formation and delayed degradation increases total plasma enzyme activity to above the reference range, falsely alerting the clinician to tissue damage (Remaley and Wilding, 1989).

There are many reasons for the loss of enzyme activity, but it is principally a result of the change in functional conformation. Unlike the cytosol, plasma is not conducive to the prevention and reduction of oxidation of peptides. Intracellularly, enzymes are protected from degradation when bound to their substrates and cofactors. In plasma enzymes, substrates and cofactors are dispersed and binding uncommon, leaving the enzyme more susceptible to degradation.

Little is known about the clearance of enzyme peptide from plasma. Small ones are cleared from plasma into urine. Some are assumed to follow the same nonspecific proteolysis as the plasma enzymes of coagulation, complement, and the fibrinolytic pathways. Others are desialated, recognized by the asialoglyco-

protein receptor on the hepatocytes, endocytosed, and degraded by the phagolysosome. An example of the latter is intestinal AP, which has unsialated terminal galactose and leads to a short half-life (Kuhlenschmidt *et al.* 1991).

B. Development of a Clinical Enzyme Assay

An enzyme, to be valuable as a clinical diagnostic aid, must be economically and readily assayed, and reasonably reflect pathological change in a specific tissue, organ, or group of organs. Even when an enzyme meets these requirements, it may not be commonly accepted in the clinical laboratory. An example is the comparison of the three liver-specific enzymes, arginase (ARG), sorbitol dehydrogenase (SDH), and alanine-amino transferase (ALT). Serum arginase and SDH are specific, sensitive markers of hepatocyte injury in most species. Serum ALT is liver specific in only some species but is used in those species, dog and cat, in preference to SDH and ARG. The reason for this acceptance of ALT and not ARG is that the ALT assay is simpler to perform. In addition, the ALT assay became available first and a large amount of clinical background data for ALT was developed before ARG and SDH assays became commercially available.

An enzyme's clinical diagnostic sensitivity and specificity for a disease or organ injury must be critically evaluated. Diagnostic tests should have reasonably high sensitivity and very high specificity. However, since in most instances serum enzyme determinations are utilized as screening tests to detect organ involvement or disease, high sensitivity and reasonable specificity are most desirable. Although sensitivity and specificity data are not always available for enzymes in current usage, their credibility has been established by years of use. Development of new enzyme assays for clinical use demands evaluation of diagnostic sensitivity and specificity to achieve credibility.

Once cytoplasmic enzymes are free of the cell and in the extracellular fluids, plasma, cerebrospinal fluid (CSF), urine, or milk, their activity can be measured as an index of the cell's integrity. This is less true of the membrane-bound enzymes such as GGT and AP whose plasma activity may be altered without a loss of the cell's integrity. Right heart insufficiency results in portal blood stasis and hepatic hypoxia becomes evident by an increase in serum ALT, but not necessarily by light microscopic histopathology.

To be of diagnostic value, a serum enzyme must have more than high tissue-specific activity. Variables to be considered when determining diagnostic value of an enzyme are range of activity of individuals within the reference population, anatomic location of the cell, location of the enzyme in or on the cell, the total mass of the tissue or the cell type, and plasma $T_{1/2}$. A wide range in the reference population's enzyme activity plasma and serum, such as serum AP in ruminants, makes it difficult to determine when an individual's value becomes abnormal thereby lowering sensitivity. For experimental purposes, however, the same enzyme within an individual is frequently sufficiently constant from day to day to be used to detect sequential changes.

When a serum enzyme lacks high specificity for an organ, a second serum enzyme can be combined with the first to increase its diagnostic value. Serum AP activity increases in bone and liver disorders. To confirm that an increased AP is of hepatic origin, serum ALT or α-glutamyltransferase (GGT) are included in the hepatic enzyme profile.

Only a few of a cell's enzymes are of diagnostic significance in serum. One reason is their dilution in the plasma of the extracellular space. Another reason is the compartment into which the cell discharges its contents. As an example, the respiratory, intestinal, and urinary tracts have high GGT-specific activity, but when damaged there is no clinically significant change in serum GGT activity. Their major cell populations discharge their contents into the lumen of the alveolus, bowel, or tubule. The discharged intracellular enzymes are then diluted by urine, feces, and pulmonary transudates and eliminated from the body, rather than accumulated as they are in plasma.

Urine, gastric, intestinal and pulmonary fluids, blood cells and fixed tissue, and plasma can contain diagnostic enzymes. Clinical enzymology of nonplasma fluids present a problem in quantification not found in plasma. Homeostasis of plasma volume and solutes makes it possible to express enzyme activity per unit of serum volume as the reference point. However, in the nonplasma body samples, water content is not a constant and expressing enzyme activity as unit per volume inappropriate. In tissue, activity is expressed as unit per weight of tissue, protein, DNA, number of cells, or nuclei. Urinary enzyme activity is expressed per mass of creatinine, because urinary water volume is highly variable but creatinine is excreted in an approximate proportion to the body's skeletal muscle mass. Fluids from the lung, stomach, and intestine are of variable volume of water and provide no consistent reference point for expressing enzyme activity. Whichever point of reference is used for expressing enzyme activity, it must be one that will permit consistent valid results within and between assays and among laboratories.

Histochemical enzymology and enzyme-linked immunocytochemistry serve to identify cell types in neoplasms and enzyme deficiencies. Histochemical procedures can only be semiquantifiable by stringent simultaneous staining of patient and control samples of the same tissue thickness.

C. Validation of an Assay

To establish the validity of a new clinical assay, the accuracy of the reference and clinical procedures is compared. The accuracy of an assay refers to how closely the assay can measure the true value of the enzyme activity as determined by the reference method. This is desirable but not always possible with unstable enzymes. A commercially available assayed quality control serum can be used for stable enzymes. The new assay method can then be compared with the reference method at low, high, and medium amounts of activity anticipated in the clinical laboratory. If the method is new only from the standpoint of the species, it can be compared over the anticipated range and sample conditions encountered in-house with the established clinical procedure.

Statements concerning confidence limits and quality assurance are commonly omitted from reports concerning enzyme activity. Precision is of particular importance because of the instability of some enzymes. The precision is a measure of the assay's reproducibility, which is characterized by the standard deviation (SD) and coefficient of variation (CV). The CV should be determined at least two and preferably three amounts of enzyme activity, including the activity at which medical decisions are made. An acceptable CV at high enzyme activity does not ensure precision at the point at which decisions are most important. Within-run and between-run precision must be determined. Research and clinical chemistry laboratories' quality assurance programs should be stated in published reports of enzyme data (Harris, 1993; Henderson, 1993).

D. Specimen Requirements

Many enzymes require metallic ions for maximal activity, and plasma containing the metal chelating anticoagulants, EDTA, citrate, or oxalate is unsatisfactory for their assay. Heparinized plasma can be used in some procedures. When in doubt use serum.

Some serum enzymes are very stable at room temperature. Refrigeration and freezing preserve many enzymes, but others deteriorate even when frozen. Stability of an enzyme's activity in one species does not mean stability in a second (Jones, 1985a, 1985b). Horse serum SDH, but not cattle, sheep, or goat, is unstable at room temperature, refrigerated, and frozen (Horney *et al.*, 1993). Urine GGT is more stable at room temperature than frozen (Van Breda Vriesman, 1968). Freezing results in the concentration of salts and enzymes, and disaggregation of some weakly bonded peptides (Beck and Sammons, 1975; Adams *et al.*, 1985; Stokke, 1974). When thawed, the protomers may randomly reaggregate into inactive or less active configurations. A list of some enzymes and their storage characteristics are found in Table 12.2.

Hemolysis and lipemia can interfere with an enzyme assay, either increasing or decreasing apparent enzyme activity. In some cases hemolysis results in the release of RBC enzymes into plasma. White and red blood cells must be separated from serum as quickly as possible because hypoglycemic blood cells leak LDH and AST into serum even before hemolysis is apparent. Lipemia can cause a false decrease or increase in activity by nature of the light defraction. Lipemic samples are to be avoided, but if there is no other choice, background subtraction with a sample blank is an acceptable method of correcting for the defraction. The ability of various analyzers to eliminate or minimize the effect of hemolysis or lipemia is quite variable (Ryder *et al.*, 1991; Glick *et al.*, 1987). Although some dry chemistry analyzers appear to use a whole blood sample for enzyme analysis, they in fact incorporate a cell separation process such as filtration and the blood must still be free of hemolysis and lipemia.

Glassware or plasticware specimen collection vials must be carefully cleaned. Detergents interfere with many assays, and only a thorough rinsing will reduce the detergent residue to a point that will not infer with the assay. Whenever possible commercially available collection vials are recommended.

A complete clinical history is essential to the interpretations of laboratory values because many drugs are themselves the cause for changes in enzyme activity (Young *et al.*, 1975).

E. Assay of Enzymes in the Clinical Laboratory

Differences in performing clinical assays are inevitable. The constant improvement in technology requires assay procedures to be modified, but the slightest modification may change the stoichiometry of the assay. Modifications of an enzyme assay for whatever reason require revalidation to ensure that zero-order kinetics are not altered (Goren and Davis, 1986). Kits commercially prepared for human medicine are commonly modified for veterinary medicine. A change may appear to be a subtle, but, in fact, all changes require

TABLE 12.2 Enzyme Stability in Serum[a]

Enzyme	Storage	Time (days)	Activity (%)
α-Amylase (EC 3.2.1.1)	Room temperature	8	100
Cholinesterase (EC 3.1.1.8)	Room temperature	8	90
	0–4°C	8	90
	Frozen	8	94
Creatine kinase[b] (EC 2.7.3.2)	Room temperature	1	25
	0–4°C	1	32–65
	Frozen	8	25
Glutamate dehydrogenase (EC 1.4.1.2)	Room temperature	2	60
	0–4°C	2	60–100
	Frozen	2	60
Aspartate aminotransferase (EC 2.6.1.1)	Room temperature	4	90
	0–4°C	8	87
	Frozen	2	90
Alanine aminotranferase (EC 2.6.1.2)	Room temperature	4	75
	0–4°C	8	78
	Frozen	8	31
L-Lactate dehydrogenase (EC 1.1.1.27)	Room temperature	8	74–88
	0–4°C	8	81
	Frozen	8	81
Alkaline phosphatase (EC 3.1.3.1)	Room temperature	8	71
	0–4°C	8	71
	Frozen	8	68
Sorbitol dehydrogenase (EC 1.1.1.14; L-iditol dehydrogenase)	Species dependent		
	0–4°C	8	71

[b] An unactivated enzyme assay procedure was used to establish these values.

revalidation of the procedure. Even a subtle change such as using a fresh versus frozen sample requires revalidation. Some species have unusually high amounts of basal activity in serum, such as amylase in dogs and AST in horses, which may exceed limits of linearity for kits prepared for human use. Normal equine and bovine serum have a large amount of background absorption in the 340-nm spectrum that is not observed in people or many other species. This background requires a patient blank or the starting absorption limits must be set higher.

Clinical biochemical enzyme assays are generally either end point or kinetic procedures. In the end point or "fixed-time" procedure, a reaction is started by the addition of sample to a reaction mixture. After a fixed incubation period the reaction is ended by the addition of a reagent that destroys or inhibits the enzyme's activity. The amount of substrate used or product produced for that period of time is determined.

Kinetic or "continuous-monitoring" assay procedures require either manual or automatic sequential recording systems and are the most common methodology in automated analysis. Kinetic assays are more rapid, sensitive, accurate, and easily controlled than end point assays, because the reaction rates can be visualized throughout the time of the assay. A constant recording device permits the graphic display of the linearity of the reaction rate. The primary advantages of the kinetic method versus the end point method are as follows: (1) When high enzyme activities are encountered, the reaction rate can be determined before substrate is exhausted, whereas, in an end point assay, when the substrate is exhausted the assay must be repeated; and (2) if an activator is present, it can be detected on the graph.

When the rate of enzyme activity is very high, approximation of zero-order kinetics becomes limited. If precision quantification is required for an enzyme assay, zero-order kinetics must be maintained. Reagents for an assay generally have only sufficient substrate to maintain zero-order kinetics for the assay's incubation period or for two to three times greater than the upper limit of the enzyme's reference values. When a high level of precision is not required and the rate of the reaction exceed the limits of linearity, results are reported as "greater than" the established upper limit

of linearity. Alternatively, the assay can be repeated on a diluted sample, or the size of the sample can be reduced and appropriate corrections for dilution made.

Immunoassays for enzymes are available. Monoclonal antibody technology permits production of specific antienzyme antibodies. These enzyme-specific antibodies are used to isolate pure enzyme for further study and as an assay standard. Combining radiolabeling with immunoassays permits the development of very specific, sensitive assays for inactive, active, and inactivated enzymes such as the zymogens of serum pepsinogen and trypsinogen. High specificity and absence of cross-reactivity in the immune-enzyme assay have disadvantages in veterinary clinical diagnostics. Without species cross-reactivity the veterinary laboratory would have to maintain a number of species-specific immunoassays for the same enzyme. There is a good correlation between the immunoenzyme assays and enzyme activity assays that have been performed. Immunoassays tend to be more expensive and complex than enzyme activity assays and may never have the multiple species advantage of measuring enzyme activity.

F. Enzymuria

Renal diseases and nephrotoxicosis are reflected in changes in enzyme activity of urine (enzymuria), but not serum. The majority of the kidneys cells face the lumen of the nephron. When the cell's integrity is lost, their contents are discharged into the luminal contents, urine. Only a few plasma enzymes escape into urine normally, but when proteinuria of a glomerulopathy occurs more plasm proteins and enzymes appear in urine. Pancreatic amylase enzymuria is diagnostic of active pancreatitis in people, but not in dogs with the same disorder. To date, in veterinary medicine, enzymuria has only been of diagnostic value in renal disease, specifically in nephrotoxicities and renal transplantation rejection (Raab, 1972; Price, 1982; Junge *et al.*, 1986; Prescott, 1982).

The enzyme content of the nephrons proximal and distal tubular epithelium differs. Attempts to localize the damage through ratios and patterns of enzymuria have met with limited success. Subcellular localization of damage in the microvillus versus intracellular appears to be possible by measuring urinary AP and GGT as indicators of nephrotoxicosis and urinary N-acetylglucosamine (NAG) as an indicator of renal hypoxia in transplant rejection. Hyperenzymuria can be a more sensitive indicator of nephrotoxicities than are light microscopic histopathology or renal function tests.

The nephron as flow-through system does not allow for the accumulation of enzymes such as occurs in plasma. If the damage to the renal epithelium is transitory, the enzymes released may clear with the urine before sampling can occur. However, if nephrotoxicity is anticipated, say with specific nephrotoxic drugs, sequential urine enzyme analysis may serve to detect onset of toxicity.

Urinary enzyme assays are more difficult to perform than are serum enzyme assays. Enzyme activity's reference is generally activity per milligram of creatinine. Urine pH, molarity, and variety of solutes differ considerably from those of serum. Some urine solutes may be inhibitors at one concentration but not at another (Beck and Sammons, 1975; Adams *et al.*, 1985; Stokke, 1974). Depending on which enzyme is being measured, inhibitors may have to be removed by dialysis or if the inhibitor is a constant, the specific gravity may have to be standardized before the assay is performed. As an example, urea in high concentration disrupts weak hydrogen bonds. Enzymes dependent on aggregation by weak hydrogen bonds may be rendered inactive.

Few if any valid commercial enzyme assays for urine are available. Before a serum enzyme assay kit is used for urine, it must be revalidated. The validation must include high and low sensitivity, limits of linearity, presence of inhibitors or activators by molecular sieve column chromatography or dialysis, storage stability, reproducibility at various solute dilutions, capability of the buffers to maintain the reaction pH over the anticipated range of salt concentrations, and pH of the urine. Urine is a very poor environment for a molecule that depends on its conformation to function.

G. Quality Assurance

Quality control and quality assurance in clinical enzymology are part of the total quality management plans and procedures of a laboratory and differ little from other areas of the clinical laboratory. Quality control (QC) is that part of a laboratory's quality assurance program which is concerned with evaluation of testing proceedures and includes reagent and equipment checks, linearity checks, and statistical control procedures. Quality assurance is concerned with broader variables ranging from sampling and identification to data reporting and turnaround time (Tiersten, 1986).

Unlike many metabolites measured in clinical chemistry laboratories, some enzymes are insufficiently stable to lend themselves to a QC program. Assayed and unassayed lyophilized QC serum with normal or abnormal activity can be purchased from commercial

sources. Unassayed QC serum is less expensive and more appropriate than assayed QC serum in the individual laboratory where the methods differs from the method used by the commercial QC sera source. Commercial programs offer a number of benefits. They generally supply a uniform QC serum over a long period of time, keep track of its rate of deterioration, and permit individual laboratories to compare their results with other laboratories using the same or a different procedure. This comparison is of particular value when evaluating infrequently performed assays.

When the QC serum's value is established, the QC serum is used each time an assay is performed, the results are recorded, and the value is plotted on a graph. The within-run and within-day precisions should be better than the day-to-day precision, because day-to-day values reflect a greater number of variables, such as reagent decay and operator idiosyncrasies. The graph will show trends or progressive changes in the value of the QC. The trends serve to detect the procedural errors before the variable becomes so great that the data are valueless.

IV. ENZYME-LINKED DIAGNOSTICS

A. Enzyme Histochemistry and Cytochemistry

Cytochemical enzyme staining is a common cytological and histochemical diagnostic procedure for cell identification. Linking enzymes to monoclonal antibodies against specific cell epitopes increases the sensitivity and specificity of detecting undifferentiated neoplastic cells (Grindem *et al.*, 1986; Facklam and Kociba, 1986) and permits identification of cell structure and products by light and electron microscopy.

B. Immobilized Enzymes

The immobilization of enzymes adsorbed to solid supports such as membranes, beads, and tubes permits physical separation of the enzyme from its substrate, buffer, and product. This separation allows for the conservation of the enzyme in diagnostics and industrial preparative methodology. Immobilized enzyme techniques applied to the potentiometric technology of ion-selective electrodes facilitates the direct assay of glucose and urea in whole blood. Membrane bound glucose oxidase catalyzes the oxidation of glucose in the sample to form hydrogen peroxide. Upon contact with a platinum electrode, the hydrogen peroxide produces an electrical current that is measured by a voltmeter. The current produced is proportional to the glucose concentration. This procedure has the potential for *in vivo* monitoring of blood metabolites.

C. Enzyme Immunodiagnostics

Conjugation of enzyme with antibody has been a major development in competitive protein binding assays. Enzyme immunoassays (EIA) have are very sensitive, are low cost, eliminate radioisotope use, and aid automation (Kurstak, 1986). Antibody specificity determines the assay's specificity. Monoclonal antibodies are more specific than polyclonal antibodies. Although radioimmunoassay (RIA) is of equal specificity and more sensitive than EIA, EIA is frequently the preferred method. The EIA reagents have relatively long shelf lives, and involve little or no government regulation. The catalytic activity of the assay enzyme amplifies the antigen–antibody complex and has the potential for measuring more than one analyte at a time in the aliquot of sample. With the use of chemiluminescence in the detection phase of the EIA, the assays are equally or more sensitive than RIA and are likely to replace RIA procedures in the future.

Enzymes are the source of sensitivity of the EIA. An EIA for mouse IgG can detect 24,000 molecules of IgG/ml (Shalev *et al.*, 1980). The sensitivity of the EIA is increased by the use of radioactive substrates. By combining (^{3}H) AMP and AP, a detection system measuring 600 molecules/ml is produced (Harris *et al.*, 1979). Two basic EIA procedures are in use to measure soluble antigens bound to solid phases. They differ in the need to separate the enzyme–antibody complex from the enzyme–antibody–antigen complex before measuring the enzyme activity. The homogeneous or nonseparation enzyme-multiplied immunosorbent technique (EMIT, Syva, Palo Alto, California) does not require a separation step. The unique feature of EMIT is that the enzyme is inactive or has limited activity when complexed with antigen (Bastiani and Wilcox-Thole, 1982). It becomes activated when the enzyme–antigen aggregates with antibody. Free antigen of the sample competes with the enzyme-labeled antigen for the antibody to produce an inverse relationship between the amount of enzyme activity and the unlabeled analyte of the sample. The EMIT is limited by the enzyme–antigen–antibody complex kinetics and to low-molecular-weight analities in toxicology, pharmacology, and endocrinology.

The second EIA procedure is a heterogenous, or separation, enzyme-linked immunosorbent assay (ELISA). In contrast to the EMIT, the enzyme in the ELISA is always active. In the ELISA procedure, the unbound enzyme-antibody and bound enzyme-

antigen complexes must be separated. This separation step makes the ELISA a more complex procedure and more versatile than the EMIT. Immobilizing the ELISA complex on a solid phase simplifies the separation step to inverting the tube or plate over a sink. ELISA is often used for semiquantifiable systems in which color changes are detected with the unaided eye. They are used to detect parvovirus in canine feces and lymphosarcoma virus in feline blood.

Enzyme-linked immunosorbent histochemistry has provided a very specific diagnostic procedure. By using antibodies against various markers of cells it has become possible to separate cell types whose light and electron microscopic features are the same on the basis of their membrane epitopes.

D. Molecular Genetics

Linking EIA with nucleotide hybridization has resulted in the development of diagnostic procedures designed to detect the nucleotide sequence of aberrant genes and latent infectious diseases. Selective use of enzymes permits the isolation of specific RNA and DNA nucleotide sequences. Given the amino acid sequence of a protein, it or a portion of its gene's nucleotide sequence can be synthesized and labeled with a radioisotope or nonisotopic labels, to provide a probe. This probe can then be hybridized with the native DNA or RNA of a cell under investigation to locate mRNA, abnormal genes, infectious agents, or genetic defects.

Restriction endonucleases of bacteria are enzymes that cleave DNA at specific sites to produce fragments of DNA. The combination of restriction endonucleases and DNA probe hybridization has produced a new technology used to identify bacteria and viruses and to phenotype genetic diseases. In the future this technology has the potential of selecting desirable as well as undesirable genetic traits in pretransplanted ova.

V. ENZYMES OF CLINICAL DIAGNOSTIC IMPORTANCE

A. Alkaline Phosphatase

Alkaline phosphatase (AP; EC 3.1.3.1.) has been utilized as an indicator of hepatic injury since the 1920s and is now the subject of more publications than any other enzyme (Stigbrand *et al.*, 1984). The endogenous substrate for the alkaline phosphatases is unknown but the multiple forms of the enzyme are capable of hydrolyzing many phosphate esters (Bretaudiere and Spillman, 1983). Numerous substrates have been utilized for AP activity determination; however, most automated analyzers utilize *p*-nitrophenylphosphate as the substrate in kinetic assays. The buffer systems utilized also differ, resulting in considerable difference in apparent AP activity in a sample and, in turn, different reference values dependent on the procedure used.

Alkaline phosphatase is a glycoprotein with subunit masses ranging from 40 to 83 kDa. In serum, the APs exist principally as a dimer and are hydrophylic. High-molecular-weight hydrophobic forms of AP have been identified as a substantial portion of serum AP in humans with cholestasis (DeBroe *et al.*, 1985; Kihn *et al.*, 1991) but high-molecular-weight forms of AP make up less than 5% of AP in cholestatic dogs (Solter and Hoffmannn, unpublished data). In tissues the APs may exist as a tetramer (Hawrylak and Stinson, 1988).

The APs are found primarily in intestine, kidney, liver, and bone. Kidney and intestine have by far the greatest activity per gram of tissue. In liver, AP is located primarily on the bile canalicular membrane of hepatocytes of healthy dogs and rats; in man it is also present on the sinusoidal surfaces.

An extensive amount of effort and interest has been directed at the AP isoenzymes in an effort to increase the diagnostic specificity of the determination of serum AP. The isoenzymes of AP are as a result of both expression of different genes and differences in post-translational modifications of the enzyme. In man and higher primates, there are at least three genes coding for AP, but in other mammalian species there exist only two genes (Goldstein *et al.*, 1980). These are referred to as intestinal AP (IAP) and tissue unspecific alkaline phosphatase (UAP). With some exceptions, the intestinal gene is expressed only in intestine and the UAP gene is expressed in bone, liver, kidney, placenta, and in lesser quantities in most other organs. In rabbits both genes are expressed in liver, kidney, and intestine (Noguchi and Yamashita, 1987). In horses, the intestinal gene along with the tissue unspecific gene is expressed in kidney (Hoffmann *et al.*, 1983a). In dogs the intestinal gene is expressed in the liver under the influence of excess glucocorticoids to produce a hyperglycosylated form of intestinal AP (CAP) (Sanecki *et al.*, 1990).

Renal AP is generally not found in serum, whereas osseus and hepatic AP have been identified in the sera of all species studied. Intestinal AP is present in rat serum under normal conditions and increases following a meal or following gavage with corn oil (Eliakim *et al.*, 1991; Hoffmann *et al.*, 1994). Although IAP has been reported in serum of horses with and without gastrointestinal disorders (Blackmore and Elton, 1975), subsequent studies failed to identify IAP in horse serum under any conditions (Hoffmann *et al.*, 1983b;

Hank *et al.*, 1993). Likewise, little or no IAP activity is present in serum of dogs and cats.

The corticosteroid-induced isoenzyme (CAP) is present in serum of glucocorticoid treated dogs, dogs with hyperadrenalcorticism, and secondarily in some dogs with prolonged illness (Sanecki *et al.*, 1990; Solter *et al.*, 1993). Little or no CAP is present in normal dog serum.

Numerous techniques have been described for the separation, identification, and quantification of AP isoenzymes. However, in general, previous assays for AP isoenzymes depended on manual techniques such as electrophoretic separation, isoelectric focusing, heat inhibition, catalytic activity, and immunologic recognition (Hoffmann and Dorner, 1977a, 1977b; Wellman *et al.*, 1982; Saini and Saini, 1978a, 1978b). Because of the cumbersome and labor-intensive nature of these assays, they have been infrequently used. More recently an automated assay that allows the quantitative determination of CAP in dog serum or intestinal AP in rat serum has been developed and utilizes the selective inhibition of osseus and hepatic AP with levamisole (Hoffmann *et al.*, 1988; Hoffmann *et al.*, 1994). In addition, a technique has been described in human AP isoenzyme analysis that involves pretreatment of serum with wheat germ lectin to selectively precipitate osseus AP (Behr and Barnert, 1986; Rosalki and Foo, 1984). Pretreatment of serum with wheat germ lectin retards electrophoretic migration of osseus AP in both dog and rat serum, allowing clear separation of osseus and hepatic AP (Kidney and Jackson, 1988; Unakami *et al.*, 1989). A combination of pretreatment of serum with WGL to precipitate osseus AP and the automated assay for CAP or intestinal IAP, allows a quantitative determination of each of the AP isoenzymes in canine serum, equine serum, and rat serum (Sanecki *et al.*, 1993; Hank *et al.*, 1993; Hoffmann *et al.*, 1994). These latter assays not only allow quantitative analysis with good precision and accuracy, but provide a cost-effective analysis of a large number of samples.

Half-lives of the various AP isoenzymes in circulation are quite variable. In dogs the $T_{1/2}$ for intestinal, renal, and placental AP is less than 6 minutes, whereas for CAP and hepatic AP it is approximately 72 hours (Hoffmann and Dorner, 1977a). Th $T_{1/2}$ for osseus AP has not been determined but its presence in serum suggests it may be of the order of hepatic AP and CAP. The short half-life of intestinal or renal AP explains, in part, their absence in serum. Likewise, the short half-life for cat intestinal AP of approximately 2 minutes and horse intestinal AP of approximately 8 minutes explains the absence of these enzymes in the serum of these two species (Hoffmann and Dorner, 1977b; Hoffmann *et al.*, 1983b). Clearance studies of rat intestinal AP resulted in a biphasic disappearance of the enzyme with the first phase having a half-life of 2.8 minutes, while the second phase was 68.3 minutes (Young *et al.*, 1984). This slower disappearance of intestinal AP in the second phase may explain the appearance of intestinal AP in rat serum.

An increase in serum UAP is well recognized as an indicator of cholestasis in many species including dogs, rats, and man. Numerous studies have shown that this increase in AP activity in liver is a result of increased synthesis regulated either at the level of transcription or translation and is not a result of increased proliferation of cells as described for GGT (Kaplan *et al.*, 1983; Komoda *et al.*, 1984; Schlaeger, 1975; Seetharam 1986). Serum increases in AP activity following bile duct ligation begin at 6–7 hours postligation in rats and reach a maximum of 7–10 times normal serum AP activity at 12–24 hours post ligation (Kaplan *et al.*, 1983; Kaplan and Righetti, 1970; Schlaeger *et al.*, 1982; Schulz and Schlaeger, 1979). In dogs an increase is not seen until approximately 24 hours after ligation with a maximum of 30–40 times normal AP activity at 4–7 days (Guelfi *et al.*, 1982; Noonan and Meyer, 1979). To some extent these differences may be attributed to the absence of a gall bladder in rats. Hepatocellular necrosis in rats treated with CCl_4 results in a five- to sixfold increase in hepatic AP activity, but only a minimal one- to twofold increase in serum AP (Schlaeger *et al.*, 1982).

The mechanism of release of AP from liver and appearance in serum is poorly understood. Although there is evidence of disruptive changes within tight junctions of hepatocytes during cholestasis (Desmet and De Vos, 1982; Boyer, 1983), it is doubtful if these alterations permit passage of macromolecules the size of AP (Jones *et al.*, 1984; DeBroe *et al.*, 1985). Recent studies using a choledochocaval shunt model show that within 12 hours of shunting of bile or taurocholic acid into blood, there is marked induction of AP synthesis and appearance of AP on the basolateral membranes and a parallel increase of serum AP (Ogawa *et al.*, 1990). This occurs in the absence of any increase in biliary pressure and any evidence of alterations in tight junctions (Toyota *et al.*, 1983). Bile acids, therefore, appear to participate in both induction and release of AP into serum. Direct release of AP from the basolateral membrane or release of membrane fragments is a more likely hypothesis for the mechanism of increased AP activity into blood than is biliary regurgitation. Additionally, there is recent evidence that induction of hepatic UAP in short-term treatment of dogs with prednisone (4mg/Kg body weight) results in markedly increased UAP in hepatic tissue and serum with no increase in hepatic tissue bile acids as seen in dogs with bile duct ligation (Solter *et al.*, 1994). This treatment results in UAP on the sinusoidal as well as lateral and bile canalicular surfaces of hepatocytes where it

could be be directly released into serum or hepatic lymph in the absence of biliary regurgitation (Solter and Hoffmann, unpublished data). The release of AP into serum by some mechanism other than biliary regurgitation is also consistant with the observation that in the absence of cholestasis in dogs with spontaneous hyperadrenocorticism or chronically treated with glucocorticoids there is a marked increase in the serum CAP activity with CAP located on the sinusoidal membrane and situated for release into lymph or plasma (Solter and Hoffmann, 1995).

Both UAP and CAP are attached to the membrane by a unique glycan-phosphatidylinositol anchor at the C'-terminal end. Serum CAP and serum UAP have the glycan inositol remnant of that anchor (Solter and Hoffmann, 1995). It is likely that UAP and CAP are released from the membrane by a serum phosphatidylinositol-specific phospholipase D known to exist in serum (Low and Prasad, 1988).

Many drugs induce AP in dogs. Glucocorticoids are well-recognized inducers of AP with the initial response to be induction of the UAP or hepatic AP isoenzyme in the first 2 days followed by induction of CAP after 5–7 days (Solter *et al.*, 1994). Glucocorticoids have considerably less effect in other species. Serum CAP is a good screening test for hyperadrenocorticism because of its high sensitivity for detecting increased cortisol secretion. It is not a diagnostic test because of its low specificity for the diagnosis of hyperadrenocorticism (Solter *et al.*, 1993; Teske, *et al.*, 1989; Kidney and Jackson, 1988). Increased serum CAP activity observed in animals with disease processes other than hyperadrenocorticism is consistent with a presumed increase in cortisol secretion as indicated by reported abnormal low dose dexamethasone suppression tests or ACTH stimulation tests in dogs with nonadrenal disease (Chastain *et al.*, 1985: Kaplan *et al.*, 1995).

In young, growing animals osseus AP is the predominant form of serum AP which decreases as maturation progresses and the epiphysis closes. Osseus AP can be as much as 10-fold greater in a 1-month-old puppy than osseus AP in the adult dog (Sanecki *et al.*, 1993). In newborn foals osseus AP can be nearly 100-fold greater than in adult serum (Hank *et al.*, 1993). Serum osseus AP increases have been observed in dogs with hyperparathyroidism, renal disease, and osteosarcoma, with the greatest increases seen in selected cases of osteosarcoma. The diagnostic value of osseus AP in domestic and laboratory animals remains to be determined.

B. Creatine Kinase

Creatine kinase isoenzymes (CK; EC 2.7.3.2) catalyze the reversible phosphorylation of creatine to form creatine phosphate.

The four CK isoenzymes are dimers of two protomers with individual masses of 40 kDa. The first three isoenzymes are numbered CK_1, CK_2, and CK_3. Brain contains the homogenous CK^1 (CK-BB) made up of two B protomers. Skeletal and heart muscle mostly contain the homogenous CK^3 (CK-MM), which is made up of two M protomers and has the longest half-life of the canine CKs (Anderson, 1976; Argiroudis *et al.*, 1982; Boyd, 1983; Fugii *et al.*, 1980; Rapaport, 1975). The CK^2 is the hybrid isoenzyme (CK-MB). A fourth variant, CK-Mt, is located between the mitochondrial membranes and makes up 15% of the total cardiac CK activity.

A number of conditions and compounds inhibit CKs. All CKs are activated by Mg^{2+}, but inhibited by an excess. Due to rapid oxidation of sulfhydryl groups at the active site they are unstable when stored at room, refrigerator, or freezing temperatures. Thiol agents added to the assay reactivate the enzymes to a degree dependent on how long they have been inactive.

Numerous methods are available for serum CK isoenzyme separation. The most common ones are electrophoresis, ion-exchange chromatography, and immunological. The immunological methods require species-specific, monoclonal, anti-CK isoenzyme antibodies. Cross-reactivities between the antihuman CK isoenzymes and animal CKs are not reported. In human medicine the immunological methods are most commonly used. Because of the need for species-specific antibodies for the immunological methods, electrophoresis and ion-exchange chromatography remain the methods in use in animals.

In human medicine serum CK isoenzymes serve as sensitive and specific indicators of cardiac infarction (Moss and Henderson, 1994). Cardiac infarction is infrequently encountered in clinical veterinary medicine where serum CK isoenzymes are of no more diagnostic value than total serum CK determination. In experimental medicine CK isoenzymes are commonly used to quantify cardiac and muscular damage (Akatas *et al.*, 1993). In domestic species, CK isoenzyme analysis has not been shown to be of significant value (Hoffmann, 1990).

The CKs may be too sensitive as indicators of muscle damage for some clinical purposes. Many cell types contain CK, with the highest specific activity in skeletal muscle. Only large increases in serum CK activity are of clinical significance (Lewis, 1978). Small amounts of bruising and intramuscular injections produce detectable rises in serum CK. Moderate transient muscle ischemia following exercise (Querengaesser *et al.*, 1994), prolonged recumbency, convulsions, or shivering results in increased serum CK_2 and CK_3.

As a result of the short serum half-life of CK activity rapidly returns to normal after a muscle damaging

incident. This problem can be overcome by complementing muscle-specific CK with the less specific but longer circulating muscle AST activity. A small increase in serum CK and marked rise in AST serves as an indicator of muscle ischemia incident days before the day of sampling.

The magnitude of serum CK increase is reported to be a quantifiable marker of exercise and intramuscular injection muscle destruction (Akatas *et al.*, 1993; Lefebvre *et al.*, 1994; Janssen *et al.*, 1989). Frequent flaws in some of these studies are the assumptions that enzyme release occurs only on cell death, release into plasma is complete, and isoenzyme degradation rates are constants. They are not (Rapaport 1975; Akatas *et al.*, 1995). At best, serum CK elevation is a crude semiquantifiable marker of reversible and irreversible muscle injury. The greater the serum CK rise, the more muscle injured.

Nutritional vitamin E and selenium deficiency myopathies result in muscle membrane instability and release of CK into serum. In the absence of exercise-induced changes in otherwise clinically normal cattle and sheep, elevated total serum CK activity suggests a tentative diagnosis of vitamin E and or selenium deficiency (Smith *et al.*, 1994). Diagnosis is confirmed by the rapid return to normal of serum CK and RBC selenium metalloenzyme, glutathione peroxidase activity per unit of hemoglobin after treatment (Blincoe and Dye, 1958; Erskine *et al.*, 1990; Manktelow, 1963; Noguchi *et al.*, 1973; Orstadius *et al.*, 1959; Owen *et al.*, 1977; Turner and Finch, 1990; Van Vleet, 1975; Van Vleet *et al.*, 1975, 1977).

A large proportion of the brain is myelin, a lipoprotein. If CK activity is expressed per unit of protein or cell rather than per gram of tissue, the brain would have the highest CK-specific activity in the body. Little CK, however, is found in normal cerebrospinal fluid (CSF). Cerebrospinal fluid CK rises in demyelinating diseases and neoplasia in a number of disorders of dogs, cats, cattle, and horses, but the sensitivity of this rise is unclear (Edwin, 1970; Edwin and Jackman, 1974; Evans *et al.*, 1975; Furr and Tyler, 1990; Mayhew *et al.*, 1977; Smith and Healy, 1968; Wilson, 1977). Total serum CK increases in some neurologic disorders not as the result of brain CK entering serum, but as the result of muscle ischemia of convulsions and prolonged immobility (Smith and Healy, 1968).

C. Alanine Aminotransferase

Cytoplasmic alanine aminotransferase (ALT; EC 2.6.1.2) (formerly glutamic pyruvic transaminase; GPT) catalyzes the reversible transamination of L-alanine and 2-oxoglutarate to pyruvate and glutamate. Pyridoxal 5'-phosphate (PP) is the cofactor of ALT and other amino transferases that form the holoenzyme. The ALT apo- and its holoenzyme bound to PP are in serum in varying ratios.

Comparing ALT or AST assay results between laboratories requires knowledge of fundamental assay differences. To obtain maximum transferase activity, both the apo- and holoenzyme must be measured. To convert the inactive apoenzyme to its functional form, PP must be added to the specimen assay and a preincubation time allowed before the assay begins (Christen and Metzler, 1984; Horder and Rej, 1983). This preincubation inconveniently lengthens the assay period and some manufactures omit the addition of pyridoxal phosphate. The low serum ALT and AST activity in hemodialysis patients returns to normal when the patient is treated with pyridoxal phosphate (Chimata *et al.*, 1994). Cephalosporin treatment of rats and dogs results in a decrease in tissue and, consequently, serum ALT and AST activity (Bailey *et al.*, 1974; Dhami *et al.*, 1979; Rhodes *et al.*, 1986). The low activity is the result of a cephalosporin metabolite and is partially corrected by the addition of PP to the assay. The assays for ALT and AST are frequently linked to LDH. When the sample contians a high concentration of lactate, the lag phase of the assay is prolonged, interfering with the transaminase assay (Rogers and Osberg, 1974).

Human and porcine ALT are relatively stable at room temperature and refrigerated, but when frozen as much as 60% of its activity is lost. This freezing instability may be an expression of the ratio of apo- to holoenzyme (Rej, 1990).

In primates, dogs, cats, rabbits, and rats the liver has the greatest ALT-specific activity. In these species an increase in serum ALT is an established sensitive, specific indicator of hepatocyte damage. Muscle also contains ALT and care must be taken to distinguish between serum ALT of muscle versus liver origin (Valentine *et al.*, 1990). Hepatic, ALT-specific activity in pigs, horses, cattle, sheep, or goats is insuffcient to be of diagnostic value (Boyd, 1983).

D. Aspartate Aminotransferase

Aspartate aminotransferase (AST; EC 2.6.1.1) (formerly glutamic oxaloacetic transaminase; GOT), catalyzes the transamination of L-aspartate and 2-oxoglutarate to oxaloacetate and glutamate. It shares many of the features of ALT such as pyridoxal-5'-phosphate cofactor. The two AST isoenzymes, cytosolic and mitochondrial, have masses of about 92 kDa and multiple posttranslational forms. The presence of AST in so many tissues makes the serum enzyme a nonspecfic but sensitive marker of soft tissue damage,

but precludes its use as an organ-specific enzyme (Boyd, 1983). Although CK is a more specific marker of muscle damage than AST, AST is frequently used to complement CK changes.

The upper normal limit of equine serum AST activity is considerably greater than that of other species (Rej and Horder, 1983). Therefore, assays established for other species are usually unsatisfactory for the measurement of increased equine serum AST. When equine serum AST is high, the specimen is diluted one-half to one-third, or the sample volume reduced and corrected for. In contrast to ALT, serum AST is stable frozen, at room temperature, and refrigerated. RBC high specfic AST activity can be released into plasma before hemolysis is observed visually and causes a falsely elevated serum value.

E. Sorbitol Dehydrogenase

Sorbitol dehydrogenase (SDH; EC 1.1.1.14; also called iditol dehydrogenase, IDH) reversibly oxidizes D-sorbitol to D-fructose with the cofactor NAD (Gerlich, 1983; Lessing and McGuinness, 1982). Sheep SDH, a metalloenzyme, has a 152-kDa mass whose four identical protomers have catalytic sites containing a single loosely bound Zn^{2+} (Reiersen *et al.*, 1994, Lindstad *et al.*, 1994).

Early reports of *in vitro* instability of human serum SDHs discouraged its use in veterinary medicine. Considerable species variation is reported. Frozen equine and bovine serum lose as much as 25% of their SDH activity in a week (Horney *et al.*, 1993).

A commercial SDH assay kit with a relatively stable, lyophilized control is available. The assay of the reversible reaction is in the direction of sorbitol formation. Because sorbitol inhibition occurs when 10% of the substrate is converted to product, a high fructose substrate concentration is required. The fructose solution's syrup-like texture requires a thorough mixing of assay solution. High endogenous keto acids, such as pyruvate and ketones, are common in the plasma of ruminents. Before recording the change in absorbtion in an SDH assay, a preincubation period is required to permit the reduction of keto acids by the other serum dehydrogenases (Gerlich, 1983). With end point assays a patient blank is necessary because of the high starting absorbance of the SDH assay and the inherently high 340-nm background absorbance of equine and bovine serum. The enzyme is inhibited when its Zn^{2+} is chelated by EDTA and oxalate anticoagulants. Heparinized plasma can be used, but serum is preferred.

Although SDH mRNA is in a number of tissues (Estonius *et al.*, 1993) appreciable amounts of enzyme activity are only found in the testis and hepatocyte (Boyd, 1983). Hepatocytes have the high SDH specific activity and increased plasma SDH is consistent with hepatocyte damage in many species (Asquith *et al.*, 1980; Lechtenberg and Nagaraja, 1991). Although liver-specific in all species, previously established ALT usage in dogs and cats has limited SDH clinical usage as an indicator of hepatocellular damage to horses, cattle, sheep, and goats.

F. Lactate Dehydrogenase

With the cofactor NAD, lactate dehydrogenase (LDH; EC 1.1.1.27) catalyzes the reversible oxidation of pyruvate to L(+)-lactate. Lactate dehydrogenase isoenzymes are tetramers of two protomers with molecular weights of about 35 kDa. The equilibrium favors lactate formation but because pyruvate is an inhibitor, the preferred assay is in the direction of pyruvate formation where it is combined with a trapping agent.

The two homomers are LDH-1 (heart; LDH-HH) and LDH-5 (liver and muscle; LDH-LL or LDH-MM). The hybrids are LDH-2 ($LDH\text{-}H^1L^3$), LDH-3 ($LDH\text{-}H^2L^2$), and LDH-4 ($LDH\text{-}H^1L^3$). Multiple forms of LDH isoenzymes have been reported and a sixth form, LDH-X, has been reported in humans. Electrophoretic and immunoinhibition methods are used to separate the isoenzyme (Henderson, 1983). The instability of homomers LDH-4 and LDH-5 permits refrigeration of specimens for isoenzyme separation, but not freezing. If frozen, the LDH protomers disassociate. When thawed they randomly reassociate.

Tissues contain various amounts of the LDH isoenzymes. Damaged tissue is identified by ratios of electrophoretically seperated serum isoenzyme profiles (Prasse, 1969). There is 150-fold greater LDH activity in RBCs than an equal volumne of plasma. Thus, minimal hemolysis appreciably increases plasma LDH. Anticoagulants such as EDTA and oxalates indirectly inhibit the enzyme. Heparinized plasma or serum is the preferred sample.

Lactate dehydrogenase isoenzyme profiles were the first isoenzyme profiles used in veterinary medicine to detect organ injury (Moore and Feldman, 1974), but they proved to have little specificity and little diagnostic value. More organ-specific procedures such as serum CK have superseded serum LDH isoenzyme profiles.

G. Cholinesterase

Two distinctly different cholinesterases (ChE) are found in the body. Both have the neurotransmitter acetylcholine as their substrate. The acetylcholinesterase (AChE; EC 3.1.1.7), "true" ChE, is located at the

myoneural junction where it hydrolyzes acetylcholine to reestablish and prepare the junction for the next signal (Whittaker, 1983). The myoneural junction AChE is also found in RBC, mouse, pig brain, and rat liver. Only a small amount of AChE is in plasma.

The ChE of plasma is "pseudo" cholinesterase or butyrylcholinesterase (ButChE; EC 3.1.1.8), which hydrolyzes butyrylcholine four times faster than acetylcholine. It is located in plasma, white matter of the brain, liver, pancreas, and intestinal mucosa. Both AChE and ButChE have similar inhibitors and activators. Because AChE is low in plasma, plasma ButChE is used as an indicator of the AChE activity at the myoneural junction. People have as many as 12 macroenzymes of ButChE's single monomer in serum, with molecular weights ranging from 80 to 340 kDa. They occur in varying amounts between individuals. While activity in an individual is constant, the population's reference ranges are wide.

There are a number of inhibitors of the ChEs including drugs and naturally occurring substances. The two most clinically important ones are organophosphate insecticides and nerve gas. The phosphoryl group of the organophosphate irreversibly binds to the ChEs, preventing acetylcholine hydrolysis and thereby allowing persistent nerve stimulation.

High environmental background concentrations of organophosphates make it necessary to establish local geographic reference values. Following changes in serum ChE in animals is a strategy for biomonitoring environmental background levels of organophosphate contamination (Halbrook *et al.*, 1992). Decreases in serum ChE activity occur in people with acute infection, pulmonary infection, muscular dystrophy, chronic renal disease, and pregnancy, and insecticide intoxication.

Serum is the specimen of choice. Small amounts of hemolysis do not interfere with the assay. Serum ChEs have variable stability. Refrigerated, equine serum ChE is stable for at least a week (Plumlee *et al.*, 1994).

H. Lipase

Serum pancreatic lipase (EC 3.1.1.3) catalyzes the hydrolysis of triglycerides preferentially at the one and three positions, releasing two fatty acids and a 2'-monoglyceride. Human pancreatic lipase is a glycoprotein with a mass of about 48 kDa (Moss and Henderson, 1994). Bile salts and the cofactor, colipase, form a complex at the lipid surface necessary for lipase's optimum activity. Lipase and colipase are of pancreatic origin. The enzyme is water soluble, but the substrate is not. The reaction takes place at the water–lipid interphase of the lipid micelle where a micelle of bile salt, colipase, enzyme complex forms. Colipase is cleared by the kidney but lipase is not. This disproportionate loss of colipase versus lipase requires colipase addition to the assay for maxium lipase activity. Colipase addition to commercial lipase assays raised the reference ranges (Junge, 1983; Lott *et al.*, 1986).

Calcium enhances lipase activity. It is speculated to do that by trapping fatty acids, shifting the equilibrium to favor product production (Tietz and Shuey, 1993).

An appreciable amount of, but not all, canine serum lipase comes from the pancreas. Total pancreatectomy in the dog results in a depletion of 50–75% of serum lipase activity (Simpson *et al.*, 1991). Gastric mucosa lipase contributes appreciably to intestinal digestion, but not to serum activity.

Clinical serum lipase assays included all lipase forms. Serum lipases are stable at room temperature, refrigerated, and frozen. Lipoprotein lipase is normally low in serum, but following treatment with heparin it contributes a recordable amount of activity to the total serum lipase activity (Greten *et al.*, 1964).

When used alone serum lipase appears to be a more specific indicator of active exocrine pancreatitis than serum amylase (Strombeck *et al.*, 1981). In the dog and cat, pancreatitis results in serum lipase increases of two to three times greater than the upper reference range limit. Serum amylase is more commonly used than lipase to confirm active pancreatitis because the lipase assays are expensive and more difficult to perform than amylase assays. Idiopathic low magnitudes of increased serum lipase activity occur in diseases and treatments other than pancreatitis (Walter *et al.*, 1992, Cook *et al.*, 1993). Prednisone and dexamethasone treatment of dogs results in varying rises in serum lipase activity. These increases have led to the erroneous diagnosis of pancreatitis (Parent, 1982; Fittschen and Bellamy, 1984).

I. α-Amylase

Isoenzymes of α-amylases (EC 3.2.1.1) are Ca^{2+}-dependent metalloenzymes that randomly catalyze the internal hydrolysis of complex carbohydrates. As an example, they hydrolyze glycogen, at α-1-4 linkages to maltose and limited dextrins. They require activator ions such as Cl^+ or Br^+ (Wahlefeld, 1983). Plasma with metal chelating anticoagulants such as EDTA and citrate are inappropriate for an amylase assay. Amylase binds with other amylases and immunoglobulins to form macroamylases.

Many canine tissues, except salivary glands, contain α-amylase activity and its mRNA (Simpson *et al.*, 1989; Mocharla *et al.*, 1990). Canine α-amylase isoenzymes I through IV are electrophoretically classified. The slow

migrating isoamylase IV appears to contain the macroamylases. Seventy-seven percent of dogs have between 5 and 62% of their total serum α-amylase activity precipitable as macroamylase (Corazza *et al.*, 1994). Human serum macroamylases have longer half-lives than the α-amylase holoenzyme. This variation in half-lives of α-amylase may be the reason for the wide range in normal canine serum activity.

Pancreas and duodenum have as much as six times the specific α-amylase activity as that found in other organs, but normally make only a small contribution to total serum α-amylases (Jacobs, 1989; Simpson *et al.*, 1991). So little pancreatic amylase is in normal canine serum that it is of no value as a marker of exocrine pancreatic deficiency. Marked increases in total serum α-amylase activity, primarily isoamylase III, are a specific indicator of active exocrine pancreatitis (Jacobs *et al.*, 1982; Cook *et al.*, 1993). The specificity of serum amylase increase as a clinical marker of exocrine pancreatitis is reduced by minor increases in activity that accompany renal diseases and the idiopathic macroamylasemias (Polzin *et al.*, 1983; Corazza *et al.*, 1994). The diagnostic significance, if any, of hypermacroamylasemia in dogs and people is not established.

Although amylaseuria is of diagnostic value in the acute pancreatitis of people, it is not of value in dogs because canine serum α-amylase is not cleared by the kidney (Eto *et al.*, 1969; Johnson *et al.*, 1977; Hudson and Strombeck, 1978; Jacobs, 1988).

Three basic α-amylase assays are saccharogenic, amyloclastic, and chromogenic procedures. Saccharogenic procedures measure the rate of genesis of glucose from starch, but are inappropriate for canine α-amylase. Canine plasma contains α-amylase and a glucoamylase (O'Donnell and McGeeny, 1975; Franzini and Bonini, 1967). The canine glucoamylase hydrolyzes the terminal maltose, produced by α-amylase, to glucose, falsely elevating the apparent α-amylase activity. Canine serum glucoamylase varies with no correlation with α-amylase or pancreatitis (Rapp, 1962).

Amyloclastic α-amylase assays measure the rate of disappearance of the starch and are unaffected by canine glucoamylase activity. A blue dye is bound to the starch. As the starch is hydrolyzed the dye is freed and the rate of release of the blue dye provides the measure of enzyme activity. Amyloclastic starch procedures have given way to synthetic substrates. They are still retained for electrophoresis to measure relative isoamylase activities.

Chromogenic α-amylase assays using dyes bound to synthetic substrates are the current clinical amylase assay. Blocked α-4-nitrophenylmaltoheptaoside and non-blocked β-4-nitrophenylmaltoheptaoside are acceptable synthetic substates for the canine α-amylase with the former the better than the latter. Unblocked α-4-nitrophenymaltoheptaoside is unacceptable substrate for the dog (Braun *et al.*, 1990).

Commercial α-amylase kits are designed for human serum and may contain insufficient substrate for canine serum. Normal canine serum, α-amylase activity is five to six times greater than human serum amylase. Kits designed for human amylase are modified for dog serum by reducing the amount of serum used or by diluting the serum with saline.

J. γ-Glutamyltransferase

γ-glutamyltransferase (GGT; EC 2.3.2.2) is a dimeric, carboxypeptidase that cleaves C-terminal glutamyl groups from synthetic substrates and transfers them to peptides and other suitable acceptors such as glycylglycine (Shaw, 1983; IFCC Expert Panel on Enzymes, 1983). As a result of a large amount of variable post-translational glycosylation (Nemesanszky and Lott, 1985; Tate *et al.*, 1988), the number of GGT isoenzymes is unclear (Milne and Doxey, 1985). Its membrane association makes it difficult to determine its mass and a consistent tissue activity. Estimates of mass range from 90 to 350 kDa. Dilution of the saline suspended kidney homogenates with either urine or serum results in an increase in activity. This increase is thought to be the result of disassociation of aggregates of enzyme and the exposure of additional active sites.

The physiological function of GGT is speculated to be associated with glutathione metabolism. All cells except muscle have some cytosolic and membrane GGT activity (Boyd, 1983; Milne and Doxey, 1985). The greatest amount of cellular GGT is in the brush borders of renal and bile duct epithelium. Serum GGT is possibly derived from the high-molecular-weight fragments of liver that also contain AP, 5'-nucleotidase, L-leucyl-β-naphthylamindase, and nucleotide pyrophosphatase. Basal serum and hepatic GGT is very low in dogs, cats, and rats as compared to ruminants, horses, and guinea pigs.

Equine serum lost 50% of its activity when stored at −30°C for 4 weeks but appreciably less at −20°C (West, 1989). Urinary GGT is relatively stable at room temperature and refrigerated, but is inactivated to varying degrees by cryoconcentration with urea (Beck and Sammons, 1975; Adams *et al.*, 1985). Inactivation of urinary GGT can be prevented by dialysis or the addition of albumin or dimethylsulfoxide to the specimen before freezing (Stokke, 1974).

Cholestatic disorders of all species examined result in increased serum GGT activity (Braun *et al.*, 1987). Prednisolone treatment induces canine hepatic and se-

rum GGT activity with no evidence of cholestasis or bile duct hyperplasia (Solter *et al.*, 1994). The mechanism of GGT increases in serum with hepatic disease has only recently been addressed. Several models of hepatic disease in rats have been utilized to develop an understanding of the conditions and events leading to increased serum GGT. Carbon tetrachloride intoxication results in very little increase in serum GGT, which is consistent with the location of GGT primarily on biliary epithelial cells and its membranous attachment. Bile duct ligation results in a continuing increase of serum GGT activity, which parallels the increase in liver GGT activity (after day 1), which in turn is proportional or parallels the morphometrically determined bile duct volume (Bulle *et al.*, 1990; Leonard *et al.*, 1984) A second model utilizing treatment with alpha naphthyl isothiocyanate (ANIT) to cause biliary cell necrosis results in a peak activity at 1–2 days and then slow return to normal. Persistent exposure to ANIT results in biliary epithelial cell proliferation and continual increases in serum GGT (Leonard *et al.*, 1984). The initial response following both bile duct ligation and ANIT treatment is a very minimal increase of serum GGT activity with a majority of the GGT lost from liver. As opposed to induction of synthesis of GGT as described for hepatic AP in cholestasis, the increase in serum GGT in both models indicates that the increase in serum GGT activity is primarily dependent on the magnitude of biliary hyperplasia. In both bile duct ligation and ANIT treatment, biliary pressure increases either as a direct result of the ligation or blockage of the biliary system with necrotic epithelial cells. A unique model, choledochocaval fistula or shunt (CCS), allows the bile to flow directly from the bile duct into the anterior vena cava resulting in increased liver and blood bile acid concentration and increased bile flow and bile acid excretion rate but no increase in biliary pressure. This model resulted in serum GGT activity nearly equal to the BDL model, and suggests that bile acids or other bile constituents actually mediate the release of GGT into serum (Putzki *et al.*, 1989). Increased biliary pressure and regurgitation of GGT through tight junctions may not be necessary to cause an increase of serum GGT.

Cow, ewe, and doe colostrums, but not mare colostrum, contain a large amount of GGT. This colostrum GGT and the colostral antibodies are transferred across the neonate's intestinal wall into the plasma.

Renal GGT is the source of urinary GGT and with urinary AP, is a marker of active nephrotoxicity (Braun *et al.*, 1987; Greco *et al.*, 1985). On a day-to-day basis, urinary GGT in normal dogs and horses is relatively constant when expressed as enzyme per gram of urinary creatinine (Brobst *et al.*, 1986; Gossett *et al.*, 1987; Uechi, *et al.*, 1994). Reports of instabilty of urinary GGTs reveal the need for strict validation of specimen storage methods.

The induction of GGT provides a means for selecting and breeding of tolerance to toxins (Campbell, 1962; Towers *et al.*, 1983). There is a rapid elevation of serum GGT in sheep after a natural exposure to sporidesmin, the hepatotoxin, of facial eczema. This serum GGT increase is the result of bile duct proliferation. Only some lines of sheep experience this bile duct disease and increase in serum GGT. By selecting the sheep that do not experience the rise, an inherently sporidesmin-resistant line of sheep is obtained.

K. Trypsin

Trypsins (EC 3.4.21.4) are serine proteases that hydrolyze the peptide bonds formed by lysine or arginine with other amino acids. Trypsinogen originates in the pancreas and is converted to trypsin by intestinal enterokinase or trypsin itself. Trypsin isoenzymes I and II are immunologically separable and have differing physical characteristics. They are activated by Ca^{2+} and Mg^{2+}. Natural irreversible inhibitors occur in soy beans, lima beans and egg whites. Both pancreatic trypsinogen and trypsin occur in plasma where trypsin is inhibited by α_1-antitrypsin and α_2-macroglobulin. Trypsins have molecular masses of 23 and 26 kDa. They and their plasma zymogens are stable at room temperature for several days and when frozen for at least 5 years.

Fecal trypsin's proteolytic activity was formally used as a mark of pancreatic sufficiency. The tests used are described in greater detail in the chapter on pancreas. Their values are limited by their destruction in the intestinal track and interference by bacterial proteases.

Plasma trypsin, trypsinogen, and antitrypsin–trypsin complex occur in plasma in proportion to pancreatic mass. Immunoassays for canine serum trypsin-like materials (TLI) measure all three forms of trypsin. Increases in serum TLI occur in canine acute pancreatitis with a great range in activity. Serum TLI decreases in canine pancreatic exocrine insufficiency (Williams and Batt, 1983, 1988; Batt, 1993) and has become the diagnostic aid of choice in the diagnosis of pancreatic insufficiency (Simpson *et al.*, 1991).

L. Glutathione Peroxidase

Glutathione peroxidase (GPx; EC 1.11.1.9) is a metalloenzyme containing four Se^{+} per mole of enzyme. It catalyzes the oxidation of reduced glutathione by peroxide to form water and oxidized glutathione.

In assays, it is coupled to glutathione reductase to produce a detectable chromogen (Faraji *et al.*, 1987). There are two enzymes with glutathione peroxidase activity. One is selino-dependent selino-GPx, and the other a selino-independent glutathione transferase. The seleno-GPx can use either hydrogen peroxide or organic hydroperoxides as substrate. Glutathione transferase uses organic hydroperoxides as its substrates and has low activity with hydrogen peroxide (Lawrence *et al.*, 1978; Lee *et al.*, 1979). It does not have a correlation with Se concentration (Scholz *et al.*, 1981).

There is good direct correlation between RBC activity and tissue selenium concentration (Anderson *et al.*, 1978; Ammerman *et al.*,, 1980). This correlation has made whole blood selino-GPx a diagnostic aid in the detection of selenium deficiency. There are discrepancies concerning selino-GPx stability in frozen hemolysates (Sheppard and Miller, 1981; Jones, 1985a,b). This lack of prolonged stability has made GPx quality control difficult. Expression of the amount of GPx activity has been based on blood volume. GPx is an intracellular enzyme and it is more appropriate to use U/mg hemoglobin or U/dl red cells.

CHAPTER

13

Hepatic Function

BUD C. TENNANT

I. INTRODUCTION

The liver has an essential role in nutrient metabolism, including the control and maintenance of the blood glucose level, in detoxification and excretion of hydrophobic metabolites and xenobiotics, in the synthesis of most plasma proteins, and in digestion through synthesis, biliary secretion, and conservation of bile acids that are essential both for optimum hydrolysis of dietary fat and for intestinal absorption of fatty acids and other lipids, including fat-soluble vitamins. The clinical manifestations of hepatic disease are directly attributable to alterations in the metabolic, excretory, synthetic, and digestive functions of the liver. The liver has great functional reserve, and signs of hepatic failure often do not develop until 70% or more of the functional capacity of the liver is lost. Importantly, even when a major fraction of the hepatocellular mass has been lost in acute hepatic injury (e.g., acute hepatitis, hepatic necrosis), recovery is possible because of the unique capacity of the liver to regenerate.

Since this chapter was written originally for the first edition of this textbook by Dr. Charles E. Cornelius, remarkable advances have been made in our understanding of the pathophysiological, biochemical, and molecular mechanisms responsible for hepatic disease. Our current knowledge of veterinary hepatology is the result of the collective work of individuals from a variety of disciplines, including practicing veterinarians, biomedical scientists, and, more recently, molecular biologists. No one individual has had a more important or sustained impact than Dr. Cornelius, and no one has been more active in maintaining a comparative perspective on the subject (Cornelius, 1993). In this chapter, the biochemical mechanisms responsible for the cardinal clinical manifestations of hepatic insufficiency are summarized, and the biochemical tests useful in the assessment of hepatic function and in the clinical diagnosis of liver diseases are described. As in previous editions, the goal of this chapter is to provide students of veterinary medicine at all stages of career development with information useful for the diagnosis and treatment of the diseases of animal patients.

II. FUNCTIONAL ANATOMY

The liver develops embryologically as an outgrowth of the primitive gut. When fully developed, the liver is located cranial to the abdominal viscera and all other

abdominal organs, and between the splanchnic and systemic circulatory systems. Unlike other mammalian organs, afferent blood to the liver is derived from two sources, the hepatic artery and the hepatic portal vein. Efferent blood leaves the liver by the hepatic vein and enters the systemic circulation via the caudal vena cava. Of the afferent blood, 10–20% comes from the hepatic artery, and the remainder from the hepatic portal vein, which drains the pancreas, spleen, stomach, small intestine, and all but the most terminal portion of the large intestine.

Hepatocytes are the principal cell type of the liver and make up at least 70% of its total volume. Like other cells of epithelial origin, the hepatocyte is functionally polarized, and the plasma membrane contains three morphologically and functionally separate domains. The sinusoidal domain is equivalent to the basolateral domain of other epithelial cells. Contact between hepatocytes is made by the intercellular domain that contains desmosomes and gap junctions. The canalicular domain is responsible for many of the excretory functions of the liver and for the initial phase of bile formation.

Hepatocytes are arranged in single-cell plates separated by sinusoids lined by vascular endothelial cells and through which blood from both the hepatic artery and the hepatic portal vein flows. Hepatic sinusoids differ from other capillaries in two important ways. First, hepatocytes normally do not rest on a conventional basement membrane, but are separated from endothelial cells by the perisinusoidal space of Dissé. Second, fenestrations in the sinusoidal lining cells allow formation of hepatic lymph in the space of Dissé that has a protein content much higher than lymph formed in conventional capillary beds, which is an ultrafiltrate of plasma characteristically low in protein content.

Terminal branches of the hepatic artery and the hepatic portal vein enter the classical liver lobule at its periphery. Blood from both sources mixes and percolates through hepatic sinusoids, then leaves the lobule via the central vein and exits the liver through branches of the hepatic vein. Obstruction of hepatic-vein outflow increases formation of hepatic lymph that is rich in protein. This may occur in congestive right heart failure, in mechanical obstruction of hepatic-vein outflow (Budd–Chiari syndrome), and in early stages of hepatic fibrosis. In advanced cirrhosis, more dense intracellular matrix forms in the space of Dissé, "capillarization" of the sinusoid decreases fenestration of the sinusoidal lining cells, and hepatic lymph is low in protein content, closely resembling the lymph produced by other normal tissues (see discussion of ascites, later).

Bile is secreted initially into the canaliculus and flows toward the periphery of the lobule in channels formed by the canaliculi of adjacent cells. Such channels may involve canalicular membranes of two or as many as four or five hepatocytes. These ultimately converge at the periphery of the lobule, forming the canals of Herring, which drain into the bile ductules of the portal tracts and ultimately into larger bile ducts that form the biliary tree. Hepatic lymph also flows toward the periphery of the lobule in the space of Dissé and exists the lobule via lymphatics located in the portal tracts. Hepatic lymph leaves the liver primarily via the hilar lymphatics, the hilar lymph nodes, and the thoracic duct. A minor fraction of hepatic lymph leaves the liver by lymph vessels associated with the hepatic vein.

The peripheral border of the classical liver lobule is formed by the most peripheral row of hepatocytes (the terminal plate) and by two, three, or more portal tracks that contain branches of the hepatic artery and the hepatic portal vein, and a bile ductule (portal triad). Blood flows from terminal branches of the hepatic artery and hepatic portal vein to the center of the lobule and the central vein. Although this lobular structure remains important in the morphologic descriptions of pathological conditions, most analyses indicate that the functional unit of the liver is the hepatic acinus, in which blood flows from one portal track toward two or more terminal collecting veins (central veins). Significant structural heterogeneity has been demonstrated between periportal hepatocytes of the hepatic acinus (Zone 1), midzonal hepatocytes (Zone 2), and perivenous hepatocytes (Zone 3) (Jungermann and Katz, 1989).

Cells of the periportal zone are more likely to divide than other hepatocytes (Grisham, 1959). Mitochondria are larger and more numerous in periportal hepatocytes than in those of the pericentral zone (Loud, 1968; Uchiyama and Asari, 1984). Fenestrae of periportal sinusoidal endothelial cells are larger than those of the pericentral region, and this may account for selective uptake of large complex molecules such as remnants of chylomicrons in periportal hepatocytes (Wisse *et al.*, 1985).

A significant oxygen gradient has been demonstrated between sinusoids of the periportal and pericentral zones. The concentrations of glucose and amino acids that arrive primarily from the hepatic portal vein are higher in periportal sinusoids during digestion. Such differences in sinusoidal nutrient concentrations are associated with important metabolic differences between zones of the hepatic acinus. The enzymes of glycolysis, gluconeogenesis, and glycogen metabolism have different activities within zones of the acinus.

Glucose-6-phosphatase, phosphoenolpyruvate carboxykinase, and fructose-1,6-diphosphatase activities are higher in periportal hepatocytes, whereas glucokinase and pyruvate kinase activities are higher in pericentral hepatocytes (Zakim, 1996). Glycogen appears to be uniformly distributed within the cells of the acinus during steady-state conditions, but during fasting, glycogen of periportal hepatocytes is utilized more rapidly, and during feeding, it is replaced more rapidly.

Two plasma-membrane transporters for glucose are expressed in the liver. GLUT-2 is the primary glucose transporter of the liver and appears to be expressed in plasma membranes of all hepatocytes. The K_m of GLUT-2 for glucose is 15 to 20 m*M*, a glucose concentration that can be reached or exceeded in the hepatic portal vein during and after feeding. Under these conditions, glucose is transported into hepatocytes for the synthesis of glycogen, amino acids, and triglycerides. Between meals, the glucose concentration in the portal vein decreases to that of the peripheral circulation, approximately 5 m*M*. During the interdigestive period, the concentration of glucose in hepatocytes is high relative to that of sinusoidal blood and GLUT-2, facilitating transport of glucose from the cytoplasm of hepatocytes into the sinusoid and ultimately to the systemic circulation to meet the energy requirements of other tissues. The GLUT-1 transporter is present only in the plasma membranes of the most pericentral hepatocytes (Tal *et al.*, 1990). The affinity of GLUT-1 for glucose is much higher (K_m 1–2 m*M*) than that of GLUT-2. Interestingly, the GLUT-1 gene is transcribed and translated by hepatocytes throughout the acinus; however, by means of a posttranslational control mechanism, it is inserted into the plasma membrane of only pericentral hepatocytes (Bilir *et al.*, 1993).

The liver plays a critical role in the removal of ammonia from the blood. Two separate reactions within the liver acinus are involved. The concentration of ammonia in the periportal sinusoids is high compared to that in the pericentral sinusoids, and most ammonia entering the liver diffuses into the hepatocytes of Zones 1 and 2. Relatively small amounts of ammonia reach hepatocytes of Zone 3. Hepatocytes of Zones 1 and 2 contain carbamoyl phosphate synthase and other enzymes of the urea cycle, and urea is synthesized in these cells. Glutamine synthase actively is confined to hepatocytes located adjacent to the terminal hepatic vein, and in these cells, glutamine synthesis from ammonia occurs. The K_m of carbamoyl phosphate synthase for ammonia is approximately 1.2 m*M*, whereas that of glutamine synthase for ammonia is 0.3 m*M* (Gumucio and Berkowitz, 1992). Synthesis of urea from ammonia in periportal hepatocytes and that of glutamine from ammonia in pericentral hepatocytes represent complementary enzymatic processes. Ammonia is first seen by periportal hepatocytes that synthesize urea utilizing a low-affinity, high-capacity system. At the end of passage through the hepatic sinusoid, the small amount of ammonia remaining is removed for glutamine synthesis, which is a high-affinity, low-capacity mechanism.

Periportal and midzonal hepatocytes are responsible primarily for the bile salt-dependent fraction of bile formation and also may be the primary site of bile salt synthesis. The enzymes necessary for fatty acid synthesis, CoA carboxylase and fatty acid synthase, are located primarily in pericentral hepatocytes. Drug-metabolizing enzymes such as cytochrome P450 are located predominantly in midzonal and perivenous hepatocytes. This may explain why carbon tetrachloride induces hepatocellular damage and fatty metamorphosis preferentially in perivenous hepatocytes (Jungermann and Katz, 1989).

III. CLINICAL MANIFESTATIONS OF HEPATIC INSUFFICIENCY

A. Icterus

1. Bile Pigment, Metabolism, and Excretion

Bilirubin is a yellow pigment produced by enzymatic degradation of heme. Approximately 80% of the bilirubin produced by normal mammals is derived from the removal of aged erythrocytes from the circulation by the reticuloendothelial systems (Robinson *et al.*, 1966; Landau and Winchell, 1970). Degradation of heme from other sources (e.g., myoglobin, the cytochromes, peroxidase, and catalase) accounts for the remaining bilirubin production. The liver contains large amounts of microsomal cytochromes (P450 and b_5) and is the most important source of bilirubin from nonerythroid sources.

The initial step in bilirubin formation is the opening of the heme (ferroprotoporphyrin) ring at the α-methene bridge (Fig. 13.1). This reaction is catalyzed by microsomal heme oxygenase (Tenhunen *et al.*, 1969, 1970a,b), a mixed-function oxidase. Cytochrome P450 serves as the terminal oxidase and requires molecular oxygen and reduced nicotinamide adenine dinucleotide phosphate (NADPH). The products of the heme oxygenase reaction are equimolar amounts of iron, biliverdin, and carbon monoxide. This apparently is the only reaction in mammalian tissues in which carbon monoxide is produced, and quantitation of respiratory carbon monoxide can be used as a measure of heme catabolism and indirectly of bilirubin production.

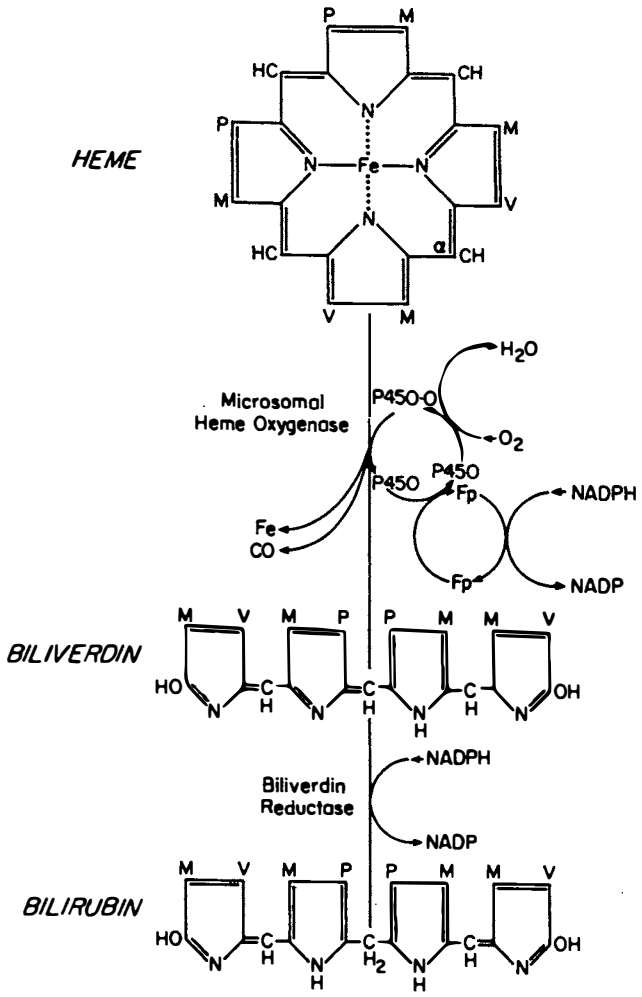

FIGURE 13.1 Enzymatic degradation of heme (ferroprotoporphyrin) and formation of bilirubin.

The second step in bilirubin formation is the reduction of biliverdin by the cytosolic enzyme biliverdin reductase, which, like heme oxygenase, requires NADPH (Tenhunen *et al.*, 1970a). In most mammals, hepatic biliverdin reductase activity is sufficient and is not normally rate-limiting in bilirubin synthesis. Biliverdin reductase activity, however, is almost completely lacking in birds, and in avian species, biliverdin is the major pigment of bile. Biliverdin also is found in significant quantities in the bile of certain mammalian species such as the rabbit, presumably because of decreased biliverdin reductase activity.

Heme oxygenase is most active in the tissues that are sites of erythrocyte removal and heme degradation. The spleen is the most important in this regard, followed by the liver and bone marrow (Tenhunen *et al.*, 1969, 1970b).

The kidney normally plays a minor role in heme degradation, but in hemolytic disorders, in which there is intravascular hemolysis and hemoglobinuria, the kidney has a quantitatively more important role. When intravascular hemolysis occurs, glomerular filtration of hemoglobin is initially prevented by the binding of hemoglobin to the plasma protein haptoglobin. When the haptoglobin binding capacity is exceeded, glomerular filtration of hemoglobin occurs and, depending on the amount filtered, some hemoglobin is reabsorbed by the tubular epithelium. This induces rapid formation of heme oxygenase in the tubule and significant bilirubin formation by the kidney (Pimstone *et al.*, 1971; de Schepper and Van Der Stock, 1972a,b). Renal degradation of hemoglobin may have a homeostatic function intended to conserve iron and minimize renal injury associated with hemoglobinuria (Pimstone, 1972).

2. *Hepatic Bilirubin Excretion*

Unconjugated bilirubin is nonpolar and is almost completely insoluble at physiologic pH. In plasma, unconjugated bilirubin is bound to albumin, which allows transport in stable aqueous solution to the liver. The hepatic mechanisms utilized in excretion of bilirubin, in general, are similar to those utilized by many other organic anions. The initial step is uptake of bilirubin by the hepatocyte. An organic acid binding protein that has been purified from basolateral (sinusoidal) plasma membranes of hepatocytes appears to play a role as both a bromosulfophthalein (BSP) and bilirubin transporter (Wolkoff *et al.*, 1985; Jacquemin *et al.*, 1991, 1994). Bilirubin disassociates from albumin prior to crossing the plasma membrane (Arias, 1974). The rate of hepatic uptake of bilirubin is regulated by the cytosolic protein ligandin (Y-protein), a low-molecular-weight cytosolic protein (4.4 to 4.6 kDa) that makes up approximately 5% of cytosolic liver protein and is identical to glutathione transferase B, the enzyme responsible for conjugation of BSP glutathione (Habig *et al.*, 1974; Kaplowitz *et al.*, 1973). In neonatal liver, the ligandin concentration is low and the neonate has a decreased capacity to excrete bilirubin. Ligandin synthesis can be induced by drugs such as phenobarbital that stimulate bilirubin excretion. Ligandin also binds other organic anions (e.g., porphyrins, BSP, indocyanine green, and certain steroid hormones such as cortisol), and intracellular binding appears to be important in their hepatic uptake.

Following uptake, bilirubin is converted to polar conjugates such as bilirubin diglucuronide. Conjugation with glucuronic acid is catalyzed by glucuronyl transferase, a microsomal enzyme that requires uridine diphosphoglyceronic acid (UDPG). Glucuronic acid esters of bilirubin have been identified in the bile of a variety of species, including the dog (Talafant, 1956),

rat (Grodsky and Carbone, 1957), and guinea pig (Schmid, 1956), and also in the bile of the horse, pig, cat, sheep, and cow (Cornelius *et al.*, 1960). Gordon *et al.* (1976) have confirmed that the diglucuronide is the major bilirubin conjugate excreted in canine bile. There is evidence, however, that the bile of dogs (Fevery *et al.*, 1971; Heirwegh *et al.*, 1975; Noir, 1976) and other species (Cornelius *et al.*, 1975a) also contain bilirubin conjugates of other carbohydrates, including glucose and xylose.

The final step in bilirubin excretion by the liver is the transport of conjugated bilirubin across the bile canaliculus into the biliary system. Intravenous infusion of unconjugated bilirubin at rates exceeding the maximal hepatic excretory capacity results in the accumulation of conjugated bilirubin in the plasma. This indicates that in the overall process by which bilirubin is transferred from plasma to bile, the rate-limiting step is canalicular transport of the conjugated pigment rather than hepatic conjugation or uptake (Arias *et al.*, 1961). The concentration gradient of bilirubin glucuronide between the hepatocyte and bile is reported to be as high as 150-fold. An ATP-dependent transport system located in the canalicular membrane is responsible for the specific unidirectional transfer of bilirubin glucuronides and conjugates of glutathione from the cytoplasma into the bile (Chowdhury *et al.*, 1994). This transport system is functionally distinct from the ATP-dependent bile acid canalicular transporter (Muller *et al.*, 1991; Arias *et al.*, 1993). Although mechanistically separate from bile acid excretion (Alpert *et al.*, 1969), bile salt excretion enhances bile flow and in so doing, increases the maximum transport capacity for bilirubin (Goresky *et al.*, 1974).

3. *Extrahepatic Metabolism of Bilirubin*

Following entry into bile, conjugated bilirubin enters the intestine. Conjugated bilirubin, a polar compound, is poorly absorbed in the small intestine and passes to the large intestine, where it is reduced to a series of colorless derivatives collectively called urobilinogens (stercobilinogens). Reduction is catalyzed by dehydrogenases of anaerobic colonic bacteria. In germ-free animals that lack intestinal microorganisms, bilirubin passes unaltered into the feces and urobilinogen is not produced (Gustafsson and Lanke, 1960).

Most of the urobilinogen formed in the colon is passed in the feces. A small fraction is absorbed into the portal circulation, transported to the liver, and excreted in the bile. A fraction (1 to 5%) of the absorbed urobilinogen passes into the general circulation and is excreted by the kidney. In the dog, urobilinogen is excreted by both glomerular filtration and tubular secretion, the latter being enhanced in acid urine (Levy *et al.*, 1968).

Although the liver is the principal site of bilirubin conjugation and excretion, alternative pathways have been demonstrated. In normal animals, these alternative mechanisms are of minor significance but may become quantitatively more important in liver disease. After total hepatectomy, dogs have been shown to develop moderate hyperbilirubinemia and bilirubinuria (Bollman and Mann, 1932). In addition to unconjugated bilirubin, the plasma of hepatectomized dogs contains the monoglucuronide (Hoffman *et al.*, 1960) and, in some studies, the diglucuronide of bilirubin (Royer *et al.*, 1965). The kidney and intestine both have been shown experimentally to be sites of conjugation of bilirubin (Royer *et al.*, 1974). Differences in extrahepatic metabolism of bilirubin may explain remarkable differences between species in the bilirubin levels reached after bile-duct obstruction (see following section).

4. *Icterus*

The clinical sign of *icterus* or *jaundice* develops when the yellow pigment bilirubin accumulates in plasma and other tissues. Yellow discoloration of tissues can first be noted by careful observation when the plasma bilirubin value exceeds 2 to 3 mg/dl and can be appreciated even by an untrained observer when the concentration exceeds 3 to 4 mg/dl. The correlation between the plasma bilirubin concentration and the degree of clinical icterus is not, however, perfect. Elevated plasma bilirubin values are usually present for one or more days before clinical icterus is apparent, and there may be a delay between the time plasma bilirubin returns to normal and the clearance of the yellow discoloration of tissues. Conjugated bilirubin is said to have a greater affinity for connective tissue than the unconjugated pigment, possibly because conjugated pigment is less acidly bound to albumin. The degree of clinical icterus is greater in cholestatic liver disease for any given level of serum bilirubin because of the predominantly conjugated hyperbilirubinemia (With, 1968).

Visible yellow discoloration of tissues is readily recognized in animals in the unpigmented sclera. The normal red color of the visible mucous membranes makes detection of a slight yellow cast more difficult. It is possible to apply pressure to the mucous membranes and temporarily reduce blood flow to the area, so that the underlying color of the tissue can be better assessed.

The color of plasma (icteric index) may be useful clinically in the evaluation of icterus. Normal canine, feline, and ovine plasma is often water-clear and free

of yellow color. The finding of yellow plasma in these species is highly suggestive of hyperbilirubinemia. Cattle absorb and transport significant quantities of carotene in plasma, and the icteric index, because it varies with the dietary intake of carotene, has limited use in this species. Equine plasma normally has a high icteric index, which in part is due to a plasma bilirubin concentration that normally is higher than that of other domestic species. There are other as yet uncharacterized non-carotene pigments, however, that also may contribute to the color of equine serum.

Notable species differences occur in the frequency with which icterus is observed in association with liver disease. In sheep and cattle dying of terminal hepatic insufficiency, there usually is a significant biochemical elevation in plasma bilirubin, but the value may not be sufficiently elevated to produce clinical icterus (Hjerpe *et al.*, 1971; Finn and Tennant, 1974). This is due possibly to the capacity of the liver to excrete bilirubin or to extrahepatic mechanisms for bilirubin excretion and/or degradation. Clinical icterus, when present in ruminants, is often associated with hemolytic anemia in which acute overproduction of bilirubin exceeds excretory capacity, for example, anaplasmosis in cattle and copper poisoning in sheep. In profound fatty liver, cattle that are critically ill may exhibit some degree of clinical icterus.

The assessment of clinical icterus in the horse is somewhat more complicated than in other species. The sclera and visible mucous membranes of most normal horses do not appear icteric, but in 10 to 15% of normal horses, a slight but definite (1/4) yellow discoloration of the sclera and/or oral mucous membranes can be detected (Tennant *et al.*, 1975). Scleral icterus of a moderate degree (2/4) may also be observed in horses with a variety of illnesses that do not involve the liver directly, such as pneumonia, impaction of the large intestine, and enteritis. Reduction in food intake is a common factor in such disorders, and fasting in the horse produces a rapid increase in plasma bilirubin concentration. In both hemolytic anemia and hepatic failure in the horse, the degree of icterus is usually remarkably greater than that seen under physiologic conditions or that is associated with reduced food intake. In the horse, severe clinical icterus is almost invariably present in acute hepatic necrosis (Thomsett, 1971; Tennant *et al.*, 1975). However, in chronic hepatic disease, icterus may be a more variable sign. In a series of 34 cases of hepatic cirrhosis in the horse, significant icterus was a presenting sign in 70% (Tennant *et al.*, 1975). Icterus was even less frequent (40%) in another series of horses with cirrhosis (Gibbons *et al.*, 1950).

The dog and cat appear to be intermediate between ruminants and the horse in their propensity to develop clinical icterus. Hemolytic disease, hepatocellular dysfunction, and extrahepatic bile-duct obstruction are characteristically associated with icterus in both dogs and cats. In experimental extrahepatic bile-duct obstruction in the dog, the plasma bilirubin increases at once following obstruction and clinical icterus is observed within I to 3 days. After 2 to 3 weeks, however, the plasma bilirubin of some dogs declines and clinical icterus may disappear. As in sheep and cattle, this may be related to adaptation of extrahepatic mechanisms of bilirubin excretion, particularly the kidney. The kidney of the dog is capable of adapting so that the rate of renal excretion of bilirubin equals the rate of formation. In cats with complete extrahepatic bile-duct obstruction, however, no such decrease is observed and persistent hyperbilirubinemia and deep icterus are characteristic.

B. Hepatic Encephalopathy

Hepatic encephalopathy is the syndrome of disturbances in cerebral function that accompany hepatic insufficiency or hepatic failure. The severity of neurologic signs may vary from subtle and intermittent behavioral changes associated with lethargy or stupor, to bizarre behavior, mania, convulsions, and coma (hepatic coma). Typically, such signs are associated with severe abnormalities in hepatic function.

Hepatic encephalopathy is a prominent clinical feature of hepatic failure in the horse. In one series of cases, 82% of horses presenting with acute hepatitis and 32% with cirrhosis had prominent neurologic abnormalities (Tennant *et al.*, 1973). Varying degrees of central-nervous derangement may be observed. Some horses stand quietly with the feet apart and the head lowered, nodding the head occasionally and appearing somnolent. The pupillary response to light may be normal or only moderately sluggish, but in some cases, vision is lost. Compulsive walking in a circle or in a single direction is often observed, and affected individuals may appear completely oblivious to their surroundings, walking over or through objects in their path ("walking disease"; Rose *et al.*, 1957). In fulminant cases, horses may become delirious with the head pressed forcibly against a wall for long periods of time. Horses may assume a variety of unusual positions or fall suddenly to the ground. Numerous unproductive attempts to rise are followed by periods of violent thrashing. When successful in rising, horses with hepatic encephalopathy may be completely uncontrollable, lunging forward violently and becoming a menace to attending personnel and equipment.

The syndrome of hepatic encephalopathy in cattle may have an abrupt onset but characteristically repre-

sents a terminal manifestation of chronic liver disease (Fowler, 1968; Pearson, 1977). Affected calves initially may appear dull, standing apart from other calves, and are anorectic. Other behavioral abnormalities may include violent charging or unusual, unrestrained bawling. Progressive dysmetria and ataxia are followed by recumbency, affected animals being unable to rise or to assume a sternal position. Tenesmus has been reported as a prominent clinical feature associated with dribbling of urine and prolapse of the rectal mucosa. Characteristically, death occurs within 2 days after onset of central nervous system signs (Finn and Tennant, 1974).

Hepatic encephalopathy is observed frequently in the dog with congenital or acquired portosystemic vascular shunts and may be one of the most prominent presenting clinical features of this form of liver disease (Ewing *et al.*, 1974; Barrett *et al.*, 1976; Cornelius *et al.*, 1975a,b; Audell *et al.*, 1974; Maddison, 1992). Neurologic signs associated with portosystemic shunts often are episodic and may be present for some months before recognition of the underlying hepatic disturbance. Depression and stupor with amaurotic blindness are observed in approximately half the cases of congenital portacaval shunts in dogs, with circling, head pressing, and intermittent seizures observed less frequently. Hepatic encephalopathy also has been associated with other primary diseases of the canine liver (Oliver, 1965; Strombeck *et al.*, 1975a; Center, 1996). Two cases of encephalopathy have been reported that were associated with apparent deficiency of argininosuccinate synthetase, a urea-cycle enzyme (Strombeck *et al.*, 1975b).

Hepatic encephalopathy must be differentiated clinically from primary inflammatory, degenerative, or neoplastic diseases of the brain, and this can be accomplished by demonstration of severe underlying hepatic disease. In the horse with acute hepatitis, clinical icterus almost always is present at the time neurologic signs are observed. In the dog and in cattle, frank clinical icterus is observed infrequently in animals with hepatic encephalopathy, so that tests of hepatic function and/or liver biopsy are required for confirmation. In cases of primary hyperammonemia due to deficiency of urea cycle enzymes, conventional hepatic function tests are not expected to be abnormal (Strombeck *et al.*, 1975b).

Factors responsible for the encephalopathy observed in hepatic failure are not completely understood. One of the important functions of the liver is the synthesis of urea from ammonia. Ammonia is present in normal peripheral blood at a concentration of 2 to 5 m*M*/liter. In portal venous blood, the concentration may be five times as high. Most of the ammonia in the hepatic portal vein is removed by the normal liver to form urea, with only a small fraction passing into the systemic circulation. In hepatic failure, synthesis of urea is reduced, and in the horse (Tennant *et al.*, 1975; Cornelius *et al.*, 1975b) and dog (Barrett *et al.*, 1976; Strombeck, 1975a), significant elevations of blood ammonia have been demonstrated. Ammonia has potent neurotoxic effects, and many of the neurologic signs of hepatic encephalopathy can be produced when toxic doses of ammonium salts are administered intravenously (Hooper, 1972).

The reactions of blood ammonia are determined by the physicochemical principles that apply to gases in solution and to the dissociation of weak bases. The ammonia:ammonium ion buffer system of blood can be described by the Henderson–Hasselbalch equation:

$$\mathrm{pH} = \mathrm{p}K_a - \log\left(\frac{\mathrm{NH_3}}{\mathrm{NH_4^+}}\right).$$

The pK_a for this system in the dog is approximately 9.1 (Bromberg *et al.*, 1960). This means that at physiologic pH (7.4), almost all of the ammonia of blood is ionized to form NH_4^+. As blood pH increases, the relative amount of free ammonia (NH_3) increases, and as the pH decreases, NH_3 decreases. Cells are almost impermeable to NH_4^+ but are permeable to NH_3, which passes through plasma membranes by nonionic diffusion (Stabenau *et al.*, 1959; Warren and Nathan, 1958; Castell and Moore, 1971). These principles are important in determining the amount of ammonia absorbed from the gastrointestinal tract or the amount that can pass from blood into brain tissue and other tissues (Dimski, 1994).

The potassium status, because of its influence on acid–base parameters, also may be an important determinant in NH_3 toxicity. Potassium deficiency ultimately favors the development of metabolic alkalosis, which in turn causes a shift in the $NH_3 \leftrightarrows NH_4^+$ equilibrium in the direction of the toxic free ammonia.

Blood ammonia ultimately is derived from dietary nitrogen. The gastrointestinal tract is the major source of blood NH_3, but NH_3 also is produced by other tissues, such as muscle and kidney. Renal ammonia is produced from glutamine and, to a lesser extent, from other amino acids. Synthesis of ammonium ion by the kidney represents a normal physiologic mechanism for H^+ excretion, and renal excretion of NH_4^+ is related directly to the pH gradient between blood and urine. The total urinary excretion of NH_4^+ is high in acid urine, and with alkaline urine, NH_4^+ excretion in the urine is low.

The conclusion that the gastrointestinal tract is the major source of blood NH_3 is based on the high concentration of NH_3 found in portal blood compared to that

in peripheral venous blood. Part of the ammonia in the hepatic portal vein is derived from the action of bacterial enzymes on dietary amino and amide nitrogen, and part is derived from urea, which is present in the normal secretions of the alimentary canal and is hydrolyzed by the bacterial urease within the lumen of the bowel, primarily in the stomach and large intestine. The question of whether intestinal urease is produced in part by mammalian cells or whether it is entirely of bacterial origin was the subject of controversy for many years. Using germfree rats, Levenson and Tennant (1963) demonstrated that intestinal urease was exclusively of bacteria in origin, and this observation has been confirmed in germfree dogs (Nance *et al.*, 1974).

The relative importance of NH_3 produced by intestinal bacteria and that produced from nonbacterial sources is still not fully known. Nance *et al.* (1971, 1974) and Nance and Kline (1971) have demonstrated that germfree dogs with Eck fistulae develop encephalopathy associated with hyperammonemia. This suggests that at least with vascular shunts, endogenous sources of NH_3 contribute significantly to encephalopathy. In this regard, the intestine can metabolize significant quantities of glutamine independent of intestinal bacteria, and approximately 30% of the glutamine nitrogen that reaches the intestine appears in the portal blood as NH_3/NH_4^+ (Windmueller and Spaeth, 1974).

The liver plays a critical role in maintenance of the blood glucose concentration, and marked hypoglycemia is sometimes associated with liver failure. In fulminant hepatic failure in the horse, the blood glucose has been reported in some cases to be as low as 20 mg/dl or less (Tennant *et al.*, 1975; Hjerpe, 1964). Hypoglycemia also has been reported in dogs with hepatic insufficiency associated with vascular shunts (Ewing *et al.*, 1974; Cornelius *et al.*, 1975a).

Other potentially neurotoxic substances have been suggested to be involved in the pathogenesis of hepatic encephalopathy, and the role of these factors has been reviewed (Maddison, 1992; Center, 1996). Indole and indolyl derivatives that are formed from tryptophan by intestinal bacteria have been suggested as encephalotoxic compounds capable of inducing hepatic coma (Zieve *et al.*, 1974). Other studies have incriminated short-chain fatty acids and, in experimental hepatic failure, total volatile fatty acids (VFAs) increase significantly prior to death (Zieve *et al.*, 1968). Increased plasma VFA concentrations also have been observed in spontaneous hepatic encephalopathy and, when infused intravenously into experimental animals, VFA produces cerebral depression followed by coma (Takahashi *et al.*, 1966). There is increasing evidence that cerebral edema is an important factor in the pathogenesis of hepatic encephalopathy (Butterworth, 1994), possibly related to increased glutamine accumulation within the brain.

C. Hepatic Photosensitivity

Photosensitivity results from hypersensitivity to sunlight induced by the presence of exogenous or endogenously produced photodynamic substances. Clinical signs of photosensitization develop when photosensitive animals are exposed to light and are caused by inflammation and necrosis of unpigmented skin (photodermatitis). A distinction is made between sunburn and photosensitization. In animals with unpigmented skin maintained for long periods of time indoors, abrupt exposure to sunlight may induce sunburn. Sunburn is a direct response of the unpigmented, unprotected skin to ultraviolet radiation (320 μm) in otherwise normal animals. Photosensitization is characteristically a more severe reaction of the skin caused by the interaction of a photodynamic substance and solar radiation. The effective wavelength of light causing photosensitization is determined by the absorption spectrum of the sensitizing substance, which may extend into the visible region of light. Sunburn and photosensitization also differ in that sunburn apparently can develop in the absence of molecular oxygen (Blum *et al.*, 1935), whereas photosensitization occurs only in the presence of molecular oxygen (Cook and Blum, 1959; Schothorst *et al.*, 1970). With sunburn, there is a characteristic delay between exposure to light and the development of erythema of the skin, soreness, or pruritus, whereas in photosensitization, initial clinical signs may be noted within minutes after exposure to sunlight (Clare, 1945).

Three forms of photosensitization are recognized in domestic animals. A primary cause of photosensitivity is ingestion of photodynamic substances not normally present in the diet. Examples are the diseases caused by ingestion of the poisonous plants *Hypericum perforatum* (St. John's wort, Klamath weed) and *Fagopyrum esculentum* (buckwheat). Administration of the parasiticide phenothiazine also causes a form of primary photosensitization. In such a case, the photosensitizing compound is phenothiazine sulfoxide, which penetrates the aqueous humor as well as the skin and may induce keratitis.

A second form of photosensitization results when the photosensitizing compound is produced endogenously. Congenital porphyria (pink tooth) of cattle is the best characterized of this group of diseases, although porphyria associated with photosensitization has also been observed in cats and swine. In cattle, there is a marked increase in production of uroporph-

yrin I, which is deposited in the teeth and bones and excreted in large quantities in the urine, causing the teeth and urine to fluoresce with ultraviolet light. There is also an increase in the protoporphyrin content of erythrocytes. Photodermatitis and hemolytic anemia that are present in the disease appear to be directly related to the photodynamic effects of these porphyrins (Kaneko *et al.*, 1971; Scott *et al.*, 1979).

A third group of diseases associated with photosensitivity are those that are secondary to hepatic disease (hepatic photosensitization). Photodermatitis associated with liver disease is recognized clinically only in herbivorous animals. Hepatic photosensitivity is observed in both acute and chronic liver diseases. Southdown sheep with congenital photosensitivity have no morphologic abnormalities of the liver in the early stages of the disease, but photodermatitis is always associated with significant biochemical defects in hepatic excretory function (Cornelius and Gronwall, 1968).

The photodynamic agent responsible for hepatic photosensitivity is phylloerythrin, a porphyrin derivative from chlorophyll (Clare, 1945; Rimington and Quin, 1934). Chlorophyll is converted to phylloerythrin by microorganisms of the rumen or large intestine that remove the magnesium atom from the chlorophyll molecule and that hydrolyze the phytyl and carboxymethoxy side chains (Quin *et al.*, 1935), leaving the porphyrin nucleus of chlorophyll intact. The phylloerythrin produced in the alimentary tract is excreted primarily in the feces. A small fraction of the relatively nonpolar porphyrin is absorbed into the portal circulation. In normal animals, phylloerythrin is quantitatively removed by the liver and excreted in the bile. Phylloerythrin is found in the bile and feces of herbivores consuming chlorophyll-containing diets and also may be demonstrated in other species that ingest chlorophyll. The comparatively large amounts excreted by ruminants are attributed to their frequently high chlorophyll intake and to the favorable conditions for microbial production of phylloerythrin within the gastrointestinal tract.

In hepatic insufficiency, phylloerythrin is incompletely cleared from the hepatic portal circulation, enters the systemic circulation, and ultimately accumulates in the skin. In the superficial layers of the skin, phylloerythrin absorbs solar energy, resulting in free radical formation. By causing peroxidation of cellular lipids and other cellular components, free radicals damage cellular organelles, including lysosomes. Inflammation and necrosis of the skin are the result of direct oxidative injury and the secondary action of lysosomal enzymes (Slater and Riley, 1965). The critical range of wavelengths (action spectrum) that results in photodermatitis in hepatic photosensitivity was shown in geeldikkop to be between 380 and 650 nm (Riemershmid and Quin, 1941) and in facial eczema between 400 and 620 nm (Clare, 1944), ranges consistent with the known absorption spectrum of phylloerythrin.

The types of hepatic disease of ruminants and horses associated with photosensitivity vary considerably, but the effects attributable to the photodynamic action of phylloerythrin are similar. The nature and severity of the cutaneous lesions depend upon the amount of phylloerythrin in the skin, and the intensity and duration of light exposure. The most common site of photodermatitis in the horse is the muzzle, which has a sparse protective covering of hair and often is unpigmented. Unpigmented areas of the distal extremities also are frequently affected (Tennant *et al.*, 1973; Fowler, 1965). In cattle, unpigmented areas of the muzzle, back, and escutcheon and the lateral aspects of teats are especially susceptible.

The areas of skin affected in sheep are those that receive the greatest exposure to light and that lack protection of pigment or wool. These include the ears, eyelids, face, lips, and coronets (Riemerschmid and Quin, 1941). The first clinical signs of photodermatitis in sheep may be apparent restlessness with shaking of the head or rubbing of affected parts. Individual animals may seek relief in the shade. Erythema and edema are the first cutaneous manifestations of photosensitization. Swelling of the lips, ears, and face have led to the descriptive terms "big head" and "facial eczema." Following edema, serum may ooze from damaged skin. Ultimately, second- or third-degree burns may develop, and the morbidity and mortality attributable to lesions of the skin may be more important than any other aspect of the underlying liver disease (Riemerschmid and Quin, 1941).

D. Ascites

The clinical sign of ascites is the result of abnormal accumulation of fluid in the peritoneal cavity. In normal animals, there is significant bidirectional movement of fluid, electrolytes, and, to a lesser degree, protein across the mesenteric capillary bed, through the interstitial space, and across the peritoneal mesothelium into the abdominal cavity. Such movements are determined by osmotic and hydrostatic forces that are described by Starling's equation: Plasma colloidal osmotic pressure minus ascitic fluid colloidal osmotic pressure equals portal capillary pressure minus intra-abdominal hydrostatic pressure. Normal portal capillary pressure on the arterial side of the capillary bed favors formation of an ultrafiltrate of plasma that is nearly protein free. On the venous side of the capillary

bed, reabsorption of interstitial fluid occurs because of a decrease in hydrostatic pressure below that of the colloidal osmotic pressure within the capillary bed exerted by plasma proteins, primarily albumin. Under normal conditions, only a small volume of free fluid is present in the peritoneal cavity.

During investigation of the mechanical factors that influence formation of lymph, Starling (1894) observed that obstruction of hepatic venous flow by ligation of the thoracic vena cava cranial to the site of entry of the hepatic veins produced a significant increase in lymph flow through the thoracic duct, and the lymph was high in protein. Obstruction of the hepatic portal vein as it entered the liver also produced an increase in the flow of thoracic duct lymph, but the protein content was low. Starling concluded that the increased flow of thoracic duct lymph following ligation of the thoracic vena cava arose from hepatic lymph, and after ligation of the portal vein, increased thoracic duct lymph was derived from mesenteric capillaries.

Hepatic lymph is produced primarily in the sinusoids and accounts normally for 25 to 50% of lymph flow in the thoracic duct (Brauer, 1963). In the dog (and other species), hepatic lymph has a much higher protein content than lymph from other tissues because of the unique permeability of the sinusoids to plasma proteins, which is due to the absence of a conventional basement membrane associated with hepatocytes and to fenestrations in the endothelial cells lining the sinusoids (Bissel and Maher, 1996; Field *et al.*, 1934). In experimental cirrhosis in the dog and other species, the flow rate of thoracic duct lymph is increased 2 to 5 times and the protein content is increased (Nix *et al.*, 1951a,b).

Ascites caused by cirrhosis of the liver is associated with increased portal vein pressure (portal hypertension). Experimental ligation of the portal vein before it enters the liver, however, results only in minimal and transient ascites or no ascites (Schilling *et al.*, 1952; Volwiler *et al.*, 1950; Berman and Hull, 1952). In the dog, ligation of either the hepatic vein (Orloff and Snyder, 1961a,b; Orloff *et al.*, 1963, 1964a,b, 1966) or the caudal vena cava at a site cranial to entry of the hepatic vein (Schilling *et al.*, 1952; Berman and Hull, 1952; Witte *et al.*, 1968, 1969a,b) produces prompt and intractable ascites. Lymph fluid has been observed to form droplets that "weep" from the surface of the liver following experimental obstruction of hepatic vein outflow (Hyatt *et al.*, 1955). Because of its origin as hepatic lymph, the protein content of such ascitic fluid may be 3.0 to 3.5 g/dl or higher. This observation is consistent with the clinical finding that the protein content of ascitic fluid in the initial stages of cirrhosis may be higher than that of conventional transudates (a modified transudate) because most of the ascitic fluid in cirrhosis is derived from the liver. As fibrosis and capillarization of the hepatic sinusoids becomes progressively more severe (Bissell and Maher, 1996), the protein content of hepatic lymph decreases and the protein content of ascitic fluid is low. It is probable that in many cases of cirrhosis, both hepatic lymph and mesenteric lymph are produced at increased rates and that ascites develops when the return of both sources of lymph to the systemic venous circulation fails to keep pace (Witte *et al.*, 1971a,b). The protein content of ascitic fluid in hepatic disease is influenced not only by the relative proportions of mesenteric and hepatic lymph that contribute to ascites, but also by the protein concentration of plasma. In advanced cirrhosis, when hypoproteinemia is present, the protein content of ascitic fluid can be expected to be proportionately low.

Although experimental portal vein obstruction per se does not result in ascites, only transient portal hypertension is actually produced by this procedure. When persistent portal hypertension is produced experimentally by aortic-portal anastomosis or when such anastomoses occur congenitally, the ascitic fluid has a characteristically low protein content because of its origin in the mesenteric capillary bed.

Serum albumin is produced exclusively in the liver and is the major determinant of plasma and tissue-fluid oncotic pressure. Hypoalbuminemia associated with chronic liver disease has been considered a factor contributing to the development of ascites, but current evidence suggests the role is not primary. For example, the intravascular and total-body albumin pool may not be greatly diminished in cirrhosis, although the concentrations of albumin in plasma may be decreased (Rothschild *et al.*, 1973; Witte *et al.*, 1971a,b). For ascites to develop, there must be an expansion in total body sodium and body water. It is known that excessive sodium chloride intake greatly enhances development of ascites (Berman and Hull, 1952), and ascites is preceded by increased sodium retention by the kidney. Aldosterone levels have been shown to be significantly increased in dogs with ascites caused by hepatic-vein obstruction, but the underlying mechanisms responsible for this steroid response are not resolved. The liver is the primary site of renin degradation, and it has been suggested that decreased degradation of renin by the diseased liver results in increased production of bradykinin, which in turn stimulates aldosterone release from the adrenal cortex (Orloff *et al.*, 1965; Howards *et al.*, 1968).

When caused by liver disease, ascites is indicative of a chronic process and characteristically is associated with cirrhosis. There are important species differences in the occurrence of ascites in chronic liver disease. In

dogs and cats with advanced hepatic cirrhosis, ascites is a relatively common sign, but it is almost never observed in horses with cirrhosis (Tennant *et al.*, 1975). Conspicuous ascites also is unusual in cattle with cirrhosis (Finn and Tennant, 1974; Whitlock and Brown, 1969), but has been observed at necropsy (Pearson, 1977). Ascites has been reported in association with liver abscesses in cattle where thrombosis of the hepatic vein adjacent to the abscess causes marked hepatomegaly (Breeze *et al.*, 1976; Selman *et al.*, 1974). In sheep, ascites has been observed in cirrhosis, but is unusual with the sclerosing cholangitis associated with fascioliasis (Hjerpe *et al.*, 1971).

It is important clinically to differentiate ascites caused by liver disease from ascites associated with other primary diseases. The distinction is made based on history and clinical signs, and on the examination of ascitic fluid. Biochemical and cytologic examinations of ascitic fluid may be useful but alone are seldom diagnostic. The protein concentration of ascitic fluid in cirrhosis is characteristically low (Center, 1996) but is variable depending on the stage of disease. In early stages, the protein content of ascitic fluid may exceed 2 to 2.5 g/dl because it is a reflection of the high protein content of lymph from the liver. Later, when serum albumin has decreased and when sinusoidal fibrosis and capillarization have developed, the protein content of hepatic lymph is low and ascitic fluid will be low in protein (1–1.5 g/dl). The protein content of ascitic fluid is generally high in peritonitis and in neoplastic diseases of the abdomen, and protein concentrations below 1.5 to 2.0 g/dl are unusual in ascitic fluid. Total nucleated cell counts in ascitic fluid from dogs with cirrhosis are seldom greater than 1000 to 2000 μl. Bloody or turbid fluid typically results from inflammatory or neoplastic processes (e.g., feline infectious peritonitis, bacterial peritonitis, neoplasia), and nucleated cell counts are elevated. Fluid deeply stained with bile pigment indicates a direct communication between the biliary system and the peritoneal cavity. In domestic animals, so-called "bile ascites" or bile peritonitis is a problem recognized most frequently in the dog and cat, caused by abdominal trauma.

IV. LABORATORY ASSESSMENT OF HEPATIC FUNCTION

The pathogenesis of hepatic disease in domestic animal species is remarkably complex, involving acute and chronic forms of hepatitis, cirrhosis, bile-duct obstruction, intrahepatic forms of cholestasis, and neoplasia. The frequency of these diseases varies with species breed, age, and, in some cases, with environment (diet, geographic location). The differential diagnosis of hepatic disease involves the evaluation of clinical history, physical examination, biochemical tests, hepatic imaging, and histopathologic examination of hepatic biopsies. In the following section, the biochemical tests that are used for the assessment of hepatic disease are described.

There are several diagnostic categories with which the clinician dealing with problems of liver disease must be concerned. In clinical patients with a history and signs suggestive of hepatic disease, laboratory tests are used for confirmation. Laboratory tests are used to assess the severity of liver disease, to establish prognosis, to define treatable causes of the complications of hepatic insufficiency (e.g., ascites, encephalopathy), and to monitor progress of hepatic disease. Finally, biochemical tests of hepatic function may be performed on clinically healthy patients that are known to have a high risk of developing liver disease, e.g., exposure to infectious agents that cause hepatitis, or a familial history of chronic liver disease requiring screening for genetically determined diseases.

A. Hepatic Enzymes

The serum enzymes used routinely in clinical diagnosis are present in high concentration in the liver. In hepatocellular or in cholestatic forms of liver injury, these hepatic enzymes are released into the serum, and increased serum activity becomes useful diagnostically. The duration of elevation in the serum activity of enzymes of hepatic origin is dependent on a variety of factors, including molecular size, intracellular location, rate of plasma clearance, rate of enzyme inactivation, and, in some cases (e.g., alkaline phosphatase [AP] and gamma glutamyl transpeptidase [GGT]), the rate of increased hepatic production.

The serum enzyme activities that are elevated when hepatic necrosis is present are alanine aminotransferase (ALT), aspartate aminotransferase (AST), ornithine carbamoyltransferase (OCT), glutamic dehydrogenase (GD), sorbitol dehydrogenase (SDH), and arginase. Elevated serum activities that suggest cholestasis (intrahepatic or extrahepatic) are AP, GGT, and 5′ nucleotidase (5′-ND).

1. Serum Alanine and Aspartate Aminotransferases

In all domestic species, the activity of AST is high in the liver and, in acute and chronic liver injury, the AST activity of serum is increased. AST activity also is high in kidney, pancreas, and erythrocytes and, when cells of these tissues are damaged, the AST activity of serum also can be expected to increase. There is

TABLE 13.1 Serum Alanine Aminotransferase (ALT) Activity of Normal Animals

no simple and specific method for determining the origin of increased serum AST activity, and additional tests are required. Two isozymes of AST are present in the liver; one is mitochondrial and the other is from the cytoplasm.

The ALT activity of the liver of dogs and cats also is high. Significant ALT activity is confined to the cytoplasm of the liver. Elevation in the activity of serum ALT (Table 13.1) is considered to be specific for hepatic injury in dogs and cats, and in small animals with hepatocellular injury, the fractional increase in activity of ALT is 4–8 times higher than the corresponding increase in AST (Center, 1996). In the large domestic species, the activity of ALT in the liver is low, and in liver injury the serum ALT is not remarkably elevated.

AST in all domestic species may be increased in skeletal muscle disease, including trauma (e.g., intramuscular injections). To differentiate AST elevations due to liver disease from those due to muscle disease, it is possible to measure serum creatine kinase (CK). In muscle disease, AST and CK both would be expected to be elevated. In acute muscle injury, CK may appear before AST is maximally elevated, and CK activity may decrease before AST activity fully declines. When myopathy coincides with liver disease in small animals, the ALT measurement may be useful, but severe muscle disease may be associated with increased serum ALT activity.

The major value of serum AST and ALT measurements is in detecting hepatocellular injury and in monitoring the progress in acute hepatitis. Both enzymes are increased in many hepatic diseases of small domestic animals and have limited value in differential diagnosis. Aminotransferases are considered useful in differentiating hepatocellular from cholestatic forms of liver injury. In severe liver disease, however, both hepatocellular and cholestatic forms of hepatic disease often coexist. Very high aminotransferase levels suggest acute hepatitis, but more modest increases in aminotransferase activity are seen in many types of liver disease, including chronic hepatocellular disease, cirrhosis, parasitic hepatopathy, and primary or metastatic neoplasia.

2. *Sorbitol Dehydrogenase*

Because of the lack of significant ALT activity in the livers of large domestic animals (Cornelius, 1963; Keller *et al.*, 1985), other liver-specific enzymes have been developed. The serum activity of SDH (Table 13.2) has been shown to be useful in assessment of hepatocellular injury in most domestic species, including dogs, horses, and ruminants, but is used primarily as a liver-specific enzyme in large domestic animals. SDH activity is not stable in serum and declines rapidly. Analysis therefore should be performed as soon after the sample is taken as possible and optimally within 8–12 hours.

3. *Arginase*

Arginase is present in significant concentration only in the liver of ureotelic mammals (Cornelius *et al.*, 1963; Dittrich *et al.*, 1974), and a relatively simple assay is available for its measurements (Mia and Koger, 1978). The plasma arginase activity in acute liver injury returns to normal more rapidly than ALT or AST (Cornelius *et al.*, 1963). In progressive hepatic necrosis, serum arginase activity remains elevated and may suggest an unfavorable prognosis. Serum arginase elevations have been demonstrated in naturally occurring liver disease of horses (Wolf *et al.*, 1967), cattle, sheep (Ross, 1966), goats (Adam *et al.*, 1974), and dogs (Harvey and Hoe, 1971). When serum arginase and

GGT are measured simultaneously, their respective specificities for necrosis and cholestasis provide valuable diagnostic information (Noonan and Meyer, 1979).

4. *Glutamic Dehydrogenase*

GD has been shown to be of value as an enzyme for assessing hepatic necrosis in sheep, goats, and cattle (Table 13.3). The enzyme is highly concentrated in ovine and bovine liver (Boyd, 1962; Keller, 1971), as well as in the livers of other domestic species (Keller *et al.*, 1985). In ruminants, GD has been reported to be elevated in hepatic necrosis (Fowler, 1971; Boyd, 1962); at parturition (Treacher and Collis, 1977); and associated with bile-duct obstruction (Ford and Gopinath, 1976).

5. *Ornithine Carbamoyltransferase*

OCT is also considered a liver-specific enzyme for the detection of hepatocellular necrosis in domestic species (Treacher and Sansom, 1969). Nearly all OCT activity is confined to the liver of cattle (Treacher and Collis, 1977) and of pigs (Dittrich *et al.*, 1974). OCT and ALT are similar in sensitivity as diagnostic tests for hepatic necrosis in the dog (Litchfield and Garland, 1974). Markiewicz *et al.* (1975) have reported that the serum activity of OCT is correlated with the severity of hepatic fascioliasis in cattle. OCT also has been suggested as a useful marker for hepatocellular injury in swine (Wilson *et al.*, 1972).

6. *Serum Alkaline Phosphatase*

The APs are a group of zinc metalloenzymes that are present in most tissues. High concentrations are found in the intestine, kidney, bone, and liver. Light and electron microscopic studies have demonstrated that alkaline phosphatase activity is highest on the absorptive or secretory surfaces of cells (Kaplan, 1972). Within liver cells, alkaline phosphatase is bound to membranes, and when liver homogenates are subjected to high-speed centrifugation, alkaline phosphatase activity sediments primarily with the microsomal and plasma membrane fractions (Emmelot *et al.*, 1964).

The actual physiologic functions of alkaline phosphatase are not fully understood. Localization of the enzyme to cell surfaces known to be responsible for active secretion or absorption suggests a role in membrane transport. There is circumstantial evidence that the alkaline phosphatase of osteoblasts may be involved in bone calcification. Activity against nucleotides (natural and artificial) may indicate a role in nucleic acid metabolism. It has been suggested that intestinal calcium-stimulated adenosine triphosphatase, which has a role in active calcium transport, and alkaline phosphatase are different activities of the same enzyme (Haussler *et al.*, 1970). A similar relationship has been demonstrated between alkaline phosphatase and other enzymes involved in active transport; for example, sodium, potassium-stimulated adenosine triphosphatase of several tissues, including the liver, has significant hydrolytic activity against substrates of alkaline phosphatase such as *p*-nitrophenyl phosphate (Ahmed and Judah, 1964).

In normal animals, the AP of serum (Table 13.4) originates primarily from liver and bone (Rogers, 1976; Hoffman and Dorner, 1975). Elevations of serum AP are observed in normal growing animals or in adult animals with increased osteoblastic activity. Serum AP activity may be elevated in both acute and chronic liver diseases, but marked elevations are indicative

of cholestasis, with the highest plasma concentrations observed in animals with cholangitis, biliary cirrhosis, or extrahepatic bile-duct obstruction.

The alkaline phosphatase isozymes of various tissues may be differentiated on the basis of differences in heat stability, urea denaturation, and inhibition by L-phenylalanine, or by electrophoretic mobility (Nagode *et al.*, 1969a,b; Ruegnitz and Schwartz, 1971). Alternatively, determination of the origin and significance of elevated serum AP can be facilitated by measuring other serum enzymes that are more specific for biliary tract disease. These include leucine aminopeptidase (Everett *et al.*, 1977), 5'-nucleotidase (Righetti and Kaplan, 1972), and GGT. When the serum AP is significantly elevated, overt clinical signs may allow separation of diseases of the liver from those of other tissues such as bone.

In contrast to serum AST and ALT, elevations in AP are not due simply to leakage of enzyme through damaged cells. It was once believed that the high AP level of serum observed in cholestatic liver disease was the result of decreased biliary excretion of the enzyme (Gutman *et al.*, 1940). It now is known that experimental obstruction of bile flow stimulates *de novo* synthesis of hepatic AP (Kaplan and Righetti, 1969, 1970), and the newly synthesized enzyme is refluxed into the circulation. Partial hepatectomy also stimulates increased synthesis of AP in regenerating hepatic tissue (Pekarthy *et al.*, 1972). It seems likely that increased synthesis of AP is involved in clinical extrahepatic bile-duct obstruction, in intrahepatic cholestasis, and in infiltrative diseases of the liver (e.g., lymphoma, metastasis) in which terminal branches of the biliary tree are obstructed, as well as in the regenerative processes that occur in the liver following injury.

There are significant species differences in the magnitude of elevation of serum AP activity in bile-duct obstruction (Fig. 13.2). For many years, it has been recognized that cats differed from dogs in that cats with extrahepatic bile-duct obstruction had "inconsistent" or negligible elevations of AP (Cantarow *et al.*, 1936), and this was thought to be due to urinary excretion of AP (Flood *et al.*, 1937). Other studies have established that cholestatic liver disease in cats can be expected to cause modest but significant elevations in AP (Everett *et al.*, 1977; Dalgaard, 1948), and induction of alkaline phosphatase synthesis following bile duct obstruction occurs in cats as in other species (Sebesta *et al.*, 1964).

In dogs, three AP isoenzymes (intestinal, steroid-induced, and hepatic) have been identified (Wellman *et al.*, 1982a). The steroid-induced isoenzyme is of hepatic origin (Wellman *et al.*, 1982b). Increased activity of the hepatic AP isoenzyme in cholestasis is due to enhanced

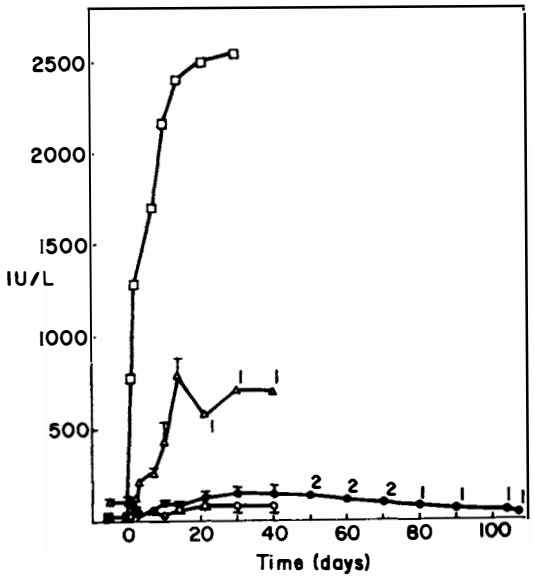

FIGURE 13.2 Comparative changes in serum alkaline phosphatase activity associated with bile duct obstruction in sheep, cats, horses, and dogs (courtesy of Dr. D. Levy). ●, ovine (5); ○, feline (6); △, equine (3); □, canine (2).

RNA translation and not to increased transcription (Seetharam *et al.*, 1986). Hepatic AP enters the serum either from the biliary canaliculus via the paracellular shunt pathway, or directly from plasma membranes. Increased bile-acid concentrations associated with cholestasis are believed to be necessary for the release and transport of solubilized hepatic AP to the serum (Schlaeger *et al.*, 1982).

Although measurement of serum GGT activity has the advantage of specificity, total serum AP activity remains the test most often performed to assess cholestasis in horses, dogs, and cats. Serum AP is less valuable in the evaluation of cholestatic syndromes of cattle and sheep because of wide fluctuations in normal AP activity (Ford, 1958; Harvey and Hoe, 1971).

Modest increases in serum AP do occur in hepatic necrosis (Noonan and Meyer, 1979). Following the experimental production of hepatic necrosis in dogs, the serum activities of arginase, ALT, and AP increase within one day, a time point at which GGT is not elevated. Following bile-duct obstruction, both AP and GGT levels markedly increase along with moderate elevations in ALT and AST, but arginase activity does not increase. This has suggested that arginase (for necrosis) and GGT (for cholestasis) may have the highest specificity in evaluating the type of hepatobiliary disease in the dog (Noonan and Meyer, 1979). Although serum GGT activity may be less affected during hepatocellular necrosis than AP, its activity is not as highly elevated as that of AP in bile-duct obstruction (Guelfi

et al., 1982). Increases in serum AP levels have been described in a variety of canine diseases associated with cholestasis (Hoe and Jabara, 1967; Abdelkader and Hauge, 1986; Center *et al.*,1985b).

7. γ-Glutamyltranspeptidase

GGT is a membrane-bound enzyme that catalyzes the transfer of γ-glutamyl groups from γ-glutamylpeptides such as glutathione to other peptides and amino acids. It is found primarily in cells with high rates of secretion or absorption. Significant GGT activity is present in the liver, kidney, pancreas, and intestine. GGT is considered a serum marker (Table 13.5) primarily for diseases of the hepatobiliary system associated with cholestasis (Braun *et al.*, 1983) and is now in general use for the diagnosis of liver diseases in animals (Table 13.6). GGT activity is relatively high in the livers of cows, horses, sheep, and goats, but GGT activity is considerably lower in dogs and cats. Although GGT activity is present in many tissues, remarkable elevations in serum activity are observed primarily in diseases of the liver. Urinary excretion of GGT has been measured to assess renal injury (Ford, 1974; Shaw, 1976).

In experimental bile-duct obstruction, serum GGT activity is increased significantly in the dog (Noonan and Meyer, 1979; Shull and Hornbuckle, 1979), sheep (Ford, 1974), and cow (Grunder, 1977). The sensitivity of GGT has been reported to be similar to that of AP as an indicator of cholestasis in the cat (Zawie and Garvey, 1984; Spano *et al.*, 1983). Serum GGT activity within a given species often correlates directly with serum AP activity in cholestatic liver injury. GGT is not increased, however, as markedly as AP in hepatic necrosis (Meyer, 1983).

B. Serum Bilirubin

Bilirubin in serum is measured by the *van den Bergh* or *"diazo"* reaction, in which bilirubin is coupled with diazotized sulfanilic acid. Azo pigments produced by this reaction are dipyrroles. Azo pigments are stable, and this characteristic has been useful in studies of the structure of bilirubin conjugates. Conjugated bilirubin reacts with diazotized sulfanilic acid in aqueous solution (the van den Bergh "direct reaction"), but unconjugated bilirubin reacts very slowly. Only after addition of an accelerator such as methanol or ethanol to the aqueous solution is the diazo reaction with unconjugated bilirubin complete ("the indirect reaction"). It is said that approximately 10% of unconjugated bilirubin in plasma will react with the diazo reagent and give a false "direct" reaction (Arias, 1974).

The requirement of an organic solvent for the diazo reaction to occur with unconjugated bilirubin suggested that the delay was related to water insolubility. There is evidence (Schmid, 1974), however, that intramolecular hydrogen bonding is more important than solubility in preventing the reaction of unconjugated bilirubin with the diazo reagent (Fog and Jellum, 1963; Nichol and Morrell, 1969). The two propionic acid side chains of bilirubin are esterified with glucuronic acid or other carbohydrates, disrupting the intramolecular hydrogen bonding (Fog and Jellum, 1963), allowing the direct diazo reaction to occur. Accelerators of the van den Bergh reaction may have a similar effect on the intramolecular hydrogen bonds of the unconjugated pigment.

Figure 13.3 summarizes the normal production and excretion of bilirubin and other bile pigments. Table 13.7 summarizes the pathophysiologic mechanisms that induce hyperbilirubinemia. Unconjugated hyperbilirubinemia is observed when there is increased production of bilirubin, as in hemolytic anemia (Fig. 13.3) or when either hepatic uptake or conjugation of bilirubin is diminished. Although the unconjugated bilirubin of serum may be significantly increased in such disorders, essentially none is filtered by the glomerulus

because the pigment is tightly bound to albumin. Consequently, bilirubinuria is not characteristic in animal patients with unconjugated hyperbilirubinemia. In hemolytic disease, the amount of bilirubin excreted by the liver, and therefore the amount that reaches the intestine, may be remarkably increased. This results in increased formation and urinary excretion of urobilinogen (Fig. 13.4).

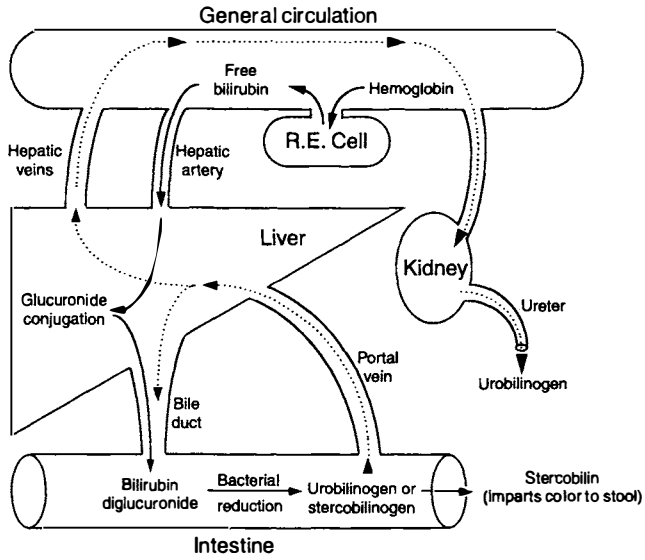

FIGURE 13.3 Normal formation, excretion, and enterohepatic circulation of bilirubin and other bile pigments.

Hyperbilirubinemia of the unconjugated type is caused either by intrahepatic cholestasis (Fig. 13.5) or extrahepatic bile duct obstruction (Fig. 13.6). When the primary defect is impaired excretion of bilirubin, hepatic uptake and conjugation may proceed at relatively normal rates, but conjugated bilirubin is refluxed into the plasma. The plasma concentration of bilirubin increases, and the conjugated pigment, which is water soluble and less firmly bound to albumin, is readily filtered by the glomerulus with resulting bilirubinuria (Fulop *et al.*, 1965; Laks *et al.*, 1963). Because bilirubin excretion into the intestine is either significantly reduced or absent, formation of urobilinogen by intestinal bacteria is remarkably reduced, and the test for urinary urobilinogen is characteristically negative in complete extrahepatic obstruction (Fig. 13.6). The therapeutic use of oral, broad-spectrum antibiotics may diminish the metabolic activity of intestinal bacteria and result in a spuriously negative test for urobilinogen in the urine.

The biochemical differentiation between unconjugated and conjugated hyperbilirubinemia using the van den Bergh reaction can be useful in assessing prehepatic and posthepatic causes of hyperbilirubinemia. In primary, severe hepatitic diseases, however, all major excretory steps (uptake, conjugation, and excretion) may be deranged and result in elevations of both conjugated and unconjugated pigment.

Important species characteristics should be considered when interpreting results of the van den Bergh

TABLE 13.7 Pathophysiologic Mechanisms Responsible for Hyperbilirubinemia[a]

	Plasma bilirubin		Urine	Urine

reaction. In general, the interpretation in dogs and cats is similar. Typically, in cholestatic disease, the conjugated fraction is elevated, representing 50 to 75% of the total serum bilirubin (Fig. 13.7). The normal horse has a much higher total serum bilirubin than any of the other domestic species (Fig. 13.8), and values as high as 4.0 mg/dl or higher have been observed in otherwise healthy individuals. In addition to hepatic and hemolytic diseases, hyperbilirubinemia is observed in horses with intestinal obstruction and a variety of other serious systemic diseases. Food restriction alone causes an abrupt increase in the unconjugated serum bilirubin of the horse (Gronwall and Mia, 1972; Tennant *et al.*, 1975), and decreased bile flow is the probable cause of the hyperbilirubinemia observed in fasting horses (Fig. 13.9).

In cattle and sheep, hyperbilirubinemia of sufficient magnitude to produce clinical icterus (≥3 mg/dl) is caused most frequently by hemolytic disease. Biochemical hyperbilirubinemia (1–2 mg/dl) without clinical icterus may be observed in sheep and cattle with fatty liver associated with ketosis/acetonemia. In such cases, the unconjugated bilirubin pigment predominates. Greater elevations in serum bilirubin and clinical icterus in ruminants associated with ketosis are unusual. Mild to moderate conjugated hyperbilirubinemia has been observed in sheep with sclerosing cholangitis caused by *Fasciola hepatica* infestation (Hjerpe

et al., 1971), and in cattle with hepatic cirrhosis (Finn and Tennant, 1974).

C. Serum Bile Acids

The primary bile acids are synthesized exclusively within the liver from cholesterol, and this represents the primary pathway of cholesterol catabolism. The

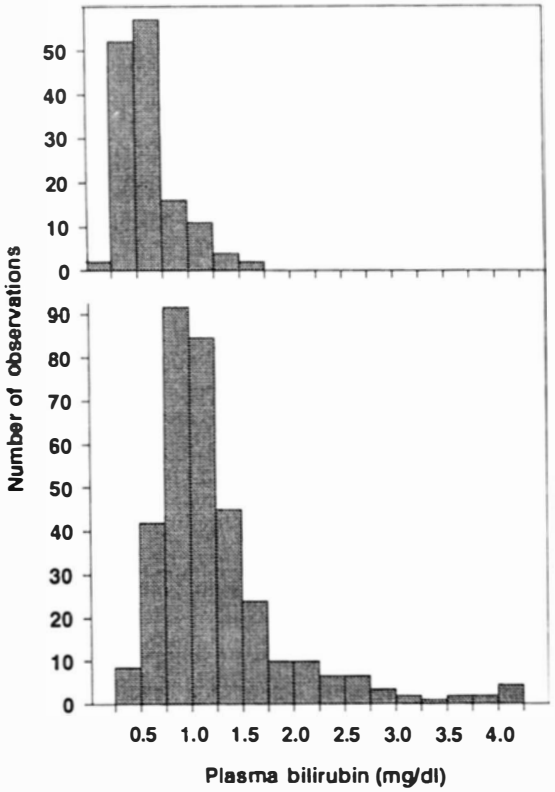

FIGURE 13.8 Total serum bilirubin concentrations of 23 normal Shetland ponies (upper; 143 observations) and 103 normal standard-sized horses (lower; 345 observations). Note the higher median values of standard-sized horses and the wide range of values in clinically healthy adults.

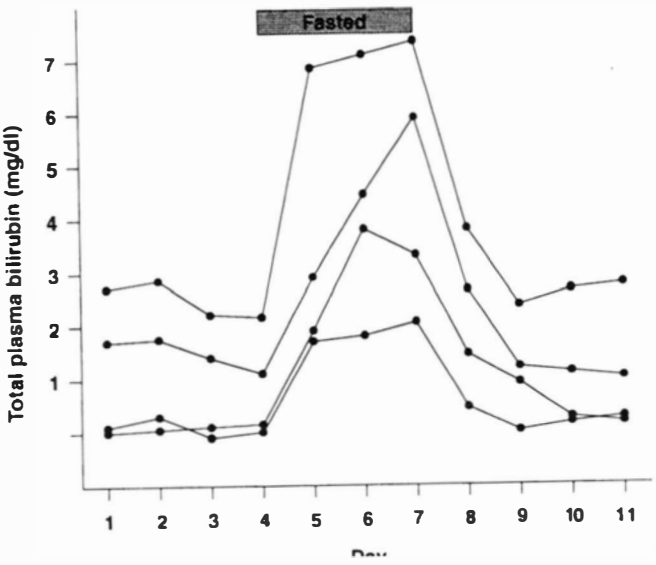

FIGURE 13.9 Serum bilirubin of horses before, during, and following a 3-day period of total fasting.

two primary bile acids of most domestic species are cholic acid, a trihydroxy bile acid, and chenodeoxycholic acid, a dihydroxy bile acid (Fig. 13.10). The major primary bile acid of swine is hyocholic acid, a trihydroxy bile acid closely synthesized from chenodeoxycholic acid (see Chapter 15). Following synthesis, the primary bile acids are secreted into bile as amino acid conjugates of either taurine or glycine. Taurine conjugates predominate in the dog, horse, and sheep. In the cat, bile acids are conjugated exclusively with taurine. Bile acids are the major component of bile, representing 67% of the total solids of bile; phospholipids make up approximately 22%, and protein, cholesterol, and bile pigments account for the remainder of biliary total solids.

Bile acid secretion is the major determinant of bile flow. In the proximal small intestine, bile acids play an important role in the digestion and absorption of fat and fat-soluble compounds (see Chapter 15). In the ileum, bile acids are efficiently absorbed by active transport mechanisms, but a small fraction of intestinal bile acids passes to the large intestine where bacterial deconjugation and dehydroxylation produces secondary bile acids. Dehydroxylation of cholic acid at the 7α position produces deoxycholic acid, and 7α dehydroxylation of chenodeoxycholic acid produces lithocholic acid. The secondary bile acids thus formed in the colon are absorbed into the portal circulation. The normal liver removes the primary and secondary bile acids efficiently from the hepatic portal vein. After reconjugation of the secondary bile acids, both primary and secondary bile acids are secreted again into the bile, completing the enteropathic circulation.

Bile acid metabolism is affected by liver disease in several ways. The synthesis of primary bile acids may be decreased and the proportions of cholic acid and chenodeoxycholic acid may changed. Unusual bile acids also may be produced. Importantly, removal of bile acids by the liver from the hepatic portal vein may be diminished, either by impaired hepatocellular function or by diversion of portal blood through shunts from the liver to the general circulation. This is particularly noticeable after meals in animals with either congenital or acquired hepatoportal shunts. The plasma bile acid concentration is increased continuously in biliary obstruction and, typically, there is increased urinary excretion of bile acids. Increases in the serum bile acid concentrations also are seen in other forms of hepatic disease, and an increased fasting serum bile acid level is specific for a significant deficit in hepatic function.

The measurement of total serum bile acids for assessment of liver disease has been greatly facilitated by development of a simplified spectrophotometric assay that has now been used for several domestic species. The predictive value of the serum bile acid test is remarkably high in the dog (Center *et al.*, 1984). In some dogs with portocaval vascular shunts, the fasting serum bile acid concentration may be within normal limits, but is increased diagnostically 2 hours following a meal (Center *et al.*, 1985a). The predictive value also may be enhanced in cats by comparing the fasting and

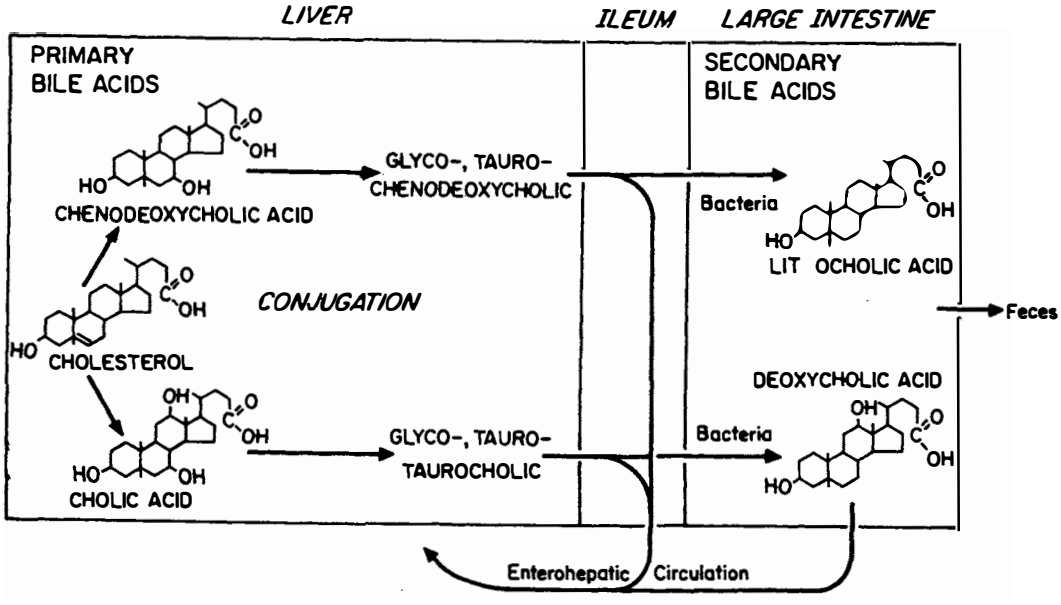

FIGURE 13.10 Metabolism of bile acids in the liver and intestinal tract. The primary bile acids are formed in the liver and the secondary bile acids in the large intestine.

2-hour postprandial bile acid levels (Center *et al.*, 1995). In the horse, fasting alone has been reported to increase the plasma bile acid concentration by decreasing hepatic bile acid clearance (Engelking and Gronwall, 1979), and food intake should be considered when interpreting the serum bile acid test in equine species.

D. Serum Proteins

The liver is the exclusive site of synthesis of albumin, the most abundant of the plasma proteins. Almost all plasma proteins are glycoproteins; in contrast, albumin contains no carbohydrate. Albumin is synthesized exclusively in the liver. Degradation of albumin occurs in the liver, as well as in other tissues, including muscle, kidney, and skin. Degradation of albumin is probably favored in the liver because of the fenestrated endothelial lining cells that allow access of almost all plasma proteins directly to the space of Dissé and to the sinusoidal surface of the hepatocyte. In the general circulation, albumin has two major functions. It is the most important determinant of plasma oncotic pressure (colloid osmotic pressure) and is a major transport protein for many hydrophobic endogenous metabolites and xenobiotics, substances that because of albumin binding remain in stable aqueous solution in the plasma.

The plasma albumin concentration is determined by the hepatic synthetic rate, which normally is in equilibrium with degradation. Hypoalbuminemia may be a clinical sign of severe hepatocellular liver disease because of defective albumin synthesis. Hypoalbuminemia also may be caused by increased albumin loss due to glomerulopathy (protein-losing nephropathy), to severe inflammation of the intestine, or to intestinal lymphangiectasia (protein-losing enteropathy). In severe, chronic hepatopathy, there is a tendency for elevations in IgM, IgG, and IgA, and both decreased albumin and increased globulin cause a decrease in the albumin/globulin ratio.

The liver is the exclusive site of synthesis of all blood coagulation proteins except factor VIII, which is synthesized in many organs. Synthesis of coagulation proteins tends to be diminished in liver disease. Plasma prothrombin (factor II) may be decreased in animals with either acute or chronic liver disease, with a corresponding increase in the prothrombin time. Factors that contribute to the abnormal prothrombin time include diminished hepatic protein synthesis, increased consumption of clotting factors associated with hemorrhage and fibrinolysis, and, in some cases, vitamin K deficiency due to decreased intake and/or decreased absorption. Vitamin K is essential for the hepatic synthesis not only of prothrombin, but also of factors VII, IX, and X. Parenteral administration of vitamin K to individual animal patients may result in improvement in prothrombin time, but coagulation time may remain prolonged. Individuals with obstructive jaundice absorb vitamin K poorly, and defects in their clotting can be improved rapidly by parenteral vitamin K administration. Fibrinogen is an acute-phase reactant and its concentration in plasma may be greatly increased in chronic inflammatory diseases or in neoplasia. Plasma fibrinogen synthesis is generally normal in mild or moderate liver disease, but may be detectably decreased in severe liver disease. Because of the rapid turnover of fibrinogen and prothrombin, the concentrations of the proteins in the plasma decrease rapidly in severe, acute liver injury, whereas albumin, the turnover rate of which is much longer, is diminished primarily in chronic liver disease with loss of significant hepatocellular mass.

The liver also is the site of synthesis of other plasma proteins important in regulation of coagulation. Plasmin, a serine protease synthesized by the liver, is necessary for fibrin degradation. Anti-thrombin 3 has potent protease activity against thrombin, plasmin, and other coagulation factors, and its primary physiological function appears to be to modulate the activity of thrombin. Heparin enhances inhibition of thrombin by antithrombin 3 by at least 1000-fold.

The complement system plays a critical role in the inflammatory response and in host defense mechanisms against infection, and most of the plasma proteins of the complement system are synthesized in the liver. *De novo* synthesis of C2, C3, C4, and factor B have been demonstrated in cultured rat hepatocytes, and syntheses of other complement proteins have been demonstrated in cultured guinea-pig hepatocytes (Ramadori *et al.*, 1986; Anthony *et al.*, 1985). The liver also is the site of synthesis of protease inhibitors, including 1-anti-trypsin, a major plasma protein that inhibits serine proteases, including granulocyte elastase and α2-macroglobulin, an inhibitor of a variety of other proteases.

E. Dye Excretion

The liver can excrete a variety of organic anions. The rate of removal of such substances can be determined and used to assess the functional capacity of the liver and hepatic blood flow. Of these, bromosulfophthalein (BSP, Bromsulphalein, Fig. 13.11) and indocyanine green (ICG, Fig. 13.12) are most frequently used in liver function studies. Following intravenous administration, these dyes are removed rapidly from the plasma, primarily by the liver, and are subsequently excreted in the bile. Delayed plasma clearance

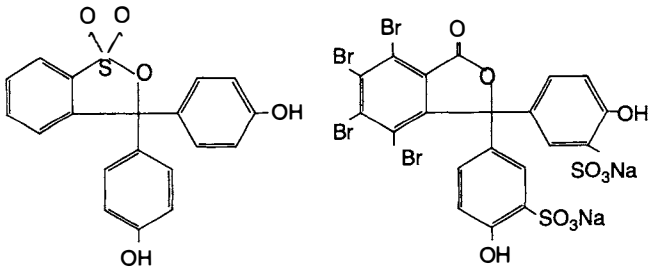

FIGURE 13.11 Phenolsulfonphthalein (PSP) is a dye that is cleared exclusively by the kidney and used in renal function tests. Sulfobromophthalein (BSP) is closely related structurally, but the modifications result in excretion almost entirely by the liver, allowing its use in the assessment of hepatic function.

indicates abnormal hepatocellular or biliary-tract function.

The overall process of hepatic excretion of BSP is similar but not identical to that of bilirubin. BSP and bilirubin appear to be transported across the plasma membrane by different routes in that membrane binding sites are not shared (Cornelius *et al.*, 1967). Within the cell, however, bilirubin and BSP compete for binding on the cytosolic protein, *ligandin.* Ligandin, by serving as an ion "sink," is thought to be an important driving force in the overall process of hepatic uptake (Levi *et al.*, 1969). The conjugation mechanisms for bilirubin and BSP are completely separate. BSP is conjugated with glutathione by action of the cytosolic enzyme S-aryl transferase-B. Although conjugation facilitates excretion of BSP, it is not an obligatory step, because approximately 50% of the BSP in bile is unconjugated. Conjugation of bilirubin with glucuronic acid or other sugars requires one of the glycosyl transferases, which are microsomal enzymes. Conjugation appears to be critical in the hepatic excretion of bilirubin. The canalicular transport of BSP is similar to that of conjugated bilirubin, but whether there is competition between the two for a carrier mechanism is unknown.

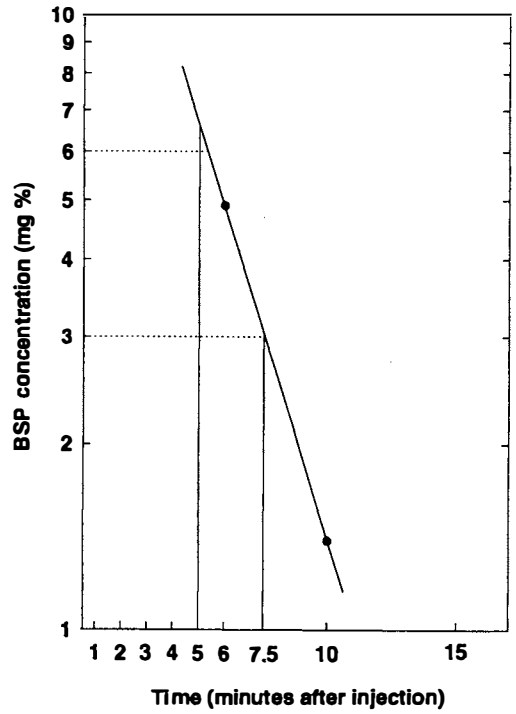

FIGURE 13.12 Calculation of $t_{1/2}$ for bromosulfophthalein (BSP) in the horse. After bolus intravenous injection, serum samples were obtained at 6 and 10 minutes, and $t_{1/2}$ calculated to be 2.5 minutes (normal).

In the icteric patient, the question arises whether competition between BSP and bilirubin will alter the results of the BSP excretion test. In general, the BSP test is seldom justified in such patients, because hepatic disease is evident and no important additional information is likely to be provided. In general, the BSP test is most useful for situations in which a suggestion of occult liver disease exists but in which the results of other liver-function tests are equivocal. The net competitive effect of bilirubin on BSP excretion is not great. For example, horses starved for 72 hours developed a threefold elevation in total bilirubin, but BSP excretion was prolonged less than 25% (Tennant, unpublished data).

In the dog and cat, a standard dose of 5 mg/kg of BSP is administered as an intravenous bolus. A sample of blood is removed at 30 minutes and the BSP concentration is determined spectrophotometrically. It is assumed that the original dose of BSP (5 mg/kg) is distributed in a plasma volume of 5 ml/kg so that the concentration of BSP in plasma at time zero is (by definition) I mg/ml. The percent retention at 30 minutes is calculated from the ratio of the concentration at time zero and at 30 minutes. Retention of 5% or less is considered to be within normal limits (Cornelius, 1970).

In the large domestic species, it often is difficult or inconvenient to obtain body-weight measurements. Because the initial slope of the disappearance curve is independent of BSP dose, a standard 1-g dosage is administered to normal-sized horses (450 kg) and 0.5 g to smaller horses. Blood samples are obtained at 6, 9, and 12 minutes following injection, the BSP concentration is determined in each, and the fractional clearance rate or plasma half time ($t_{1/2}$) is calculated (Fig. 13.13). In the horse, normal plasma $t_{1/2}$ values vary between 2.5 and 3.5 minutes. In cattle, the BSP excretion rate is similar to that in the horse. Sheep have a more rapid excretion rate, requiring samples to be

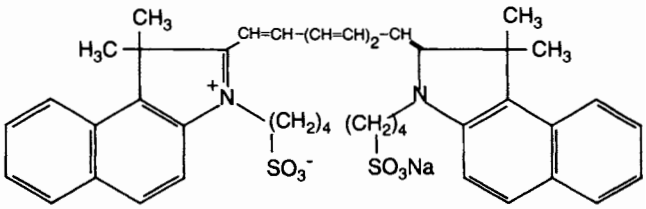

FIGURE 13.13 Indocyanine green used for quantitative assessment of hepatic excretory function.

taken at 3, 5, and 7 minutes following injection. Normal $t_{1/2}$ values range from 1.6 to 2.7 minutes (Cornelius, 1970).

The BSP test is safe, although the dye is very irritating if infiltrated perivascularly. The test should be used only when cardiovascular function is normal. If hypovolemia or hypotension is present, hepatic perfusion will be reduced and erroneously prolonged clearance rates may be observed.

1. Indocyanine Green

The clearance rate of indocyanine green also provides a useful estimate of hepatic excretion. The hepatic extraction ratio approaches 1 and the hepatic clearance corresponds to hepatic blood flow. In contrast to BSP, the plasma disappearance of ICG generally follows a single exponential. ICG, because of its commercial availability, is the dye excretion test most readily available for clinical use.

ICG clearance has been used for some time to estimate circulation time and hepatic blood flow (Keiding and Skak, 1985). The ICG clearance rate from plasma is measured after intravenous injection of various bolus doses of dye (Warren *et al.*, 1984). Because the disappearance of dye from plasma follows Michaelis–Menten kinetics, Lineweaver–Burke plot analysis will yield apparent K_m and V_{max} values for ICG removal (Paumgartner *et al.*, 1970). This method can be used to estimate the maximal dye removal capacity from a small number of submaximal clearance values. Although such multiple tests are not useful for routine practice, they provide the investigator with an extremely sensitive index of hepatic dye clearance that is independent of blood flow.

The clinically useful liver function test using ICG measures $t_{1/2}$ and fractional clearance (K) after the intravenous injection of 0.5 mg/kg (0.64 μmol/kg). Three plasma samples are usually taken between 3 and 15 minutes postinjection; ICG is measured at 805 nm and plotted on semilog paper as described earlier for BSP clearance in the horse. The value of K can be calculated from the $t_{1/2}$ value as

$$K = \ln 2 / t_{1/2},$$

(where ln 2 equals 0.693). In the dog, one can also estimate the plasma volume and hepatic blood flow by using the average hepatic extraction ratio of 18% (Ketterer *et al.*, 1960).

Normal ICG plasma clearance $t_{1/2}$ and K values for the dog using 0.5 mg/kg ICG (0.64 μmol/kg) are reported to be 8.4 ± 2.3 minutes and 0.089 ± 0.027/minute (Bonasch and Cornelius, 1964), or, using 1.0 mg/kg (1.3 μmol/kg), have been reported to be 9 ± 2 minutes and 0.081 ± 0.017/minute (Center *et al.*, 1983a); for cats at 1.5 mg/kg (1.9 μmol/kg), the values are 3.8 ± 0.9 minutes and 0.19 ± 0.045/minute (Center *et al.*, 1983b). For sheep using an ICG dose of 0.5 mg/kg (0.64 μmol/kg), the $t_{1/2}$ = 4.8 ± 0.5 minutes, and for heifers using a dose of 0.75 mg/kg (0.97 μmol/kg), the $t_{1/2}$ = 3.5 ± 0.8 minutes (Sato, 1984).

V. OVERVIEW AND CONCLUSIONS

Conventional tests of hepatic disease provide information about the integrity of the hepatocytes (ALT, AST, SDH) and the integrity of the biliary system (AP, GGT). Hepatic function can be assessed by testing the excretory capacity of the liver (bilirubin; bile acids) and its synthetic function (NH_3/urea, albumin, fibrinogen, and prothrombin).

For optimal value in interpreting the results of clinical laboratory tests, it is essential that the specific purpose(s) of the test(s) being performed be defined. As described in Section IV, laboratory tests for hepatic disease are performed clinically for a variety of purposes, including confirmation of the presence of liver disease, for assessment of the nature (e.g., hepatocellular injury, cholestasis) and severity of the disease to establish prognosis, for monitoring the clinical course of liver disease, and for screening of individuals considered to be at risk for liver disease to establish the existence of occult liver disease.

Many of the standard tests for liver disease are based on rather simple biochemical procedures that are readily automated for use in multichannel autoanalyzers. One seldom obtains the result of a single test for liver disease, but rather a panel of results or a "liver profile." In some situations, multiple tests results for liver function are received even when there is no specific clinical indication because with autoanalyzers, it may be easier to perform a large series of tests than to be selective.

In a given population of animals, some will have liver disease and some will not. If a test is applied to the whole population, a certain number of those with

the disease will have a positive test result (true positives), and some with the disease will have a negative test result (false negatives). Similarly, among those without the disease, some will have a positive test result (false positives) and in some, the test will be negative (true negatives). A test is said to be *sensitive* to the extent that it detects individuals with the disease (true positives divided by the total number with the disease; i.e., true positives plus false negatives). The test is said to be *specific* to the extent that a negative result detects patients that are free of the disease (true negatives divided by the number of subjects without the disease; i.e., true negatives plus false positives).

In the clinical setting, the sensitivity and the specificity of hepatic tests are less important than the *positive predictive value*, defined as the probability that a positive test result indicates the presence of the disease (true positives divided by true positives plus the false positives), and the *negative predictive value*, the probability that a negative test result is indicative of the absence of the disease (true negatives divided by the true negatives plus false negatives). The predictive value of a test, unfortunately, depends on the population being studied and the proportion of individuals in the population with the disease (prevalence). Even when test sensitivity and specificity are high and the number of false positives tests is low, if there are few subjects with the disease in the population, a positive test result will have relatively low positive predictive value, while a negative test result will have proportionately high negative predictive value. If the prevalence of a disease in a population is high, however, a positive result for a test with even low sensitivity and specificity will have high positive predictive value, while a negative result would have proportionately low predictive value for the absence of the disease.

Although the sensitivity of a test is often discussed, the prevalence of the disease and the positive and negative predictive values of tests are often ignored in discussions of interpretation of laboratory results. Importantly, laboratory test results from a selected group of individuals with a high prevalence of liver disease cannot be compared to a population in which the prevalence is low or to one in which the predictive value of a test in one population is similar to that of the other population.

As indicated earlier, it is unusual to perform a single test for hepatic function or disease; rather, a "profile" of hepatic test results is ordinarily obtained. The combined results of a panel of tests often provide increased sensitivity and specificity and improved predictive value in assessing severity and, in some cases, in the differentiation between acute and chronic forms of liver disease. The differential diagnosis of specific problems often is not possible with multiple laboratory tests alone, and hepatic imaging and/or liver biopsy are required. Hepatic tests, however, continue to have an important place in evaluation and monitoring of clinical patients with liver disease and in understanding the underlying pathophysiological mechanisms essential for initiation of successful treatment.

CHAPTER

14

Pancreatic Function

DUANE F. BROBST

I. INTRODUCTION

The pancreas is composed of two organs, the endocrine and exocrine portions, within one stroma. The functions of the endocrine pancreas are considered with carbohydrate metabolism elsewhere in this volume. Although the functions of the endocrine and exocrine portions of the pancreas may in some way be interrelated, this chapter is concerned with the exocrine pancreas.

The signs of exocrine pancreatic disease are often nonspecific, and physical and radiographic examination of the patient are seldom diagnostic. Because the pancreas is so difficult to evaluate using these approaches, the veterinary clinician has come to rely on biochemical function tests in the diagnosis of pancreatic disease. Still, many aspects of exocrine pancreatic physiology and pathophysiology remain enigmas despite long years of investigation. Neither have satisfactory laboratory procedures been developed that adequately identify ongoing acute pancreatitis and reflect its severity. However, an appreciation for the use and understanding of the fundamentals of the more commonly used function tests, and for tests more recently developed, requires familiarity with the physiology of the exocrine pancreas and mechanisms involved in diseases of this organ. To this end, the chapter is presented.

II. PHYSIOLOGY OF THE PANCREAS

Pancreatic secretion is composed of a mixture of viscid, enzyme-rich fluid and a watery portion containing electrolytes with a high concentration of bicarbonate (HCO_3^-). The enzymes are synthesized by the pancreatic acinar cells, which are arranged in clusters about the terminal pancreatic ductules. The epithelial cells lining the terminal and interlobular ducts, which carry pancreatic juice toward the duodenum, provide the mucin and electrolytes in the pancreatic secretion.

A. Pancreatic Fluid and Electrolytes

Stimulation of the exocrine pancreas with secretin results in production of a large volume of pancreatic fluid with a HCO_3^- concentration that can reach 140–160 mmol/liter. The mechanisms by which ductal epithelial cells secrete HCO_3^- are not well established, but secreted HCO_3^- is probably derived from CO_2 in the blood. Also, duct cells secrete HCO_3^- and H^+ ions from their apical and basolateral plasma membranes, respectively (Raeder, 1992). Secretin-dependent HCO_3^- secretion rate is greater at high pCO_2 values (but normal blood pH) than at normal pCO_2 values. Studies indicate that HCO_3^- is secreted into the duct lumen through the

action of a chloride (Cl^-)/HCO_3^- exchange mechanism (Hootman and Ondarza, 1993). The HCO_3^- and Cl concentrations in pancreatic juice have an inverse relationship with HCO_3^- concentration increasing as secretion rate increases. The involvement of Na^+, K^+-activated ATPase and carbonic anhydrase activity in ductal HCO_3^- secretion is also well established. Both enzymes are at high levels in ductal epithelial cells.

Pure pancreatic juice of dogs has a pH between 8 and 8.3 and is isosmotic with plasma. The volume of secretion by the canine pancreas is greater than by the pancreas of normally fed sheep (Taylor, 1962). In canine pancreatic juice, the HCO_3^- concentration ranges between 60 and 148 mmol/liter; in ovine pancreatic juice the HCO_3^- concentration is 15–30 mmol/liter. There is normally little fluctuation in the rate of pancreatic juice flow when food is eaten by a ruminant. This is because ingesta normally flows almost continuously into the duodenum. When food is withheld for 48 hours, however, ruminant pancreatic secretion decreases by about 50% (Taylor, 1962). The pancreas of the dog secretes two to three times as much fluid per gram of tissue and more enzyme than does the ovine pancreas. The concentration of sodium and potassium in pancreatic secretion tends to parallel plasma concentrations. Calcium concentration in pancreatic juice of the dog, however, tends to be lower than in plasma. Zimmerman *et al.* (1967) demonstrated that under conditions in which pancreatic enzymes were being formed in large amounts calcium output was greatest. They suggested calcium was not secreted with the electrolyte components of pancreatic juice, but rather with the nonelectrolyte portion, and that calcium may be a part of the amylase molecule.

Goblet cells are also present in the pancreatic ducts and they secrete mucus. The pancreatic mucus formed by these cells may produce a protective barrier against back flux of HCO_3^- and degradation of duct epithelium by digestive enzymes (Hootman and Ondarza, 1993).

Pancreatic juice of dogs plays a role in the regulation of the bacterial flora of the proximal region of the small intestine and dogs with exocrine pancreatic insufficiency (EPI) may have a greater than normal number of duodenal bacteria (Williams *et al.*, 1987). Nonenzymic and enzymic components of pancreatic secretion can influence the number and type of bacteria in the small bowel. In the absence of alkaline pancreatic juice, the increased acidity favors growth of acid-tolerant organisms such as *Lactobacillus* and *Streptococcus* species (Simpson *et al.*, 1990). Inadequate digestion of dietary constituents could also provide substrate for an altered bacterial flora. When the bacterial overgrowth in the small intestine includes obligate anaerobes, proteases from these bacteria may be responsible for reduction of mucosal enzyme activity and partial villous atrophy (Williams *et al.*, 1987).

Overgrowth of folate-producing bacteria in the proximal small intestine may result in an increase in serum folate levels and a reduction in serum cobalamin (vitamin B_{12}) levels. The reduction of vitamin B_{12} is the result of binding of the vitamin B_{12} intrinsic factor complex by intestinal bacteria (Batt and Morgan, 1982). The pancreatic secretion of dogs does have an important function in the absorption of cobalamin. Dogs with induced EPI had decreased cobalamin absorption, which was not restored by oral administration of pancreatic enzymes, despite improvement of steatorrhea (Simpson *et al.*, 1989b). In contrast, malabsorption of cobalamin was reversed by oral administration of canine pancreatic juice. Hence, both pancreatic and gastric intrinsic factors have a role in the normal absorption of cobalamin in dogs (Batt and Horadagoda, 1989).

B. Pancreatic Enzymes

The acinar cell of the exocrine pancreas secretes a mixture of enzymes involved with digestion of proteins, fats, and carbohydrates. These exocrine-derived proteins are synthesized in the area of the cell occupied by the rough endoplasmic reticulum and are packaged in condensing vacuoles near the Golgi complex. Later these proteins are in the apical portion of the cell, in zymogen granules, and are stored here until discharged from the cell by hormone-responsive exocytosis. During transport of these secretory proteins, they are at all times segregated within membrane-bound compartments and are excluded from the cytosolic space.

The type of food ingested by some animals may, with time, alter the enzymatic composition of the pancreas. Lavau *et al.* (1974) found that rats on a diet high in starch or glucose and low in fat had increased concentrations of amylase and decreased lipase in pancreatic tissue. Protein malnutrition may also be associated with alteration in the composition of pancreatic enzymes. Gyr *et al.* (1975) determined that moderate protein deficiency in monkeys caused a significant decrease in pancreatic secretion of amylase, lipase, and chymotrypsin.

Malaisse-Lagae *et al.* (1975) showed that in the rat, the concentration of enzymes in acinar cells surrounding the islets of Langerhans (peri-insular portion) differed from the rest, the teleinsular part of the pancreas. The concentration of amylase, relative to lipase, was invariably higher in the teleinsular than in the peri-insular exocrine pancreas. Their findings indicate that the secretory partition of the exocrine pancreas could be responsible for modulation in the composition of

pancreatic juice under different conditions. The peri-insular acini may differ from the teleinsular acini in the level of their secretory activity, their response to various secretagogues, and their relative content of different hydrolases. Functionally, the endocrine and exocrine cells of the pancreas may exert a mutual and direct control of their secretory activity. That is, insular hormones modify exocrine function, and exocrine factors may alter islet cell responsiveness to certain secretagogues. The close anatomic relationship between endocrine islets and exocrine acini, together with the fact that islet hormones affect exocrine pancreatic function, led to the concept of an islet–acinar axis with islet cell hormones being delivered to the exocrine interstitial space via an islet–acinar portal system or islet–acinar microcirculation. Nakagawa *et al.* (1993) established the presence of islet–acinar axis activity in the rat pancreas. They proposed that the islet–acinar axis may be responsible for increasing exocrine cell growth and enzyme synthesis, via insulin, over the long term, whereas the islet hormones somatostatin and pancreatic polypeptide provide a means to regulate rapidly the suppression of enzyme release from acinar cells. The histological differences between acinar cells surrounding islets and those located in the periphery are considered to be the result of more synthesis and less secretion of enzymes in peri-insular regions. The increase in insulin following a meal could stimulate digestive enzyme synthesis in peri-insular cells, whereas somatostatin and/or pancreatic polypeptide may inhibit immediate exocrine release of stored enzymes. Matsushita *et al.* (1994) observed that insulin exerted a direct effect on rat pancreatic acinar cells and potentiated exocrine secretion of amylase evoked by secretin in combination with cholecystokinin (CCK), in part by increasing Na^+, K^+-ATPase activity.

1. *Proteolytic Enzymes*

The major proteolytic enzymes, which are secreted as inactive proenzymes, are trypsinogen, chymotrypsinogen, and procarboxypeptidase. A concept for the activation of these pancreatic proenzymes is that enterokinase in the intestine activates trypsinogen to trypsin and the other proenzymes are then activated by trypsin; premature activation of trypsin is thought to be prevented by pancreatic-specific trypsin inhibitor. Borgström *et al.* (1991) studied the activation of proenzymes using a lecithin assay and synthetic substrates. It was observed that the first protein to be activated was procolipase followed by the activation of prophospholipase, followed by chymotrypsin and, lastly, the activation of trypsinogen. The addition of increasing amounts of pancreatic-specific trypsin inhibitor could delay the activation of the proenzymes and therefore it was believed the activation was mediated by trypsin and not enterokinase.

2. *Lipases*

Pancreatic lipase is secreted in an active form, but its activity is enhanced by bile salts. Bile salts enhance the efficiency of lipolysis by increasing the surface area of oil–water interfaces at which water-soluble lipase is effective. Colipase, a small protein synthesized in the pancreas, allows pancreatic lipase to function in spite of micellar concentrations of conjugated bile salts. Bile salts by themselves hinder lipase absorption onto triglycerides by covering the whole water–substrate interface. Colipase tends to prevent this and acts as an anchor for lipase adsorption, thus allowing lipase to hydrolyze substrate (Vandermeers-Piret *et al.*, 1977). Calcium may also be required for activation of lipase (Janowitz and Banks, 1976).

Pancreatic lipase exhibits optimal activity under alkaline conditions and hydrolyzes triglycerides to fatty acids and glycerol, but mono- and diglycerides are also end products. Pancreatic lipase has greater activity against short-chain than long-chain triglycerides (Cohen *et al.*, 1971). Phospholipases A and B also are present in pancreatic juice. Phospholipase A splits off a fatty acid from lecithin or cephalin to form lysolecithin and lysocephalin. Phospholipase B is capable of splitting off a fatty acid and lysolecithin to form glycerophosphorylcholine.

Carriere *et al.* (1993) demonstrated that, in man, gastric and pancreatic lipases act as complementary enzymes in the digestion of triglyceride although pancreatic lipase was the main enzyme responsible for lipid digestion. These investigators confirmed that gastric lipolysis resulted only from gastric lipase activity, and that bile salts, at physiological concentrations, had no effect on gastric lipolysis. Also they determined that the majority of gastric lipase secreted in the stomach remained active in the duodenum. This may partially explain why human beings with complete absence of pancreatic lipase continue to absorb a significant amount of their ingested dietary fat (Muller *et al.*, 1975).

Studies of survival of pancreatic enzymes during small intestinal transit demonstrated that the most dramatic loss of enzymatic activity occurred for lipase. In the midjejunum of man, only about 10% of duodenal lipase activity was present, whereas in the ileum, only about 1% of residual lipase activity was measured. About 74% of amylase activity survived transit from duodenum to terminal ileum and about 20% of the trypsin activity reached the ileum (Layer *et al.*, 1986). Proteases are responsible for the loss of lipase activ-

ity in duodenal juice with pancreatic lipase being more inactivated by chymotrypsin than by trypsin (Thiruvengadam and Di Magno, 1988). Inactivation of proteases, therefore, improves the intraluminal activity of lipase (Layer and Gröger, 1993). Lipase is also the most susceptible pancreatic enzyme to acid denaturation. At a pH of 4, lipase is almost completely inactivated, whereas amylase and trypsin are still active (Adler *et al.*, 1993). This explains why fat malabsorption develops earlier compared with protein and starch malabsorption (Layer and Gröger, 1993). The digestive products of fat in the duodenum regulate the rate of gastric emptying. Therefore, only with sufficient lipase activity in the duodenum would the rate of lipid hydrolysis create an adequate luminal concentration of fatty acids to slow gastric emptying (Malfertheiner and Domínguez-Muñoz, 1993).

3. *Amylase*

Pancreatic amylase is an α-amylase that catalyzes the hydrolysis of starch and glycogen to form maltoses and residual glucose. Amylase, as found in pancreatic or other body tissues and fluids, is a metalloenzyme with an absolute requirement for calcium ions (Janowitz and Banks, 1976). Optimal activity is obtained also only in the presence of a variety of inorganic anions, the most effective being chloride.

A considerable number of organs, other than pancreas, contain amylases, and differentiating these amylases from pancreatic amylase may present a problem when attempting to make a diagnosis of active pancreatitis. The maintenance of serum amylase levels following removal of the pancreas in some species suggests that nonpancreatic sources of amylase are important in the regulation of normal circulating amylase levels. Jacobs *et al.* (1982) observed four peaks of isoamylase activity in the sera and tissue of dogs. The majority of activity was present in peak 4 and the pancreas, duodenum, kidney, lung, spleen, testes, and uterus–ovaries contained peak 4 isoamylase. The pancreas contained peak 3 in addition to peak 4 isoamylase. An increase in peak 3 isoamylase was present in dogs with pancreatitis and the relative increase in peak 3 was greater than that seen for total amylase or the other isoamylases. In chickens and in mammals properties of amylase from the intestine and pancreas were found to differ. Chicken and mammalian pancreatic amylase were more dependent on chloride for activation than were intestinal amylases, and pancreatic amylase also functioned at a pH optimum greater than intestinal amylase (Osman, 1982).

C. Regulation of Pancreatic Secretion

The digestive enzymes in pancreatic juice enter the intestinal lumen at a rate that is regulated by a complex interplay of nervous and hormonal stimuli. A basal rate of pancreatic secretion exists in most animals, but with the ingestion of food a series of hormonal and neural mechanisms is set into action that activates and controls the pancreatic secretion of water, electrolytes, and digestive enzymes. The dominant hormones are secretin and CCK. Secretin is released from the upper small intestinal mucosa by the entry of H^+ into the duodenum and this stimulates the centroacinar and ductal cells of the pancreas to secrete the electrolyte-containing fluid. The HCO_3^- secreted by the pancreas neutralizes the HCl secreted by the stomach. Plasma secretin levels were measured in dogs by radioimmunoassay (Llanos *et al.*, 1977). When the pH of the stomach content of dogs decreased to less than 3, the plasma secretin level increased to 43% above basal values, and the pancreatic secretion of HCO_3^- was near maximum. The threshold for release of secretin and HCO_3^- was pH 4. Cholecystokinin is released from the duodenal mucosal cells in response to products of protein digestion, and this hormone causes some secretion of pancreatic enzymes and contraction of the gallbladder. Li and Owyang (1994) demonstrated that in rats endogenous CCK under physiological conditions acts via stimulation of a vagal afferent pathway and their studies support a neural physiological role for CCK on pancreatic enzyme secretion. Doses of exogenous CCK that produce physiological plasma CCK levels also act via stimulation of the vagal pathway. In contrast, doses of CCK that produce supraphysiological plasma CCK levels act on intrapancreatic neurons and pancreatic acini. Exocrine pancreatic secretion in conscious dogs was also stimulated by the intravenous administration of gastrin-releasing peptide (GRP) (Nustede *et al.*, 1993). CCK-related mechanisms are believed to be responsible for this stimulation since administration of a CCK receptor antagonist causes a marked reduction of GRP-induced exocrine pancreatic secretion.

Mechanisms of inhibitory control of pancreatic secretion appear little studied in comparison to stimulation of secretion. Exocrine pancreatic secretion in man is inhibited by intraduodenal infusion of either trypsin or reinfusion of pancreatic–biliary juice. Therefore, this protease-mediated negative feedback of pancreatic secretion appears to be controlled by duodenal mechanisms (Malfertheiner and Domínguez-Muñoz, 1993). Somatostatin may inhibit exocrine pancreatic secretion by inhibiting release of hormones such as CCK and secretin. Somatostatin may also alter the pancreati

response to a meal by inhibition of gastric secretion or gastric and gallbladder emptying (Heintges *et al.*, 1994).

III. PANCREATIC DISEASE

Pancreatic disease, in its various forms, is not uncommon in dogs and cats and may occur in other animals as well. The exocrine pancreas may be affected by acute or chronic disease processes that may lead to the digestive problems associated with pancreatic insufficiency.

A. Acute Pancreatitis

1. Etiology

Acute pancreatitis in any species can be a disease of variable intensity, ranging from mild edema to generalized pancreatic necrosis. The etiology of inflammatory pancreatic disease is poorly understood but some of the etiologic factors that may be responsible for acute pancreatic disease can be classified as follows.

a. Mechanical Factors

The reflux of bile from the bile duct into the pancreatic duct has been considered a possible means of pancreatitis initiation. Duodenal reflux of fatty acids following ingestion of a high-fat meal may also result in pancreatic inflammation (Attix *et al.*, 1981). Traumatic hemorrhagic pancreatitis has been reported in cats that have survived falls from buildings (Suter and Olsson, 1969). Pancreatolithiasis occurs more frequently in cattle than in any other animal, and Verine (1973) reported a frequency of 1/2700 in slaughtered cattle. The associated pancreatic lesions, however, were chronic in nature.

b. Infectious Disease

Sterile bile perfused into the main pancreatic duct of cats at basal pressure and at duct pressure in the upper physiologic range produced no inflammation. The perfusion of bile infected with *Escherichia coli* at basal pressure caused a severe acute edematous pancreatitis and at upper physiologic pressure acinar necrosis resulted. Infected bile was found to raise basal pancreatic ductal pressure by 30% (Arendt, 1993). High physiologic duct pressure may result in the conversion of mild inflammation into acinar necrosis.

c. Ischemia

When the isolated canine pancreas was subjected to reduced blood flow with low arterial pO_2, pancreatic ischemia was severe and significant injury occurred in the pancreas (Broe *et al.*, 1982). It has also been postulated that ischemia may play a role in the conversion of edematous pancreatitis to acute hemorrhagic pancreatitis.

d. Nutritional Factors

Goodhead (1971) found dogs on a poor plane of nutrition failed to develop as severe a degree of induced pancreatitis as well-nourished dogs. Orally induced zinc toxicosis in veal calves produced lesions that included necrosis of acinar tissue (Graham *et al.*, 1988).

e. Miscellaneous

Induced hypercalcemia in cats has a deleterious effect on the pancreas that results in acinar and ductal cell necrosis and eventually pancreatitis (Frick *et al.*, 1990). Following the administration of excessive amounts of calcium to a dog with hypocalcemia, pancreatic hemorrhage and necrosis also ensued (Neuman, 1975). Hormonal factors in mice (Rao *et al.*, 1982) and corticosteroids given at high levels to dogs (Attix *et al.*, 1981) may also cause pancreatitis.

2. Pathophysiology

The pancreas is very susceptible to ischemia and ischemia of this organ has been considered an initiating or promoting factor of active pancreatitis (Yotsumoto *et al.*, 1993). The reduction of pancreatic blood flow may be caused by various vasoactive mediators such as histamine, myocardial depressant factor, prostaglandins, free radicals, platelet-activating factor, and kinin. Since the pancreas contains kallikrein and is able to release kinin, the kallikrein-kinin system was investigated in rabbits to determine the effect of this system on induction of hypotension in pancreatic blood vessels and the effect of bradykinin on the aggravation of acute pancreatitis (Yotsumoto *et al.*, 1993). In rabbits with induced acute edematous pancreatitis that were administered bradykinin, blood flow to the pancreas was diminished and serum amylase and lipase levels rose significantly. Pancreatic necrosis and inflammatory reaction were greater in these rabbits than in controls. The results suggest that bradykinin has an aggravating or promoting effect on edematous pancreatitis. Although activated trypsin may have initiated the edematous pancreatitis, bradykinin appeared to have a direct effect on pancreatic acinar cells, and was a key enzyme in the activation of phospholipase A_2 and the generation of prostaglandins together with platelet-activating factor (PAF) from biomembrane phospholipids (Fig. 14.1). Induced prostaglandins and

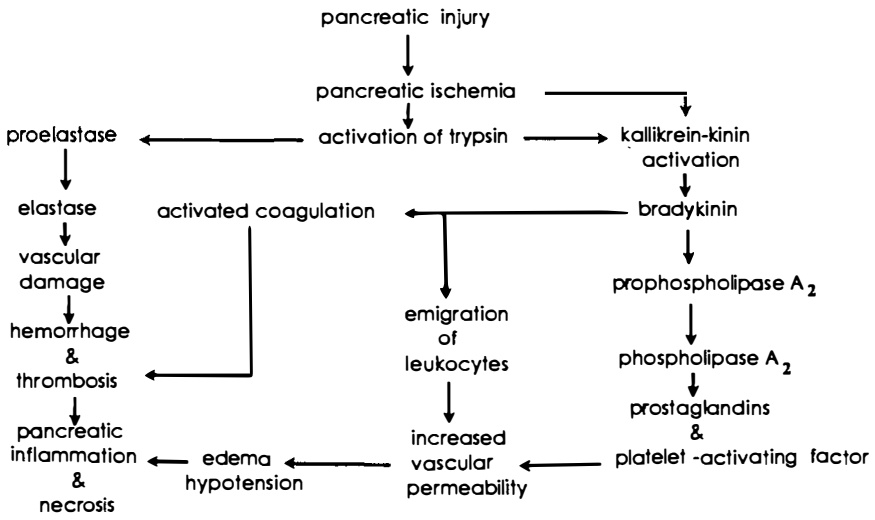

FIGURE 14.1 Etiologic and pathogenic factors in acute pancreatitis.

leukotriene activate leukocytes, cause vasodilation, and increase vascular permeability. The increased vascular permeability may enhance edema and stimulate emigration of leukocytes. It is possible that free radicals and PAF are generated in the activated leukocytes and injured vascular endothelial cells causing pancreatic injury. The activation of the blood coagulation cascade by bradykinin and vascular endothelial cell damage caused by free radicals or PAF may produce microthrombi in microcapillaries that can induce pancreatic necrosis (Yotsumoto *et al.*, 1993). The effects of PAF that may be released endogenously during the evolution of acute pancreatitis can be suppressed by a selective PAF antagonist. In rats with induced acute pancreatitis, treatment with PAF antagonist 30 minutes after induction of pancreatitis significantly inhibited the elevation of serum amylase levels and altered the progression of the disease (Formela *et al.*, 1993). The activation of elastase, probably by trypsin, may also cause vascular damage associated with hemorrhage and thrombosis (Fig. 14.1).

A point in understanding the pathogenesis of acute pancreatitis is determining where the initiating event occurs. It has been believed that pancreatic juice from small pancreatic ducts escapes into the interstitial space of the pancreas and with activation of digestive enzymes, the inflammatory process begins in the interstitial space. Steer and Meldolesi (1987) suggest the triggering action of acute pancreatitis occurs not within the interstitial space of the pancreas but within acinar cells and results from deranged transport or secretion of enzymes. These investigators have observed, in the acinar cells of both mice with pancreatitis induced by a choline-deficit diet and of animals with pancreatitis caused by excessive stimulation of pancreatic secretion, large vacuoles containing a mixture of digestive enzymes and lysosomal hydrolases. Lysosomal hydrolases are capable of activating trypsinogen and theoretically the mixture of digestive enzymes and hydrolases, and the fragility of the large vacuoles containing them were considered responsible for the release of activated enzymes into the acinar cell cytoplasm. Thus, pancreatic autodigestion may begin within the acinar cells themselves.

Studies of the pathophysiology of acute pancreatitis using a rat model have shown that the synthesis of some pancreatic enzymes was repressed during the acute phase, which might explain why the serum levels of these enzymes decrease after their initial burst (Iovanna *et al.*, 1991). The decrease in the synthesis of the trypsinogen I, chymotrypsinogen B, procarboxypeptidase A, proelastase I, and amylase was believed to be due to repressed pancreatic gene expression encoding for these exocrine enzymes. The suppression of hydrolase synthesis might be part of a defense mechanism to limit acute pancreatitis, because hydrolase enzyme activity may be involved in causing pancreatitis. In contrast to the decrease in synthesis of hydrolase enzymes in acute pancreatitis, the nonenzymatic secretory proteins actin, lithostathine, and pancreatitis-associated protein (PAP) were overexpressed by the pancreas during the acute phase. Increases in actin and lithostathine expression may be associated with pancreatic regeneration, which follows pancreatitis (Iovanna *et al.*, 1991).

3. Laboratory Diagnostic Aids

In addition to the hemogram, tests measuring the amount of pancreatic enzyme activity in the blood or other body fluids, and other laboratory procedures,

can be useful in establishing a diagnosis of acute pancreatitis. Some of these laboratory procedures, both well established and experimental, follow.

a. Serum Amylase

i. Source Experimentally induced pancreatitis in dogs produces hyperamylasemia that peaks within 12–48 hours postinduction and subsides to normal within 8–14 days (Brobst *et al.*, 1970). Hyperamylasemia may be one indication of acinar cell damage and pancreatic duct obstruction.

Serum amylase concentrations in dogs may, however, also increase secondary to extrapancreatic disorders, which may have clinical signs similar to those of pancreatitis. Several tissues of dogs, including the intestine, kidney, and uterus, have been found to have amylase activity (Stickle *et al.*, 1980). Amylase activity greater than serum values was observed in tissue extracts from the pancreas, duodenum, ileum, ovary, and testicles.

Experimentally induced acute pancreatitis in the cat, unlike the dog, is not associated with hyperamylasemia. Kitchell *et al.* (1986) have shown that in induced acute pancreatitis in cats the serum amylase level decreased during most of the experimental period. This hypoamylasemia may be due to decreased release of amylase from acinar cells, increased metabolism, or the presence of circulatory amylase inhibitory substances. Naturally occurring pancreatitis in four cats, likewise, was not associated with hyperamylasemia (Simpson *et al.*, 1994). Cats with pancreatic lesions induced by experimental hypercalcemia also had normal serum amylase activity but had a marked increase in urinary amylase (Frick *et al.*, 1990). Therefore, urine amylase activity may reflect pancreatitis in this species.

Both acute and chronic pancreatitis have been described in horses (McClure, 1987). In documented cases of pancreatitis in horses, both serum amylase and lipase activities have been elevated. The activities of these enzymes may be elevated in other gastrointestinal diseases but will generally be less than in pancreatitis.

ii. Significance It is believed that increases in serum amylase activity in the dog are generally indicative of acute pancreatic cell damage and ductal obstruction. However, because increased serum amylase activity is not specific for acute pancreatitis, some investigators have reasoned that serum amylase activity should be increased by three- to fourfold greater than the reference value to be diagnostic for pancreatitis in dogs (Strombeck *et al.*, 1981). It was concluded that serum amylase activity, without knowledge of serum lipase activity, was of little value in diagnosing pancreatitis. High serum amylase activity sometimes accompanied problems that did not involve the pancreas, and low serum amylase activity did not always rule out pancreatitis.

The evaluation of serum isoamylases, as done by electrophoresis, may provide a means of specifically identifying the acutely diseased pancreas. Simpson *et al.* (1991), however, determined that in dogs pancreatectomy did not significantly alter the activities of serum isoamylase peaks 1, 2, and 3 (the purported pancreatic-specific isoamylase) or of lipase and amylase. These findings indicated that the pancreas is not the sole source of circulating amylase, isoamylase, and lipase activities.

Serum amylase activity should also be interpreted in terms of renal function. Dogs with spontaneously occurring primary renal failure were found to have mean serum amylase activity 2.5-fold greater than normal dogs (Polzin *et al.*, 1983). When azotemia is present in dogs, additional laboratory data are required to determine whether the hyperamylasemia results from acute pancreatitis, primary renal failure, or both.

For dogs with primary renal failure, a satisfactory explanation for the hyperamylasemia is not apparent. Humans, guineas pigs, and baboons with acute pancreatitis have an increased renal clearance of amylase, relative to creatinine, and this increased clearance, in these species, has been considered useful in the diagnosis of acute pancreatitis. The dog, however, excretes little α-amylase in the urine (Brobst *et al.*, 1970). Jacobs (1989) observed that canine serum amylase, because of its polymerization with various serum proteins, has a large and heterogenous molecular size that does not permit it to be readily filtered by glomeruli. A linear relationship between urinary amylase activity and urinary protein loss supported the conclusion that urinary amylase activity is dependent on glomerular lesions. In a study of dogs with proteinuria Corazza *et al.* (1994) observed that urinary amylase activity was greater in dogs with renal insufficiency. Total serum amylase activity and macroamylasemia were also higher in dogs with renal insufficiency. Their data indicate that the mechanism responsible for high serum amylase activities in dogs with renal failure may be due to the macroamylasemia. In this study, high circulating immunocomplex concentrations in 60% of the dogs suggested a cause-and-effect relationship for the formation of macroamylasemia. The reason all dogs with proteinuria did not develop macroamylasemia was not investigated in this study.

iii. Methodology Amylase is a rather stable protein at 5°C. The enzyme requires calcium ion for activity, and thus plasma from blood samples with calcium-

chelating agents present is not acceptable for amylase determination (Hardy and Stevens, 1975).

The principle of serum amylase determination is the enzymatic hydrolysis of starch into maltose and limit dextrins. The rate of this hydrolysis is measured either by the rate of disappearance of starch (amyloclastic) or by the rate of appearance of reducing sugars (saccharogenic), that is, glucose and maltose, in the incubation mixture. The saccharogenic method for determining canine serum or plasma amylase activity gave results 70% higher than those of amyloclastic methods (Rapp, 1962; O'Donnell and McGeeney, 1975). The excess of saccharogenic activity was shown to correlate with glucoamylase activity and glucoamylase is a different molecular entity than α-amylase (O'Donnell and McGeeney, 1975). Therefore, serum amylase activity in the dog should be determined by amyloclastic methods specific for α-amylase. Glucoamylase activity is also present in the serum and plasma of cats and can interfere with the measurement of amylase activity (Ouedraogo *et al.*, 1992). As with the dog, methods specific for α-amylase such as the iodine method, starch dye, or "blocked" chromogenic substrate were recommended.

Turbidimetric and nephelometric methods are also employed to determine serum amylase activity. When a starch solution is hydrolyzed by amylase, the molecular size of the polysaccharides decreases owing to fragmentation by amylase action. This results in diminished turbidity and light scatter of the original solution. The decrease in turbidity can be measured absorptiometrically, and the decrease in light scatter can be measured nephelometrically and related to amylase activity. Turbidimetric and nephelometric methods can be simple, but the major disadvantages of these procedures are the lack of proper standards and poor substrate stability (Wu and Kao, 1984).

b. Serum Lipase

i. Source and Significance The pancreas is the primary source of serum lipase. Only pancreatic lipase is effective in liberating C_{14}, C_{16}, and C_{18} fatty acids from their triglycerides at appreciable rates; lipolytic enzymes from the duodenum and liver are much less effective (Lott *et al.*, 1986). Some investigators are of the opinion that in acute pancreatitis serum lipase concentration becomes elevated for a longer period of time than amylase. Brobst *et al.* (1970), however, determined in dogs with experimentally induced pancreatitis that serum amylase and lipase activities tend to parallel each other. Kasahara *et al.* (1975) also observed that serum activities of lipase, amylase, and elastase in dogs with experimentally induced pancreatitis parallel each other. The activities of these enzymes were higher in the pancreatic vein than in the femoral vein, indicating the enzymes did originate in the pancreas.

Hyperlipasemia, like hyperamylasemia, may, however, be associated with conditions other than acute pancreatitis. Spontaneously occurring and surgically induced renal failure in dogs caused serum lipase activity to increase three- to fivefold (Polzin *et al.*, 1983). Strombeck *et al.* (1981) also observed that serum lipase activity increased not only with pancreatitis in dogs but also with renal and hepatic diseases. On the other hand, the results of their study indicted that serum lipase activity was useful to identify pancreatitis, and low serum lipase activity almost always ruled out the possibility of pancreatitis. In their evaluation of the relationships of serum amylase and lipase activity in dogs with pancreatitis, they concluded little change in mean amylase concentration occurred until serum lipase values exceeded a set point (800 U/liter). Bellah and Bell (1989) demonstrated that exploratory laparotomy in dogs, with examination of all viscera but without any surgical procedure being done, caused serum lipase activity to rise threefold or greater although serum amylase activity did not increase. The increased lipase activity decreased to normal range by 48 hours following the laparotomy. The increase in lipase activity may have resulted from manipulation of the pancreas, stomach, liver, or intestines, however, gross and histological examination of the pancreas did reveal evidence of trauma or pancreatic disease. Likewise, in dogs treated with dexamethasone, serum lipase activity increased significantly although serum amylase activity decreased (Parent, 1982). Serum lipase activity had increased by the eighth day of administration, for dogs treated with low and high doses of dexamethasone, although evidence of pancreatic disease was not observed. It was considered possible that the increase in serum lipase activity resulted from dexamethasone-induced release from tissues other than the pancreas.

Although cats with acute experimentally induced pancreatitis had decreased serum amylase activity, their serum lipase activity increased (Kitchell *et al.*, 1986). Increased serum lipase activity appeared to be the earliest and most consistent indicator of acute pancreatitis in cats. Naturally occurring acute necrotizing pancreatitis in four cats was accompanied by hyperlipasemia in only one animal and all cats had normal serum amylase activity (Simpson *et al.*, 1994). The cat with hyperlipasemia was azotemic and decreased renal clearance of lipase may have been responsible for the increased serum lipase activity. Pancreatic lesions in the four cats were detected by abdominal ultrasonography.

Two major forms of lipase have been identified in human plasma. Using gel-filtration techniques, a single peak of lipase activity was identified in plasma from healthy subjects, whereas a separate peak of activity was present in patients with pancreatitis (Arzoglou *et al.*, 1986). The two forms of lipase were distinguished primarily by their relative molecular masses and their avidity for human pancreatic lipase antibodies.

ii. Methodology Serum lipase determination has traditionally been performed by variations of the Cherry–Crandall titrimetric procedure. This procedure is based on the hydrolysis of a lipid substrate into its constituent fatty acids. The quantity of NaOH required to neutralize the fatty acids provides a measure of lipase activity. The Cherry–Crandall method is time consuming and therefore several modifications of the procedure have evolved (Brobst and Brester, 1967). An enzymatic, kinetic procedure for determining serum lipase activity in dogs has been found suitable for automated methods and it correlated well with the Cherry–Crandall procedure (Walter *et al.*, 1992). Using the kinetic method it was determined that diseases of dogs associated with greater than twofold elevation in serum lipase activity included pancreatitis, gastritis with liver disease, and oliguric renal failure with metabolic acidosis. The serum lipase activity remained within the reference range or increased less than twofold with decreases such as gastritis, cholestasis, and colitis.

In a comparative study of current serum lipase procedures (with a titrimetric procedure serving as the standard), it was determined that those procedures utilizing colipase were in better agreement with the standard (Lott *et al.*, 1986). Colipase also increased analytical sensitivity and specificity. Colipase is present in the plasma of patients with pancreatitis, but it is usually inadequate to activate pancreatic lipase fully (Lott *et al.*, 1986). Serum and peritoneal lipase activity can also be determined by turbidimetric methods that assay triolein degradation (Robert *et al.*, 1986).

c. Miscellaneous Procedures

i. Pancreatitis-Associated Protein Acute pancreatic disease in dogs and cats is a disease of variable severity ranging from mild edema to severe necrosis. The increased activities of serum amylase and lipase are considered to be crude indicators of early pancreatitis but these enzymes do not reflect the clinical severity of the disease. It has been determined in rats with induced pancreatitis that the synthesis of pancreatic enzymes was repressed in the acute phase but that a nonenzymatic secretory protein, pancreatitis-associated protein (PAP) was overexpressed by the pancreas (Iovanna *et al.*, 1991, 1994). In human patients with acute pancreatitis, PAP values were much greater in those with pancreatic necrosis than those with mild pancreatitis. Continuous elevation of serum PAP concentration informed the clinician that pancreatitis was still in progress and stabilization of the PAP value reflected the climax of the crisis. Sustained decrease in PAP concentration reflected an improvement in the patient's condition. Thus, serum PAP values may provide information on the development and severity of acute pancreatitis.

ii. Interleukin-6 Serum concentrations of interleukin-6 (IL-6) were greater in human patients with severe acute pancreatitis than with mild pancreatitis (Heath *et al.*, 1993). The investigators believed serum concentrations of interleukin-6 could be useful as an indicator of severity of acute pancreatitis. Interleukin-6 appears to be the principal mediator of the acute-phase protein response of which C-reactive protein is an important component. C-reactive protein is a nonspecific indicator of inflammation and its serum concentration, as that of IL-6 rises with acute pancreatitis in human patients. The serum concentration of IL-6, however, peaked earlier than that of C-reactive protein (Heath *et al.*, 1993), and therefore was considered the better indicator of acute pancreatitis.

iii. Pancreatic Polypeptide Serum pancreatic polypeptide (PP) is a peptide hormone produced by cells dispersed throughout both the exocrine and endocrine pancreas. The mechanisms of action for PP may involve modulation of digestive processes by decreasing pancreatic and biliary secretion. Serum immunoreactive PP concentrations in dogs with induced pancreatitis peaked between 4 and 12 hours after induction of pancreatitis and were normal at 96 hours after induction of pancreatitis (Murtaugh *et al.*, 1985). This short period in which immunoreactive PP is elevated following the onset of pancreatitis may limit its usefulness as a diagnostic procedure; however, it may serve as an indicator of peracute inflammation.

iv. Plasma and Ascitic Fluid Trypsin and Trypsinogen Sensitive and specific radioimmunoassay techniques have been developed to characterize the molecular forms of immunoreactive pancreatic trypsin in experimental acute pancreatitis in dogs. In dogs with more mild pancreatitis trypsinogen predominated in the plasma, while in the more severe cases of acute pancreatitis significant amounts of trypsin were present bound to the protease inhibitors α_2-macroglobulin and α_1-protease. Dogs dying of acute pancreatitis had greater amounts of trypsin-like immunoreactivity (TLI) in the ascitic fluid than in the plasma, although

the plasma levels increased during the course of the disease. The survivor dogs had little activation of trypsinogen and lower concentrations of TLI in ascitic fluid and plasma (Geokas *et al.*, 1981). This work would suggest that the activation of trypsinogen resulting in inhibitor-bound forms of trypsin in ascitic fluid and plasma is important in the pathogenesis of acute pancreatitis.

The measurement of serum TLI in dogs may prove to be a specific test for acute pancreatitis. This procedure measures both serum trypsinogen and trypsin by radioimmunoassay. The immunoreactive material present in the serum of normal dogs is most likely trypsinogen and may result from leakage into the pancreatic lymphatic and venous vessels. Inflammatory or obstructive processes in residual pancreatic tissue could result in elevated serum TLI activity. Following the ligation of pancreatic ducts in dogs (Simpson *et al.*, 1989a), plasma TLI concentration was observed to increase within 24 hours and tended to peak before and to decrease more rapidly than activities of lipase and amylase. Because TLI in dogs is specifically pancreatic in origin, the assay for plasma or serum TLI concentration may be able to provide an earlier indication of acute pancreatitis than serum amylase or lipase activity. Plasma lipase activity remained elevated for longer periods of time than did TLI and thus a normal TLI concentration would not rule out pancreatitis. Increased serum TLI concentration, like increased lipase and amylase activities, may possibly also result from renal insufficiency or disease of other organs that appear to influence the half-lives of these enzymes (Simpson *et al.*, 1991). In preliminary studies using an assay specific for feline TLI, Medinger *et al.* (1993) determined that cats with acute pancreatitis also had serum TLI concentrations greater than reference range.

v. Trypsinogen-Activation Peptides (TAP) Intrapancreatic activation of trypsinogen is believed to occur either as a cause or a consequence of acute pancreatitis. In experimental acute pancreatitis in rats, extraintestinal trypsinogen activation causes a direct release of TAP into the circulation. The concentration of TAP in the plasma and urine of the rats was measured by radioimmunoassay and provided an accurate and early prediction of mortality in rats with pancreatitis ranging in severity from minimal to lethal (Schmidt *et al.*, 1992). The assay for TAP has some advantages over the TLI assay. The TAP assay has no cross-reactivity with trypsin or trypsinogen and reflects the amount of extraintestinal trypsinogen activation. Unlike TLI, TAP does not bind to α_1-protease inhibitor or α_2-macroglobulin and, thus, is entirely accessible for antibody binding.

vi. Hyperlipemia Pathologic hyperlipemia has been observed in some dogs with acute pancreatitis (Anderson and Straufuss, 1971). The lipemia is usually transient and may occur with exacerbations of acute pancreatitis. The most striking feature is an elevation of plasma triglyceride levels, which imparts a milky turbidity to the plasma. Kessler *et al.* (1962) experimentally induced pancreatitis in rabbits and found an elevation of plasma triglycerides with lipemia being present. Lipemic plasma from animals with pancreatitis inhibited the "lipemia-clearing factor," lipoprotein lipase, of normal rabbits. Correlation was close between the degree of inhibition of lipoprotein lipase and the level of plasma triglyceride. It was considered possible that inhibitors of lipoprotein lipase were released from necrotic pancreatic tissue.

B. Pancreatic Insufficiency

1. Etiology

Exocrine pancreatic insufficiency in the dog is a disorder that develops because of inadequate pancreatic digestive enzymes. The disorder is characterized by weight loss and polyphagia, and steatorrhea may be present at times. The main causes are recognized as pancreatic acinar atrophy and chronic pancreatitis. The causes of canine pancreatic atrophy are unknown. The abnormality is more common in large breeds of dogs and occurs generally in their first year of life (Anderson and Low, 1965). The acinar cells appear to undergo progressive loss of cytoplasm and zymogen granules.

Chronic pancreatis reflects repeated attacks of acute pancreatitis with progressive destruction of acinar tissue and replacement with fibrous connective tissue. The early clinical signs of chronic pancreatitis may resemble those of acute pancreatitis, with the necrotizing process smoldering asymptomatically. Chronic pancreatitis is commonly seen in the canine species. Duffell (1975) observed that chronic and subacute pancreatitis are common in the cat.

The oral administration of zinc compounds, which have been used to prevent sporidesmin poisoning in ruminants, may cause chronic pancreatitis. Sheep that were administered zinc oxide experimentally developed various degrees of pancreatic fibrosis with decreased output of pancreatic amylase and protein (Smith and Embling, 1984). Induced zinc toxicosis in veal calves produced lesions that included pancreatic atrophy, necrosis of acinar tissue, and multifocal fibrosis of pancreatic acini. Pancreatic lesions were most severe and frequent in acinar tissue compared to islet tissue. The calves developed severe diarrhea believed to be caused by EPI (Graham *et al.*, 1988). The impor-

tance of pancreatic exocrine secretion in ruminants is not well understood, but ewes and lambs deprived of pancreatic juice have been shown to have much less lipid content in intestinal lymph than did normal sheep (Gooden and Lascelles, 1973).

Chronic fibrosing pancreatitis also occurs in horses. An affected horse has a generalized, progressive dermatitis that is part of a multisystemic, chronic eosinophilic disease of unknown etiology (Nimmo Wilkie *et al.*, 1985). The pancreas of an affected horse contains eosinophilic granulomas and has loss of exocrine tissue.

2. *Pathophysiology*

With almost total destruction of the acinar tissue of the pancreas, EPI occurs (Anderson, 1972). Without trypsin, the feces contain undigested meat fiber, and there is nitrogen loss. In the absence of lipase, neutral fat is in the feces. Without pancreatic amylase, starch is lost in the feces; however, this is of less importance than the resulting disturbed protein and fat digestion. The reserve capacity of the pancreas is great, and, in humans, steatorrhea was not observed until lipase output was less than 10% of normal. Creatorrhea was observed only when trypsin output was less than 10% of normal (Di Magno *et al.*, 1973).

After total resection of the pancreas of dogs, the digestion and absorption of fat and protein is markedly disturbed, although this is not true of carbohydrates. Yoshizawa *et al.* (1976) demonstrated that in total resection of the pancreas of dogs, the absorption of olive oil was a severely impaired by the duodenal mucosa, but absorption of oleic acid and medium-chain triglycerides (MCT) was less affected. The hydrolysis of MCT by pancreatic lipase is more rapid than that of long-chain triglycerides. The degree of steatorrhea in pancreatic insufficiency thus may be reduced by feeding MCT as the source of fat.

Valdivieso (1972) demonstrated that rats with surgically induced pancreatic insufficiency absorb a substantial amount of MCT. By the use of isotope-labeled lipid, it was shown that MCTs were not hydrolyzed in the jejunum but diffused intact into the gut epithelial cells. In the cell, MCTs were partially hydrolyzed by intestinal lipase and then transferred to the portal blood partly as intact triglyceride and partly as fatty acid. In the cecum, MCTs were hydrolyzed in the lumen by a hydrolytic system independent of the pancreas. The liberated fatty acids diffused through the cecal mucosa to the portal circulation. Hypertrophy of the cecum occurred in the rats after induction of pancreatic insufficiency.

Pigeon (1982) observed that dogs with experimentally induced pancreatic insufficiency that were fed a dry dietary food, formulated for use in gastrointestinal disorders, excreted approximately 60% less fat and dry matter than when fed a popular dry dog food. Improved dry matter digestibility was found to be associated with improved fat digestion and absorption. Conditions that increased the fecal water content lead to reduced assimilation of fat.

3. *Laboratory Diagnostic Aids*

a. Serum Amylase and Lipase

Serum amylase and lipase levels may be elevated if acute exacerbations of pancreatitis occur. However, with complete destruction of acinar tissue and healing by fibrosis, serum enzyme elevations would not be expected, and enzyme activity may even be decreased.

b. Fecal Examination

Microscopic examination of feces to detect excess fecal fat has employed the use of Sudan stains to stain lipid droplets (Brobst, 1989). These screening tests, however, can be difficult to interpret and are not precise. Many dogs with established EPI may not always have excess lipid in their feces and a negative test does not rule out steatorrhea.

Fecal proteolytic activity estimates, using either the x-ray film gelatin digestion test or tubes of gelatin, have also been used as an indirect indicator of pancreatic enzyme activity. These gelatin digestion tests unfortunately are an unreliable assay of fecal proteolytic activity and give many false-negative and false-positive results. Fecal proteolytic activity assayed using an azocasein or casein substrate, however, is a reliable procedure and may be used in the diagnosis of EPI when the serum TLI test is not available. Reference values for fecal proteolytic activity in dogs have been established for a colorimetric procedure using an azocasein substrate and for a radial enzyme diffusion into agar gels containing casein substrate (Williams and Reed, 1990). These assays permit evaluation of pancreatic function provided several fecal samples are assayed. Proteolytic activity remaining after treatment of fecal samples with specific trypsin inhibitor indicated that trypsin accounted for 0–71% of the proteolytic activity. This may signify that trypsin is degraded as it passes through the intestinal tract or that there is a variation in the proportion of trypsin to total protease activity in pancreatic juice.

c. Fat Absorption

The fat absorption test is based on the principle that dietary fats must be hydrolyzed to fatty acids and glycerol prior to absorption. With reduced ability to

assimilate fats, the defect may lie in either a deficiency of pancreatic lipase or an inability of the small bowel to absorb properly digested fats. In the test, a heparinized blood sample is drawn from the fasted animal and centrifuged. A meal rich in digestible oil, such as corn or peanut oil, is fed to the animal and a second heparinized blood sample is taken 3 hours later. The turbidities of the pre- and postfeeding sample are compared. Normally, the prefeeding sample has clear plasma, whereas that postfeeding has a turbid appearance (lipemia). If the plasma samples are equally clear, one can assume either that pancreatic exocrine function is deficient or that the intestine is incapable of proper absorption (Brobst and Funk, 1972). The two conditions can be differentiated by repeating the fat meal at a later date, this time supplemented with pancreatic extract as a source of lipase. A cloudy postfeeding sample indicates that absorption from the intestine was normal and the pancreas was deficient in secretion of lipase. The degree of lipemia can also be measured spectrophotometrically or the increase in plasma triglyceride concentration over basal levels can be measured following the lipid-rich meal. A problem with any oral tolerance test, such as this, may arise when the gastric emptying time is delayed. The simultaneous ingestion of carbohydrate and protein may also reduce alimentary lipemia.

Pilsworth and Lehner (1986) demonstrated that the use of cimetidine (an inhibitor of gastric acid secretions) was a useful adjunct to oral pancreatic extract therapy in dogs with pancreatic insufficiency that failed to respond to pancreatic enzyme replacement alone. It was estimated that 90% of administered pancreatic extract was destroyed in the stomach because of its high acidity. The use of cimetidine elevates the duodenal pH, and it is suggested that solubilization of fats is increased because of bile acid actions that are inhibited at acid pH.

d. Pancreatic Chymotrypsin Activity

The duodenal juice of normal dogs contains 487 ± 129 mU/ml of chymotrypsin, and dogs with EPI have been found to contain only 1.3 ± 0.2 mU/ml (Batt and Mann, 1981). The ability of the pancreas to secrete chymotrypsin, as a measure of exocrine pancreatic function, is based on the oral administration of a synthetic peptide, *N*-benzoyl-L-tyrosyl-*p*-aminobenzoic acid (BT-PABA), and the cleaving of BT-PABA by chymotrypsin to release *p*-aminobenzoic acid (PABA). After absorption, PABA appears in the blood and urine. In normal dogs, plasma PABA concentration peaks at 60–90 minutes and then gradually declines (Batt and Mann, 1981; Strombeck and Harrold, 1982). In normal dogs, the 6-hour PABA urinary excretion has been suggested to be any value greater than 46–50% of the administered dose (Strombeck and Harrold, 1982). The measurement of plasma PABA in a 60-minute test did not identify dogs with pancreatic insufficiency as consistently as the measurement of 6-hour urinary PABA excretion. Dogs with EPI and with 6-hour PABA urinary excretion of less than 20% required pancreatic enzyme replacement therapy for remission of diarrhea (Strombeck, 1978). The combined BT-PABA: xylose absorption test has been used for simultaneous evaluation of exocrine pancreatic function and intestinal absorptive function in dogs (Rogers *et al.*, 1980). Using similar techniques for the BT-PABA:xylose test in healthy cats, the mean peak concentration of PABA was approximately half that for dogs (Sherding *et al.*, 1982). It was concluded that the large variations among cats may limit the usefulness of this test in this species. It has been observed that an appreciable but subnormal increase in plasma PABA concentration may occur in some dogs with EPI (Williams and Batt, 1988). Overgrowth of duodenal microflora is common in dogs with EPI and these investigators were of the opinion that some bacteria, particularly *Clostridium* species, may produce peptidase with a chymotrypsin-like substrate specificity. In general, procedures such as the BT-PABA test, which involve gastric emptying and intestinal factors as well as pancreatic function, may lack some specificity in evaluating pancreatic function.

Burrows and Orfely (1989) observed that when BT-PABA was administered orally to dogs as a solution in propylene glycol, the resulting plasma PABA concentration was higher than when an equal dose of BT-PABA suspended in water was administered. Therefore, published reports on the use of the BT-PABA test should state whether dissolved or suspended BT-PABA was administered. Using the solution form of BT-PABA and interpreting the results by comparison with normal absorption curves obtained after administration of the suspension form of BT-PABA could contribute to failure to diagnose EPI.

e. Serum Trypsin-Like Immunoreactivity

The determination of serum TLI concentration may be the most reliable procedure for the diagnosis of EPI in the dog. This assay can be done on a single 12-hour fasting sample. The reference range for normal dogs is 5.2–34 μg/liter and for dogs with EPI is <2.5 μg/liter (Williams and Batt, 1988). Pancreatomy in the dog was followed by a decrease in the TLI concentration to <2.5 μg/liter (Simpson *et al.*, 1991). Clinical signs of EPI are usually not observed until serum TLI concentration is <3.0 μg/liter (Williams, 1988). Dogs fed diets with serum protein content ranging from 6.8 to 39% had a serum TLI reference range of 5.7–20.1 μg/liter

(Carro and Williams, 1989). For every 1% increase in dietary protein content, the calculated serum TLI concentration increased 0.16 μg/liter. Thus, feeding of a very low protein diet may lead to decreased synthesis of pancreatic proteases. Observation of a family of dogs in which EPI had been reported suggested that the serum TLI test could reveal the presence of EPI in young puppies before clinical signs were seen and when fecal proteolytic activity was still normal (Boari *et al.*, 1994). Preliminary investigation of the serum TLI assay in cats indicated the procedure would likely be of value in the diagnosis of EPI (Medinger *et al.*, 1993).

CHAPTER

15

Gastrointestinal Function

WILLIAM E. HORNBUCKLE AND BUD C. TENNANT

I. INTRODUCTION

The digestive system is composed of the gastrointestinal (GI) tract or alimentary canal, the salivary glands, the liver, and the exocrine pancreas. The principal functions of the gastrointestinal tract are the digestion and absorption of ingested nutrients and the excretion of waste products of digestion. Most nutrients are ingested in a form that is too complex for absorption, is insoluble and therefore indigestible, or is incapable of being digested. Within the GI tract, many of these substances are solubilized and further degraded enzymatically to simple molecules whose form and small size permits their absorption across the mucosal epithelium. This chapter describes the normal biochemical processes of intestinal secretion, digestion, and absorption and, with these in perspective, the pathogenesis of the important gastrointestinal diseases of domestic animals and the biochemical basis for their diagnosis and treatment.

II. SALIVARY SECRETIONS

A. Mechanisms of Secretion

Saliva is produced by three major pairs of salivary glands and by small glands distributed throughout the buccal mucosa and submucosa. Two types of secretory

cells are found in the acinar portions of the salivary glands: (1) the mucous cells, which contain droplets of mucus, and (2) the serous cells, that contain multiple secretory granules. In those species that produce salivary amylase, the secretory granules are the zymogen precursors of this enzyme. A third cell type is found lining the striated ducts. The striations along the basal borders of these cells are caused by vertical infoldings of the cell membrane, a characteristic of epithelial cells involved in rapid movement of water and electrolytes. The primary secretion of the acinar cells is modified by active transport processes of the ductal epithelium.

The distribution of the different types of secretory cells in the salivary glands varies among species. The parotid glands of most animals are serous glands that produce a secretion of low specific gravity and osmolality containing electrolytes and proteins, including certain hydrolytic enzymes. The mandibular (submaxillary) and sublingual glands are mixed salivary glands containing both mucous and serous types of cells and producing a more viscous secretion that contains large amounts of mucus (Dukes, 1955).

B. Composition of Saliva

1. *Mucus*

Mucus is an aqueous mixture of proteoglycans and glycoproteins. One of the most completely studied glycoproteins is mucin. Salivary mucins are *O*-glycosylated, consisting of peptides with many oligosaccharides linked covalently to the hydroxyamino acids serine or threonine. The carbohydrate portion of submaxillary mucin from sheep is a disaccharide of *N*-acetylneuraminic acid (sialic acid) and *N*-acetylgalactosamine (Carlson *et al.*, 1973). The enzymes that link protein with hexosamine have been purified from sheep (Carlson *et al.*, 1973) and swine (Schachter *et al.*, 1971) mandibular glands.

The physiological functions of mucin are related to its high viscosity. *N*-Acetylneuraminic acid is the component responsible for the formation of viscous aqueous solutions and, at physiological pH, causes expansion and stiffening of the mucin molecule. The resistance of mucin to enzymatic breakdown is also due to the presence of disaccharide residues. Removal of terminal *N*-acetylneuraminic acid residues by action of neuraminidase significantly increases the susceptibility of peptide bonds to trypsin.

2. *Electrolytes*

The principal inorganic constituents of saliva are sodium, potassium, chloride, and bicarbonate that, with the exception of bicarbonate, originate directly from the plasma. Rates of salivary flow vary depending on stimulation and there are wide variations in electrolyte concentration. Saliva is formed by a process that initially requires uptake of sodium and other electrolytes from the interstitium of the terminal structural unit of the salivary gland, the acinus or end piece. Water flows passively. This primary or precursor fluid has a sodium concentration similar to that of plasma, and the potassium concentration is similar to or slightly higher than that of plasma. As the primary fluid passes from the acinus along the duct system, the concentration of sodium, potassium, and other electrolytes is changed. In most species, there is net sodium absorption and potassium secretion. Wide variations in electrolyte composition may occur depending on flow rate (Young and Schneyer, 1981), the salivary gland of origin, and the species (Table 15.1).

3. *Amylase*

The saliva of rodents contains the α-amylase ptyalin, but this enzyme activity is absent in the saliva of dogs, cats, horses, cattle, and sheep (Dukes, 1955; Young and Schneyer, 1981). Salivary amylase splits the α-1,4-glucosidic bonds of various polysaccharides and is similar in major respects to pancreatic α-amylase, which is described in Section V.B. Salivary amylase initiates digestion of starch and glycogen in the mouth in those species that secrete the enzyme. The optimal pH for amylase activity is approximately 7, so this activity ceases when the enzyme mixes with acidic gastric contents.

4. *Lipase*

Lingual lipase is secreted by Von Ebner's gland of the tongue and is important in the digestive processes of the newborn (Cook *et al.*, 1994).

C. Functions of Saliva

Saliva continuously bathes the oral cavity, which serves to protect the surface epithelium. Ingested food is moistened and lubricated by saliva, thereby facilitat-

TABLE 15.1 Electrolyte Concentration of Mandibular Gland and Parotid Gland Saliva Observed during Maximum Rates of Secretion (mmol/liter)

	Mandibular gland			Parotid gland		
	Na^+	K^+	HCO_3^-	Na^+	K^+	HCO_3^-
Sheep	20	7	23	160–175	9–10	113–140
Dog	70–100	12–15	10–30	80–110	6–14	50
Cat	40–51	9–10	26	—	—	—
Rabbit	50–100	10–40	25	110–140	10	12–30

ing mastication and swallowing. The teeth also are protected from decay by saliva, which washes food particles from the surfaces of the teeth and, because of its buffering capacity, neutralizes the organic acids produced by bacteria normally present in the mouth. Saliva is necessary for vocalization and, in some species that groom themselves, promotes cooling as it evaporates (Cook *et al.*, 1994). Additionally, it may be a source of pheromones. Salivary glands contain large number of growth factors, vasoactive serine proteases, and regulatory peptides (Cook *et al.*, 1994). There is reason to believe that these glandular constituents affect a wide range of biologic functions not necessarily limited to the alimentary system.

Ruminants produce much greater quantities of saliva than do simple-stomached animals, and their saliva has a higher pH and bicarbonate-ion concentration. In ruminants, saliva serves several unique functions (Phillipson, 1977). It is required for maintenance of the fluid composition of the contents of the rumen. The great buffering capacity of ruminant saliva is necessary to neutralize the large amounts of organic acids that are end products of rumen fermentation.

The urea in saliva can be utilized by rumen bacteria for protein synthesis. Protein synthesized in the rumen is then used to meet dietary protein requirements. In this way, urea nitrogen can be "recycled" through the amino acid pool of the body and, in ruminants, need not be considered an end stage in protein catabolism. The ability to reutilize urea has also been demonstrated in the horse; this may be of particular benefit during periods of protein deficiency (Houpt and Houpt, 1971).

III. GASTRIC SECRETIONS

The stomach is divided into two main regions on the basis of secretory function. The oxyntic-gland area corresponds approximately to the body of the stomach in most species of domestic animals and also to the fundus in the dog and cat. The oxyntic glands contain (1) oxyntic or parietal cells that produce hydrochloric acid (HCl), (2) peptic (zymogenic, chief) cells that produce pepsinogen, and (3) mucous cells. The pyloric gland area contains mucus-producing pyloric glands whose secretion is slightly alkaline. This area also contains the G cells that produce the polypeptide hormone gastrin.

A. Composition of Gastric Secretion

1. Basal vs Stimulated Secretion

There are two components of gastric secretion. The basal component is secreted continuously by the surface epithelial cells and other mucus-producing cells. This component is neutral or slightly alkaline pH. The electrolyte composition is similar to that of an ultrafiltrate of plasma (Table 15.2). The basal secretion contains large amounts of mucus, which has a cytoprotective effect on the epithelium. The secretory component produced by the oxyntic-gland cells in response to stimulation contains free HCl and pepsinogen, the principal enzyme of gastric digestion.

The composition of gastric juice depends on the relative amounts of the basal and secretory components in the juice. These amounts, in turn, are functions of the flow rate of each. In the dog, gastric juice is produced in the resting state at a rate of approximately 5 ml/hour (Gray and Bucher, 1941). The composition is similar to that of the basal component, containing practically no peptic activity or HCl. When the flow of gastric juice is stimulated maximally, the dog may produce 80 ml or more per hour of a secretion containing large amounts of peptic activity and HCl. Na^+, the principal cation in the basal secretion, is replaced to a large extent by H^+ ion. The concentration of K^+ is similar in both basal and stimulated secretions and therefore remains relatively constant at the various rates of flow.

HCl and pepsinogen are secreted by separate mechanisms, but their production appears closely linked under physiological conditions. Stimulation of the vagus nerve or intravenous injection of gastrin increases pepsinogen and HCl levels together. Other stimuli may affect the two processes differently, for example, in the dog histamine infusion stimulates HCl production maximally but appears to inhibit pepsinogen secretion (Emas and Grossman, 1967).

TABLE 15.2 Composition of Parietal and Nonparietal Secretions of Canine Gastric Mucosa

Component	Parietal secretion[a] (mmol/liter)	Nonparietal secretion[a] (mmol/liter)	Nonparietal secretion[b] (mmol/liter)
Na^+	—	155.0	138.0
H^+	159.0	—	—
K^+	7.4	7.4	4.0
Ca^{2+}	—	3.7	5.0
Cl^-	166.0	133.0	117.0
pH	<1.0	7.54[c]	7.42

[a] Determined *in vivo* using dogs with gastric fistulas (Gray and Bucher, 1941).

[b] Determined *in vitro* with isolated gastric mucosa (Altamirano, 1963).

[c] Calculated from bicarbonate concentration assuming pCO_2 of 40 torr.

2. *Pepsin*

Pepsinogen is the zymogen, or inactive precursor, of pepsin, the principal proteolytic enzyme of gastric juice. Pepsinogen was first crystallized from the gastric mucosa of swine (Herriott, 1938), and several pepsinogens have now been separated. The porcine pepsinogen has a molecular weight of approximately 43 kDa and is composed of the pepsin molecule and several smaller peptides. One of these peptides has a molecular weight of 3.2 kDa and is an inhibitor of peptic activity. Activation of pepsin from pepsinogen occurs by selective cleavage of this small basic peptide from the parent pepsinogen (Neurath and Walsh, 1976). Autocatalytic conversion begins below pH 6.0. At pH 5.4, the inhibitor peptide dissociates from the parent molecule, and at pH 3.5–4.0 the inhibitor is completely digested by pepsin.

Pepsin has a very acidic isoelectric point, being stable in acidic solution below pH 6.0 but irreversibly denatured at pH 7.0 or above. In contrast, pepsinogen is stable in neutral or slightly alkaline solution. The optimal pH for peptic activity is generally between 1.6 and 2.5, but the effect of pH may vary with the substrate. Pepsin is capable of hydrolyzing peptide bonds of most proteins, mucin being one important exception. Pepsin splits bonds involving phenylalanine, tyrosine, and leucine most readily but can hydrolyze almost all other peptide bonds.

3. *Rennin*

Rennin is another proteolytic enzyme produced by the gastric mucosa and has some characteristics that are similar to those of pepsin. It has been separated from pepsin in preparations from the stomachs of newborn calves. Rennin splits a mucopeptide from casein to form paracasein, which then reacts with calcium ion to form an insoluble coagulum. The coagulated milk protein probably delays gastric emptying and increases the efficiency of protein digestion in young calves.

4. *HCl*

HCl is produced by the oxyntic cells. When the normal mucosa is stimulated, both Cl^- and H^+ are secreted together, but current evidence suggests that H^+ and Cl^- are secreted by separate, closely coupled mechanisms. Small amounts of Cl^- are secreted continuously by unstimulated oxyntic cells in the absence of H+ secretion, and this mechanism is responsible for the negative charge of the resting mucosal surface of the stomach relative to that of the serosa. For every H^+ secreted, an electron is removed that ultimately is accepted by oxygen to form OH^-, which is neutralized within the cell by H+ from H_2CO_3. The HCO_3^- then enters the venous blood by means of a Cl^-/HCO_3^- exchange and during HCl secretion , the pH of gastric venous blood frequently is greater than that of arterial blood (Davenport, 1966).

The membrane-bound enzyme responsible for transport of H^+ by the oxyntic cell is a K^+-stimulated ATPase (Sachs *et al.*, 1976; Wallmark *et al.*, 1980) that serves as H^+/K^+ exchange pump. At the time of oxyntic cell stimulation, the secretory membrane is altered to provide augmented K^+ and Cl^- conductances (Wolosin, 1985). KCl leaves the apical cell membrane passively, and net production of HCl results from the electroneutral exchange of K^+ for H^+ (Fig. 15.1).

B. Control of Gastric Secretion

1. *General*

A variety of stimuli can initiate gastric secretion. The sight or smell of food or the presence of food within the mouth causes gastric secretion by a reflex mechanism involving the vagus nerve. The presence of certain foods within the stomach or distension of the stomach alone can also initiate both intrinsic and vagal nerve reflexes which cause secretion of gastric fluid. In addition to neural reflexes, these stimuli also cause release of gastrin from the pyloric-gland area that enters the bloodstream, stimulating gastric secretion. The release of gastrin from G cells is inhibited by excess H^+; this negative-feedback mechanism is important in the control of HCl production.

2. *Gastrin*

Gastrin has been isolated in pure form from the antral mucosa of swine (Gregory *et al.*, 1964). When administered intravenously, the purified hormone causes the secretion of HCl and pepsin and stimulates gastrointestinal motility and pancreatic secretion. Two separate peptides have been obtained from porcine gastric mucosa and have been designated gastrin I and gastrin II. Gastrin is a heptadecapeptide amide, with a pyroglutamyl N-terminal residue and with the amide of phenylalanine as the C-terminal residue (Fig. 15.2). In the center of the molecule is a sequence of five glutamyl residues that give the molecule its acidic properties. Gastrin II differs from gastrin I only in the presence of a sulfate ester group linked to the single tyrosyl residue. The C-terminal tetrapeptide amide, Trp–Met–Asp–Phe–NH_2, is identical in all species so far studied (Gregory, 1967). The tetrapeptide has all of the activities of the natural hormone. It is not as potent

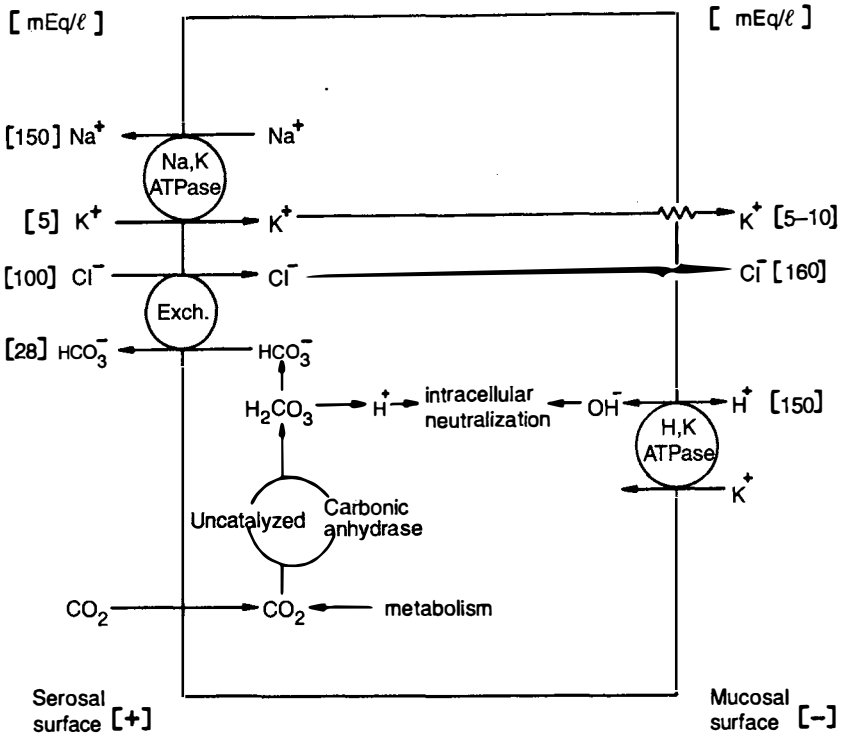

FIGURE 15.1 Movement of ions across the mucosal (apical) and serosal (basal) cell membranes of the parietal during HCl secretion.

as the parent molecule, but activity can be increased by lengthening the peptide chain.

Gastrin is released in response to vagal stimulation by distension of the pyloric antrum and by direct luminal contact with food, particularly partially hydrolyzed protein (Walsh and Grossman, 1975). Gastrin is the only hormone known to stimulate HCl secretion (Walsh and Grossman, 1975). The exact mechanism of action is not yet known.

3. *Histamine*

Histamine secreted locally within the mucosa has a major effect on the function of oxyntic cells (Soll and Grossman, 1978). Histamine has been recognized as a potent stimulant of HCl production for many years, but this effect was not inhibited by traditional antihistaminic drugs (H-1 antagonists) and, until the demonstration of H-2 receptors in the stomach (the atrium and uterus) by Black *et al.* (1972), the physiological role of histamine in HCl secretion was controversial. Specific H-2 antagonists (cimetidine) now have been shown to inhibit the secretory response not only to histamine, but to other secretory stimuli as well (Grossman and Konturek, 1974).

The complex of oxyntic cell receptors involved in the control of oxyntic cell function is shown in Fig. 15.3. When the H-2 receptor of the oxyntic cell is occupied by histamine, basal lateral adenylate cyclase is activated, resulting in increased cellular cyclic AMP (cAMP) and in a sustained secretory response. The secretagogue action of cAMP is mediated by the activity of cAMP-dependent protein kinases (Chew, 1985).

Cholinergic stimulation of the oxyntic cell involves type 1 muscarinic receptors and a calcium activation pathway. Calmodulin inhibitors such as trifluoroperazine inhibit H^+ secretion (Raphael and Machen, 1984). The Ca–calmodulin system may influence the rate of cAMP synthesis, and a more distal site of action has been suggested by the identification of a Ca-dependent protein kinase activity in a membrane fraction prepared from oxyntic cells that was rich in H^+–K^+-

FIGURE 15.2 Amino acid sequence of porcine gastrin I (Gregory, 1966). Gastrin II differs from gastrin I by the presence of a sulfate ester group on the single tyrosyl residue.

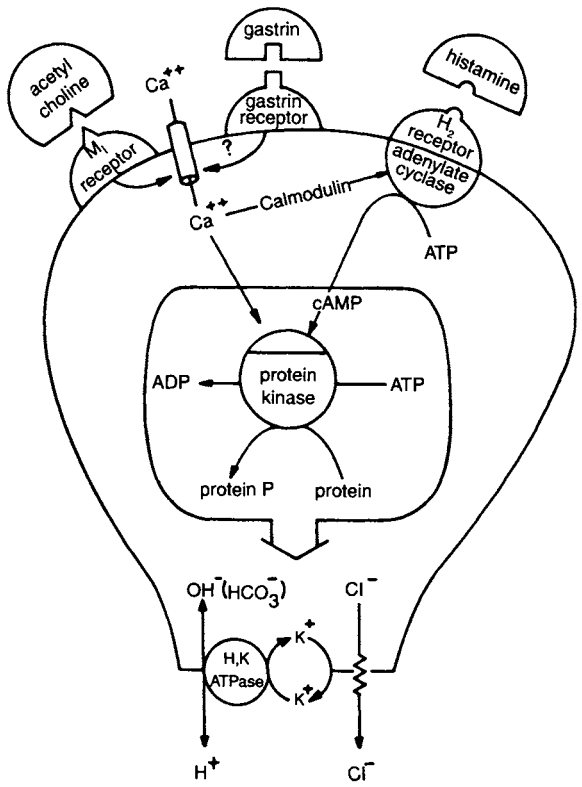

FIGURE 15.3 Pathways of secretagogue action on the parietal cell. Stimulation by gastrin and acetylcholine are mediated by entry of Ca^{2+} into the cell. Histamine activates adenylate cyclase with production of cAMP, the action of which is mediated by protein kinase.

ATPase (Schlatz *et al.*, 1981). A specific receptor for gastrin has been demonstrated on oxyntic cells, and a specific gastrin antagonist, proglutamide, inhibits H^+ production. Gastrin appears to act synergistically with histamine and acetylcholine (AcCh) to regulate H^+ production, but the actual mechanism of action of gastrin is unknown.

4. Prostaglandins

In addition to inhibiting HCl secretion, prostaglandins also act on a mucosal cell population that is distinct from oxyntic cells that secret cytoprotective substances (mucin, glycosaminoglycans). The ulcerogenic effects of inhibitors of prostaglandin synthesis (indomethacin, aspirin) apparently are the result of inhibition of the protective effect of endogenous prostaglandins.

Knowledge of the molecular aspects of receptor function of HCl secretion by oxyntic cells now provides the opportunity for specific pharmacological intervention for control and treatment of ulcerative diseases of the upper gastrointestinal tract that appear to be the result of HCl-induced mucosal injury. Gastric ulcers represent a serious problem in foals (Aclund *et al.*, 1983; Becht and Byars, 1986) and the H-2 receptor antagonist cimetidine is now used for treatment of foals with clinical signs of gastric ulceration. Ranitidine, also an inhibitor of the H-2 receptor and more potent and longer-acting than cimetidine, has been shown experimentally to inhibit HCl production in the horse (Campbell-Thompson and Merritt, 1987). Other potential therapeutic target sites have been demonstrated. Of particular importance are drugs that specifically inhibit the H^+–K^+-ATPase (Table 15.3).

TABLE 15.3 Inhibitors of Oxyntic Cell Function

A. Inhibitors of H^+–K^+-ATPase: omeprazole, verapmil, vanadate
B. Inhibitors of carbonic anhydrase: acetazolamide
C. Inhibitors of cell activation or response
   1. Calcium channel antagonists: verapamil, lanthanum
   2. Prostaglandin E_2
D. Receptor antagonists
   1. H_2-receptor antagonists: cimetidine, ranitidine
   2. Gastrin antagonists: proglumide, benzotript
   3. Anticholinergic agents: atropine
E. Inhibitors of calmodulin: trifluoroperazine

IV. Bile

A. Composition of Bile

Bile is secreted continuously by the hepatocytes into the bile canaliculi and is transported through a system of ducts to the gallbladder, where it is modified, concentrated, and stored. During digestion, bile is discharged into the lumen of the duodenum, where it aids in emulsification, hydrolysis, and solubilization of dietary lipids. The digestive functions of bile are accomplished almost exclusively by the detergent action of its major components, the bile salts and phospholipids.

B. Properties of Bile

The carboxyl group of the bile acid (BA) is completely ionized at the pH of bile and is neutralized by Na^+, resulting in the formation of bile salts. These bile salts are effective detergents. They are amphipathic molecules that have both hydrophobic and hydrophilic regions. In low concentrations, bile salts form molecular or ideal solutions, but when their concentration increases above a certain critical level, they form polymolecular aggregates known as micelles. The concen-

tration at which these molecules aggregate is called the critical micellar concentration (CMC).

Bile salt micelles are spherical and consist of a central nonpolar core and an external polar region. Fatty acids, monoglycerides, and other lipids are solubilized when they enter the central core of the micelle and are covered by the outside polar coat. Solubilization occurs only when the CMC is reached. For the bile salt–monoglyceride–fatty-acid–water system present during normal fat digestion, the CMC is approximately 2 m*M*, which normally is exceeded both in bile and in the contents of the upper small intestine (Hofmann, 1963). Phospholipids, principally lecithin, are also major components of bile. In the lumen of the small intestine, pancreatic phospholipase catalyzes the hydrolysis of lecithin, forming free fatty acid and lysolecithin. The latter compound also is a potent detergent that acts with the bile salts to disperse and solubilize lipids in the aqueous micellar phase of the intestinal contents.

C. Synthesis of Bile Acids

The primary bile acids are C-24 carboxylic acids synthesized by the liver from cholesterol. BA synthesis is the major end stage pathway for cholesterol metabolism (Danielsson, 1963). Cholic acid ($3\alpha,7\alpha,12\alpha$-trihydroxy-5β-cholanoic acid) (CA) and chenodeoxycholic acid ($3\alpha,7\alpha$-dihydroxy-5β-cholanoic acid) (CDCA) are the primary BA sunthesized by most species of domestic animals. In swine, CDCA is hydroxylated at the 6α position by the liver to yield hyocholic acid (HCA), which is a major primary BA in this species (Haslewood, 1964).

BAs are secreted as amino acid conjugates of either glycine or taurine. Taurine conjugates predominate in the dog, cat, and rat. In the rabbit, the conjugating enzyme system appears to be almost completely specific for glycine (Bremer, 1956). Both taurine and glycine conjugates are present in ruminants. In the newborn lamb, 90% of the bile acids are conjugated with taurine. As the lamb matures, glycine conjugates increase to reach one-third of the total BA in mature sheep (Peric-Golia and Socic, 1968).

Under normal conditions, only conjugated BAs are present in the bile and in the contents of the proximal small intestine. In the large intestine, the conjugated BAs are hydrolyzed rapidly by bacterial enzymes so that in the contents of the large intestine and in the feces, free or unconjugated BAs predominate. Several genera of intestinal bacteria, including *Clostridium*, *Enterococcus*, *Bacteroides*, and *Lactobacillus* (Midtvedt and Norman, 1967), are capable of splitting the amide bonds of conjugated BAs.

Intestinal bacteria also modify the basic structure of the BAs. One such reaction is the removal of the α-hydroxyl group at the 7 position of CA or CDCA. These bacterial reactions yield the secondary BAs, deoxycholic acid (DCA) and lithocholic acid (LCA) (Gustafsson *et al.*, 1957). LCA is relatively insoluble and is not reabsorbed to any great extent (Gustafsson and Norman, 1962). DCA is reabsorbed from the large intestine in significant quantities and is either rehydroxylated by the liver to CA and secreted (Lindstedt and Samuelsson, 1959) or secreted as the conjugated DCA. The extent to which bacteria transform the primary BAs depends on the nature of the diet, the composition of the intestinal microflora, and the influences of these and other factors on intestinal motility (Gustafsson *et al.*, 1966; Gustafsson and Norman, 1969a,b).

D. Enterohepatic Circulation of Bile Acids

The enterohepatic circulation begins as conjugated BAs enter the duodenum and mix with the intestinal contents, forming emulsions and micellar solutions. The BAs are not absorbed in significant amounts from the lumen of the proximal small intestine. Absorption occurs primarily in the ileum (Lack and Weiner, 1961, 1966; Weiner and Lack, 1962), where an active-transport process has been demonstrated (Dietschy *et al.*, 1966). The absorbed conjugated BAs pass unaltered into the portal circulation (Playoust and Isselbacher, 1964) and return to the liver, where the cycle begins again. This arrangement provides for optimal concentrations of BAs in the proximal small intestine, where fat digestion occurs, and then for efficient absorption after these functions have been accomplished. Absorption of unconjugated BAs from the large intestine accounts for 3–15% of the total enterohepatic circulation (Weiner and Lack, 1968).

In dogs, the total BA pool was estimated to be 1.1–1.2 g. The half-life of the bile acids in the pool ranged between 1.3 and 2.3 days and the rate of hepatic synthesis was 0.3–0.7 g/day (Wollenweber *et al.*, 1965). Because the daily requirement for bile acids greatly exceeds the normal synthetic rate, the repeated reutilization of the BA is facilitated by the enterohepatic circulation. Under steady-state conditions, the total BA pool passes through the enterohepatic circulation approximately 10 times each day (Hofmann, 1966).

The size of the BA pool depends upon the diet, the rate of hepatic synthesis, and the efficiency of the enterohepatic circulation. Surgical removal of the ileum in dogs interrupts the enterohepatic circulation, resulting in an increase in BA turnover and a reduction in the size of the BA pool (Playoust *et al.*, 1965). In

diseases of the ileum, there may be defective BA reabsorption and a bile-salt deficiency. If the deficiency is severe, impaired utilization of dietary fat may occur, resulting in steatorrhea and impaired absorption of the fat-soluble vitamins.

V. SECRETIONS OF THE EXOCRINE PANCREAS

The exocrine pancreas is an acinous gland with a general structure similar to that of the salivary glands. The cytoplasm of the secretory cells contains numerous zymogen granules, which vary in size and number depending on the activity of the gland. These granules contain the precursors of the hydrolytic enzymes responsible for digestion of the major components of the diet. Cells of the terminal ducts appear to secrete the HCO_3^- responsible for neutralizing the HCl that enters the duodenum from the stomach.

A. Composition of Pancreatic Juice

1. *Electrolyte Composition*

The cation content of pancreatic secretion is similar to that of plasma, Na^+ being the predominant cation and the concentrations of K^+ and Ca^{2+} being much lower. A unique characteristic of pancreatic fluid is its high HCO_3^- concentration and alkaline pH. In the dog, the pH ranges from 7.4 to 8.3, depending on HCO_3^- content. The volume of pancreatic secretion is directly related to its HCO_3^- content, and the pH increases and Cl^- concentration decreases as the rate of flow is increased. The Na^+ and K^+ concentrations and osmolality appear to be independent of secretory rate (Fig. 15.4).

2. *α-Amylase*

The amylase produced by the pancreas catalyzes the specific hydrolysis of α-1,4-glucosidic bonds that are present in starch and glycogen (α-1,4-glycan-4-glycan hydrolase). Pancreatic amylase appears to be essentially identical to the amylase of saliva. It is a calcium-containing metalloenzyme. Removal of calcium by dialysis inactivates the enzyme and markedly reduces the stability of the apoenzyme. Pancreatic amylase has an optimal pH for activity of 6.7–7.2 and is activated by Cl^-.

After synthesis of pancreatic α-amylase in the ribosomes, the enzyme is transferred from the endoplasmic reticulum to cytoplasmic zymogen granules for storage. It is secreted in active form upon stimulation of the acinar cells. Newborn calves (Huber *et al.*, 1961) and pigs (Walker, 1959) secrete amylase at a significantly lower rate than do mature animals. The rate of synthesis is also influenced by diet. Animals fed a high-carbohydrate diet synthesize amylase at several times the rate of animals on a high-protein diet (Ben Abdeljlil and Desnuelle, 1964).

Unbranched α-1,4-glucosidic chains, such as those found in starch, are hydrolyzed in two steps. The first is rapid and results in formation of the maltose and maltotriose. The second step is slower and involves hydrolysis of maltotriose into glucose and maltose. Polysaccharides such as amylopectin and glycogen contain branched chains with both α-1,4- and α-1,6-glucosidic linkages. When α-amylase attacks these compounds, the principal products are maltose (α-1,4-glycosidic bond), isomaltose (α-1,6-glucosidic bond), and small amounts of glucose. Final hydrolysis of the maltose and isomaltose occurs at the surface of the mucosal cell, where the enzymes maltase and isomaltase are integral parts of the microvillous membrane.

3. *Proteolytic Enzymes*

The proteolytic enzymes of the pancreas are responsible for the major portion of protein hydrolysis that occurs within the lumen of the gastrointestinal tract. Two types of peptidases are secreted by the pancreas. Trypsin, chymotrypsin, and elastase are endopeptidases that attack peptide bonds along the polypeptide chain to produce smaller peptides. The exopeptidases attack either the carboxy-terminal or the amino-terminal peptide bonds, releasing single amino acids. The principal exopeptidases secreted by the pancreas are carboxypeptidases A and B. The endopeptidases and exopeptidases act in complementary fashion (Table 15.4), ultimately producing free amino acids or very small peptides. The free amino acids are absorbed directly and the small peptides are further hydrolyzed by the aminopeptidases of the intestinal mucosa.

The pancreatic peptidases are secreted as the inactive proenzymes (zymogens), trypsinogen, chymotrypsinogen, and the procarboxypeptidases A and B. Trypsinogen is converted to active trypsin in two ways. At alkaline pH, trypsinogen can be converted autocatalytically to trypsin. The activated enzyme is then capable of converting more zymogen to active enzyme. Trypsinogen also can be activated by the enzyme enterokinase, which is produced by the duodenal mucosa. The latter reaction is highly specific in that enterokinase will activate trypsinogen but not chymotrypsinogen. Chymotrypsinogen, proelastase, and the procarboxypeptidases A and B are converted to active enzymes by the action of trypsin.

The amino acid sequences and other structural characteristics of bovine trypsinogen and chymotrypsino-

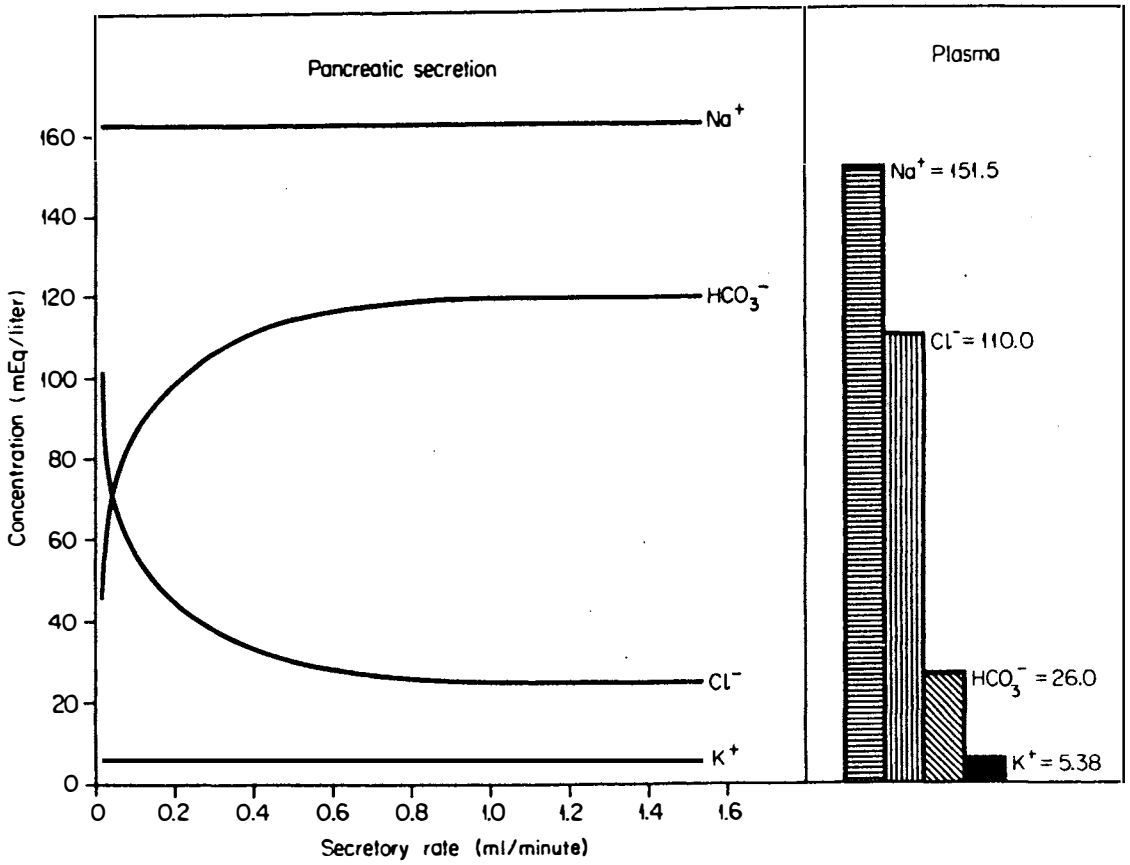

FIGURE 15.4 Influence of secretory rate on the electrolyte composition of canine pancreatic juice. From Bro-Rasmussen *et al.*, (1956).

gen have been determined (Hartley *et al.*, 1965; Hartley and Kauffman, 1966; Brown and Hartley, 1966). The polypeptide chain of trypsinogen contains 229 amino acid residues. Activation of trypsinogen occurs with hydrolysis of a single peptide bond located in the 6 position between lysine and isoleucine. As the C-terminal hexapeptide is released, enzyme activity appears along with a helical structure of the parent molecule. Chymotrypsinogen A is composed of 245 amino acid residues and has numerous structural similarities to trypsinogen. Activation of the chymotrypsinogen also occurs with cleavage of a single peptide bond.

TABLE 15.4 Relationship among the Activities of Pancreatic Endopeptidase and Exopeptidases

Enzyme	Type	Activity
Trypsin	Endopeptidase	Produces peptides with C-terminal basic amino acids
Carboxypeptidase B	Exopeptidase	Removes C-terminal basic amino acids
Chymotrypsin	Endopeptidase	Produces peptides with C-terminal aromatic amino acids
Elastase	Endopeptidase	Produces peptides with C-terminal nonpolar amino acids
Carboxypeptidase A	Exopeptidase	Removes C-terminal aromatic and nonpolar amino acids

4. Lipase

The pancreas produces several lipolytic enzymes with different substrate specificities. The most important of these from a nutritional viewpoint is the lipase responsible for hydrolysis of dietary triglyceride. This enzyme has the unique property of requiring an oil–water interface for activity so that only emulsions can be effectively attacked. The principal products of lipolysis are glycerol, monoglycerides, and fatty acids. The monoglycerides and fatty acids accumulate at the oil–water interface and can inhibit lipase activity. Transfer of these products from the interface to the aqueous phase is favored by HCO_3^- secreted by the pancreas and by the bile salts.

Two other carboxylic ester hydrolases have been characterized in pancreatic secretion. Both enzymes have an absolute requirement for bile salts, in contrast to glycerol ester hydrolase, which is actually inhibited by bile salts at pH 8. One of the enzymes requiring bile salts is a sterol ester hydrolase responsible for hydrolysis of cholesterol esters and the other enzyme hydrolyzes various water-soluble esters. The pancreas also secretes phospholipase A, which in the presence of bile converts lecithin to lysolecithin, an effective detergent that contributes to the emulsification of dietary fat.

B. Control of Pancreatic Secretions

1. Hormonal Control

Pancreatic secretion is controlled and coordinated by both neural and endocrine mechanisms. When ingesta or HCl enters the duodenum, the hormone secretin, which is produced by the duodenal mucosa, is released into the circulation. Secretin increases the volume, pH, and HCO_3^- concentration of the pancreatic secretion.

Secretin is a polypeptide hormone containing 27 amino acid residues, and all 27 amino acids are required to maintain the helical structure of the molecule and its activity (Bodanszky *et al.*, 1969). The C-terminal amide of secretin is a property shared with other polypeptide hormones such as gastrin and vasopressin that act on the flow of water in biological systems (Mutt and Jorpes, 1967). In addition to its effects on the pancreas, secretin also increases the rate of bile formation.

The secretin-stimulated pancreatic juice has a large volume and a high HCO_3^- concentration, but a low enzyme activity. Stimulation of the vagus nerve causes a significant rise in pancreatic-enzyme concentration. This type of response also is produced by cholecystokinin (pancreozymin), another polypeptide hormone produced by the duodenal mucosa that also causes contraction of the gallbladder. The C-terminal pentapeptide of cholecystokinin–pancreozymin is exactly the same as that of gastrin. This fascinating relationship suggests that gastrin and cholecystokinin–pancreozymin participate in some integrated yet poorly understood system of digestive control.

2. Other Gastrointestinal Polypeptide Hormones

In recent years, a large number of polypeptides have been isolated from the gastrointestinal mucosa and have been classified as gut hormones (Table 15.5). Some of these substances have not yet met all the rigid physiological requirements of true hormones. Some may have paracrine rather than endocrine activities, that is, they act on cells and tissues in the immediate vicinity of the cells of origin rather than being released into the vascular system.

TABLE 15.5 Gastrointestinal Peptide Hormones

Hormone	Source	Action
Gastrin	G cells of pyloric antrum	Gastric acid secretion
Secretin	S cells of duodenum and jejunum	Pancreatic fluid and HCO_3^- secretion, bile secretion
Cholecystokinin (pancreozymin)	Duodenal and jejunal mucosa; myenteric plexus	Pancreatic enzyme secretion, gall bladder contraction, and sphincter of Oddi relaxation
Somatostatin	D cells of pancreas, CNS, gastric and intestinal mucosa	Inhibits effect of gastrin on gastric secretion, inhibits pancreatic enzyme secretion, stimulates ileal water and NaCl
Enteroglucagon	L cells of small intestine, canine stomach	Control of intestinal cell growth
Gastric inhibitory polypeptide	Duodenal and jejunal mucosa	Inhibits gastric secretion and stimulates intestinal secretion
Motilin	Upper small-intestinal mucosa	Stimulates gastrointestinal motility

a. Motilin

Motilin is a polypeptide containing 22 amino acids that was originally isolated from porcine duodenal mucosa (Brown *et al.*, 1971). The amino acid composition and sequence have been described (Brown *et al.*, 1972, 1973). Immunoreactive motilin has been found in the enterochromaffin cells of the duodenum and jejunum of several species (Polak *et al.*, 1975) and, by means of radioimmunoassay, motilin has been identified in the plasma of dogs (Dryburgh and Brown, 1975). Motilin has been shown to stimulate pepsin output and motor activity of the stomach (Brown *et al.*, 1971) and to induce lower esophageal sphincter contractions (Jennewein *et al.*, 1975). Studies by Itoh *et al.* (1978) suggest that motilin plays an important role in initiating interdigestive gastrointestinal contractions.

b. Somatostatin

Somatostatin, which is named for its activity of inhibitory release of growth hormone from the pituitary gland, has been purified from ovine and bovine hypo-

thalamus. The hypothalamic hormone is composed of 14 amino acids. Somatostatin also has been demonstrated in the stomach, pancreas, and intestinal mucosa in concentrations higher than in the brain (Pearse *et al.*, 1977). Somatostatin from porcine intestine has been isolated and sequenced and contains 28 amino acids and apparently is a prohormone (Pradayrol *et al.*, 1980). Somatostatin is a potent inhibitor of insulin and glucagon release. It also inhibits gastrin release and gastric acid secretion (Barros D'Sa *et al.*, 1975; Bloom *et al.*, 1974), apparently acting independently on parietal cells and on G cells. These and a variety of other physiological effects suggest that somatostatin has important gastrointestinal regulatory functions.

c. Enteroglucagon

Enteroglucagon is the hyperglycemic, glycogenolytic factor isolated from the intestinal mucosa. It occurs in two forms, one a 3.5-kDa form and another somewhat larger (Valverde *et al.*, 1970). Enteroglucagon differs from pancreatic glucagon biochemically, immunologically, and in its mode of release. The physiological function of enteroglucagon is not known, but its release from the mucosa following a meal and the associated increase in circulating blood levels have suggested a regulatory role on bowel function (Pearse *et al.*, 1977). Enteroglucagon also differs significantly from the glucagon produced by the A cells of the gastric mucosa of the dog (Sasaki *et al.*, 1975). Canine gastric glucagon is biologically and immunochemically identical to pancreatic glucagon. Gastric glucagon appears to be unique to the dog, similar activity not being observed in the stomach of the pig or the abomasum of cattle and sheep (Sutherland and de Duve, 1948).

VI. DIGESTION AND ABSORPTION

A. Water and Electrolyte Absorption

1. Mechanisms of Mucosal Transport

The microvillous membrane of the intestinal mucosa, because of its lipid composition, acts as a barrier to water and water-soluble substances. Water and polar solutes penetrate the mucosa in one of three ways. They may pass through aqueous pores or channels that connect the luminal surface of the cell with the apical cytoplasm, they may attach to membrane carriers that facilitate passage through the lipid phase of the mucosal cell membrane, or they may pass paracellularly through tight junctions (shunt pathway). Transport of water and water-soluble compounds is influenced by the permeability characteristics of the limiting membrane and by the nature of the driving forces that provide energy for transport. Passive movement occurs either by simple diffusion or as a result of pH or concentration gradients (activity), osmotic pressure, or electrical potential that may exist across the membrane. The movement of an ion in the direction of an electrochemical gradient is considered passive. Active transport is said to occur when a substance moves in a direction opposite to that of an established electrochemical gradient.

Most water-soluble compounds, such as monosaccharides and amino acids, cannot diffuse across the intestinal mucosal membrane at rates that are adequate to meet nutritional requirements. The transport of these nutrients requires membrane carriers that are integral parts of the membrane and whose binding is highly specific. Carrier-mediated transport systems can be saturated and competitively inhibited by related compounds.

Three types of carrier transport mechanisms are recognized (Curran and Schultz, 1968).

1. *Active transport*, as stated previously, involves movement of electrolytes against an electrochemical gradient. In the case of nonelectrolytes such as glucose, active transport is defined as movement against a concentration gradient. Active transport requires metabolic energy and is inhibited by various metabolic blocking agents or by low temperature.

2. *Facilitated diffusion* occurs when the passive movement of a substance is more rapid than can be accounted for by simple diffusion. Facilitated-diffusion systems may increase the rate of movement across the membrane by two or three orders of magnitude. The responsible carrier mechanism is similar to that involved in active transport in that it displays saturation kinetics, may be inhibited competitively, and is temperature dependent. However, transport does not occur against concentration or electrochemical gradients, and direct expenditure of energy is not required.

3. *Exchange diffusion* is a transfer mechanism similar to facilitated diffusion and was postulated originally by Ussing (1947) to explain the rapid transfer of radioactive Na^+ across epithelial cell membranes *in vitro*. The mechanism involves the exchange of one ion for another of like charge (e.g., Na^+ and H^+ or Cl^- and HCO_3^-), not giving rise to net transport but contributing in a major way to unidirectional flux rate.

In the intestine, net water absorption is the result of bulk flow through pores. Diffusion in the usual sense plays no important role in water movement. When bulk flow of water occurs, it is possible for solutes to move across the membrane in the direction of flow by

a phenomenon called *solvent drag*. The effect of solvent drag on the transport of a given solute depends on the rate of volume flow and upon the reflection coefficient, an expression of the relationship between the radius of membrane pores and the radius of the solute molecule being transported. By means of solvent drag, it is possible for a solute such as urea to be transported by the intestine against a concentration gradient (Hakim and Lifson, 1964).

2. *Sodium and Chloride Absorption*

Na^+ and Cl^- are the major ions in the fluid that are transported by the intestine during absorption or secretion; under most conditions, transport of these two ions is coupled. The transport of water and electrolytes by the intestinal mucosa is a dynamic process, with rapid unidirectional fluxes of both occurring continuously. Net absorption occurs when the flow from lumen to plasma exceeds that from plasma to lumen. Active transport of Na^+ can occur along the entire length of the intestine, but the rate and net absorption is greatest in the ileum and colon. Na^+ transport is by an energy-requiring "sodium pump" mechanism that is intimately associated with the Na^+–K^+-ATPase located within the basolateral cell membrane of the absorptive epithelial cell. Three mechanisms exist for the entry of Na^+ at the brush border: (1) electrodiffusion down a concentration gradient (2) cotransport of electrolytes that either enter (Cl^-) or exit (H^+) the cell as Na^+ enters, and (3) Na^+ entry coupled with organic nonelectrolytes (glucose, amino acids). Current evidence suggests that in the absence of the absorption of nonelectrolytes, electroneutral uptake accounts for most NaCl absorption. At the brush border, Na^+ enters down a concentration gradient but exits at the basolateral cell surface against a substantial gradient. Maintenance of the transmembrane Na^+ gradient by the Na pump requires continual metabolism and generation of ATP. The Na^+–K^+-ATPase can be inhibited by cardiac glycosides such as ouabain, which are effective inhibitors of Na^+ transport. The Na^+ gradient ultimately serves as an energy source for transport of other solutes (Schultz and Curran, 1970).

In the jejunum, net absorption of sodium occurs slowly unless nonelectrolytes, such as glucose or amino acids, are absorbed simultaneously. In the ileum, Na^+ absorption is independent of glucose absorption. Net water absorption in the jejunum is almost entirely dependent upon the absorption of glucose and other nonelectrolytes, whereas absorption from the ileum is unaffected by glucose. The differential effect of glucose on absorption from the jejunum and ileum is the result of fundamental differences in electrolyte transport mechanisms in these two regions of the intestine.

As Na^+ is transported across the mucosa, an equivalent amount of anion must be transported to maintain electrical neutrality. A major fraction of Cl^- absorption can be accounted for by passive cotransport with Na^+. Under certain circumstances, Cl^- enters the cell in exchange for HCO_3^-.

3. *Potassium Absorption*

Dietary K^+ is absorbed almost entirely in the proximal small intestine. Absorption across the intestinal mucosa occurs down a concentration gradient (high luminal concentration to low plasma concentration). The intestinal fluid reaching the ileum from the jejunum has a K^+ concentration and a Na^+/K^+ ratio that are similar to those of plasma. In the ileum and colon, the rate of Na^+ absorption is much greater than that of K^+ so that, under normal conditions, the Na^+/K^+ ratio in the feces is much lower than that in plasma, approaching a ratio of 1.

4. *Water Absorption*

The absorption of water has been one of the most extensively studied aspects of intestinal transport.Water movement is the result of bulk flow through membranous pores, and simple diffusion plays only a minor role. The question of whether water is actively or passively transported has been the subject of considerable controversy and the controversy itself points to the fundamental difficulties that arise in trying to establish a definition of active transport. Hypertonic saline solutions can be absorbed from canine intestine *in vivo* and from canine and rat intestine *in vitro*. These observations indicate that water absorption can occur against an activity gradient and that the process is dependent upon metabolic energy. This suggests that an active transport process is involved, but Curran (1965) presents an alternative interpretation that is now generally accepted. This view is that water transport occurs secondarily to active solute transport and is the result of local gradients established within the mucosal membrane. Water transport is then coupled to the energy-dependent processes responsible for solute transport, but is one step removed from it.

In the dog and probably other carnivores, the ileum is the main site of net Na^+ and water absorption. In the dog, the colon accounts for no more than perhaps 20% of the total. In herbivorous animals that have a well-developed large intestine, there may actually be net secretion of water within the small intestine during digestion. For example, in the guinea pig (Powell *et*

al., 1968) and horse (Argenzio, 1975) all net absorption of water takes place in the cecum and colon.

B. Carbohydrate Digestion and Absorption

1. *Polysaccharide Digestion*

a. Starch and Glycogen

Carbohydrate is present in the diet primarily in the form of polysaccharides. The most common polysaccharides are starch, glycogen, and cellulose. Starch and glycogen are composed of long chains of glucose molecules linked together by repeating α-1,4-glucosidic bonds. Branch points of the chains are linked by α-1,6-glucosidic bonds. In those species that secrete salivary amylase, digestion of starch and glycogen begins in the mouth when this enzyme mixes with food. The action of salivary amylase is interrupted in the stomach, however, because of the low pH of the gastric secretion.

Starch digestion begins again in the proximal small intestine with the highly specific action of pancreatic amylase on α-1,4-glucosidic bonds. This enzyme catalyzes a series of stepwise hydrolytic reactions, resulting in formation of the principal end products of starch digestion, the disaccharides maltose and isomaltose and small amounts of glucose. Glucose is absorbed directly by the intestinal mucosa and transported to the portal vein. The disaccharides are hydrolyzed further by enzymes of the intestinal cell brush border.

b. Cellulose

Cellulose, like starch, is a polysaccharide of glucose, but it differs from starch in that the glucose molecules are linked by β-1,4-glucosidic bonds. Starch can be utilized by all species, but cellulose is utilized indirectly as a significant source of energy only by animals that have extensive bacterial fermentation within the gastrointestinal tract. Ruminant species digest cellulose most efficiently, but other animals in which the large intestine is well developed, such as the horse, also utilize cellulose as an important energy source.

In ruminants, hydrolysis of cellulose is accomplished by cellulytic bacteria that are part of the complex rumen microflora. The primary end products of cellulose fermentation are short-chain fatty acids—acetic, propionic, and butyric acids. These are absorbed directly from the rumen and serve as the major source of energy for ruminants. Propionic acid is the major precursor for carbohydrate synthesis in mature ruminants.

2. *Disaccharide Digestion*

Maltose and isomaltose are the disaccharide (glucose–glucose) end products of starch digestion. The diet also may contain lactose (galactose–glucose) and sucrose (fructose–glucose). Disaccharide digestion is completed at the surface of the cell by disaccharidases (Gray, 1975), which are components of the brush border (Table 15.6).

The disaccharidases have been solubilized from the brush border and partially purified. Sucrase and isomaltase have been purified together as a two-enzyme complex (Kolinska and Semenza, 1967; Gray *et al.*, 1979) and this enzyme complex accounts for the total hydrolysis of the products of amylase digestion (Gray *et al.*, 1979; Rodriguez *et al.*, 1984). The mutual mucosa contains two enzymes with lactase activity. One of these is a nonspecific β-galactosidase that hydrolyzes synthetic β-galactosides effectively but that hydrolyzes lactose at a slow rate. This enzyme has an optimal pH of 3 and is associated with the lysosomal fraction of the cell. The other lactase hydrolyzes lactose readily, is associated with the brush-border fraction of the cell, and is the enzyme of primary importance in the digestive process (Alpers, 1969).

Maltase, isomaltase, and sucrase are almost completely absent from the intestine in newborn pigs (Hartman *et al.*, 1961; Dahlqvist, 1961) and calves (Huber *et al.*, 1961). The activity of these disaccharidases increases after birth and reaches adult levels during the first months of life. Lactase activity is highest at birth and decreases gradually during the neonatal period. The relatively high lactase activity may be an advantage to the newborn in utilizing the large quantities of lactose present in their diets. Bywater and Penhale (1969) demonstrated lactase deficiency following acute enteric infections and suggested that lactose utilization may be decreased in such cases.

3. *Monosaccharide Transport*

a. Specificity of Monosaccharide Transport

Regardless of whether monosaccharides originate in the lumen of the intestine or are formed at the surface of the mucosal cell, transport across the mucosa involves processes that have a high degree of chemical specificity. Glucose and galactose are absorbed from the intestine more rapidly than other monosaccharides. Fructose is absorbed at approximately one-half of the rate of glucose, and mannose is absorbed at less than one-tenth the rate of glucose (Kohn *et al.*, 1965).

Glucose and galactose can be absorbed against a concentration gradient. The monosaccharides which

TABLE 15.6 Enzymes of the Intestinal Brush Border

Enzyme	Substrate	Product	Reference
Lactase	Lactose	Glucose, galactose	Alpers (1969), Forstner *et al.* (1968)
Sucrase	Sucrose; 1,4α-dextrins	Glucose, fructose; residual 1,6-oligosaccharides	Gray *et al.* (1979)
Isomaltase	1,6α-dextrins	Glucose	Gray *et al.* (1979), Rodriguez *et al.* (1984)
α-Limit dextrinase	1,6α-dextrins	Glucose	Taraval *et al.* (1983)
Trehalase	Trehalose	Glucose	Eichholtz (1967), Nakano *et al.* (1977)
Enterokinase	Trypsinogen	Trypsin	Grant and Hermnan-Taylor (1976)
Aminopeptidase A	Acidic amino-terminal amino acids	Acidic amino acids	Benajaiba and Maroux (1980)
Aminopeptidase N	Neutral amino-terminal amino acids	Neutral amino acids	Kim and Brophy (1976), Erickson *et al.* (1983)
γ-Glutamyl transferase	Peptides with γ-glutamyl bonds	γ-Glutamyl amino acids	Benajaiba and Maroux (1980), Hughey and Curthoys (1976)
Alkaline phosphatase	Phosphate esters	Inorganic phosphate	Eichholz (1967), Forstner *et al.* (1968)

are transported most efficiently against gradients have common structural characteristics: (1) the presence of a pyranose ring, (2) a carbon atom attached to C-5, and (3) a hydroxyl group at C-2 with the same stereoconfiguration as D-glucose. However, these features are not absolute requirements. Both D-xylose, which has no substituted carbon atom at C-5, and D-mannose, which lacks the appropriate hydroxyl configuration at C-2, can be transported against concentration gradients under certain specific experimental conditions (Csaky and Lassen, 1964; Csaky and Ho, 1966; Alvarado, 1966b).

Glucose transport is competitively inhibited by galactose (Cori, 1925; Fisher and Parsons, 1953) and by a variety of substituted hexoses that compete with glucose for carrier binding sites. The glucoside phlorizin is a potent inhibitor (Parsons *et al.*, 1958; Alvarado and Crane, 1962). Phlorizin also competes for binding sites, but has a much higher affinity for these sites than does glucose.

The absorptive surface of the mucosal cell is the microvillous membrane, or brush border. It is through this part of the plasma membrane that glucose must pass during the initial phase of mucosal transport. Techniques have been developed for isolating highly purified preparations of microvillous membranes from mucosal homogenates (Eichholz and Crane, 1965; Forstner *et al.*, 1968). Faust *et al.* (1967) studied the binding of various sugars to these isolated membrane fractions. They found that D-glucose was bound by the membrane preferentially to L-glucose or to D-mannose, and that glucose binding was completely inhibited by 0.1 m*M* phlorizin. The specificity of their observations suggested that binding represented an initial step in glucose transport, namely, attachment to a membrane carrier.

b. Sodium Requirement

The absorption of glucose and other monosaccharides is influenced significantly by Na^+ (Schultz and Curran, 1970; Kimmich, 1973). When Na^+ is present in the solution bathing the intestinal mucosa, glucose is absorbed rapidly, but when Na^+ is removed and replaced by equimolar amounts of other cations, glucose absorption virtually stops (Riklis and Quastel, 1958; Csaky, 1961; Bihler and Crane, 1962; Bihler *et al.*, 1962). Glucose absorption is inhibited by ouabain, digitalis, and other cardiac glycosides that are also inhibitors of Na^+–K^+-ATPase activity and Na^+ transport (Csaky and Hara, 1965; Schultz and Zalusky, 1964). These observations demonstrate the close relationship between the transport of glucose and that of Na^+.

c. Characteristics of the Na^+–Glucose Transporter (Carrier)

The concentrative step in the active transport of glucose occurs at the brush-border membrane and energy for this process is derived from an electrochemical Na^+ gradient (Schultz and Curran, 1970; Schultz, 1977). Under conditions of net influx, Na^+ and glucose enter in a ratio of 1:1 (Goldner et al., 1969; Hopfer and Groseclose, 1980). Cotransport of glucose and Na^+ involves a membrane transporter or carrier that is believed to be a 75-kDa polypeptide (Wright and Peerce, 1985). Na^+ activates glucose transport primarily by increasing the affinity of the carrier for glucose. A model showing two hypothetical forms of the glucose carrier is shown in Fig. 15.5. A channel or pore mechanism has been proposed in which the glucose binding site is located within the membrane. The translocation of glucose in this model is believed to be the result of a Na^+-induced conformational change in the transporter (Semenza *et al.*, 1984).

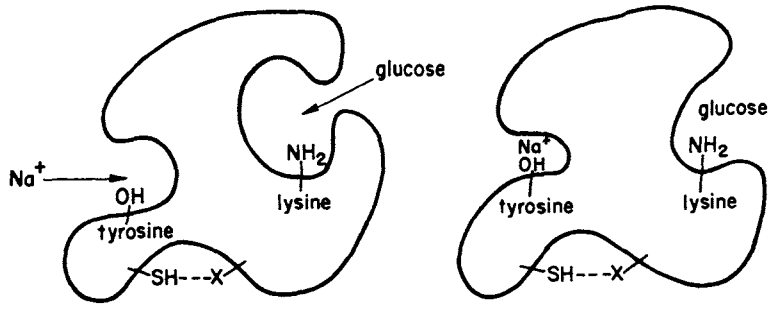

FIGURE 15.5 Model of a Na^+-activated glucose carrier of the intestinal brush border (after Wright and Peerce, 1985).

C. Protein Digestion and Absorption

1. Enzymatic Hydrolysis

The initial step in protein digestion is the enzymatic hydrolysis of peptide bonds by proteases with formation of smaller peptides and amino acids. The endopeptidases hydrolyze peptide bonds within the protein molecule and also hydrolyze certain model peptides. Exopeptidases hydrolyze either the carboxy-terminal (carboxypeptidase) or the amino-terminal (aminopeptidase) amino acids of peptides and certain proteins. Thus, a mixture of exopeptidases and endopeptidases cleave long-chain polypeptides from the ends as well as within the length of the chain, resulting in sequentially shorter and shorter polypeptide chains and amino acids.

Dietary proteins first come in contact with proteolytic enzymes in the stomach. The best known of the gastric proteases is the family of pepsins (Samloff, 1971), which hydroyze most proteins with the exception of keratins, protamines, and mucins. Pepsins are relatively nonselective and hydrolyze peptide bonds involving many amino acids, the most readily hydrolyzed of which involve leucine, phenylalanine, tyrosine, and glutamic acid (Meyer and Kelly, 1977).

The extent of proteolysis in the stomach depends on the nature of the dietary protein and the length of time the protein remains in the stomach. The food bolus mixed with saliva has a neutral or slightly alkaline pH as it enters the stomach and a period of time is required for it to mix with gastric secretions and become acidified. Proteolytic digestion begins when the pH of the gastric contents approaches 4 and occurs optimally in two pH ranges, 1.6–2.4 and 3.3–4.0 (Taylor, 1959a,b). Because of the relative lack of specificity of the pepsins, some peptide bonds of almost all dietary proteins are split during passage through the stomach. The gastric phase of protein digestion may have a minor and possibly dispensable role in overall protein assimilation (Freeman and Kim, 1978), but the reservoir function of the stomach contributes to the gradual release of nutrients, ensuring more efficient utilization in the small intestine.

Partially digested peptides pass from the stomach to the duodenum, where the acidic contents are neutralized by sodium bicarbonate present in bile and pancreatic juice. Peptic activity persists in the duodenum only during the period required to raise the pH above 4.0. The major peptidases that are active within the lumen of the small intestine are the pancreatic enzymes trypsin, chymotrypsin, elastase, and carboxypeptidases A and B. The action of these enzymes is integrated so that the endopeptidases produce peptides with C-terminal amino acids that then become substrates for the exopeptidases. Trypsin produces peptides with basic C-terminal amino acids that are particularly suited for the action of carboxypeptidase B. Chymotrypsin produces peptides with aromatic amino acids in the C-terminal position, and elastase produces peptides with C-terminal amino acids that are nonpolar. Carboxypeptidase A hydrolyzes both types of C-terminal peptide bonds (Table 15.4).

The final steps in peptide digestion are associated with mucosal epithelial cells. Almost all of the aminopeptidase activity is associated with the mucosa and very little activity is present in luminal contents. Mucosal aminopeptidase activity is located both in the cytosol and in the brush-border membrane fractions of the epithelial cell (Heizer and Laster, 1969; Kim *et al.*, 1972). These physically separate enzymes have remarkably different substrate specificities (Kim *et al.*, 1974). The brush-border enzyme has more than 50% of the activity for tripeptides, yet less than 10% of the total activity for dipeptides relative to the cytosolic enzyme(s) (Peters, 1970; Kim *et al.*, 1972). Almost all activity for tetrapeptides is present in the brush border (Freeman and Kim, 1978). Proline-containing peptides are hydrolyzed almost exclusively by cytosolic peptidases, whereas leucine aminopeptidase activity is located primarily in the brush border. The brush border peptidases appear to

have digestive functions similar to those of the disaccharidases and oligosaccharidases of the brush border.

Endopeptidase activity of the intestinal mucosa is associated primarily within the lysosomal fraction of the cell.

2. *Absorption of Proteolytic Products*

Although the subject of this section has been studied for many years, the relative amounts of the various protein digestion products (i.e., peptides vs amino acids) that are actually absorbed by intestinal mucosal cells during normal digestion remains problematic. It is a difficult process to investigate because the products of proteolysis are absorbed rapidly after they are formed, and therefore studies of luminal contents give only an estimate of the overall rate of protein digestion. Equally important, dietary protein is continually mixed with endogenous protein in the form of digestive secretions and extruded mucosal cells. Most endogenous proteins are hydrolyzed and the amino acids absorbed in a manner similar to that of dietary protein, and the two processes occur simultaneously. Endogenous protein accounts for a significant fraction of the amino acids of the intestinal contents. Even when dietary protein is labeled with a radioactive tracer, there is such rapid utilization that the tracer soon reenters the lumen in the form of endogenous protein secretion.

In adult mammals, protein is not absorbed from the intestine in quantities of nutritional significance without previous hydrolysis. Most neonatal animals absorb significant amounts of immunoglobulin and other colostral proteins, but this capacity is lost soon after birth. The intestinal mucosa, however, is not totally impermeable to large polypeptide molecules. The absorption of insulin (MW 5700, Laskowski *et al.*, 1958; Danforth and Moore, 1959), ribonuclease (MW 13,700, Alpers and Isselbacher, 1967), ferritin (Bockman and Winborn, 1966), and horseradish peroxidase (Cornell *et al.*, 1971) have all been demonstrated.

During the digestion of protein, the amino acid content of portal blood increases rapidly, but attempts to demonstrate parallel increases in peptides in the portal blood have not been uniformly successful. This has been regarded as evidence that only amino acids can be absorbed by the intestinal mucosa and that peptides are not absorbed. Although it seems clear that most dietary protein is absorbed by the mucosal epithelium in the form of free amino acids, peptides also may be taken up by the mucosal cell in quantitatively significant amounts. Peptides thus absorbed may be hydrolyzed either at the cell surface or intracellularly, and individual amino acids finally enter the portal circulation via the basolateral cell membrane.

Small peptides, under certain circumstances, may cross the intestinal epithelium intact and enter the portal circulation. Webb (1986) suggested that intact peptide absorption accounted for more than half of luminal amino acid nitrogen in the calf. The amount of peptide nitrogen entering the portal circulation in other species characteristically has been lower and variable depending upon the source of protein and on the digestibility of the peptide being investigated (Gardner, 1982, 1984).

3. *Transport of Amino Acids*

Amino acids, like glucose and certain other monosaccharides, are absorbed and transferred to the portal circulation by active transport processes. The same type of saturation kinetics observed in studies of monosaccharide absorption are observed with amino acids, which suggests the presence of carrier transport mechanisms. Certain monosaccharides inhibit amino acid transport (Saunders and Isselbacher, 1965; Newey and Smyth, 1964) and although inhibition generally has been of the noncompetitive type, competitive inhibition between galactose and cycloleucine has been demonstrated (Alvarado, 1966a), which suggests that a common carrier may be involved.

Most amino acids are transported against concentration and electrochemical gradients, and the overall transport process requires metabolic energy. The chemical specificity of these transport mechanisms is shown by the fact that the natural L-forms of various amino acids are absorbed more rapidly than the corresponding D-forms, and that only the L-amino acids appear to be actively transported. For most transport systems, Na^+ is necessary for absorption of amino acids as it is for a variety of other nonelectrolyte substances (Schultz and Curran, 1970; Gray and Cooper, 1971).

Separate transport systems exist for different groups of amino acids. Each member of a group inhibits the transport of other members competitively, suggesting that they share the same carrier. There is demonstrable overlap between groups, indicating that the overall transport process is complex (Christensen, 1984, 1985; Stevens *et al.*, 1984). The following is a summary of the designations and substrates of the recognized amino acid transport systems of the intestinal brush border (Stevens *et al.*, 1984):

1. The neutral brush-border (NBB) pathway is responsible for monoaminomonocarboxylic (neutral) amino acids and histidine. Na^+ is required and these amino acids show mutual competition for transport.
2. The monoaminodicarboxylic acids (aspartic and glutamic acid) pathway (XGA) requires Na^+. Aspartic and glutamic acids are not transported against concentration gradients. Following uptake, they are transami-

nated by the intestinal mucosa and under physiological conditions enter the portal vein as alanine.

3. The imino pathway transports imino acids, proline, hydroxyproline, methylaminoisobutyric acid, and *N*-substituted glycine derivatives sarcosine (*N*-methylglycine) and betaine (*N*-dimethylglycine). This pathway also has a Na^+ requirement.

4. Dibasic amino acids, including lysine, arginine, ornithine, and the neutral amino acid cystine, use the Y^+ pathway.

5. Phenylalanine and methionine share the PHE amino acid transport system.

The τ-glutamyl cycle has been proposed as a possible transport system for amino acids (Meister and Tate, 1976). τ-Glutamyltransferase (GGT) is a membrane-bound enzyme that is present in a number of mammalian tissues and catalyzes the initial step in glutathione degradation. The τ-glutamyl moiety of glutathione is transferred to amino acid (or peptide) receptors with the production of cysteinylglycine:

$$\text{Glutathione} + \text{amino acid} \xrightarrow{\text{GGT}} \tau\text{-glutamyl-amino acid} + \text{Cys–Gly}.$$

The highest GGT activity is present in tissues that are known to transport amino acids actively, such as the jejunal villus, the proximal convoluted tubule of the kidney, and the liver. Meister and Tate (1976) have suggested that GGT may function in translocation by interaction with extracellular amino acids and with intracellular glutathione. The hypothetical mechanism involves the noncovalent binding of extracellular amino acids to the plasma membrane, whereas intracellular glutathione interacts with GGT to yield a τ-glutamyl–enzyme complex. When the τ-glutamyl moiety is transferred to the membrane-bound amino acid, a τ-glutamyl–amino acid complex is formed that, when released from the membrane binding site, moves into the cell. The τ-glutamyl-amino acid complex is split by the action of τ-glutamyl cyclotransferase, an enzyme appropriately located in the cytosol. Glutathione is regenerated by means of the τ-glutamyl cycle, which provides good substrates for GGT (Thompson and Meister, 1975).

The τ-glutamyl cycle does not require sodium, and the previously demonstrated sodium dependence for amino acid transport would not be explained by the cycle. The cycle is not considered to be the only amino acid transport system, and its quantitative significance in individual tissues is unknown.

4. *Neonatal Absorption of Immunoglobulin*

At birth, most domestic species, including the calf, foal, lamb, pig, kitten, and pup, absorb significant quantities of colostral protein from the small intestine (Brambell, 1958). Immune globulin (Ig) either is absent in the serum of domestic species at birth or is present at low levels. Within a few hours after ingestion of colostrum, the serum Ig levels rise. This represents the principal mechanism by which the young of most domestic animal species acquire maternal immunity. Under normal environmental conditions, ingestion of colostrum is an absolute requirement for health during the neonatal period (Fig. 15.6). The rabbit is the exception in that maternal Ig is received primarily *in utero* by transplacental transfer.

Protein enters the neonatal absorptive cell by pinocytosis and passes through the cell to the lymphatics. The process is not selective, because many proteins other than Ig can be absorbed (Payne and Marsh, 1962a,b). The ability to absorb intact protein is lost by domestic species soon after birth. In the piglet, "closure" occurs within 1 to 2 days (Leary and Lecce, 1978; Westrom *et al.*, 1984) beginning in the duodenum and occurring last in the ileum (Murata and Namioka,

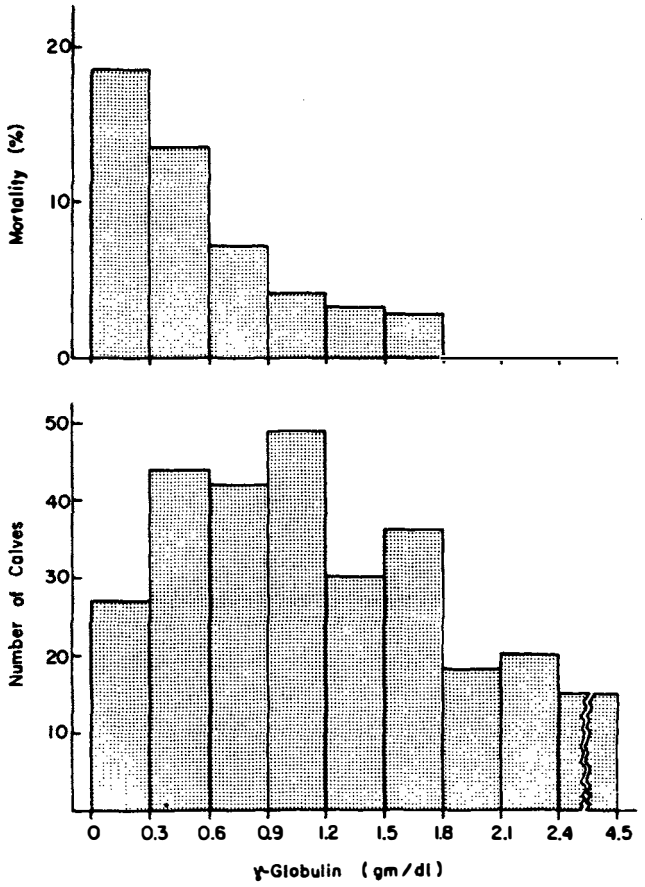

FIGURE 15.6 Histogram of the distribution of serum γ-globulin in market calves and the relation of hypogammaglobulinemia to mortality. From Braun and Tennant (1979; unpublished observations).

1977). In rodents, protein absorption normally continues for approximately 3 weeks. The mechanism of intestinal "closure" was studied by Lecce and coworkers (1964; Lecce, 1966; Lecce and Morgan, 1962), who found that complete starvation of pigs lengthened the period of protein absorption to 4–5 days, whereas early feeding shortened the period. Feeding different fractions of colostrum including lactose and galactose resulted in loss of protein absorptive capacity. The route of feeding may not be the critical factor, however. Calves that are prevented from eating but that receive nutrients parenterally lose the ability to absorb protein at the same time as control calves (Deutsch and Smith, 1957).

In the neonatal calf, Ig deficiency due to failure of colostral Ig absorption plays a role in the pathogenesis of gram-negative septicemia (Smith, 1962; Gay, 1965). Most calves deprived of colostrum develop septicemia early in life and may develop acute diarrhea before death (Smith, 1962; Wood, 1955; Tennant *et al.*, 1975). Hypogammaglobulinemia is almost always demonstrable in calves dying of gram-negative septicemia (Fey, 1971) and is the result either of insufficient Ig intake or of insufficient intestinal absorption. The Ig fraction is the essential factor in colostrum that protects against systemic infections (Penhale *et al.*, 1971).

Serum immunoglobulin values of neonatal calves vary, and a 10% incidence of hypogammaglobulinemia may occur in clinically normal calves (Tennant *et al.*, 1969a,b; House and Baker, 1968; Smith *et al.*, 1967; Thornton *et al.*, 1972; Braun *et al.*, 1973). Most such individuals probably have insufficient colostrum intake. Even when calves were given the opportunity to ingest colostrum, however, a surprising number were hypogammaglobulinemic. Some of the reasons for varying gammaglobulinemia values are recognized, but the relative importance of each is not known. The concentration of lactoglobulin, the volume consumed (Bush *et al.*, 1971; Selman *et al.*, 1971), the time elapsed from birth to ingestion of colostrum (Selman *et al.*, 1971), and the method of ingestion (natural suckling vs bucket feeding) may have an important influence on the serum IgG (Smith *et al.*, 1967; McBeath *et al.*, 1971). Calves that suckle their dams usually attain serum IgG concentrations that are higher than those attained by calves given colostrum from a bucket. The frequency of hypogammaglobulinemia may be influenced by season (Gay *et al.*, 1965b; McEwan *et al.*, 1970a), although this relationship is not consistent (Smith *et al.*, 1967; Thornton *et al.*, 1972). Familial factors also may influence development of hypogammaglobulinemia (Tennant *et al.*, 1969a).

Regardless of cause, the mortality of hypogammaglobulinemic calves is higher than that of calves with normal serum IgG levels (Gay, 1965; House and Baker, 1968; Thornton *et al.*, 1972; McEwan *et al.*, 1970a; Boyd, 1972; Naylor *et al.*, 1977). In addition to having more septicemic infections (Smith, 1962: Gay *et al.*, 1965a; Roberts *et al.*, 1954; Wood, 1955; Fey, 1971; McEwan *et al.*, 1970a), hypogammaglobulinemic calves have a greater prevalence of acute diarrheal disease (Boyd, 1972; Naylor *et al.*, 1977; Penhale *et al.*, 1970; Gay *et al.*, 1965b), which indicates that the local protective effects of Ig in the intestine are important (Fisher *et al.*, 1975; Logan and Penhale, 1971).

The prevalence of hypogammaglobulinemia and the high mortality associated with it has led to the development of several rapid tests for identification of hypogammaglobulinemic calves (McBeath *et al.*, 1971; Aschaffenburg, 1949; Fisher and McEwan, 1967a; Patterson, 1967; Stone and Gitter, 1969). The zinc sulfate turbidity test (Kunkel, 1947) was the first to be used for determination of serum immunoglobulin concentrations of neonatal calves (McEwan *et al.*, 1970b). A close correlation has been established between test results and the amount of serum IgG and IgM (Fisher and McEwan, 1967a,b; McEwan *et al.*, 1970b; Penhale *et al.*, 1967).

The sodium sulfite turbidity test is similar to the zinc sulfate test and also has been used to identify hypogammaglobulinemic calves (Stone and Gitter, 1969; Pfeiffer and McGuire, 1977). Failure of turbidity to develop when serum is added to a saturated solution of sodium sulfite indicates immunoglobulin deficiency. A semiquantitative assessment of the Ig concentration is made by grading the degree of turbidity (Stone and Gitter, 1969).

The refractometer is used as a rapid test for Ig deficiency (McBeath *et al.*, 1971: Boyd, 1972). There is a close relationship between the concentration of IgG and total serum protein (TSP) in neonatal calves (Tennant *et al.*, 1969a) and the wide variations in TSP were due to variations in IgG. Direct linear correlation between the refractive index (RI) and the Ig concentration has also been observed (McBeath *et al.*, 1971). The regression line for this relationship was independently confirmed (Tennant *et al.*, 1978). The Y intercepts in these studies were identical (4 g/ dl). The refractometer has a value as a rapid field instrument for the assessment of Ig status, but in cases of hemoconcentration it has limitations (Boyd, 1972).

The glutaraldehyde coagulation test was used originally in cattle to detect hypergammaglobulinemia in samples of whole blood (Sandholm, 1974). Glutaraldehyde has also been used in a semiquantitative test to evaluate IgG in canine (Sandholm and Kivisto, 1975) and human serum (Sandholm, 1976). This procedure has been modified to detect hypogammaglobulinemic

TABLE 15.7 Relationship between Results of the Glutaraldehyde Coagulation Test, Serum γ-Globulin Concentration, and Death Rate

Source of calves	No.	Glutaraldehyde reaction	Serum γ-globulin (g/dl) Mean (±SD)	Serum γ-globulin (g/dl) Extremes	Death rate (%)
Calves before ingestion of colostrum	10	Negative	0.18 (± 0.06)	0.1–0.25	—[a]
Calves from production unit	60	Negative	0.35 (± 0.13)	0.11–0.63	16.7[b]
	13	Incomplete	0.60 (± 0.13)	0.42–0.85	7.7
	208	Positive	1.46 (± 0.63)	0.42–4.4	3.4

[a] Samples of serum were obtained at birth, but no follow-up of calves was made.
[b] The death rate of calves that were test negative was significantly ($p < 0.1$) greater than that of test-positive calves, using t-test for significance of differences between two percentages.

calves. Calves with a negative test result (serum IgG ≤0.4 g/dl) had markedly higher mortality than calves with positive results (Table 15.7) (Tennant *et al.*, 1979), which is similar to results obtained by using the zinc sulfate turbidity test (Gay *et al.*, 1965a; McEwan *et al.*, 1970a) or other estimates of circulating IgG. Many tests can be initiated quickly using the glutaraldehyde coagulation test, and results can be evaluated rapidly without instrumentation.

D. Lipid Digestion and Absorption

1. *Absorption of Fats*

a. Luminal Phase

The fat in the diet is primarily in the form of triglycerides or long-chain fatty acids. The initial step in utilization of triglycerides occurs in the lumen of the proximal small intestine, where hydrolysis is catalyzed by pancreatic lipase. Lipase is secreted by the pancreas in active form. Because the enzyme requires an oil–water interface for activity, only emulsions of fat can be hydrolyzed. Enzyme activity is directly related to the surface area of the emulsion so the smaller the emulsion particle, the greater the total surface area of a given quantity of triglyceride and the greater the rate of hydrolysis (Benzonana and Desnuelle, 1965). Bile salts are not an absolute requirement, but favor hydrolysis by their detergent action, which causes formation of emulsions with small particle sizes, and by stimulating lipase activity within the physiological pH range of the duodenum. A colipase is present in the pancreatic secretion that facilitates the interaction of lipase with its triglyceride substrate and protects lipase from inactivation (Borgstrom and Erlanson, 1971).

Pancreatic lipase splits the ester bonds of triglycerides preferentially at the 1 and 3 positions so that the major end products of hydrolysis are 2-monoglycerides and free fatty acids. Both compounds are relatively insoluble in water but are brought rapidly into micellar solution by the detergent action of bile salts. The mixed micelles so formed have a diameter of approximately 2.0 nm and are believed to be the form in which the products of fat digestion are actually taken up by the mucosal cell (Hofmann and Small, 1967). The intraluminal events that occur in fat absorption are schematically summarized in Fig. 15.7.

b. Mucosal Phase

The initial step in intestinal transport of fat is the uptake of fatty acids and monoglycerides by the mucosal cell from micellar solution. The precise mechanism is yet unclear, but present evidence suggests that the lipid contents of the micelle are somehow discharged at the cell surface and enter the mucosal cell in molecular rather than micellar form (Isselbacher, 1967). The net effect is the absorption of the end products of lipolysis

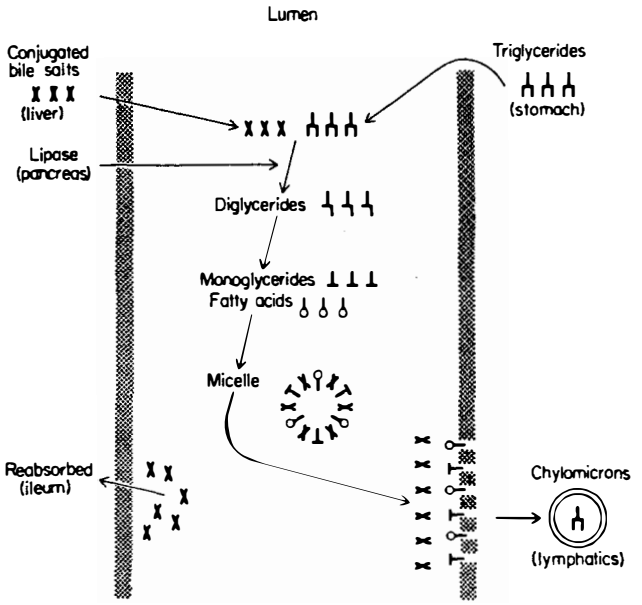

FIGURE 15.7 Intraluminal events during fat absorption. From Isselbacher (1967).

and the exclusion of bile salts, which are absorbed further down the intestine, primarily in the ileum. Uptake of fatty acids appears to be a passive process having no requirement for metabolic energy.

Within the mucosal cell, the fatty acids are transported by a soluble binding protein to the endoplasmic reticulum, where the fatty acids and monoglycerides are rapidly reesterified to triglyceride (Ockner and Manning, 1974; Ockner and Isselbacher, 1974). The two biochemical pathways for triglyceride biosynthesis in the intestine are summarized in Fig. 15.8. Direct acylation of monoglyceride occurs in the intestine and is the major pathway for lipogenesis in the intestine during normal fat absorption. The initial step in this series of reactions involves activation of fatty acids by acyl-CoA synthetase, a reaction that requires Mg^{2+}, ATP, and CoA and that has a marked specificity for long-chain fatty acids. This specificity explains the observation by Bloom *et al.* (1951) that medium- and short-chain fatty acids are not incorporated into triglycerides during intestinal transport, but enter the portal circulation as nonesterified fatty acids. The activated fatty acids then react sequentially with mono- and diglycerides to form triglycerides in steps catalyzed by mono- and diglyceride transacylases. The enzymes responsible for this series of reactions are present in the microsomal fraction of the cell (Rao and Johnston, 1966). These enzymes occur together in the endoplasmic reticulum as a "triglyceride–synthetase" complex.

An alternative route that is available for fatty acid esterification involves L-α-glycerophosphate derived either from glucose or from dietary glycerol by the action of intestinal glycerokinase. Activated fatty acid CoA derivatives react with L-α-glycerophosphate to form lysophosphatidic acid (monoglyceride phosphate), which by a second acylation forms phosphatidic acid (diglyceride phosphate). Phosphatidic acid phosphatase then hydrolyzes the phosphate ester bond, forming diglyceride, and by means of a transacylase step similar to that described earlier, triglyceride is formed. Although this pathway appears to be of minor importance for triglyceride synthesis in the intestine, intermediates in this sequence of reactions are important in the synthesis of phospholipids that are essential for stabilization of the chylomicron.

The next step in fat transport is formation of chylomicrons within the endoplasmic reticulum. The chylomicron is composed primarily of triglyceride and has an outer membranous coating of cholesterol, phospholipid, and protein (Zilversmit, 1965). The β-lipoprotein component of the chylomicron is synthesized by the intestinal mucosal cell. Inhibition of protein synthesis by puromycin or acetoxycycloheximide interferes with chylomicron formation and significantly reduces fat transport (Sabesin and Isselbacher, 1965).

The final step in fat absorption is extrusion of the chylomicra into the intercellular space opposite the basal lateral portion of the absorptive cell by reverse pinocytosis. From the intercellular space, the chylomicra pass through the basement membrane and enter the lacteal. The chylomicra then pass from the lacteals into lymph ducts and into the general circulation, thereby completely bypassing the liver during the initial phase of absorption.

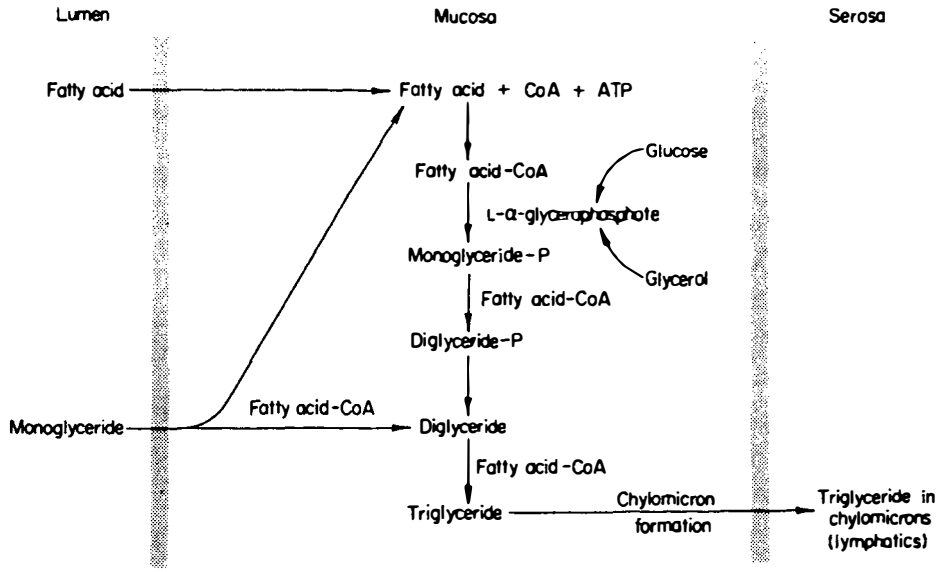

FIGURE 15.8 Biochemical reactions involved in intestinal transport of long-chain fatty acids and monoglycerides. From Isselbacher (1966).

2. *Absorption of Other Lipids*

a. Cholesterol

Dietary cholesterol is present in both free and esterified forms, but only nonesterified cholesterol is absorbed. Cholesterol esters are hydrolyzed within the lumen of the intestine by sterol esterases secreted by the pancreas. Bile salts are required both for the action of this enzyme and for the absorption of nonesterified cholesterol. In the mucosal cell, cholesterol is reesterified and transferred by way of the lymph to the general circulation. The type of triglyceride present in the diet significantly affects the absorption of cholesterol and its distribution in lymph lipids (Ockner *et al.*, 1969).

b. Vitamin A

The diet contains vitamin A activity in two principal forms: (1) as esters of preformed vitamin A alcohol (retinol) and fatty acids and (2) as provitamin A, primarily β-carotene. Vitamin A ester is hydrolyzed by a pancreatic esterase within the lumen (Murthy and Ganguly, 1962), and the free alcohol is absorbed in the upper small intestine. Vitamin A alcohol is reesterified in the mucosa primarily with palmitic acid. The vitamin A ester is absorbed by way of the lymph and after reaching the general circulation, it is rapidly cleared from the plasma and stored in the liver. In the postabsorptive state, vitamin A circulates as the free alcohol, the form released as needed from the liver by the action of hepatic retinylpalmitase esterase. The blood level of vitamin A is independent of liver reserves, and as long as a small amount of vitamin A is present in the liver, the blood level remains normal (Dowling and Wald, 1958).

In diets that lack animal fat, the carotenes, primarily β-carotene, serve as the major precursor of vitamin A. The intestinal mucosa has a primary role in conversion of provitamin A to the active vitamin, although conversion can occur to a limited degree in other tissues. The mechanism involves central cleavage of β-carotene into two active vitamin A alcohol molecules that are subsequently esterified and absorbed by the lymphatics as with preformed vitamin A.

Bile salts are required for the mucosal uptake of β-carotene and for the conversion of β-carotene to vitamin A. Uptake of carotene and release of vitamin A ester into the lymph are rate-limiting steps. Cattle absorb substantial amounts of β-carotene without prior conversion to vitamin A, and these pigments are responsible for much of the yellow color of the plasma. Most other species have no β-carotene in the plasma and it is thought that extraintestinal conversion is more efficient in these species than in cattle (Ganguly and Murthy, 1967).

c. Vitamin D

Vitamin D, like cholesterol, is a sterol that is absorbed by the intestine and transported via the lymph (Schachter *et al.*, 1964). Intestinal absorption differs, however, in that vitamin D is transported to the lymph in nonesterified form. The uptake of vitamin D by the mucosal cell is favored by the presence of bile salts. Simultaneous absorption of fat from micellar solutions increases transport of vitamin D out of the cell into the lymph, the limiting step.

One of the major actions of vitamin D is to enhance the intestinal absorption of calcium. The mechanism of action of vitamin D has been described by Wasserman and co-workers (1968; Wasserman and Taylor, 1966, 1968). They have shown that vitamin D causes synthesis of a calcium-binding protein that plays a central role in the transport of calcium.

VII. DISTURBANCES OF GASTROINTESTINAL FUNCTION

A. Vomition

Vomiting is a coordinated reflex act which results in rapid, forceful expulsion of gastric contents through the mouth. The reflex may be initiated by local gastric irritation caused by a variety of toxic irritants, infectious agents, foreign bodies, gastric tumors, or obstructions of the pyloric canal or the small intestine, or by drugs such as apomorphine or other toxic substances that act centrally on the "vomiting center" of the medulla.

Severe vomiting produces loss of large quantities of water and of H^+ and Cl^- ions. These losses cause dehydration, metabolic alkalosis with increased plasma HCO_3^-, and hypochloremia. Chronic vomiting may also be associated with the loss of significant tissue K^+ and with hypokalemia. The K^+ deficit is caused primarily by increased urinary excretion resulting from alkalosis (Leaf and Santos, 1961). Gastric secretions contain significant quantities of K^+ and losses in the vomitus also contribute to the K^+ deficiency. K^+ deficiency, which develops initially because of the alkalosis, perpetuates the alkalotic state by interfering with the ability of the kidney to conserve H^+ (Koch *et al.*, 1956; Darrow, 1964). Both K^+ and the hypovolemia caused by dehydration may result in renal tubular damage and in renal failure.

Vomiting occurs frequently in the dog, cat, and pig, but is an unusual sign in the horse, which has anatomical restrictions of the esophagus that interfere with expulsion of gastric contents. In cattle, sheep, and goats, the physiological process of rumination utilizes

neuromuscular mechanisms similar to those involved in vomiting. Uncontrolled expulsion of ruminal contents is an uncommon sign, most frequently occurring after ingestion of toxic materials or associated with traumatic reticulitis and resulting "vagal indigestion." The contents of the abomasum are not expelled directly even when the pyloric canal is obstructed. Pyloric outflow obstruction does occur in cattle that is similar metabolically to that observed in nonruminants. This obstruction may be observed in right-sided displacement of the abomasum with or without torsion, occasionally with left-sided displacement of the abomasum, in cows with functional pyloric obstruction as a result of reticuloperitonitis, and from "vagal indigestion." When the pylorus is obstructed, abomasal contents are retained, causing distension of the abomasum, which in turn stimulates further secretion and retention. Retained abomasal contents may be regurgitated into the large reservoir of the rumen and sequestered there from other fluid compartments of the body. The net result is loss of H^+ and Cl^- ions and development of metabolic alkalosis, hypochloremia, and hypokalemia (Espersen and Simesen, 1961; Svendsen, 1969). This metabolic syndrome often is associated with fluid distension of the rumen related to pyloric outflow obstruction. Similar distention of the rumen in the absence of hypochloremic, hypokalemic metabolic alkalosis suggests more proximal obstruction of rumen outflow, namely the omasum.

Chronic hypertrophic gastritis, which resembles Menetrier's disease in humans, has been demonstrated in the dog (van der Gagg *et al.*, 1976; Van Kruiningen, 1977; Happe and van der Gagg, 1977; Kipnis, 1978). Van Kruiningen's series of cases were Basenjis that had concomitant lymphocytic–plasmocytic enteritis. The primary disease, however, has been observed in other breeds without intestinal lesions. Signs of illness usually involve chronic vomiting, weight loss, and occasionally diarrhea. Hypoalbuminemia occurs in most cases. In man, hyperchlorhydria or achlorhydria can occur. The morphological changes in the stomach wall (hypertrophic rugae) and some of the clinical features help to differentiate this disease from gastric neoplasia.

Zollinger–Ellison syndrome has been reported in the dog (Straus *et al.*, 1977; van der Gagg *et al.*, 1978; Breitschwerdt *et al.*, 1986; English *et al.*, 1988). Vomiting, diarrhea, inappetence and weight loss are frequently observed. The disease is caused by pancreatic non-β islet-cell tumors that result in hypergastrinemia, hyperchlorhydria, hypertrophic gastritis, peptic esophagitis, and duodenal ulcers.

B. Gastric Dilatation–Volvulus

Gastric dilatation–volvulus (GDV) is an acute gastrointestinal disorder associated with high mortality (Wingfield *et al.*, 1976; Todoroff, 1979; Morgan, 1982; Leib and Blass, 1984). It typically occurs in large deep-chested dogs but has been reported in smaller dogs, the cat, and other species (Van Kruiningen *et al.*, 1974). Gastric dilatation precedes development of volvulus and is the result of the accumulation of gas (Caywood *et al.*, 1977; Rogolsky and Van Kruiningen, 1978; Warner and Van Kruiningen, 1978) and fluid in the stomach as a result of either mechanical or functional disturbances in pyloric outflow. As the stomach distends and rotates about the distal esophagus, displacement and occlusion of the pylorus and duodenum occur. Necrosis and perforation of the stomach wall and peritonitis are common causes of death.

Distension and displacement of the stomach causes obstruction of the caudal vena cava and portal vein resulting in venous stasis and sequestration of blood in splanchnic, renal, and posterior muscular capillary beds (Wingfield *et al.*, 1976). This decrease in circulating blood volume (venous return) and subsequent decrease in cardiac output, arterial blood pressure, and tissue perfusion culminates in hypovolemic shock. Endotoxemia, a consequence of portal-vein occlusion, contributes to the shock syndrome. The release of myocardial depressant factors from ischemic pancreatic tissue impairs the clearance of endotoxins by the reticuloendothelial system as well as causing direct cardiodepressant effects. Altered microvascular perfusion with hypoxemia and endotoxemia favors development of disseminated intravascular coagulopathy (DIC) (Lees *et al.*, 1977).

Increased plasma gastrin immunoreactivity has been reported in dogs with GDV (Leib *et al.*, 1984). Preexisting conditions of relative hypergastrinemia may predispose to GDV. Gastrin can increase caudal esophageal sphincter pressure, delay gastric emptying, and predispose to pyloric outflow obstruction by causing gastric mucosal and pyloric muscular hypertrophy.

Experimental gastric dilatation and dilatation with torsion has been studied in the dog (Wingfield *et al.*, 1974; Merkley *et al.*, 1976a, 1976b). Hyperkalemia and hyperphosphatemia were consistent findings in dogs with gastric dilatation and torsion (Wingfield *et al.*, 1974; Merkley *et al.*, 1976b). This was the result of hypovolemia, decreased renal perfusion, and renal insufficiency on the one hand and the loss of intracellular K^+ from damaged tissue on the other. Increased blood urea nitrogen (BUN) and serum creatinine (Cr) levels persisted after decompression of the stomach. Hemo

concentration and increased TSP were attributed to fluid shifts from the vascular compartment into the lumen of the alimentary tract, wall of the stomach, and peritoneal cavity. Increased alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were most apparent following decompression of the stomach and were attributed to alteration of hepatocytes and smooth muscle of the stomach and spleen. Increased of creatine kinase (CK) resulted from the effects of tissue hypoxia on striated muscle. Metabolic acidosis was attributed in part to increased production of lactic acid caused by tissue hypoxia.

A wide range of acid–base and electrolyte disturbances have been reported in clinical patients with GDV (Muir, 1982; Wingfield *et al.*, 1982; Kagan and Schaer, 1983). Dogs presenting with GDV may have normal acid–base status. Metabolic acidosis and hypokalemia commonly occur. Metabolic alkalemia and respiratory alkalosis also have been observed. Hyperkalemia is unusual. The absence of an increase in anion gap in one study indicated that the production of volatile fatty acids and lactic acid was not excessive (Wingfield *et al.*, 1982).

C. Ischemia–Reperfusion Injury

Ischemia–reperfusion injury is a contributing cause of death in horses with strangulating intestinal obstruction (Moore *et al.*, 1995) and in dogs with GDV. Together with luminal occlusion of the alimentary tract, functional constriction or mechanical obstruction of intestinal vasculature occurs. Depending on the duration and severity of ischemia, oxygenation of tissue is compromised and there is a subsequent attenuation of oxidative phosphorylation and a decrease in ATP. Anaerobic glycolysis ensues, leading to intracellular acidosis and increased intracellular concentrations of Ca^{2+}. Unless timely restoration of blood flow and oxygenation occurs, these metabolic derangements eventually contribute to cellular edema, lysosomal release of degradative enzymes, autolytic destruction of cellular organelles, and cell death.

When intestinal obstruction is relieved and tissue perfusion is reestablished, reoxygenation of tissue can result in a cascade of biochemical events that can aggravate ischemic-induced tissue injury. The resulting reperfusion injury is caused in part by oxygen free radicals (OFR), particularly superoxide (O_2^-), and hydroxyl free radicals ($OH^\cdot$), and is characterized by increased microvascular and mucosal permeability and mucosal necrosis (Moore *et al.*, 1995). The formation of OFRs is preceded by accumulation of hypoxanthine in endothelial cells and intestinal mucosal cells during ischemia. The conversion of xanthine dehydrogenase to xanthine oxidase also occurs during ischemia, a reaction that is facilitated by high intracellular levels of calcium ions and the protease calpain. When reperfusion occurs, xanthine oxidase converts hypoxanthine to uric acid and superoxide radicals. O_2^- and hydrogen peroxide (H_2O_2), a product of superoxide dismutase (SOD) reduction, are converted to highly reactive $OH^\cdot$ in the presence of an iron catalyst. $OH^\cdot$ initiates structural and functional cellular membrane damage via lipid peroxidation. The release of inflammatory mediators attending lipoperoxidation contributes to tissue injury.

Malondialdehyde (MDA) is a stable by-product of lipoperoxidation, and its detection can be utilized by investigators as an indicator of ischemia–reperfusion injury (Moore *et al.*, 1995).

Neutrophils are recruited into ischemic and reperfused tissue by xanthine oxidase-derived OFRs and chemoattractants released from cellular membranes during lipid peroxidation. Increased cytosolic calcium concentrations during ischemia and subsequent lipoperoxidation activate phospholipase A2, which in turn causes the release of platelet-activating factor (PAF), metabolites of arachidonic acid (leukotrienes and prostaglandins), and lysophosphatidylcholine. Leukotriene B4, thromboxane A2, and PAF are the primary products of phospholipid metabolism that promote infiltration and degranulation of neutrophils in affected tissue.

When neutrophils attach to endothelium, they release elastase and lactoferrin, which promotes extravasation (Moore *et al.*, 1995). The conversion of oxygen to O_2^- within neutrophils is facilitated by the NADPH oxidase system. This O_2^- is metabolized to H_2O_2, and the latter reacts with Cl^- to form hypochlorous acid. Myeloperoxidase (MPO), an enzyme contained in neutrophils, catalyzes this reaction. MPO activity in intestinal mucosal correlates well with the degree of neutrophil infiltration and mucosal injury.

Serine proteases are believed to play a contributing role in ischemia–reperfusion injury (Moore *et al.*, 1995). The pancreas is an important source of endoproteases (trypsin, chymotrypsin, and elastase) that can cause mucosal injury, particularly in the small intestine. Proteases produced by granulocytes, as well as lysosomes, are more important in mucosal injury of the large bowel. Elastase, neutral proteases, and cathepsin G are released from granulocytes during phagocytosis. Cathepsin B is a lysosomal protease that has trypsin-like activity.

Several pharmacological agents have been used in experimental and clinical studies of ischemia–

reperfusion injury (Moore *et al.*, 1995). The mechanistic rationale for many of these agents is comparable to the role of endogenous antioxidants. Examples of commonly used agents include xanthine oxidase inhibitors (allopurinol), deferroxamine, 21-aminosteroids, inhibitors of PLA2, cyclooxygenase, and lipoxygenase. Superoxide dismutase, catalase, and glutathione peroxidase (Gpx) are free-radical scavenging enzymes. Mannitol, albumin, dimethyl sulfoxide (DMSO), dimethyl thiourea, and manganese chloride represent nonenzymatic free-radical scavengers. Other agents that have been studied include nitric acid, protease inhibitors, hydroxyethylstarch, and neutrophil directed agents. Although the aforementioned agents have demonstrated efficacy in some studies, there are many inconsistencies. From a clinical perspective, success has been limited with single agents and there is more interest in combination or multimodal therapy.

D. Acute Diarrheas

The term "diarrhea" is used generically to describe the passage of abnormally fluid feces with increased frequency, increased volume, or both. The significance of diarrhea depends primarily on the underlying cause and on the secondary nutritional and metabolic disturbances that are caused by excessive fecal losses.

There are theoretically three factors that can act independently or in combination to produce diarrhea. An increase in the rate of intestinal transit is one factor believed important in functional disorders of the gastrointestinal tract in which "hypermotility" has been considered to be the primary cause. Although increased intestinal motility may be a factor in certain types of diarrheal disease, when motility patterns have been investigated, diarrheal disease has actually been associated with decreased motility (Christensen *et al.*, 1972). A second factor in the pathogenesis of diarrhea is decreased intestinal assimilation of nutrients that may result either from decreased intraluminal hydrolysis of nutrients, such as *maldigestion* due to pancreatic exocrine insufficiency or bile-salt deficiency, or from defective mucosal transport of nutrients, that is, *malabsorption*, that results from various types of inflammatory bowel disease, villus atrophy, intestinal lymphoma, or intrinsic biochemical defects in the mucosal cell that interfere with digestion and/or absorption. Finally, increased intestinal secretion of water and electrolytes is a major factor in the pathogenesis of certain types of acute diarrhea.

Enteropathogenic strains of *Escherichia coli* produce soluble enterotoxins (Smith and Halls, 1967; Kohler, 1968; Moon, 1978), which alter bidirectional Na^+ and water flux (Fig. 15.9). The most extensively studied enterotoxin is that produced by *Vibrio cholerae*. This bacterium produces a high-molecular-weight, heat-labile toxin (CT), one subunit of which has properties similar to those of the heat-labile (LT) enterotoxin produced by certain strains of *E. coli* (Richards and Douglas, 1978). The mechanism of action of CT is believed to involve the activation of adenylate cyclase. This membrane-bound enzyme converts ATP to cAMP, which through the action of protein kinase is responsible for the greatly increased secretion of water and electrolytes by the intestinal mucosa. Although species differences have been observed (Hamilton *et al.*, 1978a,b; Forsyth *et al.*, 1978), this mechanism appears to be important in the mode of action of LT of *E. coli* as well (Richards and Douglas, 1978).

Additional extensive studies have centered on the molecular mechanism of action of CT. Under physiological conditions, adenylate cyclase is activated by the binding of guanosine triphosphate to the inactive enzyme. An associated GTPase inactivates the enzyme by converting enzyme-bound GTP to GDP and inorganic phosphate. This GTP–GDP system plays a critical role in the physiological regulation of adenylate cyclase. Cholera toxin is believed to bind to the adenyl cyclase in a way that inhibits hydrolysis of GTP, thereby maintaining the enzyme in an activated state (Levinson and Blume, 1977; Johnson *et al.*, 1978; Cassel and Pfeuffer, 1978) (Fig. 15.10).

Certain enteropathogenic strains of *E. coli* produce a low-molecular-weight, heat-stable toxin (ST) alone or in addition to LT (Richards and Douglas, 1978; Moon, 1978; Hamilton *et al.*, 1978a). In epidemiological studies of neonatal diarrheal diseases of calves, most isolated strains of *E. coli* produce only ST (Moon *et al.*, 1976; Braaten and Myers, 1977; Lariviere *et al.*, 1979). In contrast to LT and CT, which induce intestinal Na^+ and water secretion only after a lag phase of several hours, ST induces intestinal secretion immediately. ST induces intestinal secretion by activating guanylate cyclase, and the mediator of intestinal secretion induced by ST is cyclic 3',5'-guanosine monophosphate (Hughes *et al.*, 1978; Field *et al.*, 1978).

Enterotoxin-induced intestinal secretion may be blocked by cycloheximide, an inhibitor of protein synthesis (Serebro *et al.*, 1969). The lack of specificity and the toxicity of cycloheximide precluded its clinical use, but acetazolamide has been shown to inhibit intestinal fluid secretion (Norris *et al.*, 1969; Moore *et al.*, 1971). Ethacrynic acid, another potent diuretic, has been shown to inhibit enterotoxin-induced fluid secretion (Carpenter *et al.*, 1969). Unfortunately, the diuretic effects of these drugs preclude their clinical use, but similar drugs with "intestinal specificity" would have

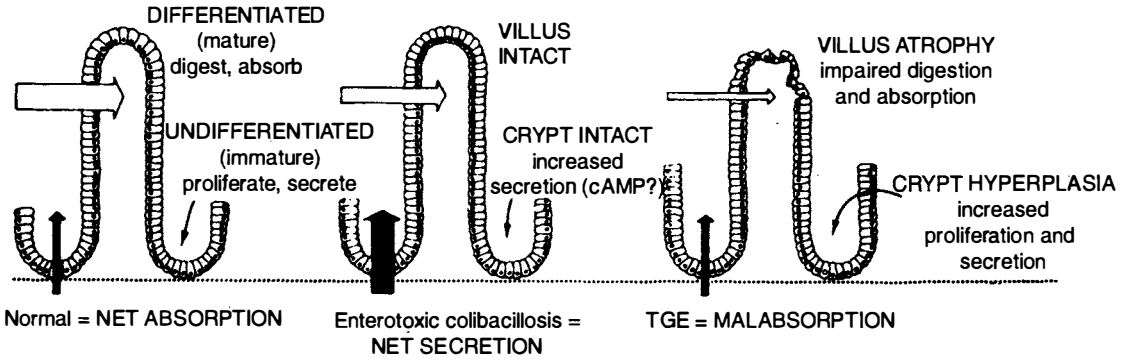

FIGURE 15.9 Pathogenesis of diarrhea caused by *E. coli* enterotoxin and by coronavirus. After Moon (1978).

significant therapeutic potential. Adenosine analogs also have been shown to inhibit cholera toxin-stimulated intestinal adenylate cyclase.

Prostaglandin E_1 (PgE_1) and CT have similar effects on electrolyte transport in rabbit ileum. Application of either to the mucosa inhibits NaCl absorption and stimulates Cl^+ secretion. Both indomethacin (Gots *et al.*, 1974) and aspirin (Farris *et al.*, 1976) inhibit enterotoxin-induced intestinal secretion in laboratory animal models, and the prostaglandins do not function as mediators in the pathogenesis of cholera (Schwartz *et al.*, 1975). However, Jones *et al.* (1977) demonstrated a positive therapeutic response to a new prostaglandin inhibitor in calves with acute enteritis.

The effects of the *E. coli* ST can be inhibited *in vitro* by the calcium channel blockers diltiazem and lodoxamide tromethamine, and the prostaglandin synthesis inhibitors indomethacin and quinacrine (Knoop and Abbey, 1981; Thomas and Knoop, 1982). Neither class of drug blocks the effect of cGMP, suggesting that calcium and prostaglandin influence the earliest step(s) in ST response: either its brush-border binding or the activation of guanylate cyclase.

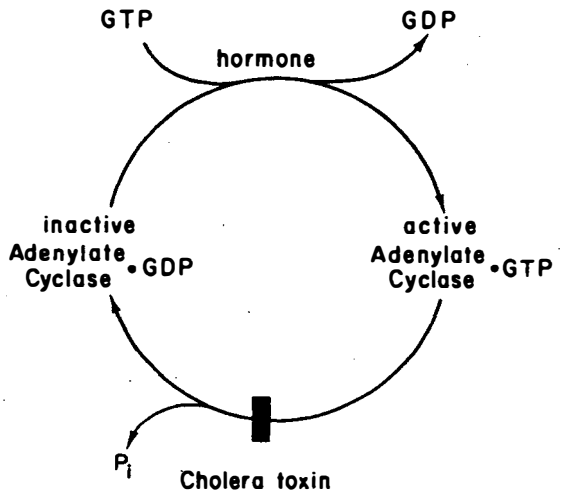

FIGURE 15.10 Mechanism of action of cholera toxin, which inhibits hydrolysis of GTP, thereby increasing adenylate cyclase activity. After Cassell and Selinger (1978).

The autonomic nervous system has important effects on intestinal ion transport and water absorption (Tapper *et al.*, 1978). Catecholamines stimulate formation of cAMP in a variety of mammalian cells (Sutherland and Rall, 1960; Schultz *et al.*, 1975), apparently by activating the GTP–GDP system described earlier (Cassel and Selinger, 1978; Ciment and deVellis, 1978). Adrenergic blocking agents, such as chlorpromazine (Holmgren *et al.*, 1978) and propranolol (Donowitz *et al.*, 1979), have significant inhibitory effects on enterotoxin-induced intestinal secretion. Although the mechanism of action of these two adrenergic blockers is not known, they represent still another class of drugs that may be of therapeutic benefit.

The intestinal "adsorbent" drug Pepto-Bismol, containing bismuth subsalicylate, and Attapulgite, a heat-treated silicate, have antienterotoxic effects (Drucker *et al.*, 1977; Ericsson *et al.*, 1977; Gyles and Zigler, 1978). Therapeutic trials with bismuth subsalicylate show significant therapeutic benefit in certain large-volume diarrheal diseases of humans that are enterotoxigenic in origin (Portnoy *et al.*, 1976; DuPont *et al.*, 1977; DuPont, 1978). The mechanism of the intestinal secretion inhibition is not known, but the chemical relation of bismuth subsalicylate to other known prostaglandin inhibitors is known. It is possible that such drugs, by decreasing endogenous production of prostaglandin, decrease the basal level of cyclic nucleotides, which in turn causes an increase in the threshold of response to enterotoxin. Salicylates also may stimulate sodium chloride absorption (Powell *et al.*, 1979). Collectively, these observations suggest that new, innovative methods for therapy and control of acute clinical diarrheal disease may be developed.

Acute diarrhea represents the leading cause of morbidity and mortality in neonatal calves and pigs. The

pathogenesis of the neonatal enteric infection is complex, often involving nutritional or environmental factors as well as infectious agents, such as enteropathogenic strains of *E. coli*, the transmissible gastroenteritis virus (TGE), rotaviruses, and other bacterial and viral pathogens. The severe clinical signs and frequently fatal outcome of acute diarrheal disease are often directly related to dehydration and to associated H^+ and electrolyte disturbances (Dalton *et al.*, 1965; Fisher and McEwan, 1967b; Tennant *et al.*, 1972, 1978).

In acute diarrhea with large-volume, watery stools, the fecal fluid originates primarily from the small intestine. The electrolyte composition of the stool in such cases is similar to that of the fluid found normally in the lumen of the small intestine, which in turn is similar to that of an ultrafiltrate of the plasma. The rapid dehydration that accompanies acute enteritis in the newborn soon produces hemoconcentration and leads to hypovolemic shock. These cases are characterized by metabolic acidosis (Dalton *et al.*, 1965; Phillips and Knox, 1969) caused by (1) decreased excretion of H^+ due to decreased renal perfusion and (2) increased production of organic acids, the result of decreased tissue oxygenation, which leads to excessive anaerobic glycolysis. Hyperkalemia also is observed characteristically in young, severely dehydrated animals. Hyperkalemia in such cases is the result of increased movement of cellular K^+ into the extracellular fluid and to decreased renal excretion. Cardiac irregularities caused by hyperkalemia can be demonstrated with the electrocardiogram, and cardiac arrest related to hyperkalemia is a direct cause of death in calves with acute diarrhea (Fisher, 1965; Fisher and McEwan, 1967b). Marked hypoglycemia also has been observed occasionally prior to death in calves with acute enteric infections. Hypoglycemia is believed to be due to decreased gluconeogenesis and increased anaerobic glycolysis, the result of hypovolemic shock (Tennant *et al.*, 1968). The sequence of metabolic changes that occur during acute neonatal diarrhea is summarized in Fig. 15.11.

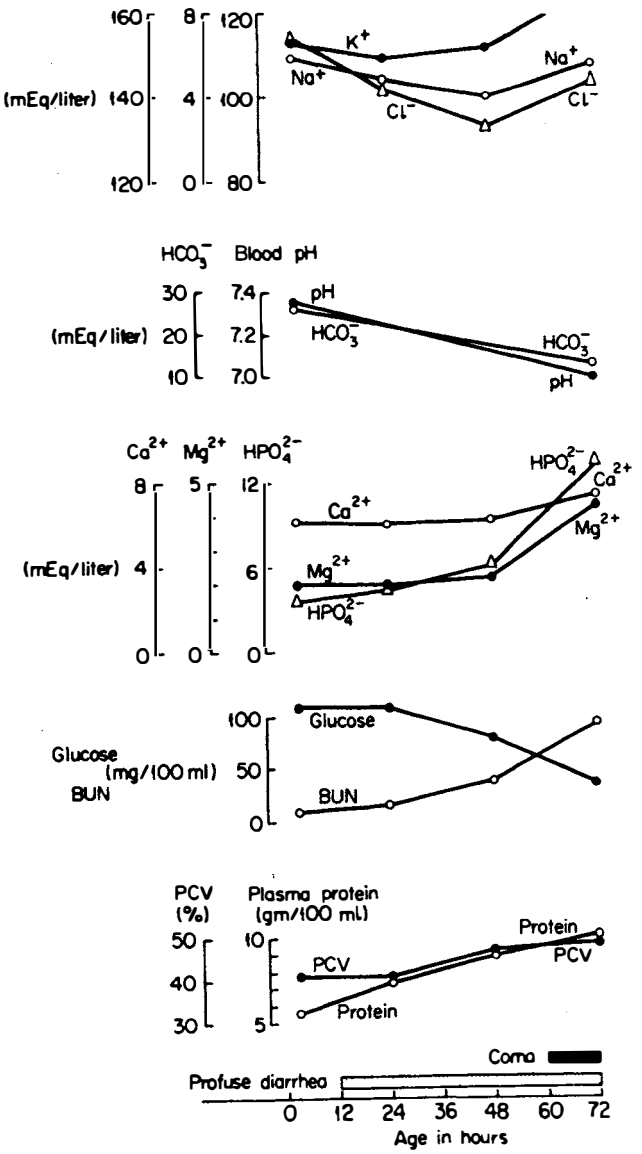

FIGURE 15.11 Metabolic alterations during the course of fatal enteric infection in a neonatal calf. From Tennant *et al.* (1972).

In chronic forms of diarrheal disease, excessive fecal losses of electrolyte and fluid are compensated in part by renal conservation mechanisms and in part by ingestion. If water is consumed without adequate ingestion of electrolytes, hyponatremia and hypokalemia may develop (Tasker, 1967; Patterson *et al.*, 1968). In such cases, the osmolality of the plasma is significantly decreased and hypotonic dehydration occurs. In longer-standing cases of chronic diarrhea, the plasma K^+ concentration may become dangerously low. It is imperative, in this case, that intravenous fluids contain sufficient K^+ to prevent further reduction in concentration and to avoid additional cardiac irregularities or cardiac arrest.

E. Intestinal Malabsorption

Decreased absorption of nutrients may occur either as a result of defective intraluminal digestion (maldigestion) associated with pancreatic insufficiency (juvenile pancreatic atrophy, chronic pancreatitis) (Anderson and Low, 1965a,b) or because of defects in mucosal transport (malabsorption). Intestinal malabsorption is associated with several types of intes-

tinal disease including chronic inflammatory diseases (lymphocytic–plasmacytic enteropathy, eosinophilic enteritis), granulomatous diseases (Johne's disease, intestinal parasitism), and lymphoma. The cardinal clinical signs of malabsorption include persistent or recurrent diarrhea, steatorrhea, and weight loss. In the horse, small-intestinal malabsorption such as that associated with granulomatous enteritis may be associated with weight loss, but diarrhea may not be present because of the compensatory capacity of the uninvolved cecum and colon.

The initial reports of primary or idiopathic intestinal malabsorption in dogs (Miller, 1960; Vernon, 1962; Kaneko *et al.*, 1965) were compared to nontropical sprue (adult celiac disease, gluten-induced enteropathy) of humans, but association with gluten sensitivity was not demonstrated. Wheat-sensitive enteropathy has been described in the Irish setter breed (Batt *et al.*, 1984d). Most of the dogs were seen between 7 months and 2 years of age and had poor weight gain, weight loss, inappetence, or hyperphagia. Diarrhea was not a consistent observation. The most consistent morphologic abnormality in peroral jejunal biopsies was partial villus atrophy. Enzymatic changes included decreased mucosal alkaline phosphatase and peptidases, whereas disaccharidases and GGT activities were unaffected. Recovery of morphological and biochemical abnormalities occurred in affected dogs that received cereal-free diets, but recurred when wheat flour was added to the ration. A variety of other causes of intestinal malabsorption have been reported in the dog (Van Kruiningen, 1968; Ewing, 1971; Van Kruiningen and Hayden, 1972; Hill, 1972; Hill and Kelly, 1974; Schall, 1974; Anderson, 1975, 1977; Burrows *et al.*, 1979). An enteropathy said to resemble tropical sprue in humans has been described in German shepherds by Batt *et al.* (1983a). Affected dogs were five years of age or older and had diarrhea and weight loss for at least four months before the diagnosis was made. Peroral jejunal biopsies revealed partial villus atrophy and variable infiltrations of lymphocytes and plasma cells in the lamina propria. Subcellar biochemical studies of jejunal enterocytes revealed decreased activity of many brush-border enzymes and increased lysosomal enzymes.

Enteropathy associated with bacterial overgrowth of the small intestine also has been observed in German shepherds (Batt *et al.*, 1984). The dogs were 2 years of age or less, and all had chronic histories of intermittent diarrhea with or without weight loss. Bacterial counts of greater than 10^6 colonies per milliliter were observed in duodenal fluid. Enterococci, *E. coli*, and *Clostridium* spp. were identified in cultures. Peroral jejunal biopsies revealed no characteristic histopathologic changes. A deficiency of the immunoglobulin, IgA, may explain the vulnerability of these German shepherds to intestinal bacterial overgrowth (Whitbread *et al.*, 1984).

Intestinal malabsorption is reported less frequently in the cat than in the dog (Theran and Carpenter, 1968; Wilkinson, 1969). Malabsorption syndromes similar to those recognized in dogs are being recognized with increased frequency in farm animals (Blood *et al.*, 1979). Meuten *et al.* (1978), Cimprich (1974), and Merritt *et al.* (1976) have reported malabsorption in the horse secondary to chronic granulomatous enteritis, and specific amino acid malabsorption has been reported in Johne's disease (Patterson and Berrett, 1969).

Steatorrhea, the presence of excessive amounts of fat in the feces, is a prominent sign of intestinal malabsorption in dogs. The stools are bulky, gray or tan, and, grossly, may have an oily appearance. The normal dog excretes 3–5 g fat in the stool each day. This level of fecal fat is quite constant and is independent of dietary fat intake over a wide range of 15 to 48 g/day (Heersma and Annegers, 1948). In intestinal malabsorption, the ability to absorb fat is decreased and fecal fat excretion increases significantly. Under these conditions, the amount of fecal fat excreted becomes proportional to dietary intake.

Merritt *et al.*, (1979) reported that body weight is an important factor in fat output. In small dogs (i.e., less than 10–15 kg body weight) with intestinal malabsorption, the abnormality in fecal fat output was quantitatively less severe than in larger dogs. Fecal fat excretion for normal dogs was 0.24 ± 0.01 g/kg body weight per day.

Steatorrhea can be documented qualitatively by staining the fresh stool with a lipophilic stain, such as Sudan III, and observing increased numbers of oil droplets under the light microscope. In experienced hands, this method is a reliable diagnostic procedure (Drummey *et al.*, 1961). The following methods can be used to demonstrate neutral and split fats. For neutral fat, two drops of water are added to a stool sample on a glass slide and mixed. Two drops of 95% ethanol are then added and mixed, followed by several drops of a saturated solution of Sudan III in 95% ethanol. A coverslip is applied to the mixture, which is then examined for yellow or pale-orange refractile globules of fat, particularly at the edges of the coverslip. Normally, two or three fat droplets per high-power field are present. A large number of neutral fat droplets suggests a lack of pancreatic lipase activity, that is, exocrine pancreatic insufficiency.

For free fatty acids (split fats), several drops of 36% acetic acid are added to a stool sample on a glass slide and mixed. Several drops of Sudan III solution are then added and mixed. A coverslip is applied, and the slide

gently heated over an alcohol burner until it begins to boil. The slide is air cooled and then quickly heated again. This procedure is repeated two or three times. The warm slide is examined for stained free fatty acid droplets, which, when warm, appear as deep-orange fat droplets from which spicules and soaps, resembling the pinna of the ear, form as the preparation cools. Normal stools may contain many tiny droplets of fatty acids (up to 100 per high-power field). With increasing amounts of split fats, the droplets become larger and more numerous, which suggests an abnormality in fat absorption.

Quantitation of fecal fat is the most accurate method of assessing steatorrhea (Burrows *et al.*, 1979) with dietary fat balance being determined for a period of 48–72 hours. Fecal fat is analyzed using a modification of the technique of van de Kamer *et al.* (1949), which employs ether extraction of fecal lipid and titration of fatty acids. The results are expressed as grams of neutral fat excreted per 24 hours. Merritt *et al.* (1979) have suggested that dogs be fed 50 g fat per kilogram per day for two to three days prior to fecal collection. Analysis of a 24-hour collection of stool when this is done is believed to be as accurate as a 72-hour stool collection. Results are expressed as fat excretion in grams per kilogram body weight.

In addition to malabsorption of fat, the canine malabsorption syndrome is associated with decreased absorption of other nutrients. These defects in absorption are responsible for the progressive malnutrition that is a cardinal feature of the disease. There may be malabsorption of vitamin D and/or calcium that results in osteomalacia. Anemia may result from malabsorption of iron or of the B vitamins required for normal erythropoiesis. Malabsorption of vitamin K can result in hypoprothrombinemia and delayed clotting of blood. Glucose malabsorption has been documented by Kaneko *et al.* (1965), and it is likely that amino acids are similarly malabsorbed at the small-intestinal level. Carbohydrate and fat malabsorption unquestionably contribute to the energy deficit that results in weight loss. Amino acid malabsorption may contribute to development of hypoproteinemia, although increased intestinal loss of plasma proteins is believed to be more important.

The diagnosis of idiopathic canine malabsorption is made only after other primary inflammatory, neoplastic, or parasitic diseases of the intestine and diseases of the pancreas, liver, or stomach that result in defective intraluminal digestion are ruled out. The presence of parasitic infection is established by examining the feces for parasite cysts or ova. Other inflammatory or neoplastic diseases of the intestine may be suggested on the basis of clinical or radiological examination, but a definitive diagnosis usually depends on histopathological examination of an intestinal biopsy specimen.

Both idiopathic and secondary intestinal malabsorption must be differentiated from those diseases in which there is decreased intraluminal hydrolysis of nutrients. The latter are due most frequently to pancreatic exocrine insufficiency as a result of chronic pancreatitis or juvenile atrophy. In these diseases, hydrolysis of the major dietary constituents is reduced because of the lack of pancreatic enzymes. Intraluminal hydrolysis of fat may also be decreased because of a deficiency of bile salts caused either by decreased hepatic secretion or by bile-duct obstruction. Experimentally, however, complete diversion of bile flow in the dog actually has a quantitatively small effect on fat absorption (Wells *et al.*, 1955; Hill and Kidder, 1972a).

The problems of pancreatic exocrine deficiency are discussed in detail elsewhere, in the chapter on pancreatic function. The simplest and perhaps most widely used test to differentiate intestinal malabsorption from pancreatic exocrine insufficiency is that described by Jasper (1954). The test is employed to detect reduction in trypsin-like activity in the feces of dogs with decreased pancreatic exocrine secretion (Grossman, 1962). There is wide variation in normal activity, making interpretation of the test difficult (Frankland, 1969; Hill and Kidder, 1970; Burrows *et al.*, 1979).

The test reveals only the presence or absence of hydrolysis of gelatin and does not differentiate gelatinase activity produced by intestinal bacteria from that secreted by the pancreas. There is evidence in some species that trypsin is almost completely destroyed by bacteria during its passage through the intestine, and that the proteinase activity of the feces is primarily of bacterial origin (Borgstrom *et al.*, 1959). Despite these deficiencies, the test is clinically useful. Fecal gelatinase activity is detected consistently in cases of intestinal malabsorption and is virtually always absent in severe pancreatic exocrine insufficiency. Burrows *et al.* (1979) observed that in comparison to clinically normal dogs, the 24-hour trypsin output in dogs with pancreatic insufficiency was significantly lower, whereas in dogs with malabsorption the trypsin output was significantly higher.

An indirect method to detect chymotrypsin activity has been described as a means of differentiating dogs with pancreatic exocrine insufficiency from those with intestinal malabsorption (Imondin *et al.*, 1972; Freudiger and Bigler, 1977; Strombeck, 1978; Strombeck and Harrold, 1982; Batt *et al.*, 1979; Batt and Mann, 1981; Zimmer and Todd, 1985). The synthetic peptide *n*-benzoyltyrosine-*p*-aminobenzoic acid (bentiromide) is orally administered to dogs. If chymotrypsin is present in the duodenum, hydrolysis of the bentiro-

mide occurs, and *p*-aminobenzoic acid (PABA) is released, which is subsequently absorbed and then excreted in the urine within 6 hours. The urine and/or plasma are analyzed for PABA. Less than 43% PABA excretion identifies dogs with suspected pancreatic exocrine insufficiency (Strombeck, 1978). Thirty- or 60-minute blood levels of PABA are used to detect dogs with pancreatic exocrine disease (Zimmer and Todd, 1985), but this method did not identify dogs with exocrine pancreatic insufficiency as consistently as the 6-hour urinary excretion (Strombeck and Harrold, 1982). Factors that may influence results of the bentiromide test include the rate of gastric emptying, intestinal absorption of the PABA, and peptide cleavage by other peptidases (Batt *et al.*, 1979).

A radioimmunoassay for trypsin-like immunoreactivity (TLI) is currently widely used to identify dogs with pancreatic exocrine insufficiency (Williams and Batt, 1983; Williams, *et al.*, 1987) and is useful in differentiating maldigestion from primary malabsorption. The TLI in normal dog serum is trypsinogen. The route of entry of trypsinogen into the systemic circulation is believed to be the pancreatic venous or lymphatic vessels. Trypsinogen release in inflammatory pancreatic disease (i.e., acute or chronic pancreatitis) may increase TLI values. Increased TLI values have been reported in a dog with confirmed pancreatic exocrine insufficiency that had normal PABA values and fecal proteolytic activity (Williams and Batt, 1986). In most cases of pancreatic exocrine insufficiency, TLI is remarkably reduced compared to that of normal dogs or dogs with intestinal malabsorption.

F. Tests of Intestinal Absorption

1. *Oleic Acid and Triolein Absorption*

Several tests have been developed for the clinical evaluation of intestinal absorptive capacity. The absorption of ^{131}I-labeled oleic acid and ^{131}I-labeled triolein has been studied extensively in normal dogs (Turner, 1958; Michaelson *et al.*, 1960), and Kaneko *et al.* (1965) used this test to study dogs with intestinal malabsorption. The day before administration of the ^{131}I-labeled compound, a small amount of Lugol's iodine solution is administered to block thyroidal uptake of the isotope. Tracer amounts of the test substances are mixed with nonradioactive carrier and are administered orally. Absorption is determined by measuring the radioactivity of the plasma at intervals following administration and calculating the percentage of the dose absorbed on the basis of plasma volume.

The ^{131}I-oleic acid and ^{131}I-triolein tests performed in sequence are used to differentiate steatorrhea caused by pancreatic enzyme deficiency from that caused by a primary defect in absorption (Kallfelz *et al.*, 1968). If steatorrhea is caused by a lack of pancreatic lipase, oleic acid absorption will be normal, whereas that of triolein, which requires lipolysis for absorption, will be significantly reduced. The absorption of both compounds is reduced in intestinal malabsorption.

2. *Vitamin A Absorption*

The vitamin A absorption test measures intestinal lipid absorption (Hayden and Van Kruiningen, 1976). Normal absorption of vitamin A requires secretion of bile and pancreatic enzymes. After oral administration of 200,000 units of vitamin A in normal dogs, serum vitamin A concentrations reach their peak at 6–8 hours, with values ranging between three and five times fasting serum levels. There are small differences in vitamin A absorption between breeds, and delayed gastric emptying will also alter results.

3. *Glucose Absorption*

The absorption of glucose can be evaluated by the oral glucose tolerance test (OGTT) where a oral test dose of glucose is given and the blood glucose levels are measured at half-hour intervals for 3 to 4 hours. In canine malabsorption, the OGTT curve of blood glucose is diminished or flat (Kaneko *et al.*, 1965). The test also has been used in the horse for evaluation of small intestinal malabsorption (Roberts and Hill, 1973). Dogs with pancreatic exocrine deficiency may have "diabetic" or high OGTT curves (Hill and Kidder, 1972b). The major disadvantage of this test is that it does not differentiate between decreased intestinal absorption and increased tissue uptake after absorption. This problem can be alleviated by comparing results of the OGTT with those of the intravenous glucose tolerance test (IVGTT). Hill and Kidder (1972a) reported that normal dogs on low-carbohydrate/high protein diets can have "diabetic" tolerance curves; thus, test dogs should be on a high-carbohydrate diet for 3 to 5 days before testing.

4. *D-Xylose Absorption*

D-Xylose is used clinically to evaluate intestinal absorption (Craig and Atkinson, 1988). D-Xylose is not metabolized by the body to any significant degree and the problems of evaluating tissue utilization that occur with glucose are avoided. Because large amounts of D-xylose must be used, the rate of absorption is proportional to luminal concentration and independent of active transport processes.

A D-xylose absorption test for dogs has been described by Van Kruiningen (1968). In this procedure,

a standard 25-g dose of D-xylose is administered by stomach tube. During the 5-hour period after administration, the patient is confined in a metabolism cage and urine is collected. At the end of the 5-hour test period, the urine remaining in the bladder is removed by catheter and the total quantity excreted in 5 hours is determined. Normal dogs excreted an average of 12.2 g of the 25-g dose during the test period, with a range of 9.1–16.5 g. Because this test is dependent on the rate of intestinal absorption as well as the rate of renal excretion, it is necessary to establish that kidney function is normal.

A modified D-xylose tolerance test is now most widely used clinically (Hill *et al.*, 1970; Hayden and Van Kruiningen, 1973). Dogs are fasted overnight, a baseline blood sample is taken, and D-xylose is administered by stomach tube at the rate of 0.5 g/kg. A control test is performed on a normal dog simultaneously. Blood samples are taken at ½, 1, 2, 3, 4, and 5 hours after administration. The D-xylose concentration in the blood is determined by the method of Roe and Rice (1948) or by the phloroglucinol microassay (Merritt and Duelly, 1983). The phloroglucinol procedure is more economical, requires less plasma, and is technically easier than the orcinol–ferric chloride procedure of Roe and Rice (Merritt and Duelly, 1983). Maximal blood levels of D-xylose are normally reached at 1 hour after administration. A D-xylose level of at least 45 mg/dl within 60–90 minutes is expected in normal dogs (Hill *et al.*, 1970).

The D-xylose absorption test is also used for differential diagnosis of equine diarrheal diseases (Roberts, 1974). Bolton *et al.* (1976) reported that a dosage of 0.5 g D-xylose per kilogram body weight was useful in detecting horses with intestinal malabsorption. The peak plasma concentration in normal horses is less than one-third of that seen in normal dogs given D-xylose at comparable doses.

5. *Vitamin B_{12} and Folic Acid Absorption*

Serum folate and vitamin B_{12} levels (Waters and Mollin, 1961) have been recommended as screening tests for dogs suspected of having intestinal malabsorption (Batt and Morgan, 1982b). The primary site of folate absorption is the jejunum and vitamin B_{12} is absorbed primarily in the ileum. Structural and functional disturbances of the small intestinal mucosa are associated with reduced serum levels of folate, vitamin B_{12}, or both depending on the segment(s) of the small intestine involved. Although serum folate levels can decrease markedly within several days, the folate concentration within erythrocytes decreases much more slowly, so low erythrocyte folate values may be a more accurate indicator of a chronic disorder. Overgrowth of folate-producing bacteria in the proximal small intestine can result in a spurious increase in serum folate levels and reduced serum levels of vitamin B_{12}. The reduction of vitamin B_{12} is the result of binding of the vitamin B_{12}–intrinsic factor complex by intestinal bacteria.

6. *Other Tests for Assessment of Intestinal Function*

Simultaneous evaluation of pancreatic exocrine function and intestinal absorptive function is used in dogs (Stradley *et al.*, 1979; Rogers *et al.*, 1980) and cats (Sherding *et al.*, 1982; Hawkins *et al.*, 1986). The combined bentiromide and D-xylose absorption tests has proven to be useful diagnostically in dogs. Blood is normally taken at 0, ½, 1, 1½, 2, 2½, and 3 hours after oral administration of the test solution, but a single blood sample taken at 1½ hours was adequate for differential diagnostic purposes (Stradley *et al.*, 1979). The combined bentiromide/D-xylose absorption test was of limited usefulness in cats because of marked individual variations. Peak blood PABA levels (60–120 minutes) and peak blood D-xylose levels (30–120 minutes) in healthy cats were less than those of normal dogs, and blood D-xylose levels in cats with infiltrative small bowel disease were not abnormal (Hawkins *et al.*, 1986).

The content of exhaled hydrogen gas has been evaluated as an indicator of carbohydrate malassimilation in dogs (Washabau *et al.*, 1986), cats (Muir *et al.*, 1991), calves (Holland *et al.*, 1986), and humans (Perman, 1991). Unabsorbed carbohydrate is fermented by bacteria in the colon to H_2 and organic acids. Of the H_2, 10–14% is absorbed and excreted by the lungs (Washabau *et al.*, 1986). Increases in pulmonary H_2 excretion can occur in normal dogs fed rations containing wheat or corn flour. Increased H_2 excretion normally occurs in most species receiving lactulose. Mild increases in H_2 excretion occur in normal humans and dogs receiving xylose, but not in cats.

Breath H_2 excretion has diagnostic value in determining mouth-to-cecum transit time and for identifying small-intestinal bacterial overgrowth (Muir *et al.*, 1991). False-negative H_2 breath tests have been seen in humans receiving antibiotics. Diet as well as variations in bacterial flora can also cause false-positive test results.

The nitrosonapthol test qualitatively measures urinary excretion of 4-hydroxyphenylacetic acid and related compounds that are intestinal bacterial degradation products of tyrosine. The test has been used to differentiate pancreatic or small-intestinal diarrheal diseases from those associated primarily with large-

bowel disease (Burrows and Jezyk, 1983). The test was positive in 77% of the dogs with pancreatic and small-intestinal disease and in only 9.5% of those dogs with large-bowel disease. Positive tests were associated with bacterial overgrowth of the small intestine and became negative during antibiotic treatment that resulted in clinical improvement. The test may be useful in dogs to select patients with small-intestinal bacterial overgrowth that might respond to antibiotic therapy.

G. Small-Intestinal Bacterial Overgrowth

Small-intestinal bacterial overgrowth (SIBO) is defined as an increase in the number of bacterial organisms cultured from the duodenum or proximal jejunum during the interdigestive phase (Burrows *et al.*, 1994). In the dog, total bacterial counts exceeding 10^5 colony-forming units per milliliter (cfu/ml) of proximal jejunal or duodenal fluid and anaerobic bacterial counts exceeding 10^4 cfu/ml are seen. Healthy cats have higher numbers of bacterial flora in their small intestine than do other species (Johnston *et al.*, 1993), in numbers that approximate those for SIBO in dogs and man. In most clinical situations, SIBO occurs secondary to partial intestinal obstructions or other forms of primary mucosal injury, defective or deficient immunologic responses, and intestinal motility disorders. SIBO has been reported in dogs with chronic intestinal diseases (Rutgers *et al.*, 1988, 1993, 1995) and pancreatic exocrine insufficiency (Williams *et al.*, 1987; Simpson *et al.*, 1990). Much of the literature pertains to German shepherds with subnormal levels of IgA (Westermarck *et al.*, 1993; Delles *et al.*, 1993, 1994; Willard *et al.*, 1994). SIBO has also been reported in beagle dogs with normal IgA levels (Batt *et al.*, 1992).

In the absence of primary disease, dogs with SIBO may be subclinical or have chronic manifestations of diarrhea and/or weight loss. Chronic SIBO can cause inflammatory bowel disease, but histopathologic findings usually are mild to negligible. The lesions consist of villlus atrophy and infiltrations of lymphocytes and plasmacytes in the lamina propria. There is substantial but reversible biochemical injury to enterocytes of the brush-border membrane (Batt and McLean, 1987). Aerobic bacteria, such as enterococci and *Escherichia coli*, cause a selective loss of brush-border alkaline phosphatase activity and peroxisomal catalase, as well as changes that are consistent with mitochondrial disruption. There are exceptions but aerobic overgrowth is typical for the dog in contrast to anerobic overgrowth in humans. The high floral counts in the intestines of cats are thought to predispose them to certain nutritional deficiencies, such as taurine deficiency, and intestinal disturbances attributed to deconjugated bile salts (Johnston *et al.*, 1993).

All of the aforementioned histopathologic and biochemical changes can be improved by antibiotic administration (Batt *et al.*, 1993). Dietary supplementation with fructo-oligosaccharide in IgA-deficient German shepherds resulted in decreased bacterial counts in luminal fluid and intestinal mucosa tissue (Willard *et al.*, 1995). Plasma-cell infiltrations in jejunal villi were decreased by feeding different protein sources (Edwards *et al.*, 1995).

The culturing and quantitation of intestinal bacterial flora (Simpson *et al.*, 1990) is the definitive means of diagnosing SIBO. Less invasive diagnostic methods include determination of serum folate and cobalamin levels and the nitrosonaphthal test on urine (Burrows *et al.*, 1995). Deconjugation of bile acids by intestinal flora, with a subsequent disproportionate increase in unconjugated bile acids in the circulation, is seen in humans with bacterial overgrowth (Einarsson *et al.*, 1992).

H. Gastric Helicobacteriosis

Gastric helicobacteriosis has been associated with chronic gastritis, atrophic gastritis, peptic ulcer disease, adenocarcinoma, and lymphoma in humans (Handt *et al.*, 1994; Isaacson 1994; Parsonnett *et al.*, 1991). Therapeutic modalities in human medicine have been directed predominately at *Helicobacter pylori* (Labenz *et al.*, 1993; Cutler and Schubert, 1993). Spontaneous and experimental disease caused by *H. pylori* is also seen in nonhuman primates, dogs, cats, and pigs. Helicobacter infections in animals, based on studies of *H. pylori* and *H. felis*, has serious public health implications (Handt *et al.*, 1994). *H. felis*, *H. heilmannii* (*Gastrospirillum hominis*), and other large "gastrospirillum-like" bacteria have also been associated with clinical signs of vomiting and/or chronic gastritis in dogs, cats, and cheetahs (Geyer *et al.*, 1993; Eaton *et al.*, 1991). *H. mustelae* causes similar problems in the ferret (Gottfried *et al.*, 1990). Experimental disease induced by *H. pylori* and *H. felis* has been produced in gnotobiotic dogs, casts, pigs, rats, and mice (Lee *et al.*, 1992; Radin *et al.*, 1990).

The ulcerogenic and neoplastic manifestations of helicobacter-induced disease observed in humans has not been seen in the dog and cat. Lymphoplasmacytic cellular infiltration of the lamina propria of the stomach, accompanied by eosinophils and some neutrophils, is characteristic of *H. pylori* or *H. felis* infections. Lymphoid follicle formation, particularly in the antrum of the stomach, is a prominent histologic lesion in some cases. Helicobacter organisms can be demonstrated by impression smears, contrast-phase microscopy, urease mapping, and histopathology of gastric mucosa. Serologic activity of helicobacter infection can

be monitored. Unique culture characteristics, fatty-acid composition, and DNA typing are utilized to identify subspecies of the organism.

The majority of dogs and cats with helicobacter infections are asymptomatic. Transmission of infection is thought to be by oral–oral or anal–oral mechanisms. The importance of this infection is its zoonotic potential to infect people, in whom much more serious health problems are encountered.

I. Intestinal Permeability

Changes in intestinal mucosal permeability can be a factor in the pathogenesis of mucosal injury and subsequent gastrointestinal disease (Burrows *et al.*, 1995, Sanderson and Walker, 1993). Whether as a primary or secondary disorder, increased permeability predisposes to the passage of intraluminal macromolecules across the intestinal mucosa. Depending on the noxious or antigenic characteristics of these macromolecules, pathologic features of toxic or immune-mediated injury may occur. A primary mucosal permeability defect is suspected in humans and Irish setters with gluten-induced enteropathy (Batt *et al.*, 1984; Hall and Batt, 1991a,b). Enhanced mucosal permeability due to small intestinal bacterial overgrowth has been reported in clinically healthy beagles (Batt *et al.*, 1992). Seondary permeability disorders have been resolved by appropriate treatment of giardiasis and bacterial overgrowth in dogs (Batt *et al.*, 1988; Hall and Batt, 1990).

Clinicopathologic evaluation of intestinal permeability is based on the oral administration of simple, nondigestible molecules (probes) and their recovery in urine (Papasouliatis *et al.*, 1993; Elwood *et al.*, 1993). Inappropriate levels of these probes in urine indicates abnormal macromolecular permeation through transcellular and/or paracellular pathways. Polyethylene glycols, ^{51}CR-labeled ethylenediaminetetraacetate (^{51}EDTA) (Hall *et al.*, 1989,1990, Hall and Batt, 1991; Batt *et al.*, 1992) and nonhydrolyzable sugars have been used in permeability tests. The disaccharides cellobiose and lactulose and the monosaccharides mannitol and L-rhamnose are unable to penetrate healthy enterocytes (Papasouliatis *et al.*, 1993). In the presence of abnormal mucosal permeability, the disaccharides passively diffuse through the mucosa via paracellular pathways and the monosaccharides diffuse passively transcellularly.

Differential sugar absorption and calculated disaccharide-to-monosaccharide excretion ratio is preferred over single sugar measurements. The use of lactulose and mannitol in the evaluation of intestinal permeability has been reported in healthy cats (Papasouliotis *et al.*, 1993; Bulsma *et al.*, 1995). The cellobiose-to-mannitol urinary excretion ratio was increased in Irish setters with gluten-sensitive enteropathy (Hall and Batt, 1991). Simultaneous quantification of rhamnose, lactulose, 3-O-methyl-D-glucose, and xylose in urine by a unique chromatographic technique has been reported to assess both intestinal function and permeability (Sorensen *et al.*, 1993).

J. Protein-Losing Enteropathy

Albumin, IgG, and other plasma proteins are present in low concentration in normal gastrointestinal secretions. Because protein usually undergoes complete degradation within the intestinal lumen, it has been suggested that the gastrointestinal tract must have a physiological role in the catabolism of plasma proteins. The relative significance of this pathway, however, has been the subject of considerable controversy. Some investigators have concluded, for example, that as much as 50% or more of the normal catabolism of albumin (Glenert *et al.*, 1961, 1962; Campbell *et al.*, 1961; Wetterfors, 1964, 1965; Wetterfors *et al.*, 1965) and τ-globulin (Andersen *et al.*, 1963) may occur in the gastrointestinal tract. Others believe that the physiological role of the intestine in plasma protein catabolism is far less significant, accounting for about 10% of the total catabolism (Waldmann *et al.*, 1967, 1969; Katz *et al.*, 1960; Franks *et al.*, 1963a,b).

Regardless of questions concerning the physiological significance of the gastrointestinal tract in plasma protein catabolism, it is well established that normal intestinal losses are substantially increased in a variety of gastrointestinal diseases, collectively referred to as the protein-losing enteropathies (PLEs). The increased loss causes hypoproteinemia (especially hypoalbuminemia), which may be observed in various types of chronic enteric diseases. The excessive losses are the result of ulcerations or other mucosal changes that alter permeability or obstruct lymphatic drainage from the intestine. If severe, hypoalbuminemia may result in retention of fluid with development of ascites and subcutaneous edema of pendant areas.

Excessive plasma protein loss has been seen in swine with chronic ileitis (Nielsen, 1966), in calves with acute enteric infections (Marsh *et al.*, 1969), in cattle with parasitic or other inflammatory abomasal disease (Nielsen and Nansen, 1967; Halliday *et al.*, 1968; Murry, 1969) and in Johne's disease (Patterson *et al.*, 1967; Nielsen and Andersen, 1967; Patterson and Berrett, 1969). In addition to the classic mucosal and submucosal lesions of Johne's disease, Nielsen and Andersen (1967) demonstrated the presence of secondary intestinal lymphangiectasia. Meuten *et al.* (1978) observed PLE associated with granulomatous enteritis in two horses.

PLE is seen with some frequency in the dog (Campbell *et al.*, 1968; Farrow and Penny, 1969; Hill, 1972; Finco *et al.*, 1973; Hayden and Van Kruiningen, 1973; Mattheeuws *et al.*, 1974; Hill and Kelly, 1974; Milstein and Sanford, 1977; Barton *et al.*, 1978; Olson and Zimmer, 1978). The most common cause appears to be lymphocytic–plasmacytic enteropathy (Tams and Twedt, 1981; Tams, 1987). Intestinal lymphangiectasia also has been reported as a cause of increased intestinal protein loss. Increased plasma protein loss from the stomach has been seen in dogs with hypertrophic gastritis.

Increased intestinal protein loss is the most likely cause of the hypoalbuminemia associated with certain other enteric diseases, including lymphoma and malabsorptive syndromes. Munro (1974) demonstrated that protein loss in dogs with experimentally induced protein-losing gastropathy occurs by an intercellular route. Isotope-labeled polyvinylpyrrolidine (^{131}I-PVP), ^{51}Cr-labeled ceruloplasmin, and ^{51}Cr-labeled albumin have been used to evaluate enteric protein loss in the dog (Finco *et al.*, 1973; Barton *et al.*, 1978; Hill and Kelly, 1974; van der Gagg *et al.*, 1976; Olson and Zimmer, 1978). Fecal α-1-protease inhibitor (α1-PI) is minimally degraded as it passes down the gastrointestinal tract. In conditions where there is excessive loss of plasma protein into the gut, there is an increase in fecal α1-PI (Williams, 1991).

K. Canine Ulcerative Colitis

Canine ulcerative colitis was first described by Cello (1964). Since then, canine ulcerative colitis, including granulomatous colitis of boxer dogs, has been reported by others (Van Kruiningen *et al.*, 1965; Kennedy and Cello, 1966; Koch and Skelley, 1967; Sander and Langham, 1968; Ewing and Gomez, 1973, Gomez *et al.*, 1977; Russell *et al.*, 1971). In boxer dogs, the disease is characterized by intractable diarrhea that is often hemorrhagic. Histopathologically, there is a granulomatous or histiocytic submucosal infiltrate and the macrophages are laden with periodic-acid-Schiff-positive material. Electron photomicrography demonstrated bacteria in the macrophages (Russell *et al.*, 1977). Cases of ulcerative colitis in dogs have been attributed to trichuriasis, balantidiasis, protothecosis, histoplasmosis, eosinophilic ulcerative colitis, or neoplasia (Lorenz, 1975). Severe ulcerative colitis also has been reported in the cat, and in some the feline leukemia virus (FELV) is demonstrated. Shindel *et al.* (1978) have described colonic lesions in cats caused by feline panleukopenia.

Biochemical manifestations of ulcerative colitis depend upon the duration and severity of illness, the degree of colorectal involvement, and the presence of systemic complications. In severe cases of long duration with extensive colorectal involvement, hypoalbuminemia and hypergammaglobulinemia are often observed. Hypoalbuminemia is attributed to increased loss of plasma through the denuded and inflamed colorectal mucosa and hypergammaglobulinemia is the response to the continuing chronic inflammation.

VIII. DISTURBANCES OF RUMEN FUNCTION

The digestive process of ruminants differs from that of other animals because rumen microbial digestion occurs prior to other normal digestive processes. The short-chain fatty acids (acetic, propionic, and butyric acids) are the primary end products of rumen fermentation and are the chief sources of energy available to ruminants from the diet (Hungate *et al.*, 1961). Cellulose, which undergoes only limited digestion in most simple-stomached animals, is readily digested because of the cellulytic bacteria in the rumen. Significant quantities of nonprotein nitrogen (NPN) can also be used by ruminal bacteria for protein synthesis, and this bacterial protein subsequently can be utilized to meet the protein requirements of the animal. Under experimental conditions, ruminants may grow and reproduce while receiving diets containing only NPN, for example, urea, as sources of nitrogen. Bacterial production of vitamins can also meet essentially all the requirements of ruminants.

Although it is nutritionally essential, bacterial fermentation within the rumen presents certain unusual hazards for ruminants. For example, when rapid changes in diet occur, the products of fermentation can be released more rapidly than they can be removed or utilized. Acute rumen tympany, acute indigestion, or D-lactic acidosis and urea poisoning are diseases that result from such abrupt changes in diet (Hungate, 1966, 1968).

A. Acute Rumen Indigestion (Rumen Overload, Lactic Acidosis)

Acute rumen indigestion occurs in sheep or cattle consuming high-roughage diets when they inadvertently are allowed access to large amounts of readily fermentable carbohydrate, such as grain or apples (Dunlop, 1972). *Streptococcus bovis* is the rumen microorganism believed to be chiefly responsible for rapid fermentation and for production of large quantities of lactic acid (Hungate *et al.*, 1952; Krogh, 1963a,b).

When lactic acid accumulates more rapidly than it is absorbed, rumen pH falls and rumen atony develops. Rumen bacteria produce a racemic mixture of lactic acid. Some L-lactate is absorbed and metabolized by the liver and other tissues, but D-lactate cannot be utilized and contributes significantly to the acid load of the body. The excessive lactic acid production results in metabolic acidosis, characterized by reduced blood pH and HCO_3^- concentration and by a fall in urine pH from a normal alkaline value to as low as pH 5.0. Fluid accumulates in the rumen because of the increased osmolality of the rumen fluid. This accumulation of fluid into the rumen causes hemoconcentration, which in turn may lead to hypovolemic shock and death (Hyldgaard-Jensen and Simesen, 1966). If affected animals survive the initial period of rapid fermentation, chemical rumenitis induced by the hyperosmolality of the rumen fluid and by the excess lactic acid may develop. Secondary mycotic rumenitis may then follow, which in severe cases can be fatal. In surviving cattle, metastatic hepatic abscesses may also occur.

B. Acute Rumen Tympany (Bloat)

The rumen of mature cattle can produce 1.2–2.0 liters of gas per minute (Hungate *et al.*, 1965). The gas is the product of rumen fermentation and is composed primarily of carbon dioxide (CO_2) and methane. CO_2 is also released when salivary HCO_3^- comes in contact with the organic acids in the rumen. Under normal conditions, these large amounts of gas are continually removed by eructation.

Any factor that interferes with eructation can produce acute tympany of the rumen (bloat), leading to rapid death. Interruption of the normal eructation reflex or mechanical obstruction of the esophagus typically results in free-gas bloat. The most important form of bloat, however, is seen in cattle consuming large quantities of legumes or in feedlot cattle on high-concentrate diets. The primary factor in these more common forms of bloat is a change in the ruminal contents to a foamy or frothy character because of altered surface tension. Gas becomes trapped in small bubbles within the rumen and cannot be eliminated by eructation (Clarke and Reid, 1974).

The chemical changes that cause foam to form within the rumen are not fully understood. Some reports (Nichols, 1966; Nichols and Deese, 1966) suggest that plant pectin and pectin methyl esterase, a plant enzyme, are critical factors. The enzyme acts on pectin to release pectic and galacturonic acids, which greatly increase the viscosity of the rumen fluid, resulting in formation of a highly stable foam. A soluble legume protein fraction with ribulose diphosphate carboxylase activity has been suggested as another important dietary factor in the pathogenesis of bloat (Howarth, 1975). Slime-producing bacteria also have been incriminated in the pathogenesis of frothy bloat. These microorganisms produce an extracellular polysaccharide that results in stable foam formation.

Effective medical treatment and control are directed toward decreasing or preventing foam formation. This has been accomplished with certain nonionic detergents with surfactant properties that break up or prevent formation of foam within the rumen (Bartley, 1965). Another approach has been the prophylactic administration of sodium alkyl sulfonate, which inhibits pectin methyl esterase activity and prevents foam formation by eliminating the products of this enzyme reaction (Nichols, 1963). Antifoaming agents such as poloxalene administered before ingestion of bloat-producing diets have been shown to be effective prophylactically (Howarth, 1975; Stiles *et al.*, 1971). Silicone antifoaming agents also have been used for this purpose (Clark and Reid, 1974). Genetic selection of cattle that are less susceptible to rumen tympany has also been pursued (Howarth, 1975).

C. Urea Poisoning

Unlike monogastric animals, ruminants, via their microbial flora, can effectively use nonprotein nitrogen to meet some of their dietary protein requirements. Urea, biuret (Oltjen *et al.*, 1969) and ammonium salts (Webb *et al.*, 1973) can serve as dietary NPN sources. Urea, which is the most frequently used, is hydrolyzed by ruminal bacterial urease into CO_2 and NH_3. The free NH_3 is incorporated into amino acids and protein by the rumen microorganisms. The bacterial protein is digested and absorbed in the abomasum and small intestine along with dietary protein.

Signs of urea poisoning typically develop within minutes after consumption of food containing toxic amounts of urea. Clinical manifestations reflect the encephalotoxic effects of excess absorbed NH_3 (Word *et al.*, 1969; Elmer and Barclay, 1971). Tolerance to urea may be significantly increased by increasing the amount of urea in the diet gradually or by adding readily fermentable carbohydrate to the diet. Ruminants can actually adapt and thrive on a diet in which urea is the sole source of dietary nitrogen. However, if urea is fed at more than 3% in the diet in unadapted animals, toxic effects are very likely to occur.

Urea poisoning may occur accidentally when animals gorge on large amounts of urea-containing dietary supplement, when there has been an error in formulation of bulk feed, or when the urea-containing additive is incompletely mixed. Oral administration o

acetic acid has been shown to reduce acute urea toxicity, apparently by decreasing absorption of free NH_3 from the rumen. Normally, NH_3 is in equilibrium,

$$NH_3 + H^+ \longrightarrow NH_4^+$$

with only 1% in the free form. Acidification shifts the equilibrium further to the right, thereby reducing the amount of the NH_3. Because only the free form crosses cell membranes, the net effect is a reduction of absorption of NH_3 by the cell. Acetic acid is used as a treatment for urea poisoning, but it is of more value as a prophylactic agent (Word *et al.*, 1969).

CHAPTER

16

Skeletal Muscle Function

GEORGE H. CARDINET III

I. INTRODUCTION

Skeletal muscles comprise approximately 50% of the body's weight; hence, skeletal muscle cells (myofibers) constitute the largest mass of cells in the body that have similar morphological and physiological properties. The protoplasmic properties of contractility and conductility that characterize myofibers are an expression of specialized sarcoplasmic organelles, principally membranes and filaments, which are highly ordered and compartmentalized to serve those functions which in turn impart a distinctive morphology to the myofibers. Studies of muscles have provided excellent examples of the integration of form and function whereby molecular and organelle structure and function can be directly related to cellular morphology and function, which in turn can be related to the morphology and function of the organs and organisms they serve.

Skeletal muscles of the body are appropriately considered to be organs. The forces developed during contraction differ qualitatively and quantitatively among different muscles of the body. In addition, skeletal muscles differ in their vascular and nerve supplies and

constituent myofiber populations, all of which confer differences in their morphology and function. Whereas skeletal muscles participate in the functioning of virtually all organ systems of the body, skeletal muscle function must be considered when assessing other organ systems in healthy and diseased states.

An attempt is made in this chapter to outline the great diversity that exists in skeletal muscles. By so doing, it is hoped that the knowledge and techniques developed over the past three decades will find their rightful introduction and application to increase our recognition and understanding of neuromuscular disorders in clinical veterinary medicine.

There are, no doubt, numerous neuromuscular disorders in domestic animals that remain unrecognized today, and the observations made by Innes (1951) more than 45 years ago are worthy of citing here in hopes of stimulating the interest of young veterinary pathologists and clinicians to be diligent in their pursuit of disorders with muscular weakness:

> I have drawn attention before to the fact that no diseases are recognized until they are found by looking with great care. One need only scan the veterinary literature of the last twenty years for this to be confirmed, and a long list of conditions could be compiled which might have been discovered years previously if more meticulous methods of pathological examinations had been used. Veterinary Pathology has still a long road to travel before it achieves the profundity of human pathology, and this is not said in any deprecatory sense of past achievements. There are many reasons why this is so, but lack of volume of material studies and inattention to the lessons to be learned from medical work have played a part. In veterinary work, unfortunately, also the question of economics always intrudes, and in the end we are constantly influenced by a consideration of what is, or is not, important.
>
> In conducting autopsy examinations of animals there is usually an immense amount of bias in selection of tissues for histological work; in the case of skeletal muscles (from my own experience) no doubt they are mostly ignored unless macroscopical changes are very obvious.

Since 1951, significant advances have been made. Most notable have been the comparative biomedical investigations (Harris, 1979) that resulted from the original recognition and descriptions of hereditary muscular dystrophies in the mouse (Michelson *et al.*, 1955), chicken (Asmundson and Julian, 1956), hamster (Homburger *et al.*, 1962), turkey (Harper and Parker, 1964, 1967), sheep (McGavin and Baynes, 1969), mink (Hegreberg *et al.*, 1974; Hamilton *et al.*, 1974), dog (Cooper *et al.*, 1988; Kornegay *et al.*, 1988), and cat (Carpenter *et al.*, 1989; Gaschen *et al.*, 1992).

In domestic animals, which are more commonly considered of clinical importance, significant advances have occurred in recent years. The methods of biotechnology and molecular genetics have revealed insights into the etiology and pathogenesis of neuromuscular disorders; however, there is a continuing need for vast improvements in our knowledge and understanding of neuromuscular diseases in animals. In compiling the revisions for this chapter, the author is pleased to find and summarize significant advances with regard to newer descriptions of hereditary, metabolic, and immune disorders of muscle in domestic animals.

II. SPECIALIZATION OF THE SARCOLEMMA AND SARCOPLASM FOR MUSCULAR CONTRACTION

A. Neuromuscular Transmission: Excitation–Conduction

The plasmalemma of the skeletal myofiber (sarcolemma) is specialized for the protoplasmic properties of excitation and conduction. These properties are largely due to the presence of ion channels for sodium, potassium, calcium, and chloride that regulate the selective and nonselective conductance of these ions across the sarcolemma, either into or out of the myofiber. Recent advances in our knowledge have revealed that abnormal functioning of these ion channels accounts for muscle weakness through altered excitability of the sarcolemma.

The neuromuscular junction or motor end plate is the synaptic site for chemical transmission of excitation from the presynaptic axon terminal of a motoneuron to the postsynaptic skeletal myofiber (Fig. 16.1). The axon terminal rests within a primary depression of sarcolemma, the primary cleft, and contains numerous small clear vesicles that contain acetylcholine (ACh), the neurotransmitter for excitation of skeletal myofibers. Each vesicle contains a quantum of neurotransmitter, consisting of 6000 to 8000 molecules of ACh. Arising from the primary cleft underlying the axon terminal are numerous smaller secondary clefts and complementary folds. The space within the primary and secondary clefts, located between the axon terminal and the postsynaptic sarcolemma, comprises the synaptic cleft. This space is filled with basal lamina containing acetylcholinesterase (AChE).

Arrival of a nerve action potential at the axon terminal results in activation of voltage-gated calcium ion channels associated with the active zone of the presynaptic membrane. The calcium influx initiates a calcium-dependent fusion of approximately 200 vesicles with the active zone of the presynaptic membrane and the subsequent release of ACh by exocytosis. The ACh released diffuses across the synaptic cleft to bind with acetylcholine receptors (AChRs), which are concentrated on the crests of the secondary folds of the postsynaptic sarcolemma. Somewhat deeper within the troughs of the secondary folds are voltage-gated so-

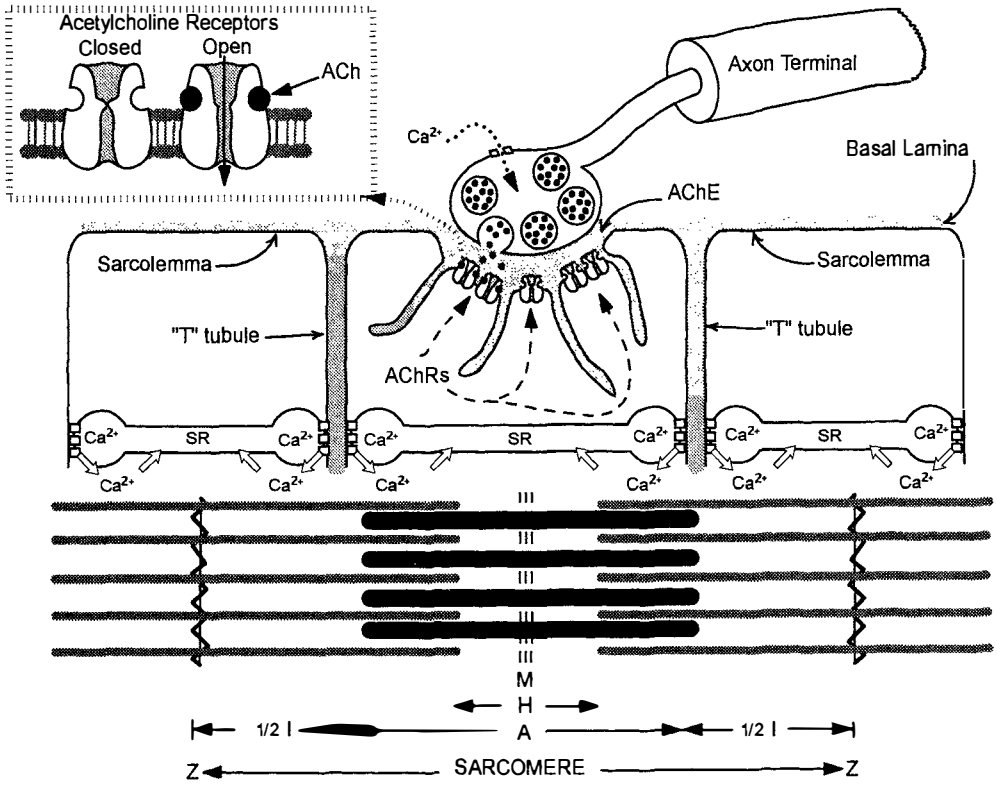

FIGURE 16.1 Excitation of myofibers to contract involves neuromuscular transmission and the subsequent release of calcium ions into the sarcoplasm. Arrival of an impulse at the axon terminal activates voltage-gated calcium ion channels, resulting in the influx of calcium ions that initiate the calcium-dependent release of the neurotransmitter acetylcholine (ACh) by exocytosis. Liberated ACh diffuses across the synaptic cleft to bind with ACh receptors (two molecules of ACh per receptor) on the postsynaptic sarcolemma. Binding of ACh with AChRs increases the conductance of sodium and potassium ions across the postsynaptic membrane to produce a local end-plate potential at the neuromuscular junction. The end-plate potential generates a muscle action potential that spreads away from the neuromuscular junction in all directions over the surface of the myofiber and into its depths via the transverse (T) tubules. Within the depths of the myofibers, excitation is coupled to contraction through the release of calcium ions from terminal cisternae of the sarcoplasmic reticulum (SR) through calcium release channels of the terminal cisternae. The calcium release channels form small "feet" that extend from the terminal cisternae to the T tubules. The liberated calcium ions bind to the regulatory protein troponin and release the inhibitory action of the regulatory proteins on the contractile events that lead to sliding of the thin (actin) and thick (myosin) filaments. The liberated ACh is subsequently hydrolyzed by AChE (acetylcholinesterase) within the basal lamina of the synaptic cleft.

dium ion channels, which are also present within the sarcolemma throughout nonjunctional regions of the myofiber.

Excitation of the myofiber is initiated by the reversible binding of ACh with AChRs. The structure of the AChR is very similar among animal species. The AChR molecule is an integral transmembrane protein that forms a nonselective cation channel composed of five subunits consisting of two α-subunits and single β-, γ-, and δ-subunits. Each α-subunit possesses a binding site for ACh. The binding of ACh with AChR (two ACh molecules/receptor) results in a local depolarization of the postsynaptic membrane caused by the transient increased conductance of the AChR cation ion channels to sodium and potassium ions. The amplitude of the end-plate potential (depolarization) is proportional to the number of ACh–AChR complexes formed.

In addition to the quantal release of ACh in response to a nerve action potential (impulse) at the axon terminal, release of single quanta of ACh occurs spontaneously, in the absence of an impulse. In both instances, the quantal release of ACh is dependent on the activation of voltage-gated calcium ion channels and calcium conductance into the axon terminal; hence, low calcium ion concentrations at the axon terminal will reduce the quantal release of ACh.

At rest, individual quanta of ACh are spontaneously released at a slow rate and cause transient, low-

amplitude depolarizations at the end plate. These are referred to as miniature end-plate potentials (MEEPs). With the arrival of a nerve action potential, approximately 200 quanta are released and with the increased number of ACh–AChR combinations, there is a greater conductance of sodium and potassium ions that form a large amplitude depolarization, the end-plate potential (EEP). When the amplitude of the EEP exceeds threshold, a wave of depolarization (muscle action potential, MAP) is generated over the sarcolemma, away from the end plate in all directions. The MAP is propagated by voltage-gated sodium channels over the surface of the myofiber and into its depths via transverse (T) tubules. The T-tubules are invaginations of the sarcolemma that transverse the long axis of the myofiber and their lumina openly communicate with the extracellular fluid space. The transient binding of ACh to AChRs is abolished by diffusion of ACh away from the receptors and its hydrolysis by AChE.

B. Coupling Excitation to Contraction

Excitation–contraction coupling involves the transformation of depolarizing events in the sarcolemma into the initiation of mechanical shortening of the myofibrils within the myofiber by calcium ions released from the terminal cisternae of the sarcoplasmic reticulum (SR). These events occur within the depths of the myofiber at "triads" where the T-tubules form junctional complexes with adjacent terminal cisternae of the SR. The sarcoplasmic reticulum functions in the uptake, storage, and release of calcium ions to regulate the concentration of calcium ions in the aqueous sarcoplasm bathing the myofilaments and other organelles. The concentration of calcium in the SR is aided by the presence of calsequestrin, a calcium-binding protein present within the lumen of the cisternae.

At the T–SR junctional complex of triads, the sarcolemma contains voltage-sensitive dihydropyridine receptors (DHPRs) and the terminal cisternae of the SR possess ryanodine-sensitive calcium ion channels (ryanodine receptors) that form "feet" that fill the gap between the terminal cisternae and T-tubules. With depolarization of the sarcolemma within the T-tubules, DHPRs interact with ryanodine receptors to mediate the voltage-dependent release of calcium ions from the SR into the sarcoplasm, elevating the calcium ion concentration from $\leq 10^{-7}$ to $\leq 10^{-6}$ *M*. This elevation in calcium ion concentrations initiates contraction through its interaction with the regulatory proteins that serve to inhibit shortening at low calcium ion concentrations. Relaxation is initiated by a reduction in the sarcoplasmic calcium ion concentration by active transport of calcium ions into the lumen of the SR by a calcium-ATPase pump within the SR membrane. For further details concerning the structures and functions involved in neuromuscular transmission and coupling of excitation to contraction refer to Engel (1994a), Horowitz (1994), Lindstrom (1994), and Magleby (1994).

C. Muscular Contraction

Muscular contraction results from the transformation of chemical energy into mechanical energy. The energy for contraction is derived from the hydrolysis of adenosine triphosphate (ATP) into adenosine diphosphate (ADP) and inorganic phosphate (Fig. 16.2). That hydrolysis is catalyzed by the actin-activated adenosine triphosphatase (ATPase) activity present in the S_1 fraction of the myosin mōlecule.

Chemically, the transformation of energy is associated with the cyclical association and disassociation of the contractile proteins actin and myosin, whereas mechanically the transformation is associated with shortening of sarcomeres, which is achieved by conformational changes of the myosin molecules that result in sliding of the overlapping arrays of thick (myosin) and thin (actin) myofilaments (Huxley, 1983).

The ATP required for contraction is not stored in significant quantities. Therefore, ATP must be readily produced through the metabolism of fats, carbohydrates, and creatine phosphate stores to support the energy requirements for contraction. Aerobically, ATP is produced in muscle mitochondria by oxidative phosphorylation coupled to electron transport through the oxidation of (1) fatty acids mobilized from triglyceride fat stores in muscle and fat depots and (2) glucose from liver and muscle glycogen stores. The oxidation of glucose through acetyl-CoA also produces ATP by substrate phosphorylation of ADP in the sarcoplasm. Anaerobically, ATP is produced in the aqueous sarcoplasm through substrate phosphorylation of ADP by (1) creatine kinase, utilizing creatine phosphate stores; (2) adenylate kinase, utilizing ADP produced by the ATP hydrolysis; and (3) glyco(geno)lysis, utilizing glucose derived from both liver and muscle glycogen stores.

1. Myofilaments and Contractile Proteins

The cŏntractile proteins are myosin, the principal component of thick myofilaments, and actin, the principal component of thin myofilaments. Lateral projections of the thick myofilaments (myosin cross-bridges) are the constituents of myosin which form the reactive sites of cyclical association and disassociation that occurs between myosin and actin during contraction. The

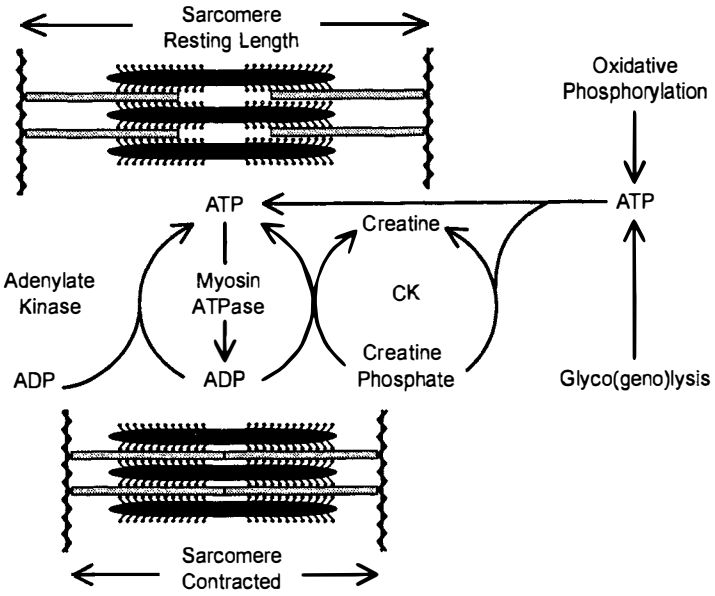

FIGURE 16.2 Muscular contraction involves the shortening of sarcomeres by sliding of the overlapping arrays of thick (myosin) and thin (actin) myofilaments. The energy for contraction is derived from the hydrolysis of ATP in the presence of an actin-activated ATPase present within the head regions of the myosin thick filament cross-bridges. The ATP is generated by the energy metabolism of the myofiber, principally by anaerobic glycolysis or oxidative phosphorylation. The utilization of ATP may be direct from those sources or indirect from the phosphorylation of ADP from creatine phosphate by creatine kinase (CK).

force-generating step for sliding of the filaments past each other results from changes in the angle of the cross-bridge attachments (Fig. 16.3).

a. Thick Myofilaments and Myosin

To gain an understanding of the physicochemical changes that occur at the cross-bridges, the composition and properties of myosin need to be considered. Myosin is an asymmetric protein with both structural and enzymatic protein properties. It is composed of two myosin heavy chains (polypeptide chains with an approximate molecular mass of 200,000 Da; Gershman *et al.*, 1969; Gazith *et al.*, 1970), and four myosin light chains (polypeptide chains with molecular masses ranging from 16,000 to 27,000 Da; Lowey and Risby, 1971; Sarkar *et al.*, 1971; Weeds and Lowey, 1971; Lowey, 1994).

The two myosin heavy chains are arranged in a double helix to form a long fibrous portion and at one end each heavy chain is folded to form a globular head domain (one head/heavy chain; two heads/myosin molecule). The four myosin light chains are contained within the globular heads (two per head) near the junction of the head and neck domains. There are two classes of light chains: (1) two identical DTNB light chains, which disassociate from their globular heads with the thiol reagent 5, 5′-dithiobis(2-nitrobenzoic acid) (DTNB), and (2) two related but different species of "alkali light chains," (A1 and A2) which disassociate at a high pH (Weeds, 1969; Gazith *et al.*, 1970; Weeds and Lowey, 1971; Lowey, 1994).

The principal biochemical properties of myosin are its ATP-binding capacity, actin-binding capacity, and actin-activated ATPase activity. The actin-activated ATPase activity of myosin appears to reside primarily in the heavy chains; however, disassociation of the alkali light chains from the globular head regions results in some loss of activity, whereas disassociation of the DTNB light chains does not (Wagner and Weeds, 1977). Myosin isoforms exist based on their alkaline light chain composition; that is, A1 myosin, A2 myosin, and A1,A2 myosin (Lowey *et al.*, 1979; Lowey, 1994).

The myosin molecule is composed of head, neck, and tail domains. Proteolytic digestion of myosin with trypsin results in the formation of two fragments: (1) heavy meromyosin (HMM), which is composed of the two globular heads of myosin and a short neck domain composed of the initial segment of the fibrous portion, and (2) light meromyosin (LMM), the tail domain composed of the remaining long fibrous portion of the molecule. The HMM fragments correspond

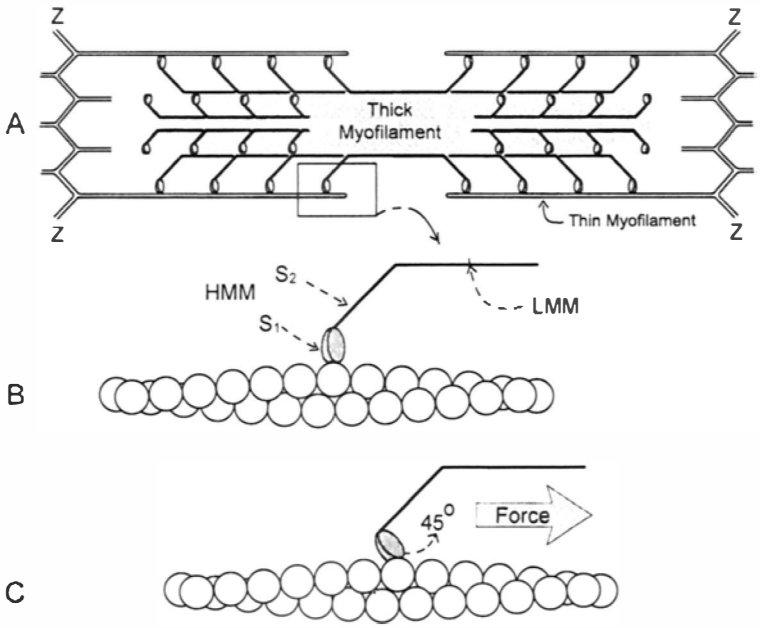

FIGURE 16.3 Schematic presentation of myosin cross-bridges on thick myofilaments. (A) Portions of the myosin molecules (cross-bridges) project from the thick myofilaments and make contact with the thin myofilaments. (B) The light meromyosin (**LMM**) portion of myosin molecules form the major structural component (backbone) of the thick myofilament, and the heavy meromyosin (**HMM**) component forms the cross-bridge connections between the thick and thin myofilaments. The cross-bridges of myosin are composed of two fractions: the S_1 fraction, a globular protein fraction composed of two heads, each possessing binding capacities for ATP and actin and the actin-activated ATPase activity of myosin, and the S_2 fraction, a fibrous protein fraction that forms the flexible linkage between the S_1 fraction and the LMM portion of myosin. (C) The force for sliding of the myofilaments results from a change in the angle of attachment (i.e., a change from 90 to 45°) between the S_1 globular head and actin filament.

structurally to the cross-bridges, whereas the LMM fragments comprise the bulk of the thick myofilaments (Huxley, 1983; Fig. 16.3). Papain digestion results in two subfragments of HMM: subfragment 1 (S_1), the globular head domain, and subfragment 2 (S_2), the short fibrous neck domain. The actin-binding capacity, ATP-binding capacity, and actin-activated ATPase activity of myosin reside in the S_1 fragment, whereas the S_2 fragment comprises the flexible linkage between the globular head of the cross-bridge and the LMM fragment. Thus, the S^1 portion of the myosin molecule that possesses the characteristic chemical properties of myosin is structurally located on the terminal portion of the cross-bridges at the site of interaction with the actin of the thin myofilaments.

b. Thin Myofilaments and Actin

The thin filaments are composed of two F-actin strands arranged in a double helical configuration. The F-actin strands are polymers of the globular protein G-actin and each G-actin monomer possesses a complementary binding site for the myosin S_1 fragment. Upon combining with myosin, actin activates the ATPase activity of the myosin S_1 fragment (Huxley, 1983).

c. Myosin–Actin Cross-Bridge Cycle

Contraction is a physiochemical cycle in which the cyclic interaction of actin and myosin (association, change in angulation of cross-bridge attachments, and disassociation) and hydrolysis of ATP are interdependent and complex (Lymn and Taylor, 1971; Eisenberg and Kielley, 1974; Fig. 16.4). In the noncontracting state, actin and myosin are combined at the cross-bridges (step 1, Fig. 16.4), and the angle of attachment between the cross-bridge heads and the actin filaments is 45°. With the addition of ATP, ATP is bound to each globular head (two molecules ATP/myosin molecule) and there is a rapid disassociation of actin and myosin (step 2, Fig. 16.4). The ATP is cleaved to form a myosin–products complex, and the globular head moves to a

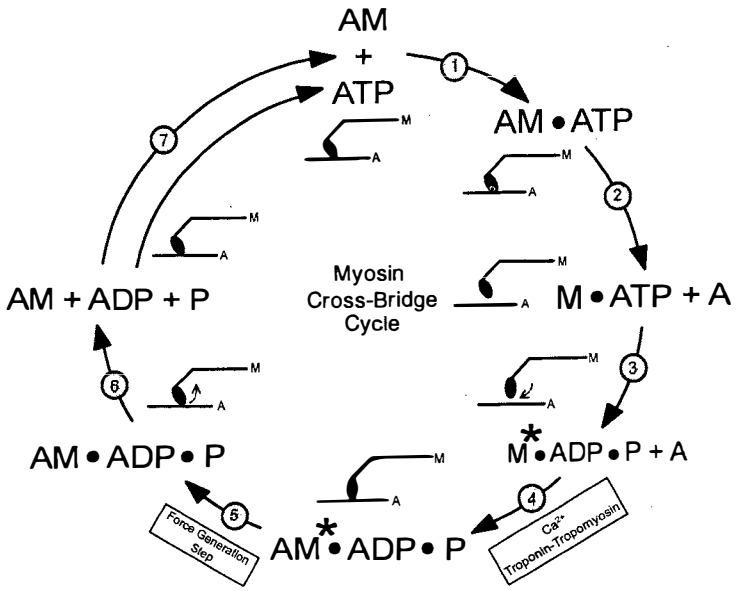

FIGURE 16.4 Muscular contraction results from the cyclical association and disassociation of actin (A) and myosin (M) in which conformational changes occur in the cross-bridge linkages between the thick and thin myofilaments, associated with the hydrolysis of ATP.

new location on the thin filament (step 3, Fig. 16.4), which permits the angle of attachment to become 90° when the myosin–products complex recombines with the actin filament (Step 4, Fig. 16.4). This recombination step between the myosin–products complex and actin is controlled by the regulatory proteins troponin and tropomyosin in response to calcium ion concentrations (discussed later). The force for contraction is generated by movement of the cross-bridge head to a 45° angle of attachment (step 5, Fig. 16.4), and the cycle is completed with the detachment of the hydrolytic products of ATP from the head (step 6, Fig. 16.4). With the formation of ATP through rephosphorylation (step 7, Fig. 16.4), the cycle may be repeated. Measurements indicate that each cycle (stroke) shortens a sarcomere by 12 nm (Barden and Mason, 1978).

Rigor mortis, the rigid and stiff condition of skeletal muscles that develops following death, involves cessation of the cross-bridge cycle in the post–force-generating step (step 6, Fig. 16.4). After death, when all ATP stores have been utilized, disassociation of actin and myosin will not occur and the contraction cycle is terminated with a large number of actin–myosin complexes formed with the myosin heads set at 45°.

2. *Thin Myofilaments and Regulatory Proteins*

Two proteins (tropomyosin and troponin) working in concert with calcium regulate muscle contraction (Ebashi *et al.*, 1969). Tropomyosin, a fibrous protein, is arranged along the length of the thin filaments, within the grooves of the two F-actin strands. Troponin is a globular protein complex composed of three subunits: TN-I (troponin inhibitory component), TN-T (tropomyosin-binding component), and TN-C (calcium-binding component). The TN-T component attaches the complex to tropomyosin at intervals along the thin myofilaments. With low sarcoplasmic calcium concentrations ($\leq 10^{-7}$ M), tropomyosin molecules block the myosin-binding sites on actin, which prevents the interaction of actin and myosin. At higher concentrations ($\leq 10^{-6} M$), calcium ions combine with the TN-C component to initiate a conformational change in the TN-I component, which results in the movement of tropomyosin to free the myosin-binding sites on actin. With the myosin-binding site on actin exposed, actin and myosin combine and initiate the cyclical changes associated with that interaction. When calcium ion concentrations are reduced through uptake of calcium by the SR calcium–ATPase pump, the process is reversed and the interaction of actin and myosin is inhibited.

3. *Cytoskeletal Filaments and Accessory Proteins*

The organization of myofilaments within sarcomeres and the organization of myofibrils is supported by a complex cytoskeletal network of intermediate filaments (Wang and Ramirez-Mitchell, 1983). Intermediate filaments and a number of accessory proteins that form fine filaments function to (1) maintain the align-

ment of myofilaments and sarcomeres, (2) attach and maintain alignment of adjacent myofibrils, (3) attach the sarcomeres of peripheral myofibrils to the sarcolemma, and (4) connect terminal sarcomeres to the sarcolemma at myotendinous junctions. Collectively, the cytoskeletal filaments function to maintain the structural and functional relationships of the myofilaments and transfer the forces developed by the myofilaments to the sarcolemma.

a. Alignment of Myofilaments, Sarcomeres, and Myofibrils

Thick myofilaments are attached to Z-lines by small filaments composed of the protein titan (Maruyama, 1986; Pierbon-Bormoli *et al.*, 1989). The titan filaments arise near the M-line within the axes of the thick filaments and span the length of the thick filament as well as the I-band region to attach to the Z-line. Within the I-band region, the titan filaments provide an elastic attachment to the Z-line, which imparts a passive elasticity to sarcomeres. An additional protein, nebulin, forms small filaments that run the length of thin myofilaments and may regulate the length of thin myofilaments.

At the periphery of myofibrils, adjacent Z-lines within the same sarcomere are connected by intermediate filaments of desmin. Also, intermediate filaments of desmin encircle the circumference of Z-lines and appear to form linkages with Z-lines of adjacent myofibrils to aid in the alignment of sarcomeres in register with adjacent myofibrils (Tokuyasu *et al.*, 1983).

b. Attachment of Myofilaments to the Sarcolemma

At the periphery of myofibrils adjacent to the sarcolemma there are riblike attachments (costomeres) which are present on either side of Z-lines (Pardo *et al.*, 1983). Desmin filaments appear to be anchored to the sarcolemma by a number of adhesion proteins such as vinculin.

At myotendinous junctions, the thin myofilaments of the last sarcomere attach to the sarcolemma, which is thrown into numerous villous projections. The thin myofilaments are anchored by the proteins α-actinin and vinculin, among others. Growth in the length of muscle fibers occurs at the myotendinous junctions by the addition of new sarcomeres (William and Goldspink, 1971).

III. HETEROGENEITY OF SKELETAL MUSCLE

A. Gross Muscle Coloration

Differences in gross coloration of muscles have long been recognized and reviewed by Needham (1926). A variation in coloration is noted not only among species of animals, but also among individual muscles within the same individual. The coloration of some muscles ranges from deep red to pale, whereas other muscles exhibit intermediate shades of coloration. Early workers believed that the differences in coloration were due to differences in the content of blood within the muscles; however, it was later shown that the red coloration was associated with the presence of myoglobin, and other cytochromes within the myofibers.

As a result of these differences in coloration, the terms "red" and "white" were introduced to distinguish between muscles of different gross coloration. Subsequently, numerous biochemical, histochemical, and physiological studies have been conducted with selected muscles from a variety of species. As a result, the terms "red" and "white" have come to imply more specific meanings, such as the physiological properties and populations of myofiber types within a muscle.

B. Physiological Properties

Muscle coloration was observed to be associated with significant differences in the physiological properties of muscular contraction. It was demonstrated that the speed of contraction of red muscles was most often slower than that of white muscles in a variety of animals (Lee *et al.*, 1916; Denny-Brown, 1929). In addition, redness of a muscle was associated with the development of tetanus at lower frequencies of stimulation, the development of smaller twitch tensions, and a greater resistance to fatigue. Conversely, white muscles required greater frequencies of stimulation for the development of tetanus, developed larger twitch tensions, and tended to fatigue quickly.

Whereas muscles were found to differ in their physiological properties of contraction, the terminology of slow-contracting or slow-twitch and fast-contracting or fast-twitch muscles evolved. Moreover, since speed of contraction was closely associated with gross muscle coloration, the terms "red" and "white" came to be used interchangeably with "slow" and "fast," respectively. However, there are numerous exceptions to this association of gross coloration with physiological properties of contraction. Therefore, direct associations must not be assumed.

C. Motor Units

The morphological and functional unit of skeletal muscles is the motor unit. The motor unit is composed of (1) the motoneuron, consisting of its cell body located within the central nervous system (selected cranial nerve nuclei or the ventral horn of the spinal cord), and its axon, which extends along the ventral root and

peripheral nerve; (2) the neuromuscular junctions, and (3) the myofibers innervated by the motoneuron.

Motoneurons may differ based on their rates of discharge: (1) phasic motoneurons with a fast discharge rate and (2) tonic motoneurons with a slow discharge rate (Granit *et al.*, 1957). In addition, the phasic motoneurons are characterized by shorter afterhyperpolarization potentials, faster conduction velocities, and larger axons than the tonic motoneurons (Eccles *et al.*, 1958). Investigations of these parameters in motoneurons of slow-contracting and fast-contracting muscles indicate that tonic motoneurons, which discharge at rates of 10–20 per second, innervate slow-contracting muscles, and phasic motoneurons, which discharge at rates of 30–60 per second, innervate fast-contracting muscle (Eccles *et al.*, 1958). Thus, there are at least two types of motor units that differ in their physiological properties and type of motoneuron innervation.

Physiological measurements performed on isolated motor units in the cat have revealed two types of fast-twitch motor units and one type of slow-twitch unit (Burke *et al.*, 1973; Burke and Tsairis, 1973; Burke, 1994). Some fast-twitch motor units are resistant to fatigue and designated FR units (i.e., fast twitch, resistant to fatigue); others fatigue rapidly and are designated FF units (i.e., fast twitch, fatigable). All of the slow-twitch units were resistant to fatigue, and were merely designated S units (i.e., slow twitch). The average number of muscle fibers per motor unit ranged from 550 to 650.

D. Quantitative Biochemistry

1. Metabolic Pathways That Generate Energy (ATP) for Contraction

Quantitative differences in enzyme activities and various substrate concentrations have been reported between red and white muscles. Those biochemical differences between red and white muscles reflect differences in their principal metabolic pathways active in the generation of energy (ATP) for muscular contraction (Fig. 16.5).

a. Aerobic and Anaerobic Energy Metabolism

In general, white muscles are biochemically suited to derive energy for contraction by substrate phosphorylation via anaerobic glyco(geno)lysis. White muscles tend to have higher concentrations of glycogen and creatine phosphate as well as higher activities for enzymes associated with glycogenolysis and glycolysis, with the exception of hexokinase. Red muscles, on the other hand, generally have higher concentrations of triglycerides and myoglobin and are better suited to derive their energy by oxidative phosphorylation via the electron transport system following the oxidation of fatty acids and glucose via the Krebs cycle (Green, 1951; Lawrie, 1952, 1953; Ogata, 1960; Domonkos, 1961; Domonkos and Latzkovits, 1961a, 1961b; George and Talesara, 1961; Beatty *et al.*, 1963, 1966b, 1967; Blanchaer, 1964; Dawson and Romanul, 1964; George and Bokdawala, 1964; George and Iype, 1964; Dawson and Kaplan, 1965; Cosmos, 1966; Cosmos and Butler, 1967; Beecher *et al.*, 1968; Bass *et al.*, 1969; Kubista *et al.*, 1971; Crabtree and Newsholme, 1972; Staudte and Pette, 1972; Baldwin *et al.*, 1973b; Pette, 1975).

Whereas anaerobic glycolysis and glycogenolysis are greater in white muscles, red muscles have (1) greater glycogen synthetase activities (Stubbs and Blanchaer, 1965; Bocek and Beatty, 1966; Beatty and Bocek, 1970), (2) higher glycogenesis (Bocek *et al.*, 1966a, 1966b), and (3) higher hexokinase activities (Peter *et al.*, 1968; Bass *et al.*, 1969; Cardinet *et al.*, 1972; Crabtree and Newsholme, 1972; Pette, 1975). Explanations for those differences are not self-evident because similar relative activities for glycogenesis and glycogenolysis as well as hexokinase and glycolysis might be anticipated. Rather than having a relationship with other glycolytic enzymes, hexokinase activities demonstrate a constant relationship with mitochondrial citrate synthase activity.

Aerobic glycolysis via the pentose cycle does not appear to be a principal metabolic pathway in skeletal muscle (Glock and McLean, 1954; Green and Landau, 1965; Beatty *et al.*, 1966a, 1966c; Beatty and Bocek, 1970). The role of amino acids in the energy metabolism of muscle is uncertain. Transaminase activities are higher in red muscle of the chicken (Cardinet *et al.*, 1972). Also, amino acid uptake, incorporation, and turnover in skeletal muscle protein are greater in red muscle (Goldberg, 1967). Studies with ^{3}H-labeled amino acids have shown that, with the exception of alanine, all amino acids tested are more rapidly incorporated into red muscle protein (Citoler *et al.*, 1966). Alanine produced in muscle may function in the transport of amino groups to the liver, particularly during exercise (Felig and Wahren, 1971; Felig, 1977); however, that role is disputed by some. In the liver, alanine may be reconverted to glucose and transported back to muscle as part of the glucose-alanine cycle between muscle and liver.

Oxidation of fatty acids is an important energy source for muscle and is dependent on several factors, including carbohydrate availability, state of physical conditioning, and the intensity and duration of exercise (Issekutz *et al.*, 1965, 1966; Paul and Issekutz, 1967; Mole *et al.*, 1971; Holloszy *et al.*, 1971; Pande and Blanchaer, 1971; Therriault *et al.*, 1973; Issekutz *et al.*, 1975). Red muscle has been shown to contain larger quantities of lipid than white muscle (Beatty and Bo-

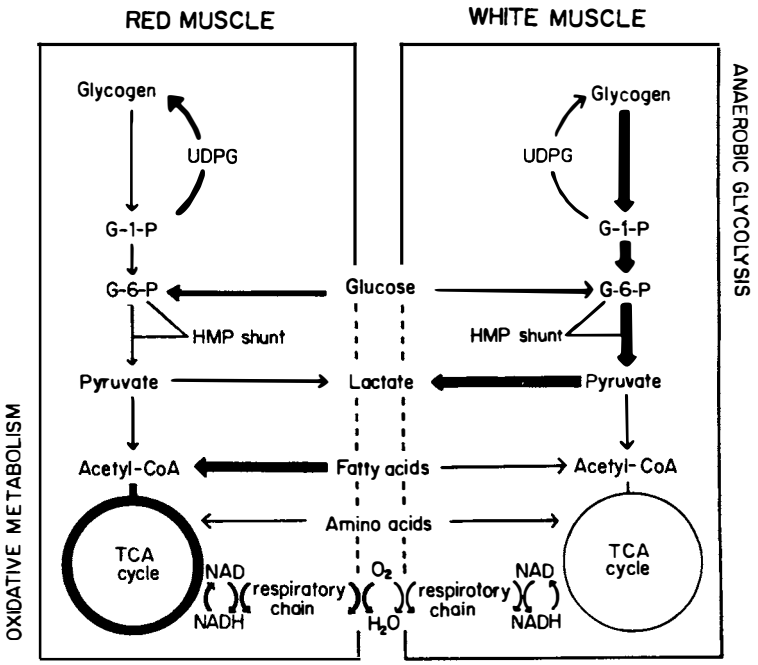

FIGURE 16.5 Schematic representation of some differences in energy-yielding metabolic pathways of red and white muscles. In red muscles, energy for contraction is derived primarily by oxidative phosphorylation resulting from the oxidation of fatty acids, carbohydrates, and perhaps amino acids via the tricarboxylic acid (TCA) cycle. White muscles derive their energy primarily via anaerobic glycogenolysis and glycolysis through the degradation of glycogen and glucose to lactate. Aerobic glycolysis via the HMP (hexose monophosphate) shunt is a minor pathway in both types of muscle.

cek, 1970). The activities of palmitate-activating enzyme and carnitine acyltransferases were twice as high in red as in white muscle mitochondria. Studies indicate that red muscle is potentially capable of deriving more usable energy from free fatty acids than is white muscle (Pande and Blanchaer, 1971).

b. Purine Nucleotide Cycle

During muscular contraction ammonia is produced through the deamination of AMP to inosine monophosphate (IMP) by AMP deaminase as part of the purine nucleotide cycle (Lowenstein, 1972). The cycle involves (1) the deamination of AMP to form IMP and ammonia, (2) the deamination of aspartate and the hydrolysis of guanosine triphosphate to form adenylsuccinate, and (3) the cleavage of adenylsuccinate to form fumarate and AMP. The activity of AMP deaminase was found to be greater in white muscles than red muscles.

The suggested functions of the purine nucleotide cycle subserve the energy requirements for muscular contraction through (1) maintenance of a high ATP/ADP ratio by regulating the relative AMP, ADP, and ATP levels through the removal of AMP, (2) regulation of phosphofructokinase (PFK) activity by elevations in ammonia, (3) regulation of phosphorylase activity by accumulation of IMP, (4) replenishment of citric acid cycle intermediates by the production of fumarate, and (5) deamination of amino acids for oxidative metabolism through the formation of aspartate (Terjung *et al.*, 1986).

From the foregoing, it is evident that the deamination of AMP can serve to promote ATP synthesis by (1) stimulating anaerobic glyco(geno)lysis through the activation of phosphorylase *b* by IMP, and the activation of PFK by ammonia, and (2) supporting oxidative metabolism through the production of intermediates into the TCA cycle.

The degradation of adenine nucleotides in equine muscle appears to occur mainly through deamination of AMP. Reported AMP deaminase activities are greatest for equine middle gluteal muscles, which were approximately double reported values for muscles of the rat and rabbit (Cutmore *et al.*, 1986). In the dog, the degradation of adenine nucleotides via AMP deaminase appears to be limited and occurs principally through the formation of adenosine by the action of 5′-nucleotidase (Brockman and McKenzie, 1983).

2. *Metabolic Pathway for Utilization of Energy (ATP) for Contraction: Myosin-ATPase*

As previously discussed, the actin-activated myosin ATPase activity catalyzes the cyclical physiochemical interactions of actin and myosin during contraction (Fig. 16.4). Furthermore, the intrinsic speed of contraction (sarcomere shortening) has been demonstrated to be proportional to the activity of actin-activated myosin-ATPase (Barany, 1967; Mommaerts, 1969) and differences exist between the myosin-ATPase activities of fast-contracting and slow-contracting muscles (Close, 1972). From those observations it is postulated that the rate-limiting step of sarcomere shortening during contraction is the hydrolysis of ATP. Concomitant with the different actin-activated ATPase activities of myosins from fast-contracting and slow-contracting muscles, their alkali light-chain compositions also differ (Lowey and Risby, 1971; Sarkar *et al.*, 1971). Slow- and fast-contracting muscles contain similar amounts of myosin; however, the ATPase activities of slow-contracting muscles are lower than in fast-contracting muscles and their pH dependency and liability in acid and alkaline conditions also differ (Barany *et al.*, 1965; Seidel, 1967).

E. Histology and Histochemistry

1. *Morphologic Variations of Myofibers*

Different types of myofibers were recognized by early microscopists. By examination of unstained sections or in combination with various lipid stains, two basic types of myofibers were described. One type of myofiber was dark or opaque and contained numerous granules and lipid droplets between the myofibrils. The other type of myofiber was light or translucent and contained few granules and lipid droplets. These myofibers were referred to as dark and light myofibers, respectively. In addition, myofibers intermediate to dark and light myofibers were described (Bullard, 1912). The most common finding was that mammalian muscles contained variable percentages of dark and light myofibers and therefore were mixed with respect to their myofiber-type composition. However, in certain instances, such as in the rabbit, guinea pig, and chicken, some muscles were found to contain predominantly dark myofibers and their gross coloration was red, whereas other muscles were found to contain predominantly light myofibers and their gross coloration was white. Although there was no unanimous agreement by early investigators, the tendency for myofibers of red muscles to be darker than the myofibers of white muscles led to the designation of dark and light myofibers as red and white myofibers, respectively.

2. *Histochemical Properties of Myofibers*

Histochemical and biochemical studies of red and white muscles tended to support the concept that gross muscle coloration is associated with the myofiber-type composition of a muscle (Nachmias and Padykula, 1958; Dubowitz and Pearse, 1960; Stein and Padykula, 1962; Romanul, 1964; Beatty *et al.*, 1966b; Bocek and Beatty, 1966; Cosmos and Butler, 1967; Gauthier, 1969). With the development and introduction of histochemical techniques to studies of muscle, the heterogeneity of myofibers within a muscle became more obvious. Since these techniques localized enzyme systems at the cellular level, their application involved implications of biochemical and functional heterogeneity of myofibers that had been suggested by the early microscopists.

a. Histoenzymic Properties Associated with Aerobic and Anaerobic Energy Metabolism

Histochemical studies of succinate dehydrogenase (SDH), reduced nicotinamide adenine dinucleotide–tetrazolium reductase (NADH-TR), and reduced nicotinamide adenine dinucleotide phosphate–tetrazolium reductase (NADPH-TR) demonstrated that the red or dark granular myofibers had higher activities for these enzymes than the white or less granular light myofibers (Padykula, 1952; Wachstein and Meisel, 1955; Nachmias and Padykula, 1958; Dubowitz and Pearse, 1960). In conjunction with electron microscopic observations, the activities of these enzymes were localized in mitochondria. The granules and higher activities of these enzymes in the dark or red myofibers correspond to greater numbers of mitochondria. Studies of red and white myofibers of the rat diaphragm and semitendinosus have revealed that the mitochondria of red myofibers are large with abundant cristae, and the white myofibers have fewer mitochondria, which are smaller and have fewer cristae. Associated with the large mitochondria of the red myofibers are lipid inclusions. Therefore, the granules and lipid droplets described by early microscopists correspond to mitochondria and lipid inclusions, respectively (Padykula and Gauthier, 1963, 1967; Gauthier and Padykula, 1966; Gauthier, 1969).

A reciprocal histochemical profile for red and white myofibers was observed between mitochondrial enzymes and phosphorylase, an indicator of anaerobic glyco(geno)lysis (Dubowitz and Pearse, 1960). Red myofibers with high mitochondrial enzyme activities had low phosphorylase activities, whereas the reverse was true of white myofibers and a classification of myofibers was introduced in which red and white myofibers were designated as type I and type II myofibers, respec-

tively (Dubowitz and Pearse, 1960). Owing to the fact that various intermediate histochemical reactions of myofibers exist between the extreme or classical characteristics described for red or type I myofibers and white or type II myofibers, other classifications were proposed. Stein and Padykula (1962) proposed a classification of A, B, and C myofibers based on their SDH reactions that roughly corresponds with the classification of white, intermediate, and red muscle myofibers, respectively (Padykula and Gauthier, 1967). As many as eight myofiber types were described in rat muscle, where esterase activity was found to be more precisely reciprocal with phosphorylase activity, suggesting a reciprocity between anaerobic glycolysis and lipid metabolism (Romanul, 1964).

Histochemical localization of glycogen synthetase is varied. In human muscle its activity was usually parallel with that of phosphorylase in type II or white fibers (Engel, 1962), but reciprocal and higher in type I or red fibers of rat and monkey muscle (Hess and Pearse, 1961; Bocek and Beatty, 1966), a finding that is in agreement with quantitative results in the rat and monkey.

b. Histoenzymic Properties Associated with Myosin-ATPase

In addition to employing histochemical stains for enzymes of ATP-generating metabolic pathways, myofibers have been differentiated histochemically into type 1 and type 2 myofibers based on their staining reaction for myofibrillar ATPase (Engel, 1962, 1965). Furthermore, type 2 myofibers, classified by the myofibrillar ATPase staining reaction, may be further subdivided into type 2A, type 2B, and type 2C myofibers based on the lability of their ATPase activity following preincubation in acid media (Brooke and Kaiser, 1970). This classification scheme is generally applicable to all mammalian species except for canine muscles, which do not contain classical type 2B myofibers (Braund *et al.*, 1978; Orvis and Cardinet, 1981; Snow *et al.*, 1982).

Of all the histochemical techniques applied to date, the myofibrillar ATPase reaction best differentiates myofiber types and it is the preferred method for classification of myofiber types. If the actin-activated myosin ATPase activity is rate limiting in the speed of contraction, it follows that the histochemical method for myofibrillar ATPase would be anticipated to be a specific method for the differentiation of myofiber types in association with their speed of contraction. Further, it has been found that fast type myosin is required for the histochemical demonstration of type 2 fibers (Staron and Pette, 1986).

Most limb muscles are "mixed," and contain variable proportions of type 1, type 2A, and type 2B myofibers. Type 2C myofibers are normally rare in mature muscle. These fibers presumably represent a transition stage between type 1 and type 2A or 2B myofibers. Neonatal myofibers are initially type 2C–like, which differentiate into type 1, type 2A, and/or type 2B myofibers (Brooke and Kaiser, 1970; Braund and Lincoln, 1981; Cardinet *et al.*, 1982).

Beyond the conventional type 1, 2A, 2B, and 2C classification of myofibers in limb muscles, an additional subset of the type 2 myofiber has been identified in the masticatory muscles of carnivores and primates (Maxwell *et al.*, 1980; Orvis and Cardinet, 1981; Rowlerson *et al.*, 1981, 1983; Shelton *et al.*, 1985). The histochemical myosin ATPase reaction of masticatory type 2 myofibers in those species is stable following acid preincubation at pH 4.2–4.3, a property which is similar to that of type 2C fibers. These fibers have been designated type 2M.

c. Relationships with Functional Properties

Because gross muscle coloration was often associated with the myofiber-type composition of a muscle and its contraction speed, myofiber types became equated with the speed of contraction. Therefore, red or type 1 myofibers were referred to as slow or tonic and white or type 2 myofibers as fast or phasic. That concept was based primarily on indirect evidence and while most evidence tended to support that concept, there were many exceptions. Some red muscles that were slow contracting contained myofibers with intermediate staining intensities for mitochondrial enzymes, whereas some fast-contracting muscles contained significant numbers of red myofibers. It was suggested that fast-twitch myofibers were both red and white, and slow-twitch myofibers were intermediate (Barnard *et al.*, 1970). Also, studies of diaphragm muscles in small mammals (Gauthier and Padykula, 1966) and thyroarytenoid muscles in rabbits (Hall-Craggs, 1968) showed that some red muscles were fast contracting rather than slow. Because those muscles contained myofibers with many characteristics of red myofibers based on mitochondrial enzyme histochemistry, it was concluded that not all red myofiber types were slow contracting.

More direct evidence that supports and clarifies the interrelationships of physiological properties and histochemical properties of myofibers has come from combined studies of single motor units. In the rat, fatigability of motor units was correlated with the histochemical properties of the myofibers comprising the units (Edstrom and Kugelberg, 1968). Fatigable motor

units were composed of type A myofibers, whereas fatigue-resistant motor units were composed of type C myofibers according to the myofiber typing classification of Stein and Padykula (1962).

In the cat, three physiological types of motor units were classified in the medial gastrocnemius muscle on the basis of their contraction times and fatigability (Burke *et al.*, 1973; Burke and Tsairis, 1973; Burke, 1994). Two types of motor units were fast contracting, but differed in their sensitivity to fatigue. One type of motor unit, designated FR, was fast twitch and resistant to fatigue, and the second type of motor unit, designated FF, was fast twitch but fatigued rapidly. The third type of motor unit, designated S, was slow twitch and resistant to fatigue.

The myofibers present in each motor unit type within the muscle were identified in sections by their glycogen depletion patterns following tetanic stimulation. By staining adjacent sections for the histochemical demonstration of their myofibrillar ATPase and oxidative enzyme activities, it was found that the slow-twitch motor units were composed of type 1 myofibers (light staining for myofibrillar ATPase) and the fast-twitch motor units were composed of type 2 myofibers (dark staining for myofibrillar ATPase). The myofibers comprising the FR and FF units were further characterized by the lability of their myofibrillar ATPase activity to acid preincubation and it was found that FR units were composed of type 2A myofibers and FF units were composed of type 2B myofibers. The fatigue resistance of the S and FR units was found to be related to the high oxidative enzyme capacities of the type 1 and type 2A myofibers. The functional characteristics of type 2C and type 2M motor units have not been established. Based on their histochemical features, they are presumed to be fast twitch and fatigue resistant.

The physiological and histochemical properties and classifications of myofibers are summarized in (Table 16.1) and illustrated in Fig. 16.6. Assessment of the histochemical profiles of myofibers in each physiological type of unit revealed that each motor unit was homogeneous with respect to its myofiber-type composition (Fig. 16.7).

d. Myofiber Types and Myosin Isoforms

Each myofiber type is composed of a different myosin isoform (reviewed by Pette and Vrbova, 1985). With regard to myosin heavy chains (HC) and light chains (LC), slow-twitch, type 1 myofibers possess heavy chains (HC-s), alkali light chains (LC-s1a, LC-s1b), and DTNB light chains (LC-s2), which are distinct from fast-twitch, type 2 myofiber heavy chains (HC-f), alkali light chains (LC-f1, LC-f3), and DTNB light chains (LC-f2).

Type 2A and type 2B myofibers have identical light-chain compositions but different heavy chains (HC-fA and HC-fB, respectively). Type 2M fibers also have a distinct heavy-chain (HC-m) and light-chain (LC-f1M and LC-f2M) composition (Shelton *et al.*, 1985a). Type 2C fibers contain a mixture of fast and slow heavy and light chains (Billeter *et al.*, 1980; Snow *et al.*, 1981). From the foregoing and in consideration of the nine HC and LC combinations possible for myosin isoforms, more than the three defined myofiber (motor unit) types are likely to be present in limb muscles. Isoform variations are also present for the regulatory proteins troponin and tropomyosin in association with the fiber type specific myosin isoforms.

IV. NEURONAL TROPHIC INFLUENCES ON MUSCLE

Trophic influences of nerve on muscle may be defined as those functions of the nerve that affect or regulate the metabolism of the muscle (Guth, 1968). This definition should encompass structural and physiological properties as well, since the structure of the myofiber and its organelles, physiological properties, and biochemical properties are all interdependent.

The implication of neuronal influences on muscle integrity has long been recognized by studies of denervation whereby numerous morphological, physiological, and biochemical changes result when a myofiber is separated from its axon (Gutmann, 1962). Precisely how motoneurons exert their trophic influence on myofibers has been a subject of considerable interest. Two general postulates have been considered: (1) the influence of motoneurons is due to the frequency (activity) of their impulse discharges (Vrbova, 1963; Salmons and Vrbova, 1969; Pette *et al.*, 1973; Sreter *et al.*, 1973; Lomo *et al.*, 1974) and/or (2) the influence of motoneurons is mediated by specific trophic substances liberated by the motoneuron at the neuromuscular junction (Buller *et al.*, 1960).

A. Cross-Innervation Studies

More precise implications concerning the influence of the motoneuron on speed of contraction and myofiber types were first demonstrated in a series of experiments in which nerves to fast and slow muscles were cross-united (Buller *et al.*, 1960; Buller and Lewis, 1965; Close, 1965; Romanul and Van Der Meulen, 1966, 1967; Dubowitz, 1967; Robbins *et al.*, 1969; Barany and Close,

TABLE 16.1 Physiological and Histochemical Properties and Classifications of Principal Myofiber Types in Limb Muscles

	Myofiber types		
Physiological properties			
Twitch contraction	Slow twitch	Fast twitch	Fast twitch
Fatiguability	Resistant	Resistant	Fatiguable
Histochemical properties			
Myofibrillar ATPase stain (pH 9.4)	Light	Dark	Dark
Preincubation at pH 4.5	Dark	Light	Dark
Preincubation at pH 4.2	Dark	Light	Light
NADH-TR stain	Intermediate to dark	Dark	Light
Phosphorylase stain	Light	Dark	Dark
Classifications			
Engel (1962, 1965)	I	II	II
Stein and Padykula (1962)	B	C	A
Padykula and Gauthier (1967)	Intermediate	Red	White
Brooke and Kaiser (1970)	1	1A	2B
Ashmore and Doerr (1971)	β-Red	α-Red	α-White
Peter *et al.* (1972)	Slow twitch–oxidative	Fast twitch–oxidative glycolytic	Fast twitch–glycolytic
Burke *et al.* (1973)	S	FR	FF
	(Slow twitch–fatigue resistant)	(Fast twitch–fatigue resistant)	(Fast twitch–fatiguable)

1971; Weeds *et al.*, 1974; Sreter *et al.*, 1975). In this experimental design, motoneurons that normally innervate slow muscles come to innervate muscles that are normally fast, and motoneurons that normally innervate fast muscles come to innervate muscles that are normally slow. These experiments resulted in a reversal of contractile properties; that is, fast-twitch muscles become slow, and slow-twitch muscles become fast. Accompanying these changes in the speed of contraction was a corresponding change in the enzyme histochemical profiles of the myofibers. Hence, slow muscles that have myofiber populations with histochemical characteristics of high oxidative, low glycolytic, and low myofibrillar ATPase activities were changed to myofiber populations that tended to have low oxidative, high glycolytic, and high myofibrillar ATPase activities when innervated by a nerve that normally innervates a fast-twitch muscle. Converse changes occur by cross-union of a fast-twitch muscle with the nerve of a slow-contracting muscle (Romanul and Van Der Meulen, 1966, 1967; Dubowitz, 1967; Robbins *et al.*, 1969). Therefore, the motoneuron influences (1) the type of energy metabolism employed by a myofiber and all the structural changes in fiber organelles that this implies and (2) the myofiber's physiological properties of contraction. The changes in contraction speed brought about by neuronal influences are presumably due to a direct effect on the type of myosin-ATPase produced within a myofiber (Barany and Close, 1971; Weeds *et al.*, 1974; Sreter *et al.*, 1975).

The evidence derived from these experiments suggests that the motoneuron directs the phenotypic expression of myofibers and that the myofiber maintains the potential for differentiation and redifferentiation of its phenotype at the direction of the nervous system.

B. Chronic Stimulation Studies

With the abolition of low-frequency (tonic) impulse stimulation through deafferentation or tenotomy, the slow-twitch soleus muscle becomes faster (Buller *et al.*, 1960; Buller and Lewis, 1965). Also, high-frequency (phasic) impulse stimulation of the nerve to the slow-twitch soleus muscle resulted in its conversion to a fast-twitch muscle (Salmons and Vrbova, 1969; Pette *et al.*, 1973; Sreter *et al.*, 1973; Hennig and Lomo, 1987).

Conversely, low-frequency stimulation or merely increased impulse stimulation of the nerves to fast-twitch muscles results in their transformation to slow twitch (reviewed by Pette and Vrbova, 1985). These findings provided evidence that it was the activity of motoneurons that determined the morpho-physiochemic properties of myofibers. In studies employing stimulation of the nerve supply, it is difficult to separate the effects of evoked muscle activity and putative neurotrophic substances because changes in the nerve impulse activity may also change the amount and type of trophic substances (Lomo, 1986). However, direct stimulation of denervated muscles has effected the

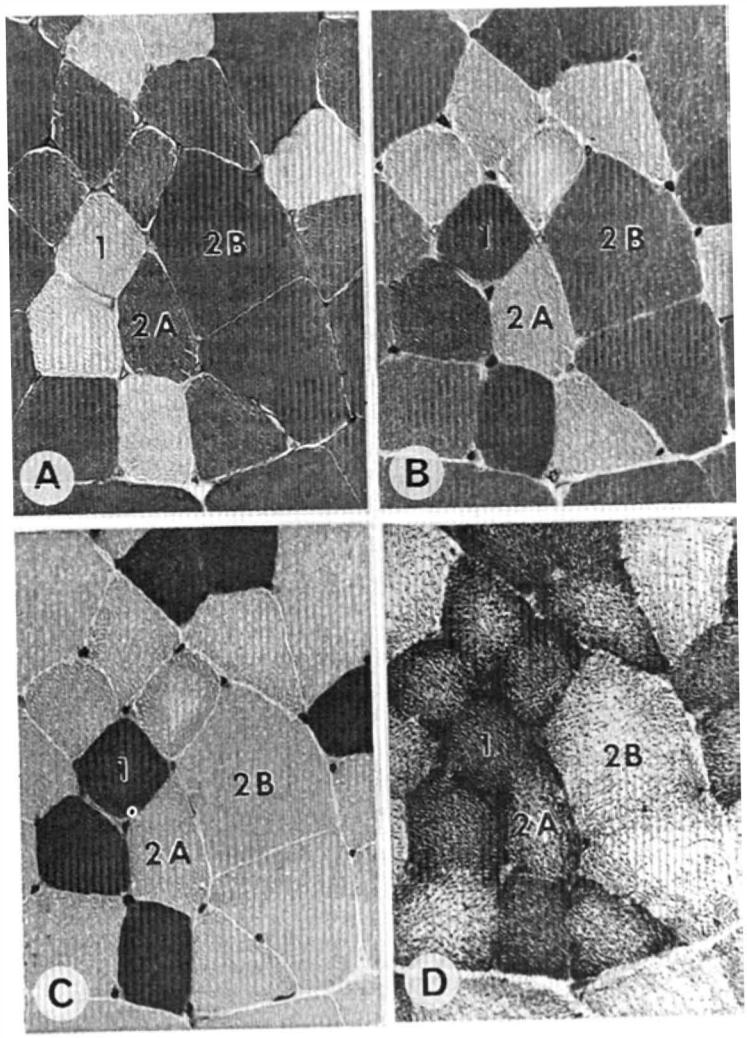

FIGURE 16.6 Serial sections of cat medial gastrocnemius muscle incubated for the histochemical demonstration of (A) myofibrillar ATPase, incubated at pH 9.4; (B) myofibrillar ATPase, preincubated at pH 4.5; (C) myofibrillar ATPase, preincubated at pH 4.2; and (D) NADH-TR. Type 1 myofibers comprise slow-twitch motor units that are resistant to fatigue. Type 2A myofibers comprise fast-twitch motor units that are resistant to fatigue, and type 2B myofibers comprise fast-twitch motor units that fatigue rapidly.

same transformations (Lomo *et al.*, 1974; Hennig and Lomo, 1987), a finding that further supports the concept that "activity" per se is the trophic influence. It is concluded that "activity" controls gene expression in mammalian myofibers (Pette and Vrbova, 1985).

V. EXERCISE, ADAPTATIONS TO TRAINING, AND PERFORMANCE

Exercise induces major biochemical adaptations in skeletal muscle. The nutritional state, intensity and duration of exercise, and degree of physical fitness are all factors that qualitatively and quantitatively affect the metabolic pathways used in the generation of energy for muscular contraction.

A. Exercise Intensity and Sources of Energy

The rate of energy utilization during intense exercise can be as much as 200 times greater than at rest and the rate of ATP utilization is closely associated with the rate of ATP synthesis (Holloszy, 1982). Hence, the availability of ATP is a central requirement for sustaining the rate and duration of exercise. Since the stores of creatine phosphate and ATP available for immediate use within myofibers are small, the metabolic path-

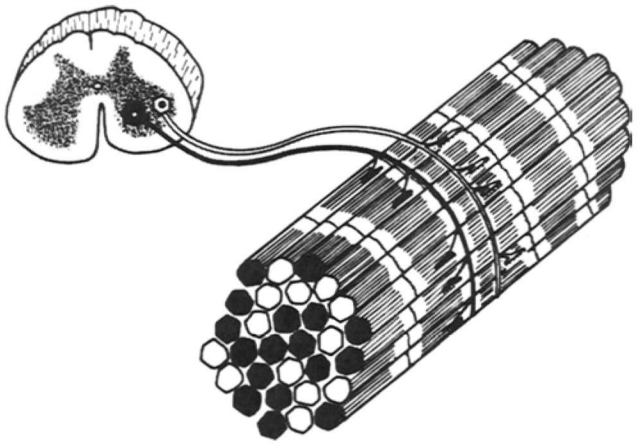

FIGURE 16.7 Schematic representation of the homogeneity of skeletal muscle motor units. Motor units have a homogeneous myofiber-type composition whereby slow-twitch motor units are composed of only type 1 myofibers (light staining for myosin ATPase). Fast-twitch units are composed of only type 2A (fast twitch, fatigue resistant) myofibers or only type 2B (fast twitch, fatigable) myofibers (dark staining for myosin ATPase).

ways for ATP synthesis serve a vital function in the maintenance of exercise.

The main fuels for muscular contraction are fatty acids and glucose, which are supplied by intramuscular and extramuscular depots during exercise. Glucose or glycogen may be metabolized to synthesize ATP through either aerobic or anaerobic pathways, whereas fat metabolism is only aerobic. It is estimated that 65% or more of the oxygen utilization during moderate to heavy exercise is accounted for by the oxidation of carbohydrates and that exhaustion coincides with glycogen depletion (Holloszy, 1982; Sahlin, 1986). Intramuscular depots are the triglyceride and glycogen inclusions of the sarcoplasm, and the extramuscular depots are adipose tissues and the liver (Issekutz *et al.*, 1966; Paul and Issekutz, 1967; Holloszy *et al.*, 1971; Paul, 1971; Terjung *et al.*, 1972; Baldwin *et al.*, 1973a; Therriault *et al.*, 1973; Lindholm *et al.*, 1974a). The rate-limiting factor in the extramuscular supply of glucose to working muscle is glucose uptake by the myofiber. The rate-limiting factor in the plasma free fatty acid (FFA) supply appears to be the rate of FFA release from adipose tissues (Issekutz *et al.*, 1965, 1966).

At rest, oxidation of FFA and stored triglycerides contributes the bulk of the fuel used for maintaining muscle tone, whereas the oxidation of glucose accounts for only 10–20% of the CO_2 produced (Havel, 1971). At the onset of exercise, energy is initially derived from creatine phosphate and anaerobic glyco(geno)lysis, which is accompanied by an increased production of lactate. However, as the duration of exercise is increased and blood flow increases, there is a shift to aerobic metabolism in which glucose, FFA, and triglycerides are oxidized and lactate production decreases (Havel, 1971; Rowell, 1971; Wahren *et al.*, 1971; Baldwin *et al.*, 1973b). At low to moderate exercise intensities, the oxidation of fatty acids provides the major source of energy. At moderate to high exercise intensities, the oxidation of fatty acids decreases and carbohydrates account for 50% or more of the amount of substrate utilized (Hagenfeld and Wahren, 1971; Saltin and Karlsson, 1971; Therriault *et al.*, 1973; Wahren, 1977). At moderately high exercise intensities, muscle glycogen and triglyceride depots decrease and muscle glycogen accounts for approximately 70% of the glucose oxidized, and 70% of the fatty acids oxidized are derived from muscle triglyceride depots. At maximal workloads, glycogen utilization is high and the major source of fuel (Hultman and Nilsson, 1971; Froberg *et al.*, 1971).

Evidence exists that not all fibers are activated at once but that motor units are recruited with respect to their oxidative capacities (Baldwin *et al.*, 1973b). Measurements of rates of glycogen and triglyceride depletion in rats indicate that, in prolonged work of moderate intensity, the red and intermediate fibers are the first to become activated. Once the workload exceeds the capacity of the red and intermediate fibers, the white motor units are then activated by the central nervous system (Baldwin *et al.*, 1973a, 1973b). Similarly, glycogen depletion studies of fiber types in the horse suggest that the order of myofiber recruitment is type 1, type 2A, and type 2B (Lindholm *et al.*, 1974; Snow *et al.*, 1981, 1982; Essen-Gustavsson *et al.*, 1984; Hodgson *et al.*, 1984a; Valberg, 1986). With moderate intensity, type 1 and type 2A myofibers are preferentially recruited, whereas moderate intensity of long duration or maximal exercise intensity is required for recruitment of type 2B myofibers. With maximal intensity (galloping) exercise in thoroughbreds, glycogen depletion is greatest in type 2A and type 2B fibers, and type 1 fibers are either not recruited or there is a glycogen sparing effect during high-intensity, short-duration exercise (Hodgson *et al.*, 1984b). On the other hand, maximal intensity (trotting) exercise in standardbreds results in glycogen depletion of all type 1, most type 2A, and many type 2B myofibers (Valberg, 1986).

B. Adaptations to Exercise Training

The principal metabolic adaptation of skeletal muscles to training is an increase in oxidative capacity to utilize fat, carbohydrate, and ketones (Holloszy, 1982; Holloszy *et al.*, 1986. Oxygen consumption is similar in trained and untrained subjects for a given workload, but there is a lower production of CO_2 and hence a

lower respiratory quotient (RQ) in trained subjects (Holloszy *et al.*, 1971, 1977; Saltin and Karlsson, 1971). Although several factors may affect the RQ, a major factor would be the source of energy for contraction, and fat utilization yields lower RQ values than carbohydrate utilization (Paul, 1971). The capacity for oxidation of palmitate, oleate, linoleate, palmityl-CoA, and palmitylcarnitine, as well as the activities for carnitine palmityltransferase, palmityl-CoA, dehydrogenase and mitochondrial ATP-dependent palmityl-CoA synthetase were doubled in rats subjected to a training program (Mole *et al.*, 1971). Also, the turnover of FFA is significantly greater in trained than in untrained dogs (Issekutz *et al.*, 1966).

Myoglobin content is greater in trained rats (Holloszy *et al.*, 1971) and pigs (Jorgensen and Hyldgaard-Jensen, 1975) in which the myoglobin functions to facilitate O_2 utilization by enhancing the intrafiber O_2 transport between the sarcolemma and mitochondria. The mitochondrial protein content increases approximately 60% (Holloszy, 1967; Mole *et al.*, 1971), which is associated with increased size and numbers of mitochondria in trained rats (Gollnick and King, 1969). An increase in mitochondrial size but not number, has been reported in trained men (Morgan *et al.*, 1972). Cristae double their density within muscle mitochondria of trained rats (Holloszy *et al.*, 1971). Mitochondrial coupling factor 1, mitochondrial ATPase, and cytochrome *c* are increased in trained subjects, whereas mitochondrial creatine kinase and adenylate kinase activities were not increased (Oscai and Holloszy, 1971). Increased SDH activities following training have been reported in humans (Gollnick *et al.*, 1972; Saltin *et al.*, 1977), rats (Holloszy, 1967), and pigs (Jorgensen and Hyldgaard-Jensen, 1975) as have levels of NADH-cytochrome *c* reductase, succinate oxidase, cytochrome oxidase, citrate synthase, and NADH in trained rats (Holloszy, 1967; Kowalski *et al.*, 1969; Holloszy *et al.*, 1971) and guinea pigs (Barnard *et al.*, 1970). In horses, training results in increased activities for citrate synthase, hexokinase, and 3-OH-acyl-CoA dehydrogenase (Cutmore *et al.*, 1985; Hodgson *et al.*, 1985).

Muscles of trained horses have a higher proportion of type 2A to type 2B fibers than untrained horses (Essen-Gustavsson and Lindholm, 1985) and training increases the oxidative capacity of equine type 2B fibers.

With training, muscle glycogen is increased (Gollnick *et al.*, 1972). The rate of lactate production is closely related to the intensity of exercise (Hermansen, 1971; Wahren, 1977) and lactate production is lower in trained than in untrained subjects performing the same exercise. The increased plasma lactate concentrations are directly correlated with decreases in plasma FFA due to a reduction in FFA release from adipose tissues (Edwards *et al.*, 1971; Hermansen, 1971; Jorfeldt, 1971; Karlsson, 1971; Saltin and Essen, 1971; Saltin and Karlsson, 1971, Lindholm and Saltin, 1974; Issekutz *et al.*, 1975; Snow and Mackenzie, 1977). Glycogenolytic and glycolytic enzyme activities are unchanged or only slightly decreased in both red and white muscles of trained rats with the exception of hexokinase. Hexokinase activities are markedly increased in trained rats and guinea pigs (Holloszy *et al.*, 1971; Baldwin *et al.*, 1973b; Peter *et al.*, 1968; Lamb *et al.*, 1969). Although the increase occurred in both red and white muscles, the percent increase was greatest in red muscles (Baldwin *et al.*, 1973b). In the horse, training increases AMP deaminase activity, which would serve to facilitate glyco(geno)lysis through activation of PFK.

In summary, the major metabolic consequences of the adaptations of muscle to endurance exercise are a slower utilization of muscle glycogen and blood glucose, a greater reliance on fat oxidation, and less lactate production during a given intensity (Holloszy and Coyle, 1984). At workloads below maximal O_2 utilization, aerobic pathways are the principal sources of energy through the oxidation of fatty acids and glucose. This correlates with the evidence that type 1 and type 2A (red) myofibers are activated first and their metabolic orientation is toward aerobic pathways. With workloads approaching maximal O_2 utilization, the sources of energy are derived principally from anaerobic pathways through glyco(geno)lysis. Type 2B (white) myofibers are recruited only with increased workload intensities and their metabolic energy derivation is mainly by anaerobic pathways. All of the complexities of energy derivation and fiber-type activities are not totally understood for all combinations of workload intensities and durations but one can conceive a general scheme of alterations in enzyme activities correlating to specific myofiber types in response to the type of exercise and the energy demands to support that exercise.

C. Performance and Athletic Potential

Various forms of exercise usually emphasize speed or endurance, or some combination of the two. Athletic ability reflects the efficiency of an individual to attain the desired speed and/or endurance required through the combined effects of genetic and environmental factors such as training. Obviously, the ability to manipulate myofiber properties to attain the appropriate balance of speed and endurance would be desirable for developing the best athletes for selected activities.

Studies of myofiber types in dogs and horses reveal that genetic selection of breeds for their speed (e.g.

greyhounds and thoroughbreds) has resulted in more fast-twitch, type 2 myofibers within their muscles of propulsion compared to breeds selected for sustained, low-intensity activities (Gunn, 1978; Snow and Guy, 1980; Guy and Snow, 1981).

Whereas cross-innervation and chronic stimulation studies suggest that "activity" controls gene expression in muscle, "activity" in the form of exercise training holds the potential for improving speed and/or endurance. As we have seen, training activity improves endurance performance through improved oxidation of fats and carbohydrates. For example, in standardbred horses training results in greater type 2A/2B ratios, and the best performers had the highest ratios (Essen-Gustavsson and Lindholm, 1985). Beyond the effects of training on ATP synthetic pathways, evidence also exists that high-intensity interval training can result in transformations of fiber types in the order of type 2B-to-type 2A-to-type 1 in both rats and humans (Green *et al.*, 1984; Luginbuhl *et al.*, 1984; Simoneau *et al.*, 1985). For now, there is little evidence for transformations from slow, type 1 to fast, type 2 through exercise training.

VI. DIAGNOSTIC LABORATORY METHODS FOR THE EVALUATION OF NEUROMUSCULAR DISORDERS

Muscular weakness is the principal clinical sign of neuromuscular disorders. Manifestations of muscular weakness may be functional (e.g., paresis, paralysis, gait abnormalities, exercise-related weakness, dysphagia, regurgitation, dyspnea, and dysphonia) and/or physical (e.g., gross atrophy, hypotrophy, hypertrophy, and skeletal deformities).

Instituting measures of prevention and/or therapy of neuromuscular disorders depends on an accurate definition of the functional and physical manifestations of muscle weakness and the identification of the specific pathoanatomic motor unit component(s) involved (i.e., neurons in neuropathies, neuromuscular junctions in disorders of neuromuscular transmission, or myofibers in myopathies) and, when possible, identification of the specific cellular dysfunctions underyling the muscular weakness.

The evaluation of neuromuscular disorders requires a coordinated approach and special examinations, some of which fall outside the scope of this chapter. These involve the neurologic examination and include the signalment (e.g., species, breed, age, sex), history (e.g., congenital or acquired, course of the disease, exposures, and responses to treatment), findings (e.g., presence and distribution of signs, neurologic deficits, and abnormal reflexes) and electrodiagnostic tests that involve electromyography (EMG), and the evaluation of sensory and motor nerve conduction velocity measurements and evoked MAPs.

Standard hematologic and clinical chemistry panels are indicated to provide general screening that would suggest possible infectious, immune, or metabolic abnormalities.

In addition to these evaluations, there are some more specific tests that provide insight into the pathoanatomic involvement and in some instances specific identification of the etiology and pathogenesis of the muscular weakness.

A. Muscle-Specific Serum Enzyme Determinations Used in the Diagnosis of Neuromuscular Disorders

A valuable adjunct to the clinical diagnosis of neuromuscular diseases has been the utilization of serum enzyme determinations. This involves the detection of enzymes in serum or plasma. The activities or concentrations of the enzymes are usually low in serum or plasma because they are normally located within healthy myofibers. Necrosis of myofibers is a primary example of a process by which serum activities of intracellular enzymes are elevated and the elevations are roughly proportional to the mass of tissue involved. Elevations in serum enzyme activities may also occur in association with increased cell permeability (leakage), increased enzyme production by the parenchymal cells, obstructions to normal enzyme excretory routes, increased amount of enzyme-forming tissue, delayed removal or inactivation of enzyme (Cornelius, 1967), and perhaps cell secretion.

The initial examination of a patient with muscle weakness should always include the measurement of muscle-specific enzyme activities. This provides immediate information concerning the possible presence of muscle necrosis and provides a course-grain analysis for distinguishing between myopathies and neuropathies. Despite the ready availability of such tests, they are often underutilized or employed only after the fact and their usefulness has passed.

1. Creatine Kinase

The most widely used serum enzyme determination in neuromuscular diseases of domestic animals is that for creatine kinase (CK), previously designated creatine phosphokinase (CPK). In muscle, this enzyme functions in making ATP available for contraction by the phosphorylation of ADP from creatine phosphate (Fig. 16.2).

The use of serum CK has offered greater promise of organ specificity in diseases of muscle than most other enzyme determinations employed to date. Analysis of tissues from humans indicates that significant CK activities are present in skeletal muscle, myocardium, and brain, with lesser amounts in the gastrointestinal tract, uterus, urinary bladder, kidney, and thyroid (Dawson and Fine, 1967). The diversity of organs tested in other animals is not as broad but those tested correlate well with these findings. The liver has negligible amounts of CK (Oliver, 1955; Tanzer and Gilvarg, 1959; Colombo *et al.*, 1962; Eppenberger *et al.*, 1962; Cardinet *et al.*, 1967; Dawson and Fine, 1967).

Some normal values for CK activity have been determined in domestic animals (Table 16.2); these vary with physical activity, restraint, biopsy (Anderson, 1975; Blackmore and Elton, 1975; Rose *et al.*, 1977; Tarrant and McVeigh, 1979), age, and sex (Heffron *et al.*, 1976). Intramuscular injections may also increase CK activities due to local areas of muscle necrosis (Nevins *et al.*, 1973; Steiness *et al.*, 1978). The amount of CK liberated following intramuscular injection of a drug depends on the properties of the injected solution and on such muscle factors as species differences in muscle CK activity, local blood flow, susceptibility of the muscles and local muscle binding of the drug (Steiness *et al.*, 1978). Therefore, an accurate history is important in evaluating CK activities.

TABLE 16.2 Normal Values of Serum Creatine Kinase Activity in Some Domestic Animals

Species	Age	Sex	CK activity (U/liter) Mean	Std. dev.	Range
Canine[a]	0–4 months	Male	4.7	±0.3	1.2–8.2
		Female	3.0	±0.2	1.2–5.5
	4–6 months	Male	2.4	±0.2	0.1–6.6
		Female	1.8	±0.2	0.4–6.2
	6–12 months	Male	1.8	±0.2	0.4–5.6
		Female	0.8	±0.2	0.0–7.5
	>12 months	Male	1.2	±0.3	0.2–2.6
		Female	0.8	±0.1	0.0–1.8
Canine[b]	>12 months	Both sexes	22.7	±7.3	9.9–28.8
Caprine[a]		Female	0.9	±0.9	0.0–2.5
Equine[a,c]	3–12 years		1.3	±0.9	0.0–3.6
Feline[a]		Male	1.7	±1.1	0.4–3.4
		Female	1.9	±1.3	0.0–4.5
Ovine[a]		Male	0.8	±0.6	0.0–2.9
		Female	0.5	±0.3	0.0–0.9
Gallus domesticus[d]	27–134 days		—	—	38.1–59.1
	1 year	Male	109	—	—
		Female	50	—	—

[a] Enzyme activities determined without reducing agents. Data from Cardinet (1969).

[b] Enzyme activities determined in the presence of glutathione. Data from Heffron *et al.* (1976).

[c] Unexercised; not in training. Enzyme activities determined without reducing agents. Data from Cardinet (1969).

[d] Enzyme activities determined in the presence of cysteine. Data from Holliday *et al.* (1965).

There are three principal isoenzymic forms of CK. Creatine kinase has a dimeric structure consisting of M (muscle) subunits and B (brain) subunits, which combine to form the three heterogeneous MM (or CK3), MB (or CK2), and BB (or CK1) isoenzymes (Dawson *et al.*, 1965, 1967). A fourth variant form, CK-Mt, is found in mitochondrial membranes and may account for up to 15% of the total cardiac CK activity. The isoenzymes can be separated by three different methods: (1) electrophoresis, (2) immunological techniques, and (3) ion-exchange chromatography (Fiolet *et al.*, 1977).

The pattern of isoenzyme distribution varies among the organs of different species. Thus, identification of the isoenzymes present can be used to help determine the tissue source of elevations in CK (Eppenberger *et al.*, 1964a; Dawson *et al.*, 1965; Dawson and Fine, 1967; Van der Veen and Willebrands, 1966; Sherwin *et al.*, 1969; Klein *et al.*, 1973). Ontogenic studies in the rat revealed that all organs investigated contained only BB-CK in early stages of fetal development. In skeletal muscle, BB-CK forms slowly disappear and are initially replaced by MB-CK forms followed by CK-MM forms. Mixtures of isoenzymes occur during the transition. In the adult pattern, MB-CK forms have been variously reported to be present or absent. The inconsistency in noting the presence of MB-CK forms in skeletal muscle of animals may be due to the source of skeletal muscle sampled since all skeletal muscles may not contain the MB-CK isoenzyme (Sherwin *et al.*, 1967; Thorstensson *et al.*, 1976). However, other studies indicate that, although there is more MM-CK in white muscle of the rat than in red, there is no MB-CK fraction in either (Dawson and Fine, 1967). Reasons for the discrepancies in the detection of MB-CK forms in mammalian skeletal muscles are not evident. The adult isoenzyme pattern in muscles of the rat appears at 90 days after birth, whereas in cardiac muscle, the shift occurs earlier and the adult pattern has both MB-CK and MM-CK forms. In the brain, BB-CK is the major isoenzyme throughout life (Eppenberger *et al.*, 1964a). An unusual sex linkage of muscle CK isoforms has been reported in Harris' hawks (Morizot *et al.*, 1987). The total CK activity of breast muscle was similar in males and females; however, the females had three isoenzymic forms, but males had only one, which was judged to be BB-CK.

Determinations of serum isoenzyme patterns have found clinical application in human medicine. The determination of MB forms is generally advocated as the best biochemical diagnostic tool for acute myocardial infarction (Fiolet *et al.*, 1977). However, studies of the isoenzyme composition in cardiac muscle of the horse reveals that less than 1.5 to 3.9% of the total CK activity is attributable to the MB-CK form. Hence, its determination cannot be used for detection of myocardial disorders in the horse (Fujii *et al.*, 1980; Argiroudis *et al.*, 1982).

Changes in serum isoenzyme patterns have been observed in various neuromuscular disorders and Duchenne muscular dystrophy (Goto *et al.*, 1969; Somer *et al.*, 1976). In the horse, one study found that horses with a previous history of rhabdomyolysis had higher serum MM-CK and BB-CK activities, but lower MB-CK activities than control horses (Johnson and Perce, 1981). With modest exercise the affected horse had a significant decrease in serum MM-CK and BB-CK, and increase in MB-CK. The significance of those findings has not been elucidated.

Elevations in total CK activities have been reported in the hereditary muscular dystrophies of chickens (Holliday *et al.*, 1965; Wagner *et al.*, 1971) and Syrian hamsters (Eppenberger *et al.*, 1964b); in selenium-vitamin E deficiencies of cattle (Allen *et al.*, 1975; Van Vleet *et al.*, 1977), sheep (Whanger *et al.*, 1970), and swine (Ruth and Van Vleet, 1974); in myodegeneration due to ingestion of toxic plants in cattle (Henson *et al.*, 1965); in the arthrogryposis-hydranencephaly syndrome in calves (Hamada, 1974); in capture myopathies involving a moose (Haigh *et al.*, 1977) and pronghorns (Chalmers and Barrett, 1977); and in paralytic myoglobinuria involving horses (Gerber, 1964; Cardinet *et al.*, 1967; Lindholm *et al.*, 1974b) and a double-muscled heifer (Holmes *et al.*, 1972). Elevations in CK activities have also been reported in polioencephalomalacia and focal symmetric encephalomalacia of sheep and it has been suggested that CK determinations may be of value in diagnosing diseases of the central nervous system (Smith and Healy, 1968). However, in diseases of the central nervous system that involve motor function, elevations of CK may be from skeletal muscle rather than from the central nervous system. This appears to be the case in central nervous system disorders in man (Cao *et al.*, 1969).

Diseases of muscle are classified, whenever possible, as to the origin or site of the primary lesion. Myopathies are those diseases in which the primary defect or disease process is considered to be limited to the myofibers, and neuropathies are those diseases of muscle which are secondary changes due to defects or diseases of the neuron (e.g., denervation). Although CK determinations may be specific for diseases of muscle, they do not provide information relative to the origin of the disease process. However, elevations of CK are generally higher in myopathies than neuropathies because myonecrosis is much more prevalent in myopathies than neuropathies. More precise information regarding the origin of muscle diseases can be obtained by the use of histological and histochemical examination of muscle biopsies.

In a comparative study, the behavior of CK was found to be distinctly different from that of serum aspartate aminotransferase (AST or GOT) during the course of paralytic myoglobinuria in horses (Fig. 16.8). The latter enzyme is discussed in the next section. Elevations in AST activities were present for weeks after the onset of clinical disease, whereas CK activities remained elevated for only a few days. The course of elevations of these enzymes in this disease can be directly attributed to different disappearance rates of their activity in the plasma (Fig. 16.9).

Although CK is more specific for myonecrosis than AST, the simultaneous determinations of AST and CK in the horse are potentially valuable diagnostic and prognostic aids owing to the different disappearance rates of their serum or plasma activities. (1) Elevated CK activities indicate that myonecrosis is active or has recently occurred; (2) persistent elevations of CK indicate that myonecrosis continues to be active; and (3) elevated AST due to myonecrosis accompanied by decreasing or normal CK activities indicates that myonecrosis is no longer active. It has not been established whether there are similar differences in the disappearance rates of AST and CK activities in the plasma of other animal species. Therefore, it is not known whether the same assessment of myonecrosis through

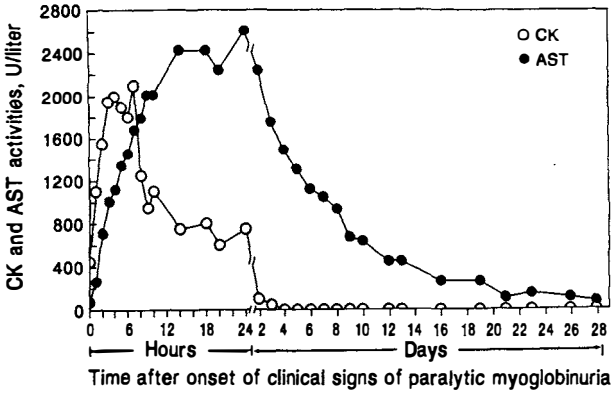

FIGURE 16.8 The difference in the time course of elevations in AST and CK activities due to muscle necrosis (equine paralytic myoglobinuria). The AST activity remained elevated for much longer periods than CK activity. Adapted from Cardinet *et al.* (1967).

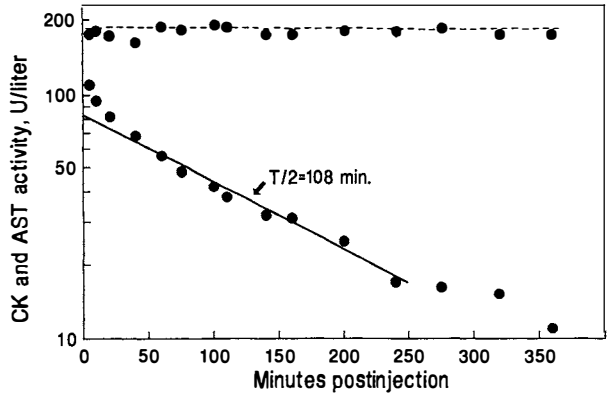

FIGURE 16.9 Disappearance of AST (dotted-dashed line) and CK (dotted-solid line) activities in the serum of a horse following the intravenous injection of AST and CK. The differences in the course of serum elevations of these two enzymes due to necrosis in the horse are the result of differences in their disappearance rates in the serum. Adapted from Cardinet *et al.* (1967).

the simultaneous determination of AST and CK activities can be applied to species other than the horse.

The normal CK values presented in Table 16.2 were determined by the method of Tanzer and Gilvarg (1959). Storage of serum at 0 to −5°C results in a loss of activity; however, the addition of reducing agents such as cysteine or glutathione to the incubating medium increases the serum activities, and the losses due to storage are minimized (Okinaka *et al.*, 1964; Weismann *et al.*, 1966; Hess *et al.*, 1968). The cysteine or glutathione reactivates the CK activity lost during storage, therefore, the addition of those reducing agents to the incubating medium is the method of choice and necessitates the establishment of normal "activated" values.

2. *Aspartate Aminotransferase*

Another enzyme that has been used as a diagnostic aid in neuromuscular disorders of domestic animals is serum aspartate aminotransferase (AST) formerly called glutamic oxaloacetic transaminase (GOT). Some normal values of AST activity reported for domestic animals are summarized in Table 16.3. Normal values do not appear to differ greatly between sexes, although reported values for cows (Cornelius *et al.*, 1959a) are somewhat higher than values for bulls (Roussel and Stallcup, 1966). Differences associated with age have been reported in sheep (Lagace *et al.*, 1961) and there are seasonal differences in bulls (Roussel and Stallcup, 1966). Also, physical activity is associated with higher values in horses (Cornelius and Burnham, 1963; Cardinet *et al.*, 1963, 1967; Blackmore and Elton, 1975).

Elevations of AST activities have been reported in white muscle disease of lambs, cows, and swine (Blincoe and Dye, 1958; Kuttler and Marble, 1958; Swingle *et al.*, 1959; Blincoe and Marble, 1960; Whanger *et al.*, 1970; Ruth and Van Vleet, 1974), tying up and paralytic myoglobinuria in horses (Cornelius and Burnham, 1963; Cardinet *et al.*, 1963, 1967; Lindholm *et al.*, 1974b), azoturia in a double-muscled heifer (Holmes *et al.*, 1972), hereditary muscular dystrophy in chickens (Cornelius *et al.*, 1959b), myodegeneration due to ingestion of toxic plants in cattle (Henson *et al.*, 1965), and capture myopathy in a moose (Haigh *et al.*, 1977) and in pronghorns (Chalmers and Barrett, 1977). Although the use of AST determinations has proven valuable as a diagnostic aid, the enzyme lacks organ specificity since in addition to high concentrations in skeletal and cardiac muscle, AST activities are also high in the liver as well as other organs and tissues, including the red blood cells (RBCs) (Cornelius *et al.*, 1959a; Nagode *et al.*, 1966; Cardinet *et al.*, 1967).

3. *Lactate Dehydrogenase*
